Most lizards can hear; details of the acuity of hearing, however, are largely unknown. The majority have a tympanum, tympanic cavity, and eustachian tube. The tympanum, usually exposed at the surface of the head or at the end of a short open tube, may be covered by scales or may be absent. In general the last two conditions are characteristic of lizards that lead a more or less completely subterranean life and presumably do not hear airborne sounds. The middle ear of these burrowers is usually degenerate as well, often lacking the tympanic cavity and eustachian tube.

Snakes have neither tympanum nor eustachian tube, and the stapes is attached to the quadrate bone on which the lower jaw swings. It is unlikely that snakes can hear airborne sounds, although they are obviously sensitive to vibrations in the ground. A loud sound above a snake does not elicit any response provided the object making the sound does not move or, if it does, the movements are not seen by the snake. On the other hand, the same snake will raise its head slightly and flick its tongue in and out rapidly if the ground behind it is tapped or scratched. Snakes undoubtedly "hear" these vibrations by means of bone conduction. Sound waves travel more rapidly and strongly in solids than in the air and are probably transmitted first to the inner ear of snakes through the lower jaw, which is normally touching the ground, thence to the quadrate bone, and finally to the stapes. Burrowing lizards presumably hear ground vibrations in the same way.

Crocodilians, all of which have an external ear consisting of a short tube closed by a strong valvular flap and ending at the tympanum, have rather keen hearing. The American alligator (Alligator *mississippiensis*) can hear sounds within a range of 50 to 4,000 cycles per second. The hearing of crocodilians is involved not only in detection of prey and enemies but also in their social behaviour, for males roar or bellow either to threaten other males or to attract females.

Although turtles have well-developed middle ears and usually large tympana, their ability to hear airborne sounds is still an open question. Measurements of the impulses of the auditory nerve between the inner ear and the auditory centre of the brain show that the inner ear in several species of turtles is sensitive to airborne sounds in the range of 50 to 2,000 cycles per second, but this does not prove that the animals are aware of the sounds.

Chemoreception. Chemical-sensitive organs, used by many reptiles to find their prey, are located in the nose and in the roof of the mouth. Part of the lining of the nose consists of cells subserving the function of smell and corresponding to similar cells in other vertebrates. The second chemoreceptor is Jacobson's organ, originally an outpocketing of the nasal sac in amphibians and remaining so in the tuatara and crocodilians. It has been lost by turtles. Jacobson's organ is best developed in lizards and snakes, in which its connection with the nasal cavity has been closed and is replaced by an opening into the mouth. The nerve connecting Jacobson's organ to the brain is a branch of the olfactory nerve.

Jacobson's organ

The use of Jacobson's organ is most obvious in snakes. If *a* strong odour or vibration stimulates a snake, its tongue is flicked in and out rapidly. Wtih each retraction the forked tip touches the opening of Jacobson's organ in the roof of the mouth, transmitting any chemical fragments adhering to the tongue. In effect, Jacobson's organ is a supplement to taste and is a short-range chemical receptor, as contrasted with the long-range testing of the true sense of smell located in the nasal tube.

Some snakes (notably the large vipers) and lizards (especially skinks and burrowing species of other farnilies) rely upon the olfactory tissue and Jacobson's organ to locate food, almost to the exclusion of other senses. Other reptiles, such as certain diurnal lizards and crocodilians, appear not to use scent in searching for prey, though they may use their sense of smell for locating a mate.

Some snakes, notably pit vipers, boas, and pythons, have special heat-sensitive organs on their heads as part of their food-detecting apparatus. Just below and behind the nostril of a pit viper is the pit that gives the group its common name. The lip scales of many pythons and boas have depressions (labial pits) that are analogous to the viper's pit. The labial pits of pythons and boas are lined with skin thinner than that covering the rest of the head and are supplied with dense networks of blood capillaries and nerve fibres. The facial pit of the viper is relatively deeper than the boa's labial pits and consists of two chambers separated by a thin membrane bearing a rich supply of fine blood vessels and nerves. In experiments using warm and cold covered electric light bulbs, pit vipers and pitted boas have been shown to detect temperature differences of less than 0.6" C (1.1° F).

Since many pit vipers, pythons, and boas are nocturnal and feed largely on mammals and birds, the facial sense organs enable them to direct their strikes accurately in the dark, once their warm-blooded prey arrives within range. The approach of the prey to that point is probably detected by the chemical receptors — either the nose, Jacobson's organ, or both.

Thermal relationships. Reptiles are often described as being cold-blooded, which is not always true. Their body temperatures are not always low, but they have no internal mechanism for regulating body temperature and thus approximate closely the temperature of their surroundings. This condition is termed poikilothermy. Mammals and birds maintain their relatively high body temperatures at a fairly constant level by physiological means that are independent of the external environment, a condition called homoiothermy. When the body temperature of a dog or a man falls below the normal range, he begins to shiver, blood vessels in the skin contract, muscular activity generates heat, and the contraction of the superficial blood vessels, by reducing the volume of blood flow at the surface, reduces heat loss by radiation. By contrast, a reptile, when its body temperature falls below the optimum, must move to some portion of the environment having a higher temperature; in less than optimal temperatures, its activity drops, its movements become sluggish, its heartbeat slows, and its rate of breathing drops. In short, it becomes incapable of the normal activities required for growth, reproduction, and survival.

Mammals and birds have some physiological means of cooling their bodies (*e.g.*, panting and sweating, expansion of superficial blood vessels), but a reptile must ordinarily move away from a spot in which the temperature is too high or it will perish very quickly. Some reptiles also pant, but most of their temperature accommodations are behavioral (*e.g.*, orienting to sun or wind, raising body from the ground).

Range of body temperatures

Each group of reptiles has its own characteristic thermal range. One genus of lizards, for example, may require temperatures of 29"–32" C (84°–90° F) for maximum efficiency, and another may require 24"–27" C (75°–81° F). As a result of such physiological differences, lizards of the two groups will be active at different times of the day or occupy slightly different habitats.

In general the normal activity temperatures of reptiles are lower than those of most mammals; however, a few sun-loving (heliothermic) lizards (*e.g.*, the greater earless lizard, Holbrookia texana, of southwestern United States) have average activity temperatures above 38° C (100" F), several degrees higher than the average human body temperature. Such high temperatures are exceptional, and the majority of lizards have normal activity temperatures in the 27°–35° C (81°–95° F) range.

EVOLUTION AND PALEONTOLOGY

Historical development. Reptiles occupy an evolutionary position between amphibians, on the one hand, and the birds and mammals on the other, the last two classes having evolved from reptilian ancestors. Reptiles first appear in the fossil record of the Carboniferous Period, over 280,000,000 years ago. By the Triassic, about 50,000,000 years later, they began to dominate the terrestrial life of the world and continued that dominance through the Mesozoic Era (65,000,000–225,000,000 years ago). Reptiles succeeded in adapting to deserts, swamps, forests, grasslands, rivers, lakes, and even the air and the seas. Coincident with the rise of mammals at the end of the Mesozoic, most reptilian groups became extinct.

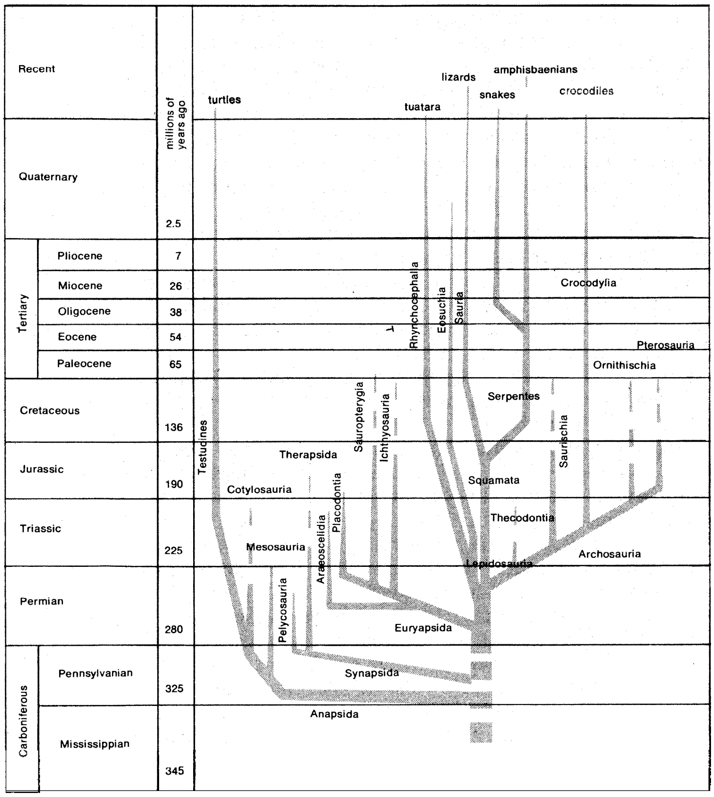

Figure 4: Family tree of the reptiles.

The big evolutionary step made by reptiles was the final emancipation from life in water, for, until that step was taken, vertebrates could not exploit all of the Earth's surface. That breakthrough required two basic changes, the first of which took place in the skin. Modem amphibians have naked skins that lack horny scales, hair, and other protective devices. One small amphibian group, the caecilians, has small fishlike scales embedded in the skin; similar scales occurred in certain extinct amphibians. Because of their thinness and position, such amphibian scales are no protection against desiccation, one of the principal hazards of life for all animals, vertebrate and invertebrate. This susceptibility to drying out forces amphibians to remain in water or in very humid places, thus limiting their exploitation of the terrestrial environment. Reptiles evolved a different type of scale consisting of keratin (or horn) deposited in the outermost layer of the skin. This type of scale was in a position and of a thickness to prevent desiccation.

Consequences of amniote egg

The second basic change made by the reptiles was the development of the amniote egg. This development expanded the possibilities of exploiting terrestrial environments. The egg could be laid under rocks or logs, in holes in the ground, in deserts or forests—in fact, almost anywhere except in water.

The development of the reptilian egg had several other consequences. An egg that is enclosed by a shell must be fertilized before that shell is deposited, thus necessitating internal fertilization. The evolution of a land egg also increased the efficiency of the life cycle of terrestrial vertebrates. An amphibian, hatching from an aquatic egg, must develop and grow in water in a larval form, the tadpole. The history of a reptile, on the other hand, is one of development and growth of adult structures adapted for a terrestrial life. It need not develop gills or a lateral line system (series of sense organs), which are needed by the aquatic tadpole and which must be resorbed and reworked into other structures. This important change in the type of development was made possible by a great increase in the amount of yolk in the reptilian egg.

The large amount of yolk also permitted the lengthening of the embryonic period, which in turn allowed the development of all structures that are necessary for successful existence on land. When a reptile hatches, it is ready to carry out all of the activities of the adult (with the exception of reproduction), and in the same environment and manner.

After reptiles acquired scaly protection for their skin and an egg that did not have to be laid in water, they were free to move over most of the Earth's surface. That freedom set the stage for the evolution of the many varied types of reptiles and, ultimately, for the evolution of birds and mammals.

Fossil distribution. What is known of the fossil record of reptiles shows that most of the major groups, or orders, were worldwide or nearly so at some time in their individual histories. Few orders are known from South America and Australia; the absence of most major groups from these areas more likely is explained on the basis of lack of preservation or lack of discovery of fossil beds than on the basis of a genuine absence of the animals throughout such a long interval as the Mesozoic. In the following discussion the names of present-day continents are used, though it should be understood that continental outlines in the past did not always coincide with those of today.

Few orders of reptiles are known from Paleozoic times —*i.e.*, Carboniferous (280,000,000–345,000,000 years ago) and Permian (225,000,000–280,000,000 years ago). The stem reptiles, the Cotylosauria, have been found in Carboniferous deposits of eastern and western North America and western Europe and in Permian beds of the Soviet Union and Africa. Presumably, they also lived in Asia during this interval of over 100,000,000 years, but their remains have yet to be found there. In the same period the Pelycosauria lived in North America and Europe, where their fossils are well-known, and possibly in Africa and Asia. The related mammal-like Therapsida and perhaps other forms were fossilized in Africa and

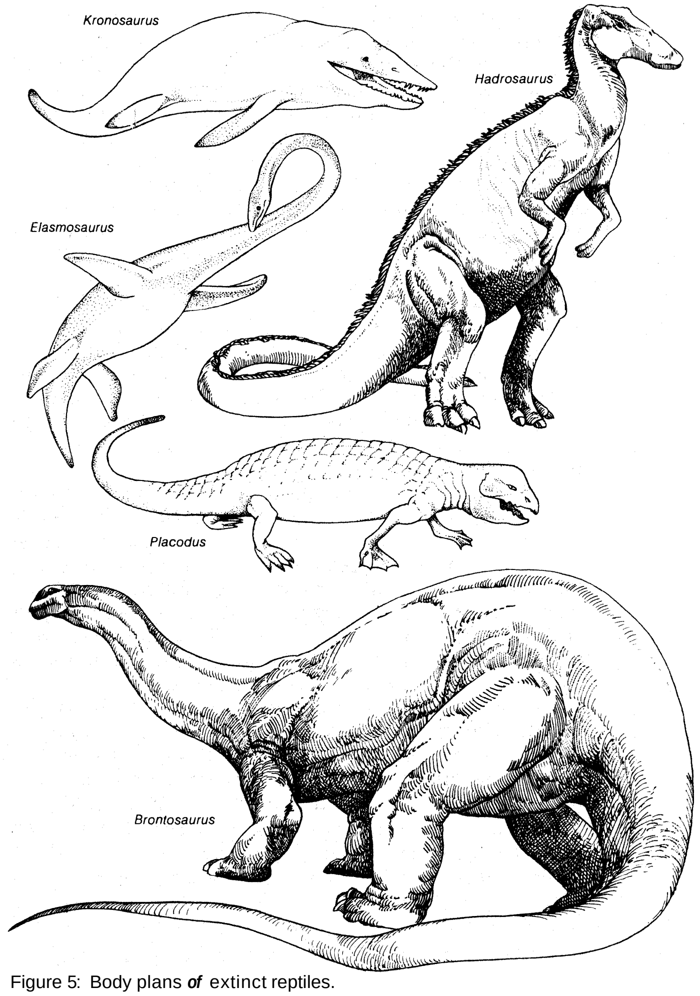

Figure 5: Body plans of extinct reptiles.

Europe. The probable ancestors of turtles appeared in Africa, and the first diapsids (reptiles having two-arched temporal structures) appeared in Africa and Europe in the Permian.

By the Triassic (190,000,000–225,000,000 years ago), the earliest portion of the Mesozoic, the mammal-like reptiles had spread to all of the continents except Australia. Turtles were still in Africa and had spread at least as far as Europe. The Ichthyosauria were living in seas covering what is now western North America and western Europe and may have been much more widely distributed, considering their oceanic habitat. North America at that time was also the home of primitive diapsids (Thecodontia), phytosaurs (suborder Phytosauria), and the earliest dinosaurs (Saurischia) and crocodiles. Besides the mammal-like therapsids, Eurasia and Africa in the Triassic had phytosaurs, the first Rhynchocephalia, and the early dinosaurs. The major groups of reptiles, therefore, were essentially worldwide in distribution by the Triassic.

Appearance of giant dinosaurs

The giant dinosaurs began their efflorescence in the Jurassic (136,000,000–190,000,000 years ago). The big carnivorous types, such as *Allosaurus*, roamed the landscapes of the major continents, presumably preying on even larger herbivorous dinosaurs (Brontosaurus, Diplodocus, etc.), whose remains have been found in North America, Europe, Africa, and Australia. Marine ichthyosaurs and plesiosaurs (order Sauropterygia) still swam in the shallow seas of both hemispheres. The ornithischian dinosaurs (Ornithischia), the ancestors of the duck-billed and horned dinosaurs, became widely distributed in the Jurassic. One group, the armoured stegosaurians (suborder Stegosauria), left fossils in North America, Europe, and Africa. The flying reptiles (Pterosauria) also made their appearance at least in Africa and Europe during the Jurassic.

The culmination of dinosaur evolution occurred in the Cretaceous (65,000,000–136,000,000 years ago), when every part of the world had herbivorous ornithischian dinosaurs: the ankylosaurs (suborder Ankylosauria), medium-sized dinosaurs armoured with heavy plates and large spines, ranging from South America to Africa; the duck-billed dinosaurs (suborder Ornithopoda), ranging from North America to Africa; and the horned dinosaurs (suborder Ceratopsia) in North America and Asia. Everywhere they were preyed upon by the big carnivorous types, which culminated in North America in the gigantic carnivore Tyrannosaurus. The skies over North America, Africa, and Europe (and probably Asia and South America as well) were the province of the flying reptiles (Pterosauria). There were also inconspicuous groups that later inherited the reptilian world. Lizards (suborder Sauria) appeared in most continents, and snakes (suborder Serpentes) appeared in some places. Birds, having splintered off from reptilian ancestors in the Jurassic, became more numerous in the Cretaceous; mammals, which ultimately replaced most of the reptiles, were represented on most continents by small creatures.

Through all this evolutionary activity, the conservative turtles continued their plodding evolutionary pace, changing but little, yet lasting through all. (Ed.)

CLASSIFICATION

Distinguishing taxonomic features. The major reptile groups are distinguished on the basis of vertebral and skull features, particularly the number and positions of the temporal fenestrae (*i.e.*, large openings in the temporal bone). Beyond these, the pelvic structure and that of the teeth and limbs are important. Any extraordinary structural development (*e.g.*, the wings of pterosaurs, the shell of turtles) is also a major factor in the system of classification. In recent reptiles (four out of some 17 orders), the structure of the heart, the male secondary sex organs, the extent and kind of dermal armour, and the structure of other soft organs are used. Discoveries in serology (the study of blood serum) and karyology (the study of cell nuclei) have had little effect, as yet, on the systems of classification.

Annotated classification. The following classification of the reptiles is based on that of A.S. Romer (1956, 1966), the American vertebrate paleontologist, as later modified by himself (1968) and in minor respects by E.H. Colbert (1965), B.W. Halstead (1969), and H.G. Dowling (1971). No single system of reptile classification is acceptable to all herpetologists, and widely differing views are held by various authorities. Considerable change in the recognition and content of both major and minor categories is to be expected. Groups marked with a dagger (†) are extinct and known only from fossils.

CLASS REPTILIA

Air-breathing, vertebrate animals without hair or feathers, the body usually covered with infolded epidermal scales. The occipital condyle (a protuberance where the skull attaches to the 1st vertebra) is single (except in transitional forms such as Therapsida), and representatives with well-developed limbs have 2 or more sacral vertebrae. The single auditory bone, the columella, is equivalent to the mammalian stapes. The lower jaw is made up of several bones and connects to the braincase by way of the quadrate bone and often by way of the supratemporal, the squamosal, or both. The systemic arch (part of the aorta) is paired; the respiratory and systemic portions of the circulatory system are incompletely separated. The red blood cells contain nuclei. Reproduction typically is by leathery-shelled or calcareous-shelled eggs with specialized membranes (chorion and amnion) that help to protect the embryo. In some lizards and snakes and in some extinct reptiles (*e.g.*, ichthyosaurs) the eggs are retained in the oviducts of the mother, sometimes with a placental connection, and the young are born alive. There are about 6,000 living species.

Subclass Anapsida

Pennsylvanian to present. Skull typically without temporal openings.

†*Order* Cotylosauria (cotylosaurs)

Lower Pennsylvanian (300,000,000–325,000,000 years ago) to Upper Triassic (190,000,000–210,000,000 years ago). Vertebrae amphicoelous (*i.e.*, concave at both ends) with small intercentra (crescentic elements between vertebrae); neural arches (the portion of the vertebra that encloses the nerve cord from above) convex. Skull with large toothed flange on pterygoid (a bone of the lower part of the skull); a lateral temporal fenestra (between jugal and squamosal) in some advanced forms. Mostly small and lizard-like.

?Order Mesosauria (mesosaurs)

Upper Pennsylvanian (280,000,000–300,000,000 years ago) or Lower Permian (250,000,006–280,000,000 years ago) of South Africa and South America. A small fish-eating aquatic reptile with cotylosaur-like vertebrae. The temporal region of the skull is poorly known, but there may have been a lateral fenestra. Slender, long-jawed reptiles 40–90 cm long.

Order Testudines (or Chelonia: turtles)

Upper (possibly Middle) Triassic to present. Skull without pineal (on the midline of the "forehead") or temporal fenestrae, though the temporal region may be emarginated, or indented. Jaws toothless (though there were palatine teeth in some extinct forms), with a horny beak. A shell (dorsal carapace and ventral plastron) covers the body and encloses the pectoral and pelvic girdles. Most modern turtles have shells less than 60 cm long, but oceanic forms have larger ones (2.7 m), and those of some extinct turtles exceeded 3.6 m in length.

Subclass Lepidosauria (lepidosaurians)

Upper Permian *(225,000,000–250,000,000* years ago) to present. Primitive forms had 2 openings in the temporal region of the skull; most of the descendants have lost the lower (jugal–quadratojugal) temporal arch. The earliest known forms already had a jaw that was shortened. Usually a pineal eye (degenerate, median eyelike structure), no trend toward bipedalism. Ribs single-headed in advanced forms.

†*Order* Eosuchia (eosuchians)

Upper Permian to Eocene (38,000,000–54,000,000 years ago). Primitive lizard-like reptiles with 2 temporal arches and without a beaked snout.

Order Rhynchocephalia (beaked reptiles)

Lower Triassic to present. Scaled reptiles with 2 temporal arches. The premaxillary overhangs the lower jaw as a beak; the teeth are acrodont (*i.e.,* attached to the edge of the jaw rather than inserted in sockets). The vertebrae are amphicoelous, and the ribs are single-headed. Mostly lizard-like forms 30–90 cm long; one group (rhynchosaurs) attained lengths of up to 180 cm. One living species.

Order Squamata (scaly reptiles)

Lizards, snakes, and amphisbaenians. Upper Triassic to present. The quadrate is freed by loss of the lower (jugal–quadratojugal) arch and reduction of the squamosal to allow some movement at both ends. Vertebrae procoelous (*i.e.*, with the centre part concave on the anterior side, convex on the posterior side) except in a few geckos (Sauria), in which they are amphicoelous. Living species possess unique paired copulatory structure (hemipenes).

Suborder Sauria (lizards). Upper Triassic to present. Most generalized suborder; most species with well-developed limbs, an external ear opening, movable eyelids, or some combination of these structures. The skull typically has a pineal opening, and epipterygoid, lacrimal, and jugal bones. About 3,000 living species (see SAURIA).

Suborder *Amphisbaenia* (amphisbaenians). Eocene to present. Highly specialized, limbless. burrowing reptiles with the eyes hidden under the skin, no pineal opening, and the body scales fused into annuli, or rings. The skull is solidly constructed as a burrowing wedge. About 140 living species.

Suborder Serpentes (snakes). Upper Cretaceous (65,000,000–100,000,000 years ago) to present. A highly specialized group, without pectoral limbs or girdle, pelvic limbs rudimentary when present. Without external ear or movable eyelids. Upper temporal arch (postorbital–squamosal) absent, leaving quadrate movable at both ends. No pineal opening; no epipterygoid, lacrimal, or jugal bones. About 2,500 living species (see SERPENTES).

Subclass Archosauria (ruling reptiles)

Upper Permian to present. Reptiles with 2 temporal openings (diapsid) and a tendency toward bipedalism. Most have long hindlegs and short forelimbs. Typically without a pined opening in the skull, but with an antorbital fenestra and one on the outer surface of the lower jaw. Ribs typically 2-headed, at least anteriorly. Ischium and pubis (bones of pelvis) elongated. Teeth in deep sockets (thecodont). Most with some armour.

†*Order* Thecodontia (primitive archosaurs)

Upper Permian to Upper Triassic. Lightly built bipedal or more heavily armoured reptiles, some (phytosaurs) crocodile-like and presumably amphibious, but with nostrils far back on the snout. Most had at least 2 rows of bony plates along the spine.

Order Crocodylia (crocodilians)

Upper Triassic to present. Aquatic or amphibious reptiles, rather generalized in body form, but with a flattened skull, the nostrils on the tip of the snout, and a well-developed secondary palate. Typically, the pubis is excluded from the acetabulum, or hip socket, and the 5th toe is reduced to a stump; 21 living species (see CROCODILIA)

†Order Saurischia (carnivorous dinosaurs and giant herbivorous dinosaurs)

Middle Triassic (200,000,000 years ago) to Upper Cretaceous. Pelvis triradiate (*i.e.*, 3-branched). Some reduction in digits. Forelimbs usually distinctly shorter than hind. Three to 7 sacral vertebrae. Some herbivorous forms were more than 24 m long.

†*Order* Ornithischia (herbivorous dinosaurs)

Upper Triassic to Upper Cretaceous. Pelvis tetraradiate (*i.e.*, 4-branched). Typically with a beaklike structure in the front part of the mouth and grinding teeth in the rear. Toes often with hooflike structures. Many with heavy armour and horns. Largest about 9 m long.

†*Order* Pterosauria (pterydactyls)

Lower Jurassic (150,000,000–190,000,000 years ago) to Upper Cretaceous. Highly specialized flying reptiles with hollow bones; 4th digit of the forelimb greatly elongated to support the flying membrane of the wing. Early forms toothed and with long tails; later forms tendedto be larger and to have lost both teeth and tail.

†**Subclass Euryapsida** (plesiosaurs and relatives)

Lower Permian to Upper Cretaceous. Mainly aquatic reptiles with an upper temporal opening (between postorbital, squamosal, and parietal bones), and a broad plate of bone below.

†*Order* Araeoscelidia (primitive euryapsids)

Lower Permian to Upper Triassic. Primitive terrestrial reptiles with lizard-like proportions, some with a specialized cervical region.

?Order Sauropterygia (nothosaurs and plesiosaurs)

Middle Triassic to Upper Cretaceous. Aquatic reptiles with strongly developed ventral ribs, dorsally placed nostrils, and a highly modified palate (pterygoids and often palatines are joined in the midline). Limbs paddle-like in advanced forms.

†*Order* Placodontia (placodonts)

Lower to Upper Triassic. A side branch of euryapsids, apparently mollusk eaters. In some the body was armoured and turtle-like in form.

†*Order* Ichthyosauria (ichthyosaurs)

Middle Triassic to Upper Cretaceous. Highly aquatic reptiles with porpoise-like bodies, a dorsal fin, and a reversed-heterocercal tail (*i.e.*, with the lower lobe longer than the upper). Limbs paddle-like; snout often elongated and beaklike.

†**Subclass Synapsida** (mammal-like reptiles)

Lower Pennsylvanian to Middle Jurassic (160,000,000 years ago). A single lateral temporal opening with the postorbital and squamosal bones joining above it in primitive forms; the opening extends upward to the parietal in later forms. Pineal present. Teeth differentiated. Two coracoids in pectoral girdle.

†*Order* ***Pelycosauria*** (primitive synapsids, pelycosaurs)

Lower Pennsylvanian to Middle Permian (250,000,000 years ago), especially in Europe and North America. Neural arches higher and less swollen than in the contemporary cotylosaurs. Abdominal ribs present in most.

†*Order* ***Therapsida*** (advanced synapsids, therapsids)

Middle Permian to Middle Jurassic, mainly in South Africa. Temporal opening expanded in advanced forms, a secondary palate formed. Occipital condyle double and dentary bone much enlarged.

Critical appraisal. A natural classification of reptiles is more difficult than that of many animals because the main evolution of the group was during Mesozoic time; 13 of 17 recognized orders are extinct. The consequent reliance on osteological (bone) characters may have obscured some important evolutionary trends, and there is little agreement among herpetologists and paleontologists on reptile taxonomy. Even the major categories of reptile classification are still in dispute. Although the ideas of Watson, Colbert, and Romer have dominated the field, some authorities question most of the basic elements—from subclass to suborder--on which the framework of their classification depends. Halstead, for example, would discard the entire system of reptile subclasses and recognize a "superclass Reptilia" with seven reshuffled "classes."

On the other hand, there is general agreement that the base reptilian stock is the Cotylosauria, which evolved from an amphibian labyrinthodont stock (the captorhinomorphs) at about the Mississippian–Pennsylvanian transition. It is also quite clear that the cotylosaurs early divided into two lines, one of which (the pelycosaurs) represented the stock that gave rise to the mammals. Another branch led to all of the other reptiles, and, later, to the birds as well. Thus, most of the questions of reptilian evolution and classification deal with inter-reptilian relations, rather than with their relationships with other animals.

Research and Development, Industrial

Research and development, a phrase unheard of in the early part of the 20th century, became in the latter part a universal watchword in industrialized nations. The concept of research is as old as science, whereas the concept of the intimate relationship between research and subsequent development was not generally recognized until after World War II.

Basic and applied research

The distinction between basic and applied research was established in the first half of the present century; basic research was defined as the work of scientists and others who pursued their investigations without conscious goals apart from the desire to unravel the secrets of nature. In modem industrial research and development programs, basic research, though sometimes called pure research, is usually not entirely pure; it is commonly directed toward a generalized goal, such as the investigation of a newly discovered frontier of technology that promises to relate to the problems of a given industry. Applied research carries the findings of basic research to a point at which they can be exploited to meet a specific need. Development includes the steps necessary to bring a new or modified product or process into production. In Europe, the U.S., Japan, and, to a lesser extent, elsewhere, the unified concept of research and development has been an integral part of economic planning, both by government and by private industry.

HISTORY

The origins of industrial research. The first organized attempt to harness scientific skill to communal needs took place in the 1790s, when the young revolutionary government in France was defending itself against most of the rest of Europe. The results were remarkable. Explosive shells, the semaphore telegraph, the captive observation balloon, and the first method of making gunpowder with consistent properties all were developed during this period.

The lesson was not learned permanently, however, and another half-century was to pass before industry started to call on the services of scientists to any serious extent. At first the scientists consisted only of a few gifted individuals. Robert W. Bunsen, in Germany, advised on the design of blast furnaces. William H. Perkin, in England, showed how dyes could be synthesized in the laboratory and then in the factory. William Thomson (Lord Kelvin), in Scotland, supervised the manufacture of telecommunication cables. In the U.S., Leo H. Baekeland, a Belgian, produced Bakelite, the first of the plastics. There were inventors, too, such as John B. Dunlop, Samuel Morse, and Alexander Graham Bell, who owed their success more to intuition, skill, and commercial acumen than to scientific understanding.

Early industrial laboratories. While industry in the U.S. and most of western Europe was still feeding on the ideas of isolated individuals, in Germany a carefully planned effort was being mounted to exploit the opportunities that scientific advances made possible. Siemens, Krupp, Zeiss, and others were establishing laboratories and, as early as 1900, employed several hundred people on scientific research. In 1870 the ***Physicalische Technische Reichsanstalt*** was set up to establish common standards of measurement throughout German industry. It was followed by the Kaiser Wilhelm Gesellschaft (later renamed after Max Planck), which provided facilities for scientific cooperation between companies.

In the U.S., the Cambria Iron Company set up a small laboratory in 1867, as did the Pennsylvania Railroad in 1875. The first case of a laboratory that spent a significant part of its parent company's revenues was that of the Edison Electric Light Company, which employed a staff of 20 men in 1878. The U.S. National Bureau of Standards was established in 1901, 31 years after its German counterpart, and it was not until the years immediately preceding World War I that the major American companies started to take research seriously. It was in this period that General Electric, Du Pont, American Telephone & Telegraph Company, Westinghouse, Eastman Kodak, and Standard Oil set up laboratories for the first time.

Except for Germany, progress in Europe was even slower. When the National Physical Laboratory was founded in England in 1900, there was considerabie pubiic comment on the danger to Britain's economic position of German dominance in industrial research, but there was little action. Even in France, which had an outstanding record in pure science, industrial penetration was negligible.

The effect of World War I. World War I produced a dramatic change. Attempts at rapid expansion of the arms industry in the belligerent as well as in most of the neutral countries exposed weaknesses in technology as well as in organization and brought an immediate appreciation of the need for more scientific support. The Department of Scientific and Industrial Research in the U.K. was founded in 1915, and the National Research Council in the United States in 1916. These bodies were given the task of stimulating and coordinating the scientific support to the war effort, and one of their most important long-term achievements was to convince industrialists, in their own countries and in others, that adequate and properly conducted research and development were essential to success.

The inter-war years

At the end of the war the larger companies in all the industrialized countries embarked on ambitious plans to establish laboratories of their own; and, in spite of the inevitable confusion in the control of activities that were novel to most of the participants, there followed a decade of remarkable technical progress. The automobile, the airplane, the radio receiver, the long-distance telephone, and many other inventions developed from temperamental toys into reliable and efficient mechanisms in this period. The widespread improvement in industrial efficiency produced by this first major injection of scientific effort went far to offset the deteriorating financial and economic situation.

Unfortunately, the economic pressures on industry reached crisis levels by the early 1930s, and the major companies started to seek savings in their research and development expenditure. It was not until World War II that the level of effort in the U.S. and the U.K. returned to that of 1930. Over much of the European continent the Depression had the same effect, and in many countries the course of the war prevented recovery after 1939. In Germany, Nazi ideology tended to be hostile to basic scientific research, and effort was concentrated on short-term work.

Expansion after World War II. The picture at the end of World War II provided sharp contrasts. In large parts of Europe, industry had been devastated, but the U.S. was immensely stronger than ever before. At the same time, the brilliant achievements of the men who had produced radar, the atomic bomb, and the V-2 rocket had created a public awareness of the potential value of research that ensured it a major place in postwar plans. The only limit was set by the shortage of trained men and the demands of academic and other forms of work.

Since 1945 the number of trained men has increased each year. In most industrial countries, the increase has continued at about 5 percent each year as new graduates have become available. The U.S. effort has stressed aircraft, defense, and space. Indirectly, U.S. industry in general has benefitted from this work, a situation that compensates in part for the fact that in specifically nonmilitary areas the number of men employed in the U.S. is lower in relation to population than in a number of other countries.

Outside the air, space, and defense fields the amount of effort in different industries follows much the same pattern in different countries. An important point is that countries that, like Japan, have no significant aircraft or space industries have substantially more manpower available for use in the other sectors.

Research in the U.S.S.R.

It is unfortunate that few figures are available for the U.S.S.R. The high quality of Soviet work on aircraft and space exploration is evident, and most visitors to research laboratories have been impressed by the facilities and by the calibre of the staff. What is known of Soviet military and naval equipment indicates a satisfactory level of effort and competence. The general impression gained by some observers is that the rest of the industrial effort has suffered from the concentration of necessarily limited resources in particular fields. Without figures that command more confidence than any that are available, this must remain conjecture.

TYPES OF LABORATORIES

Company laboratories. Company laboratories fall into three clear categories: research laboratories, development laboratories, and test laboratories.

Research laboratories. Most of these laboratories carry out both basic and applied work. They usually support a company as a whole, rather than any one division or department. They may be located at a considerable distance from any other part of the company and have managements reporting independently to the board of directors. Bell Telephone Laboratories is an outstanding example. There the transistor and coaxial cable were developed, and pioneer work in satellite communications was carried out. In Frankfurt, Germany, the research centre of Farbwerke-Hoechst has successfully synthesized several new dyestuffs.

Development laborafories. These installations are specifically committed to the support of particular processes or product lines. They are normally under the direct control of the division responsible for manufacture and marketing and are often within walking distance of the manufacturing area. In Germany, for example, the Bayer Company's development laboratories have constructed car body shells made from a plastic material up to 55 percent lighter than steel plate but with the same strength.

Test laboratories. These laboratories may serve a whole company or group of companies or only a single manufacturing establishment. They are responsible for monitoring the quality of output. This often requires chemical, physical, and metallurgical analyses of incoming materials, as well as checks at every stage of a process. These laboratories may be part of a manufacturing organization, but many companies give them an independent status.

Government laboratories. ***United States government.*** The pattern followed by different countries varies widely. The general policy of the U.S. government has been not to set up laboratories of its own, even for military work, but to offer research and development contracts, usually on the basis of competitive bidding, to private companies. The most important reason for this has been a belief that the right place to develop equipment is very close to the place at which it will eventually be manufactured.

There are exceptions to the rule. One is the type of laboratory represented by the National Bureau of Standards, a central authority on problems of measurement and standardization. Another is the type of laboratory supported by the Department of Agriculture, set up by the government in the belief that research in this field is necessary but that the industry had neither the finances nor the organization to maintain it. The continuing support of successive administrations has resulted in a large and authoritative body carrying out research over a wide field for the benefit of the farming community and thus, indirectly, of the whole nation.

Atomic Energy Commission

A third type of government laboratory is represented by the Atomic Energy Commission. In this case the U.S. government recognized a situation of potential danger and also opportunity of such a nature that it was not practicable for it to be handled by private individuals. It therefore set up a body to deal with the situation, allocating funds directly and maintaining close control of the objectives and timing of research. A similar challenge is faced by the National Aeronautics and Space Administration. Although much of the detailed research and development work is contracted to private industry, overall control, as well as much of the most important work, is handled directly by the central organization.

U.K. and other countries. A different type of policy has been followed in the United Kingdom. A chain of government laboratories supports the requirements of the armed forces. The Royal Radar Establishment; the Signals Research and Development Establishment; and the Atomic Energy Research Establishment, Weapons

Group are three of the best known. These carry out a great deal of the basic and applied research from which new weapons and military techniques emerge, and they play a major part in negotiating and monitoring the contracts placed with private industry for the eventual development and production of equipment for the armed forces.

In addition to these military laboratories, the United Kingdom government supports a number of civilian establishments, such as the National Engineering Laboratory, the Road Research Laboratory, and the Hydraulics Research Laboratory. These have a considerable degree of independence in selecting projects that will bring the greatest benefit to industry as a whole, and their results are made available to all. They maintain close liaison with the research associations (see below, ***Research associations)*** and with private industry and attempt to concentrate their work in areas that for one reason or another are not covered elsewhere.

In Germany, as in the U.K., defense research is the responsibility of a chain of government laboratories, but they are much smaller. Most of the work is done for them on contract by the research associations. They place very little research with private industry and call upon it only in the later stages of development.

In Japan there is a chain of laboratories, such as the National Aerospace Laboratory, the National Institute of Resources, and the Technical Research and Development Institute for Defence, which serve the needs of government departments. They work closely with the research associations that support particular industries. The military laboratories carry out the bulk of defense research and development themselves, and they are also responsible for the placing of contracts with private industry. These are usually confined to the later stages of development and are expected to lead almost directly to production.

The French system is similar, but the directly controlled government laboratories are even smaller and do little more than direct and coordinate work done by the research associations.

Factors common in all countries

In spite of differences in organization, the day-to-day conduct of government-sponsored research and development in all countries has much in common. In every case a comparatively small number of government employees keep in constant touch with the whole of the scientific and technical community and dispense contracts in the way that they consider will make the best use of the resources available in the broad national interest. The fact that in some countries it is done in laboratories under direct governmental control, in others in those under private control, and in yet others in those in which responsibility is split, is of secondary importance. In every case, the men who hold the purse strings determine how the work will be done.

Independent laboratories. The concept of a laboratory that maintains itself solely by selling research originated with the Mellon Institute in Pittsburgh before World War I. The difficulties that have to be faced are formidable, for a great deal of research work yields no immediate or obvious reward and it is extremely difficult to satisfy a customer that he is getting value for his money. Nevertheless, a number of such bodies, including the Battelle Memorial Institute, Columbus, Ohio, and the Stanford Research Institute, Menlo Park, California, have become large and successful. These organizations offer the services of workers of high professional standing who cover between them a wide range of disciplines. They undertake studies and investigations on any subject within their competence for fees that are negotiated with each customer; and, although they do not expect to make profits, they are required to be self-supporting.

Another type of organization is represented by Arthur D. Little, Inc., Cambridge, Massachusetts, which is run on strictly commercial lines, seeking to make a commercially viable profit from the resources employed. Only one or two organizations of similar type have been established in western Europe, and they have not grown to a size comparable with those in America.

Both in Europe and in the U.S., there are a great number of small laboratories providing specialist analytical, spectographic, metallurgical, and similar services to industry. Most of their clients are companies that lack adequate facilities of their own and that in course of time either learn to stand on their own feet or go out of business. But the constant appearance of new companies and the increasing need for technical understanding in established companies results in a slow but steady increase in the number of independent specialist laboratories serving them.

Research associations. A more important part of the industrial research and development effort in western Europe and in Japan is represented by the research associations. Each is concerned with a single industry. Germany, France, and the U.K. each have about 50 of these associations, and Italy and Japan about half as many. The smallest employ 30 or 40 scientists, and the largest as many as 600. Examples are the British Glass Industry Research Association in Sheffield, the Institut Français du Pétrole, des Carburants et Lubrifiants in Paris, the Max-Planck-Institut für Eisenforschung in Diisseldorf, the Centro di Studio per l'Elettronica e le Telecomunicazioni in Milan, and the Textile Research Institute in Yokohama. These laboratories are mainly concerned with the long-term problems of the industries they serve, but they are on occasion called in to help with immediate technical difficulties beyond the powers of local staff.

In European countries other than the U.K., they carry out substantial work under contract to the defense departments.

Financing and control

The method of financing and controlling work varies slightly in different countries. In the U.K., costs are shared by government and industry, and control lies with councils elected by the companies served. In France and Germany the laboratories are government financed but largely independent in their activities. In Japan they are directly controlled by the appropriate ministries but are industry oriented, unlike the U.K. government civil establishments previously mentioned, which are applications oriented.

University laboratories. In principle, university laboratories are completely independent and free to investigate anything that interests them. In practice, many of them are anxious to keep in touch with industry and to focus their research effort on problems wtih direct applications. Similarly, industrial scientists wish to maintain contact with advanced academic research. The result is a constant interchange between universities and industry; industrialists suggest problems for university research and provide funds to support it, and university staffs act as consultants and advisers to industry. In addition, government may play a direct role by funding university research, especially in defense-related fields.

PROPRIETARY RESEARCH AND DEVELOPMENT

Product planning. The basic purpose of the laboratories of private industry is to provide new products for manufacture. One difficulty facing those who plan these projects is the relationship between development costs and predicted sales. In the early stages of development, costs are low. They increase to a maximum and decline slowly, disappearing as early production difficulties are overcome.

Similarly, production rises slowly at first, then more rapidly, and finally reaches a plateau. After a time, production starts to fall, sales declining gradually as the product becomes obsolete or abruptly as it is replaced by a new one.

At any particular time, a company may have a number of products at different stages of the cycle. Laboratory managers must ensure that the total development effort required is neither greater nor less than that available, and the production managers must be satisfied that the eventual demands upon their resources will be sufficient to keep them fully loaded but not overloaded.

New product proposals

To maintain such an optimum condition, a steady flow of new product proposals is required. Each must be studied by technical, commercial, financial, and manufacturing experts. Planning, then, consists of selecting for development new products that promise to employ the resources available in the most profitable manner. The laboratories have a key part to play in proposing projects as well as in carrying them out.

Types of project. Basic research, applied research, and development have been described earlier. The way in which projects are carried out can best be illustrated by examples typical of each, taken from different industries.

Basic research. In the mid-1960s the scientists of a company manufacturing memory systems for electronic computers reported to their management that the magnetic core matrices then in general use could eventually be superseded by optical means. They were instructed to carry out a basic research project in this field. A small team spent several weeks studying the available literature and produced a plan for a specific project.

Their method involved printing information in the form of black and white marks on a plate, illuminated by a very finely focussed beam of light. The light was designed to scan the plate by being passed through crystals made of a material that deflects light by an amount that depends upon the electric potenial applied to it. As it falls upon a black or white mark, the change in reflected light can be indicated by a photosensitive detector.

The project was broken down into a number of tasks. One group studied the printing of information on plates; another studied the problem of focussing a light beam. A third team studied the problem of the crystals that were to deflect the beam.

Eventually there emerged a system that demonstrated that an optical memory store was technically possible. Its performance was then compared with the requirements determined by market research. The improvements and additions necessary to make possible the design of a salable product were listed, and in due course these became the subject of applied-research projects.

Applied research. A classical applied-research project was carried out by an English pharmaceutical firm in 1938.

Basic research work had shown that a benzene ring with an amino group in one position and a sulfonamido group in the opposite one had antibiotic properties. Substitution of the hydrogen atoms in the groups changed both the effectiveness of the substance in killing bacteria and its toxicity to the patient. The problem was to find the substitution that gave the best combination. A team of chemists set out to synthesize every possible derivative of the original substance, while teams of bacteriologists and biologists determined the effect of each one on bacteria and on mice.

Gradually a pattern emerged. Certain types of substitution increased one effect; others increased the other. As the more promising substances were identified, medical workers tested them on human patients, and eventually one compound was found to give the best ratio of antibiotic power to toxicity.

Testing for the optimum compound

This completed the applied-research stage, but development was still required. The synthesis of the drug had to be transferred from the laboratory bench to the factory, and this had to be associated with marketing plans. Finally, the checks and tests by which manufacture could be controlled and the final product monitored had to be established.

Development. The problems of development are illustrated by a program that resulted in a new model of a transistor radio. Technical uncertainties had been resolved before the start of the project. The components to be used had been established, and new techniques required had been explored in applied-research projects. Each stage in the development program had to result in a set of drawings and a list of materials that would enable production engineers who knew very little about the final product to set up lines upon which it could be manufactured. The whole effort was aimed at a particular level of output at a chosen date, which was linked with a sales plan. Each stage in the design had a firm date for completion, and each part of the equipment was required to pass performance and environmental tests specified at the start of the project.

Value engineering and cost analysis. In the areas in which technology advances fastest, new products and new materials are required in a constant flow, but there are many industries in which the rate of change is gentle. Although ships, automobiles, telephones, and television receivers have changed over the last quarter of a century, the changes have not been spectacular. Nevertheless, a manufacturer who used methods even ten years old could not survive in these businesses. The task of laboratories working in these areas is to keep every facet of the production process under review and to maintain a steady stream of improvements. Although each in itself may be trivial, the total effect is many times as large as the margin between success and failure in a competitive situation.

These efforts to improve existing products and processes have been formalized under the titles of value engineering and cost analysis.

In value engineering every complete product and every component has its primary function described by a verb and a noun. For example, an automobile's dynamo, or generator, generates electricity. The engineer considers all other possible methods of generation, calculates a cost for each, and compares the lowest figure with that for the existing dynamo. If the ratio is reasonably close to unity, he can accept the dynamo as an efficient component. If not, he examines the alternatives. The same treatment is applied in tum to each of the parts out of which the chosen component is built, until it is clear that the best possible value is being obtained.

Cost analysis approaches the same fundamental problem from a different angle. It takes each part of an assembly and calculates the cost of obtaining it, taking full account of purchased material, labour, and other factors. This focusses attention upon the most expensive items and makes it possible to apply the principal effort in seeking economies at the points of maximum reward.

These two processes are unending. Every new material, every new manufacturing technique, every new way of carrying out an operation gives the engineer a chance to improve his product, and it is from these continuing improvements that the high degree of economy and reliability of most modem equipment derives.

Management of research. There are wide differences in the organization and management of industrial laboratories. Many of these are due to the fact that, unlike the majority of human activities in which it is desirable that the participants should concentrate on their work without excessive discussion, it is crucial to a research and development program that there should be continual discussion and mutual criticism among the participants. The organization must encourage this by keeping the appropriate people in close contact. At the same time, the chain of command must be such that decisions are made promptly and implemented without confusion or misunderstanding.

A system of organization common in research departments is subdivision according to scientific specialty. The laboratory manager allocates each project to a particular area or splits it among several. Each worker is surrounded by colleagues of similar background who can give him the help and stimulation that he needs. In another type of structure, the subdivisions are stages in the research process, such as basic research, applied research, development, and design. This type of structure is appropriate to establishments in which the problems are of a more straightforward nature and the chief requirement is to maintain time schedules and engineering standards. It is frequently used by companies that produce a large number of fairly similar products.

Organizing by project

Still another type of organization is common in laboratories handling a small number of large projects. Here the individual project is the basic organizational unit. Each project leader reports directly to top management and controls a staff that fluctuates with the requirements of the project. This requires that staff be able to move freely from one area to another and involves situations in which project leaders direct the activities of technical experts whose status and remuneration may be higher than their own.

Whatever management organization is chosen, it faces the task of controlling projects that contain unknown and unpredictable factors. When they are reasonably simple, this can be done by the use of bar charts. Such charts break the project down into discrete activities, each of which is estimated individually, and make it possible to determine the manpower requirements week by week. As the work goes forward, progress can be marked on the chart and an estimate made of the effect of any delay or difficulty upon the date of completion.

Control systems. In the mid-1950s, sophisticated methods of project control began to appear. The original systems were known by initials such as PERT (program evaluation and review technique) and CPA (critical path analysis). Many variations and extensions are in use. They have proved particularly valuable in the development of large military networks in which the work of hundreds of separate contractors has to be coordinated, and their use is now common in all types of research and development projects, as well as in civil engineering and construction work.

Monitoring costs. It is necessary to monitor not only technical progress and time but also costs. The simplest method is to calculate the cost of each man in terms of direct salary and overhead and then to record the number of hours that he spends each week on a particular project. To this is added the cost of materials and services used.

Certain overhead items, such as the cost of lighting, heating, floor space, and depreciation of equipment, are simple to assess, but there is considerable variation of practice in the allocation of the costs of individuals. In some laboratories, senior staff, who spend much of their time in administrative and managerial activities, are treated as overhead and not charged directly to specific projects. In others an attempt is made to allocate their cost in as realistic a manner as is possible among the projects with which they are concerned.

Similar differences exist in the treatment of laboratory assistants, print-room services, consultants, and computer time. Every increase in the number of items charged directly to projects increases the accuracy of management costing and control, but it also increases the amount of nonproductive and paper-generating work; thus, a balance must be struck.

A similar balance must be struck in the charge made against a project for each hour spent on it. If each man has his own rate calculated in terms of total remuneration per hour of work, including salary and fringe benefits, much time is spent in unfruitful calculation. A common compromise is to divide staff into two or three grades and to have a flat charge for each grade. Even here there is a discrepancy between the laboratories that charge the same rate of overhead for each grade and those that charge an amount proportional to the average salary.

THE ROLE OF GOVERNMENT

World War I brought home to every government involved the importance of having its armed forces supported by an industry using the most advanced scientific techniques. Since then it has been generally accepted that it is frequently desirable to encourage research and development for reasons of economic growth as well as national security. This has resulted in massive support from public funds for many sorts of laboratories.

Through World War II this support was limited to research and development of direct military significance, but in more recent years the types of equipment used by the armed forces have become so extensive and so complicated that it is no longer practicable to distinguish between the requirements of an efficient armament industry and those of an efficient civilian industry. Advanced communication systems, aircraft engines, computers, and nuclear-power generators have been just as important to one as to the other. This fact has led governments to become the greatest single sponsors of industrial research, and by 1970 the U.S. government alone was supporting $10,000,000,000 worth of work.

"Spin-off"

During the 1960s it became clear that the "spin-off," or civilian and commercial application of work done under defense contracts, was giving the industries who benefitted a crucial advantage over their competitors, particularly over those in countries in which comparable assistance was not available. The dominance of U.S. firms in computer development and in microelectronics was generally attributed to this cause, and the outstanding success of the British aeroengine industry could hardly have been achieved without it. There were obvious examples, such as the communication satellites, which derived from work on military rocket propulsion, and more subtle ones, such as the highly reliable electronic components, developed to make weapons safe, which made it possible to produce television sets with far longer life between failures than before. The reaction of most industrial countries was to increase government support of private research. In the U.K. the Ministry of Technology, set up in 1964, took responsibility for allocating funds to private industry for research projects with no direct military application. The usual practice has been to contribute 50 percent of the cost of the work, the private company providing the balance.

Placing of research contracts. In the U.S. and in most western European countries, research contracts placed by government departments originate in the decision of a scientifically or technicallv oriented executive of the department that certain work should be done. This leads to the preparation of a specification of the work, which is then offered to industry, to private research institutes, and to universities for competitive bidding.

The terms of contract have varied widely. During the years of World War II it was common to offer contracts on a cost-plus basis. The contractor kept records of the hours worked by his staff and the materials used; these were checked by government auditors and paid for at a negotiated rate together with a fixed percentage as profit. Criticisms of this system led to fixed-price contracts, but these have the drawback that it is often so difficult to define the end point of a research contract that the contractor can treat a fixed-price agreement as if it were cost-plus. Another problem is that when the end point can be exactly defined, but there are genuine uncertainties in the program, the most attractive bid may come from a contractor who, through ignorance, takes too light a view of the difficulties. Yet another formula that has been tried is to offer contracts on a cost-plus-fixed-profit (rather than cost-plus-percentage) basis.

Fixed-price contracts

In all these cases the main concern of the officer who sponsors the contract is to get the work done as efficiently as possible. With the many uncertainties of research and development, true economy is more likely to lie in high-quality work than in low pricing. Consequently, in every country in which the government is a substantial supporter of private research and development, the departments concerned have set up elaborate systems of monitoring work and of keeping in touch with the performance and capabilities of the companies willing to undertake it. In negotiating contracts, the sponsors attempt to place them where they will be handled most successfully. At the same time, they are concerned to keep together teams that are likely to do good work for them in the future. Within this framework the struggle of the customer to negotiate the best price that he can for the work that he wants and that of the contractor to get a good return for the commitment of his resources follows normal commercial practice.

Patent rights. There are wide variations in the way patent rights that arise from research contracts are treated. In some cases the rights are the exclusive property of the government, and in others they belong to the contractor. A common compromise is for the government to retain all rights when anyone uses the patents to supply a government department but for the contractor to retain them when another party is involved. Thus, the government can place production orders with any contractor that it chooses, and the company that carried out the development is obliged to release information to him. If, however, the new contractor wishes to sell in the open market, he is obliged to negotiate a license and pay a royalty to the original development laboratories.

BIBLIOGRAPHY. Very little was written on the subject of industrial research and development until the end of World War II. Since then an increasing number of books have appeared, and articles in technical and management journals have become too numerous for most people to read. The list that follows is reasonably representative of literature in the English language. Most of the books mentioned give numerous references to other works.

History: K. BIRR, *Pioneering in Industrial Research: The Story of the General Electric Research Laboratory* (1958); W.R. MacLAURIN and R.J. HARMAN, *Invention and Innovation in the Radio Industry* (1949), a detailed account of the technical problems solved in one area; H. MELVILLE, *The Department of Scientific and Industrial Research* (1962), a history of a government research department; OECD DIRECTORATE FOR SCIENTIFIC AFFAIRS, *International Statistical Year for Research and Development: The Overall Level and Structure of R and D Efforts in* OECD *Member Countries* (1963–64).

Organization: A.O. STANLEY and K.M. WHITE, *Organizing the R & D Function* (1965), descriptions of the organizational structures of leading U.S. companies; I.D.L. BALL (ed.), *Industrial Research in Britain* (1968), details and statistics of U.K. industry; J. COCKCROFT (ed.), *The Organization of Research Establishments* (1965), essays by directors of 15 leading U.K. and U.S. laboratories; G.S. MONTEITH, *R. and D. Administration* (1969), a detailed description of administrative procedures in the U.K. and U.S., with an extensive bibliography.

Government: Report of the Committee on the Management and Control of Research and Development (HMSO 1961); *Basic Research and National Goals* (1965), a report of the National Academy of Sciences.

General: D. ALLISON (ed.), *The R and D Game* (1969), essays by 15 authors covering the whole field from creativity to administration, with an extensive bibliography; E.D. REEVES, *Management of Industrial Research* (1967), a discussion of the integration of R and D into corporate structure; T.S. McLEOD, *Management of Research, Development and Design in Industry* (1969), basic problems of technical management; C. HEYER (ed.), *Handbook of Industrial Research Management*, 2nd ed. (1968), essays by American managers on R and D problems as seen from the Board Room level; E. MORISON, *Men, Machines and Modern Times* (1966), an account of resistance encountered by new inventions.

Project management: K.G. LOCKYER, *An Introduction to Critical Path Analysis*, 2nd ed. (1967); J.J. MODER and C.R. PHILLIPS, *Project Management with CPM and PERT* (1964).

Resnais, Alain

Resnais.
By courtesy of the French Film Office, New York

With *Hiroshima mon amour*, his first feature-length motion picture, Alain Resnais attained pre-eminence among the innovative New Wave directors (who appeared in France in the late 1950s) particularly for the finesse with which he combined a traditional form and a radical content. In his preference for elaborate rehearsals of his actors, Resnais belongs to the classical cinema; but his social, political, and spiritual milieu is that of the "Left Bank" school of film makers, so called for their political philosophy as well as for a formidable intellectuality related to the cosmopolitan bohemianism of the Saint-Germain-des-PrCs district, on the Left Bank of the Seine, in Paris. The orientation of this group is opposite to that of the *Cahiers du Cinéma* subsection of the New Wave, which tended toward a politically quietist anarchism and drew upon a deliberately conventional, often Catholic, bourgeois culture—and whose editorial offices were in the fashionable Champs-ElysCes across the Seine. Though less well publicized and far less prolific, the "Left Bank" group (of whom Resnais was the spearhead) anticipated the political upheavals of Paris in 1968 and has dominated French cinema culture from the late 1960s.

Alain Resnais was born in Vannes, Brittany, on June 3, 1922, the son of a well-to-do pharmacist. A victim of chronic asthma, the young Resnais became solitary and intensely interested in creative activity, characteristics that would remain salient through his adulthood. While still a boy, he was given a movie camera, and at the age of 14 he directed his classmates in a film version of a popular thriller, *Fantômas.*

His illness exempted him from military service in World War II; and in 1940 he went to Paris, where he studied cinema at the Institut des Hautes Études Cinématographiques. During the German occupation of France, he became interested in theatre; later he would reproach himself for having become too immersed in it to join the underground resistance movement, but his brief stage career helped develop his sensitivity to actors and his technique of rehearsing them for his films.

Despite his interest in theatre, films remained his first love (along with comic strips, which he considers a kindred medium); and in 1947 he initiated a series of short films devoted to the visual arts with *Chateaux de France*, which he made by cycling and camping through the country. Having little interest in the French commercial film industry of the time, he continued making shorts—on van Gogh, Gauguin, and Picasso's painting "Guernica," among others—for the next nine years. Even in such documentary-like works, Resnais's profound vision of man's ominous alienation from his own humanity began to be expressed. He received commissions for political and propaganda films, whose immediate purpose he fulfilled but also transcended artistically. Thus, his documentary about concentration camps, *Nuit et brouilfard* ("Night and Fog"), with a commentary by a former inmate, the contemporary poet Jean Cayrol, stressed "the concentrationary beast slumbering within us all." *Le Chant du styrène*, written by author and critic Raymond Queneau, nominally publicizing the versatility of the plastic polystyrene, became a meditation on the transformation of matter from amorphous nature into bright, banal household implements.

Early documentaries

The postponement of popular success in his career permitted his art to mature all the more intensively. The solitude he experienced in childhood reappeared thematically in his sensitivity to the evanescence of experience, to the passing of time, and to the discrepancies between individual consciousnesses—themes that inspired comparisons to the philosophy of Henri Bergson and to the novels of Marcel Proust. His youthful fascination with comic-strip fantasies matured into a realization of the quietly monstrous forces within man and society. In his films Resnais shows man at his most sensitive, confronting his own devious barbarism—in the form of the atom bomb in *Hiroshima mon amour*, of a sumptuous but chilling dreamworld in *L'Année dernière à Marienbad (Last Year at Marienbad)*, of police torture in *Muriel*. He repeatedly presents human relationships that are .characterized by reticence, modesty, immaculate courtesy, and a stimulating respect for others, together with overtones of solitude. Resnais has regularly worked with such distinguished French literary figures as Marguerite Duras and Alain Robbe-Grillet, encouraging them to write the script as a piece of literature rather than as a screenplay. He then

Collaboration with literary figures

transposes their vision into cinematic terms, in a style richly impregnated with his own sensibility.

A bachelor, Resnais lives quietly in Paris. His close friends include many lesser known actors and technicians he has worked with. His films epitomize the unusual blend of circumspection and commitment in his own personality. Although he has dealt regularly with problems of personal and political action, his radical commitment is often underestimated by critics who are mesmerized by his immaculate style. His short films have had several brushes with government censorship. *Les Statues rneurent aussi* ("Statues Also Die"), his study of African art, was banned for 12 years for references to colonialism that he refused to alter. Some critics condemned *Hiroshima mon amour* for its sympathetic treatment of the heroine, once a wartime collaborationist and now an interracial adulteress who advocates internationalism and the "New Morality." Even when Resnais deals explicitly with political figures, however, as in *La Guerre est finie* ("The War Is Over"), his scrupulosity and tragic humanism are so much in evidence that his work transcends partisan feelings.

MAJOR WORKS

Van Gogh (1948); Gauguin (1950); Guernica (1950); Les Statues meurent aussi (1953); Nuit et brouillard (1955); Toute la mémoire du monde (1956); Le Chant du styrène (1958); Hiroshima mon amour (1959); L'Année dernihre à Marienbad (1961; Last Year at Marienbad); Muriel (1963); La Guerre est finie (1966); Loin de Vietnam (1967; Far from Vietnam), an episode; *Je t'aime, je t'aime (1968).*

BIBLIOGRAPHY. ROY ARMES, *The Cinema of Alain Resnais* (1968), a useful general survey; JOHN WARD, *Alain Resnais; or, the Theme of Time* (1968), a thoughtful study, preoccupied with Resnais as Bergsonian. *(Scripts): Hiroshima mon anzour (1960;* Eng. trans., *1966); L'Année dernihre à Marienbad (1961); La Guerre est finie (1966).*

Respiration, Disorders of

The prime function of the respiratory system is the exchange of gas between the blood and the external atmosphere—the removal of carbon dioxide (CO_2) from the blood and the enrichment of the blood with oxygen. The functioning units for this purpose are the alveoli in the lungs, minute air sacs whose membranous walls are filled with a network of microscopic blood vessels, the capillaries; through the alveolar walls and thin walls of the capillaries the gases are diffused. The rest of the system provides passageways for ventilation, the removal of air laden with carbon dioxide from the lungs and its replacement with fresh air. (See also RESPIRATORY SYSTEM, HUMAN; RESPIRATION, HUMAN.)

Oxygen and the lung structure

Each of the basic disorders of respiration is a disturbance of one aspect of the normal functioning of the lung, or arises from interference with one of the physiological processes concerned with delivery of oxygen to the tissues or removal of carbon dioxide from them. Oxygen, on which man's metabolic processes entirely depend, is, by comparison with CO_2, a relatively insoluble gas, so that it passes through membranes or water barriers considerably less quickly than carbon dioxide. Clearly, it is this relative insolubility of oxygen that accounts for some of the aspects of lung structure in man. The internal surface area of the human lung is about 750 square feet, this size being achieved within the chest cage by the extreme smallness of the alveoli of the lung. This smallness in turn would not be feasible except for the presence of a surface-active material that lines the alveoli to reduce the high tension which would otherwise exist at the gas-liquid interface of such a small volume. The tissues separating gas and blood are exceedingly fine, and the blood flowing through the lung flows through very small channels. Not more than about 100 cubic centimetres (cc) of blood—about half a cupful—is in the pulmonary capillaries at any one time, although the flow through the lung at rest is approximately five litres per minute.

BASIC DISORDERS OF RESPIRATION

Interference with ventilation. Obviously gross interference with ventilation as in asphyxiation and drowning prevents effective gas exchange. Respiration may be halted also by severe electric shock or by sudden brain hemorrhage. In all these instances recovery may occur if ventilation can be quickly reestablished. The quick clearance of any material that may be in the airway of the affected person and the prompt application of mouth-to-mouth resuscitation are techniques that may save lives. Older methods of artificial respiration were relatively ineffective, and the direct method of mouth-to-mouth breathing has largely supplanted all other first-aid techniques. In this method, the nose of the subject is held, and his lungs are inflated by expiration of the person giving the treatment. Approximately ten inflations a minute are made, and the lungs are allowed to empty spontaneously. There is little danger of overinflation of the lung, and effective ventilation can be maintained for a considerable period by this method. A small rubber bag and valve system with a mouthpiece, apparatus commonly found wherever there is danger of asphyxiation or drowning, provides equally effective ventilation. Police and first-aid workers are normally trained in use of the apparatus. If the victim's heart has not completely stopped at the time ventilation is begun by this method, there is good hope that resuscitation may be achieved. In drowning, there is more hazard from fresh than from salt water, because very considerable dilution of the blood occurs if much fresh water is aspirated into the lung, whereas the salts in seawater prevent this blood dilution. There is thus a better chance of resuscitation after apparent drowning in salt water than in fresh.

Paralysis or artificial relaxation of respiratory muscles

Since the body contains practically no stored oxygen, the brain can withstand deprivation of oxygen for only a few minutes. Interference with normal ventilation may occur as a result of disease of the respiratory muscles, of which acute poliomyelitis is a severe example. Other diseases that cause chronic loss of muscle power may progress to involve inadequate ventilation and respiratory failure. Respiration may be depressed by the administration of such drugs as morphine or by the accidental ingestion of poisons of many kinds. In most instances the drug acts on the respiratory centre, causing a severe depression of its activity and consequent failure to maintain normal ventilation. Curare and similar compounds are used in anesthesia to cause total muscle relaxation and, when this is done, ventilation is maintained artificially during the surgical procedure. In severe cases of asthma, the obstruction of airflow may be so severe that the total ventilation of the victim is endangered; in these circumstances acute respiratory failure may occur and may be dangerous to life. In all of these instances, mechanisms have been brought into play that have prevented effective ventilation of the lungs.

Oxygen pressures at high altitudes

Reduction of oxygen pressure. The transport of gas across the lungs depends on the process of diffusion, the rate of transfer of oxygen from gas to blood across the alveolar membrane of the lung being dependent on the difference in partial pressure that exists on the two sides. The partial pressure of oxygen in the alveoli is maintained by the process of ventilation, but the active process of oxygen uptake from the alveoli means that the average alveolar oxygen pressure is bound to be less than that in outside air. At sea level the oxygen pressure, expressed in millimetres (mm) of mercury (Hg), is about 150 (approximately one-fifth of the barometric pressure of 760 mm mercury, since oxygen is about one-fifth of the atmosphere); a normal man, breathing at sea level, has an average alveolar oxygen pressure of about 100 mm mercury. As man goes higher above sea level, the barometric pressure drops continuously; when he has reached 18,000 feet (about 5,500 metres [m]) it is only about half of that at sea level. Consequently, ascent to any altitude means that the oxygen pressure in the environment is lower than it is at sea level. A population living at an altitude of 6,000 feet (about 1,830 m), in Johannesburg, South Africa, or in Denver, Colorado, is bound to have a slightly lower arterial oxygen pressure at rest than does the sea level population, and it will be found to have, in addition, a slightly lower carbon dioxide pressure. This is because the subject at altitude is stimulated by the low oxygen pressure to ventilate rather more than the dweller at sea level; and, since the carbon dioxide in the blood is a direct reflection of alveolar ventilation, it consequently is lower in those living at high altitude. The processes of adjustment to altitude are complex, but they include the following important physiological mechanisms:

1. The oxygen content of blood is not much reduced when the pressure to which it is exposed falls from 100 mm mercury to 70 mm mercury, so that the quantity of oxygen carried by the blood is relatively well maintained down to the lower pressure. This relationship is of material assistance to man living at altitudes up to 10,000 feet (about 3,050 m). The curve relating oxygen content to oxygen pressure falls steeply after a pressure of approximately 70 mm Hg is reached.

2. The arterial oxygen tension of blood is continuously measured and controlled by chemoreceptors, small bodies situated at the division of the carotid artery in the neck, which stimulate ventilation when a fall in oxygen pressure in arterial blood occurs.

3. During the first three weeks at higher altitudes, a man becomes progressively more sensitive to carbon dioxide. The exact nature of this process is not fully understood, but it is known to depend on changes in the concentration of hydrogen ion occurring between the cerebrospinal fluid and the arterial blood. Although the carbon dioxide tension in cerebrospinal fluid is bound to be the same as that of blood (because equilibrium is readily achieved with a gas as soluble as CO_2), there is an active process of transport of bicarbonate ion (HCO_3) from cerebrospinal fluid, so that a hydrogen ion difference is established between cerebrospinal fluid and blood (*i.e.*, cerebrospinal fluid becomes more acid than blood) as the heavy breathing and hyperventilation of acute exposure to altitude occurs. The result is that centrally placed chemoreceptors in the medulla of the brain trigger a more sensitive setting of the respiratory control system to carbon dioxide.

4. Long-term residence at high altitude occasions changes in the blood that enable more oxygen to be carried. This process occurs slowly, but with long-term residence at altitudes of 15,000 and 16,000 feet (about 4,570 and 4,875 m) represents an important part of adaptation to the environment. Residents at high altitude, and more particularly those who have been born there, are believed to develop or to have richer capillaries in muscle tissue to facilitate oxygen exchange between blood and tissue cells.

Acute altitude sickness

These adaptive processes may break down in a number of ways. The unacclimatized person who is abruptly moved to 16,000 feet or so and made to do physical work suffers from acute altitude sickness with headache, nausea and vomiting, inability to sleep, and extreme fatigue. These acute effects result from hypoxia (deficiency of oxygen reaching the tissues of the body), but the exact mechanism is not understood in detail. In some instances, fluid will accumulate in the lungs of unacclimatized persons working at high altitudes. This dangerous complication was encountered on a large scale in the 1960s when Indian troops were flown from sea level to altitudes of about 16,000 feet to repel the invasion of India by China. Acclimatization is important for mountaineers and consists essentially of three weeks of graded exercise to progressively higher altitudes, permitting the regulatory processes of the body, particularly the chemoreceptors, to adjust the ventilation to the correct level. The kidney also requires time to adjust the bicarbonate level of blood to the lowering of CO, tension within it, so that the acidity-alkalinity relation of arterial blood may be maintained constant.

The disease of chronic mountain sickness (Monge's disease) occurring in residents at high altitude is characterized by severe hypoxia and secondary congestive heart failure. The increase in red blood cells (polycythemia) may be extreme. Chronic mountain sickness appears to result from failure of the stimulus of oxygen lack to have sufficient effect on ventilation. Prompt relief occurs when the affected person is brought to a lower altitude, but the disease is likely to recur if he returns to high altitude. The reason for the breakdown in ventilatory stimulus is not well understood.

Other circumstances in which oxygen intake may be inadequate include being trapped in a space from which oxygen has been removed by combustion or in which oxygen is deficient so that victims may suffer acute hypoxia before they are aware of the danger.

Inadequate oxygenation of the blood. Arterial tension may be depressed even though the environmental oxygen tension is normal, as when ventilation is grossly reduced by some interference with breathing, as noted above, or when there is severe lung dysfunction. Most commonly, although ventilation is maintained, the mismatch between the blood perfusion of the lung and the ventilation of it results in large volumes of blood flowing through parts of the lung that are very poorly ventilated. A variety of clinical conditions give rise to this not uncommon condition. Prompt treatment with enriched oxygen mixtures usually restores the arterial oxygen tension to normal without difficulty.

Another circumstance in which there is deficient oxygenation of blood, although the inspired oxygen tension is normal, is when fluid accumulates in the lungs. In this condition, callea pulmonary edema, leakage of fluid from the pulmonary capillaries into pulmonary tissue causes diminishing ventilation of the affected part of the lung and may lead to considerable hypoxia. Pulmonary edema occurs either when the pulmonary capillary bed has been damaged or when the lungs are subjected to an acute elevation of blood pressure, a condition most commonly occurring when function of the left ventricle of the heart is failing.

Quantity of oxygen. The carriage of oxygen by the blood is primarily dependent on the amount of hemoglobin in it. When the hemoglobin is grossly reduced, as in anemia, the amount of oxygen that may be carried by any given amount of blood is proportionately reduced. Blood travelling through the lung, however, will still equilibrate completely with the alveolar gas, and so the arterial oxygen tension is normal. In these circumstances of anemia, the reduced amount of oxygen that each given amount of blood is carrying leads to a compensatory increase in the output of the heart to permit maintenance of a normal delivery of oxygen per minute to the tissues.

Effects of anemia

Carbon monoxide poisoning

Carbon monoxide poisoning has unique physiological features that make this gas extremely dangerous to those who do not know they may be exposed to it. The odourless gas, carbon monoxide (CO), commonly produced by incomplete combustion of any hydrocarbon, is a major part of automobile exhaust. Hemoglobin has several hundred times the affinity for CO that it does for oxygen, which means that when CO is breathed, the hemoglobin travelling through the lung will combine with CO in preference to oxygen. Thus when CO is bound in this way to hemoglobin (Hb), the hemoglobin cannot pick up oxygen. In addition, the presence of carbon monoxide hemoglobin (COHb) in the blood affects the release of oxygen by the remaining unaffected hemoglobin in such a way that the oxygen tension within working'tissues becomes grossly reduced, although the arterial oxygen tension has remained normal. This shift in the release of oxygen by hemoglobin is a major reason why a saturation of half the hemoglobin with carbon monoxide (COHb percentage = 50 percent) causes severe and dangerous incapacity in an individual, whereas removal of half the hemoglobin (hemoglobin = 50 percent normal) as in anemia causes much less severe effects. CO is additionally dangerous because it does not stimulate ventilation and thus gives little warning of its presence. The cherry pink colour of carbon monoxide hemoglobin causes the victim to appear to be well oxygenated, and may mislead observers as to the dangerously low level of tissue oxygenation. The effects of carbon monoxide are insidious. If men are unaware that they are being progressively poisoned by this gas, they may only realize the hazard of their situation when too weak to take action to correct it.

SPECIAL SITUATIONS AFFECTING RESPIRATION

Respiration during swimming and diving. There may be considerable danger to a swimmer if he greatly increases his ventilation just before he jumps into the water. Hyperventilation at rest will reduce the carbon dioxide tension of the blood, but because of the shape of the oxygen dissociation curve, it does not increase significantly the amount of oxygen in the body. If the swimmer then jumps into the water and swims hard with his face under water, he will not be stimulated to take a breath until the oxygen tension in his blood has reached such low levels that he may well lose consciousness. Hyperventilation before he jumps thus postpones the moment at which a rising CO_2 tension will force him to breathe, but danger arises because his arterial oxygen pressure may have fallen to very low levels.

Scuba diving, with apparatus supplying gas to the diver at a pressure equal to the pressure exerted by the water on his chest wall, permits underwater diving to depths of up to 100 feet (30.5 m). Thus the diver can breathe without difficulty. An important hazard of scuba diving, however, is that a rupture of lung alveoli may occur during a rapid ascent from depth. If the diver's airway is closed during ascent, the diminishing pressure on the chest leads to rapid gas expansion with possible rupture of alveoli and the occurrence of air embolism, the presence of air bubbles in the bloodstream. It is important that subjects be trained to ascend with the glottis open so that the airway through the larynx is open.

In diving in which the diver is enclosed in an airtight costume including a brass headpiece, and air is pumped down to him from the surface, since the diver is breathing at the pressure of the water in which he is working, the pressure of nitrogen and oxygen in the air he is breathing will be greatly increased over its pressure at sea level.

Problems of breathing air

Two problems thus arise. First, oxygen at increased pressure has toxic effects. Although pure oxygen at sea-level pressure can be breathed for two hours safely, even at this pressure if it is breathed for long it causes changes in the lung and has secondary effects in the liver and brain. With the increased pressure under water, the acute elevation of oxygen pressure to several thousand millimetres of mercury may cause acute oxygen poisoning that leads to muscular twitching and, if unchecked, to dangerous convulsions. Thus the oxygen pressure when diving at depth has to be most carefully controlled. For example, in a simulated dive in a pressure chamber to a pressure equivalent to a depth of 1,000 feet under water, the inspired oxygen concentration was reduced from the normal 20 percent to 0.9 percent to attain the desired oxygen partial pressure of 150 mm Hg. The second problem of breathing air when under water is that the pressure of nitrogen is increased, thus increasing nitrogen tension through the body, swiftly in those regions with a large blood supply and slowly in organs with a poor blood supply. The diver may descend to considerable depths as fast as he wishes; but, having remained at such depths, he is unable to ascend quickly because a too rapid ascent from depth causes nitrogen to bubble out of the blood and bring on the syndrome known as "bends." In mild form "bends" may amount to no more than transient joint pains and some skin itching, but severe "bends" cause gas embolization and death. Because of this hazard, divers breathing air and working at considerable depths have to ascend gradually; after working for two hours at a depth of 300 feet (about 90 m), a diver may have to take five or six hours to ascend safely to the surface.

Advantages of helium-oxygen mixture

Because of the requirement of slow ascent, divers going to great depths use helium and oxygen mixtures. Helium is much less soluble in body tissues than nitrogen and has the added advantage of being easier to breathe at depth than nitrogen. The economics of men working at a depth of 300 feet, in terms of their working time as against their decompression time, have led to the development of a laboratory on the sea floor ("sealab") in which men may live for up to three weeks. Once saturation has occurred with gas at the higher pressure, the decompression time is the same if one has spent three weeks at depth as if one had spent only eight or nine hours at depth; thus it is economic to keep men at depth for much longer periods under these conditions. Divers leave the "sealab" for an hour or so to work and return for rest and food.

Abnormalities of rhythm. Under normal resting conditions, the volume of air taken in with each breath is approximately constant and the respiratory rhythm is regular. Where there is disease of blood vessels in the brain, enlargement of the heart, and a considerable slowing of the circulation, the breathing may oscillate with periods of increased tidal volume alternating with periods of very shallow breathing. This condition, known as Cheyne-Stokes respiration, is thought to result from the oscillation of the feedback circuitry that controls respiration. In Biot's respiration, the breathing frequency and tidal volume are irregularly irregular as a consequence of depression of the respiratory centre in the midbrain. This condition results from brain damage and also occasionally from overdose of a sedative drug.

Respiratory problems in space, A major problem posed by space exploration is that of withstanding the acceleration necessary to leave the Earth's atmosphere and the deceleration caused by reentry into the Earth's atmosphere. Under conditions of severe acceleration, the blood flow through the lung becomes inevitably restricted to the most dependent part of the lung in the gravitational field; and as this part of the lung may become collapsed, there may be a serious disorder of gas exchange. Some degree of minor atelectasis (collapse of small lung unit) probably commonly occurs in these circumstances but is quickly rectified by the taking of a few deep breaths once the accelerative force is over. The stage of weightlessness (zero gravitation) does not seem to cause problems for the normal function of the lung, and indeed the distribution of ventilation and perfusion in the resting situation within the lung may be slightly more uniform under these conditions than in the presence of the normal gravitational pull of the Earth, It is not known whether readjustment to Earth's gravitational field after a prolonged period of weightlessness can be easily achieved, but the reverse adaptation from the Earth's gravitational field to the state of weightlessness does not seem to cause difficulty. Under conditions of considerable acceleration (three times gravity or 3g) the ability of a man to perform physical work may be affected by the limitations imposed on gas exchange across the lung.

(D.V.B.)

Respiration, Human

Respiration is the process by which sufficient oxygen for their needs is delivered to body cells and most of the carbon dioxide that these cells form is eliminated into the atmosphere. This process is carried out by (1) a physiologic pump that moves oxygen-rich air and carbon dioxide-laden air between the atmosphere and the surface for gas exchange with blood; (2) a transport system between this surface and the body cells; and (3) a control system matching pumping and transport to the requirements of the cells. The pumping of air is done by the chest, abdomen, and lungs. The surface for exchange of oxygen and carbon dioxide consists of the walls of the alveoli—minute air sacs in the lungs—and of the walls of the tiny blood vessels in the alveolar walls. Transport of oxygen and carbon dioxide is carried out by the blood as it is pumped by the heart through the blood vessels. Control is maintained by the nervous system, which activates muscles in response to impulses from receptors sensitive to cellular needs. Thus, many structures and organs besides those of the respiratory system are involved in respiration: the lungs, the bronchi, the trachea, the throat, and the nose.

While a presentation of respiration divides itself logically into a consideration of each part of the process individually, all organs and structures work interdependently in creating an optimal oxygen and carbon dioxide environment for the cell. This article is intended to deal primarily with the processes of breathing and the transport of oxygen and carbon dioxide. Cellular respiration is dealt with in the article METABOLISM, breathing of organisms other than man in RESPIRATION AND RESPIRATORY SYSTEMS.

Mechanics of breathing. Air moves in and out of the lungs in response to differences in pressure. When the air pressure within the alveolar spaces falls below atmospheric pressure, air enters the lungs (inspiration), provided the larynx is open; when the air pressure within the alveoli exceeds atmospheric pressure, air is blown from the lungs (expiration). The flow of air is rapid or slow in proportion to the magnitude of the pressure differences. Because atmospheric pressure remains relatively constant, flow is determined by how much above or below atmospheric pressure the pressure within the lungs rises or falls.

Alveolar pressure fluctuations are caused by expansion and contraction of the lungs resulting from tensing and relaxing of the muscles of the chest and abdomen. Each small increment of expansion transiently increases the space enclosing lung air. There is, therefore, less air per unit volume within the lungs and pressure falls. A difference in air pressure between atmosphere and lungs is created, and air flows in until equilibrium with atmospheric pressure is restored at a higher lung volume. When the muscles of inspiration relax, the volume of chest and lungs decreases, lung air becomes transiently compressed, its pressure rises above atmospheric pressure, and flow into the atmosphere results until pressure equilibrium is reached at the original lung volume. This, then, is the sequence of events during each normal respiratory cycle: lung volume change, leading to pressure difference, resulting in flow of air into or out of the lung, and establishment of a new lung volume.

Elastic properties of lung

The lung–chest system. The forces that normally cause changes in volume of the chest and lungs stem not only from muscle contraction but from the elastic properties of both the lung and the chest. A lung is similar to a balloon in that it resists stretch, tending to collapse almost totally unless held inflated by a pressure difference between its inside and outside. This tendency of the lung to collapse or pull away from the chest is measurable by carefully placing a blunt needle between the outside of the lung and the inside of the chest wall, thereby allowing the lung to separate from the chest at this particular spot. The pressure measured in the small pleural space so created is substantially below atmospheric pressure at a time when the pressure within the lung itself equals atmospheric pressure. This negative (below atmospheric) pressure is a measure, therefore, of the force required to keep the lung distended. The force increases (pleural pressure becomes more negative) as the lung is stretched and its volume increases during inspiration. The force also increases in proportion to the rapidity with which air is drawn into the lung and decreases in proportion to the force with which air is expelled from the lungs. In summary, the pleural pressure reflects primarily two forces: (1) the force required to keep the lung inflated against its elastic recoil and (2) the force required to cause airflow in and out of the lung. Because the pleural pressure is below atmospheric pressure, air is sucked into the chest and the lung collapses (pneumothorax) when the chest wall is perforated, as by a wound or by a surgical incision.

The force required to maintain inflation of the lung and to cause airflow is provided by the chest and diaphragm (the muscular partition between chest and abdomen), which are in turn stretched inward by the pull of the lungs. The lung-chest system thus acts as two opposed coiled springs, the length of each of which is affected by the other. Were it not for the outward traction of the chest on the lungs, these would collapse; and were it not for the inward traction of the lungs on the chest and diaphragm, the chest would expand to a larger size and the diaphragm would fall from its dome-shaped position within the chest.

The role of muscles. The role of respiratory muscles is to displace the equilibrium of elastic forces in lung and chest in one direction or the other by adding muscular contraction. During inspiration, muscle contraction is added to the outward elastic force of the chest to increase the traction on the lung required for its additional stretch. When these muscles relax, the additional retraction of lung returns the system to its equilibrium position.

Contraction of the abdominal muscles displaces the equilibrium in the opposite direction by adding increased abdominal pressure to the retraction of lungs, thereby further raising the diaphragm and causing forceful expiration. This additional muscular force is removed on relaxation and the original lung volume is restored. During ordinary breathing, muscular contraction occurs only on inspiration, expiration being accomplished "passively" by elastic recoil of the lung.

At total relaxation of the muscles of inspiration and expiration, the lung is distended to a volume—called the functional residual capacity—of about 40 percent of its maximum volume at the end of full inspiration. Further reduction of the lung volume results from maximal contraction of the expiratory muscles of chest and abdomen. The volume in these circumstances is known as the residual volume; it is about 20 percent of the volume at the end of full inspiration (known as the total lung capacity). Additional collapse of the lung to its "minimal air" can be accomplished only by opening the chest wall and creating a pneumothorax.

The membrane of the surface of the lung (visceral pleura) and on the inside of the chest (parietal pleura) are normally kept in close proximity (despite the pull of lung and chest in opposite directions) by surface tension of the thin layer of fluid covering these surfaces. The strength of this bond can be appreciated by the attempt to pull apart two smooth surfaces, such as pieces of glass, separated by a film of water.

The respiratory pump and its performance. The energy expended on breathing is used primarily in stretching the lung–chest system and thus causing airflow. It normally amounts to 1 percent of the basal energy requirements of the body but rises substantially during exercise or illness. The respiratory pump is versatile, capable of increasing its output 25 times, from a normal resting level of about six litres (366 cubic inches) per minute to 150 litres (9,150 cubic inches) per minute in adults. Pressures within the lungs can be raised to 130 centimetres of water (about 1.8 pounds per square inch) by the so-called Valsalva manoeuvre—*i.e.,* a forceful contraction of the chest and abdominal muscles against a closed glottis (*i.e.,* with no space between the vocal cords). Airflow velocity, normally reaching 30 litres (1,830 cubic inches) per minute in quiet breathing, can be raised voluntarily' to 400 litres (24,400 cubic inches) per minute. Cough is accomplished by suddenly opening the larynx during a brief Valsalva manoeuvre. The resultant high-speed jet of air is an effective means of clearing the airways of excessive secretions or foreign particles. The beating of cilia (hairline projections) from cells lining the airways normally maintains a steady flow of secretions toward the nose, cough resulting only when this action cannot keep pace with the rate at which secretions are produced.

An infant takes 33 breaths per minute with a tidal volume (the amount of air breathed in and out in one cycle) of 15 millilitres, totalling about 0.5 litre—approximately one pint—per minute as compared to adult values of 14 breaths, 500 millilitres, and seven litres (14 pints), respectively.

If the force of surface tension is responsible for the adherence of parietal and visceral pleurae, it is reasonable to question what keeps the lungs' alveolar walls (also fluid-covered) from sticking together and thus eliminating alveolar air spaces. In fact, such adherence occasionally does occur and is one of the dreaded complications of premature births. Normal lungs, however, contain a substance—a phosphalipid surfactant—that reduces surface tension and keeps alveolar walls separated.

Composition of lung air and arterial blood. Lung, or pulmonary, air contains less oxygen, more carbon dioxide, and more water vapour than atmospheric air. Oxygen is lost to the blood of the pulmonary capillaries (the smallest blood vessels), carbon dioxide is added from venous blood entering the pulmonary capillaries, and the water vapour content is raised by virtue of saturation at body temperature (37" C, 98.6" F). The Table lists representative values for room air, tracheal air at the end of inspiration, and alveolar air in terms of both concentration and partial pressure.

Concentrations and Partial Pressures of Respiratory Gases at Inspiration

key: F—concentration; P—partial pressure (mm Hg)

	dry room		trachea		alveoli	
	F	P	F	P	F	P
Nitrogen (N_2)	.7900	600	.7408	563	.7408	563
Oxygen (O_2)	.2096	159	.1960	149	.1447	110
Carbon dioxide (CO_2)	.0004	1	.0004	1	.0527	40
Water vapour (H_2O)	.0	0	,0618	47	.0618	47
	1.000	760	1.000	760	1.000	760

Composition of air in alveoli

The alveoli. Of the four gases in alveolar air, two (water vapour and nitrogen) have fixed concentrations, whereas the concentration of the other two (oxygen and carbon dioxide) is variable within limits. When the volume of air entering and leaving the alveoli per minute (ventilation) is increased, carbon dioxide is "blown off" from the lungs and body and its partial pressure in the alveoli falls; when ventilation is decreased, the alveolar partial pressure of carbon dioxide rises. Any such change in partial pressure of carbon dioxide is attended by an opposite variation in the concentration of oxygen. This occurs because the total pressure of the air remains relatively constant, as does that of two of its components, water vapour and nitrogen; any change in concentration of one of the two remaining components must be accompanied by an opposite change in the other.

The management of the pressure of oxygen in blood and in tissue fluid hinges, therefore, on eliminating carbon dioxide by ventilation of the alveoli. One of the remarkable attributes of the respiratory system is the delicacy with which alveolar ventilation is modulated to meet varying rates of carbon dioxide production and of oxygen utilization by the body, as during exercise or fever. When alveolar ventilation does fail, carbon dioxide retention (hypercapnia) and a deficit of oxygen (hypoxia) ensue. In such an event, the pressure of oxygen in alveoli and blood can be maintained only by adding oxygen to inspired air.

The airways and "dead space." Air in the airways (bronchi, trachea, throat, and nose) at the end of inspiration differs from room air only in that it is saturated with water vapour at body temperature. At the end of expiration, on the other hand, the airways are filled with alveolar air in equilibrium with the gases in the pulmonary capillary blood.

The volume of the airways, approximately 150 millilitres (about 0.3 pint) in adults, is referred to as dead-space volume because no exchange of gases with blood occurs in the airways. To the extent that alveoli also fail to exchange gases with blood effectively, as when pulmonary capillaries are absent, they add to the airway, or anatomic dead space, an increment referred to as physiologic dead space. The sum of the anatomic and physiologic dead spaces is normally not more than one-third of a normal breath (one tidal volume).

Inasmuch as total ventilation is the sum of alveolar ventilation plus dead-space ventilation, ventilatory effort for a given alveolar ventilation is reduced or augmented as dead space is reduced or increased. Economy of respiratory effort requires, therefore, that both anatomic and physiologic dead spaces be as low as possible. One of the effects of reducing the blood flow through capillaries that are nevertheless ventilated, as in certain diseases of the lung, is to increase physiologic dead space. In any case, expired air is a mixture originating in parts of the lung that are imperfused (anatomic dead space) and perfused to varying degrees.

Anatomic and physiologic bypasses

The arterial blood. Just as air leaving the lungs is a mixture, so also is the blood returning to the heart from the lungs. This is true for two reasons: (1) Some blood bypasses the gas-exchanging surface entirely (anatomic shunt). (2) Some alveoli are ventilated less than is required in order to maintain an optimal concentration or partial pressure of oxygen (physiologic shunt); the blood returning from such alveoli is, therefore, more like venous blood. The mixture of circulating arterial blood accordingly reflects the magnitude both of the anatomic shunts (increased by some forms of congenital heart disease) and of the physiologic shunts (increased by some lung diseases), as well as reflecting the general level of alveolar ventilation.

In summary, both expired air and arterial blood are mixtures. The mix of expired air reflects in part the nonuniformity of the perfusion of blood through the alveoli; the amount of oxygen in the arterial blood is a measure of the nonuniformity of alveolar ventilation.

Diffusion of oxygen and carbon dioxide between air and blood. Gases are exchanged between alveolar air and pulmonary capillary blood by diffusion in response to differences in partial pressure (the pressure of one of the components of a mixture of gases). Since the partial pressure of oxygen in alveolar air is higher than that of the venous blood entering the lung, oxygen enters the fluid and red blood cells in the capillaries until its pressure there virtually equals its pressure in the alveoli. And since carbon dioxide has a higher partial pressure in venous blood than in alveolar air, it diffuses from the capillaries into the alveoli until there is an equilibrium of pressures. Because the rate of diffusion between a liquid and a gas depends in part on the solubility of the gas in the liquid and, further, because carbon dioxide is about 20 times more soluble than oxygen in lung fluid, equilibrium in the exchange of carbon dioxide is reached more rapidly than for oxygen.

A given red blood cell normally remains within a pulmonary capillary approximately 0.7 second, substantially longer than the time required for oxygen-exchange equilibrium in normal circumstances. When some abnormality in the capillary wall or the red cells slows down the passage of oxygen, a deficit of oxygen in the blood results unless the alveolar partial pressure of oxygen is raised either by hyperventilation with air low in carbon dioxide or by breathing an oxygen-enriched mixture.

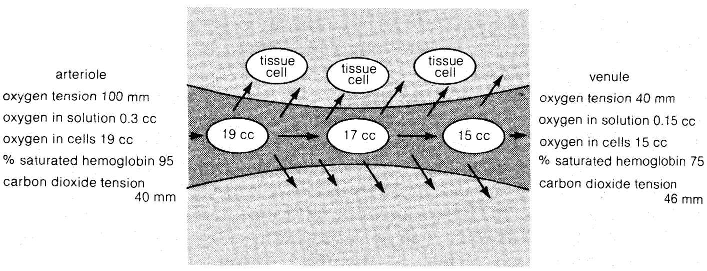
The effectiveness of the lung in carrying out diffusion (pulmonary diffusing capacity) can be measured in terms of how much oxygen or some other gas, usually carbon monoxide, diffuses from alveoli to capillaries per unit difference in the partial pressures at those two sites. Diffusing capacity increases from infancy to adulthood and with exercise, suggesting an increase in surface area of the alveolar capillary bed. Diffusing capacity is lowered when the number of alveoli and capillaries has been reduced or when the structures between alveoli and capillary channels are thickened.

Gas transport. Oxygen and carbon dioxide are transported between tissue cells and the lungs by the blood. The quantity transported is determined both by the rapidity with which the blood circulates and by the proportion of gas delivered that is removed by the tissues.

The rapidity of circulation is determined by the output of the heart, which in turn is responsive to overall body requirements. Local flows can be increased selectively, as occurs, for example, in the flow through skeletal muscles during exercise. The performance of the heart and circulatory regulation are, therefore, important determinants of gas transport.

Oxygen in solution and in red blood cells

Transport of oxygen. Oxygen is transported both in solution within the plasma (the blood except for its blood cells) and in combination with hemoglobin within the red blood cells. The oxygen dissolved in plasma is approximately 0.3 millilitre per 100 millilitres of blood. In the same quantity of blood (100 millilitres) there are approximately 14 grams of hemoglobin, which carries



arteriole

Passage of oxygen from blood to tissues in a resting organ (see text).
From Samson Wright's Applied Physiology, **revised by** Cyril A. Keele and Eric Neil, 11th ed. (1965); Oxford University Press

18.76 millilitres of oxygen, more than 60 times the amount in solution in the plasma.

Not all of the oxygen transported is transferred to the tissue cells. The amount they extract depends in part on their rate of energy expenditure. Changes in oxygen requirements of the tissue cells are met by changes in either the rate at which oxygen is delivered by the blood (how much blood perfuses a tissue per unit of time) or the degree to which oxygen is extracted from a given quantity of blood or by both processes.

Oxygen escapes from arterial blood into tissue fluid in response to a difference in partial pressure. The partial pressure at equilibrium between tissue and arterial blood becomes the partial pressure of oxygen in venous blood returning to the lung for replenishment of oxygen and completion of the transport cycle.

The amount of oxygen held combined with hemoglobin varies with the partial pressure to which the hemoglobin or blood is exposed. The relationship between amount held and partial pressure is such that hemoglobin is practically fully saturated by exposure to alveolar partial pressure of oxygen and holds oxygen relatively poorly at tissue partial pressures. It arrives at the tissue "fully loaded," therefore, and normally, when it leaves, has released about one-fifth of its oxygen (see the illustration). Delivery to the tissues is favoured also by the fact that carbaminohemoglobin (see below) formed in the tissue capillaries has a relatively poor affinity for oxygen.

Hemoglobin in the fetus differs from that in the adult in having greater affinity for, or tendency to combine with, oxygen at a given partial pressure of oxygen. This characteristic makes it possible for fetal blood to carry sufficient oxygen despite its low partial pressure of oxygen (about one-third that of maternal blood). The normal low oxygen level of fetal blood is caused by the dilution of arterial maternal blood by deoxygenated fetal venous blood in the placenta.

In a recent discovery, red blood cells were found to contain a substance—2,3-diphosphoglycerate—capable of increasing the availability of oxygen to tissues by reducing the tendency of hemoglobin to hold oxygen at its low partial pressure. It was found that the quantity of the substance in the red blood cells increases with gains in altitude, with occurrences of the diseases emphysema (abnormal inflation of the lungs) and anemia (characterized by a low number of normal red blood cells or low quantity of normal hemoglobin), and in other circumstances in which delivery of oxygen to tissues is in jeopardy.

Four methods of CO_2 transport

Carbon dioxide transport. Venous blood leaving the tissues contains about 52 millilitres of carbon dioxide per 100 millilitres; arterial blood leaving the lungs contains about 48 millilitres. The four-millilitre difference, representing the amount removed in the expired air, is transported in four forms: (1) a negligible amount as carbonic acid (H_2CO_3); (2) about 0.3 millilitre as free gas in solution; (3) about 1.2 millilitres combined with protein (carbaminohemoglobin); and (4)about 2.5 millilitres as bicarbonate ions (HCO_3^-). Almost all of the gas, therefore, is transported in two forms, either as carbaminohemoglobin (30 percent of the total) or bicarbonate (63 percent).

Hemoglobin's ability to transport carbon dioxide from the tissues to the lungs and release it there is enhanced because hemoglobin lean in oxygen (reduced hemoglobin) combines more readily with carbon dioxide than hemoglobin rich in oxygen (oxyhemoglobin). Thus when oxygen-laden hemoglobin arrives at the tissues and releases oxygen, it then tends to pick up carbon dioxide, becoming carbaminohemoglobin. Conversely, when hemoglobin laden with carbon dioxide arrives in the lung and takes up oxygen, it tends to release carbon dioxide, which is diffused into the lung alveoli and breathed out.

The major part (63 percent) of the carbon dioxide that has diffused from the tissues with the blood of the capillaries and has been transported as bicarbonate combines with water to form carbonic acid (H_2CO_3). The reaction is slow when the enzyme carbonic anhydrase is absent from the red blood cells; usually, however, the enzyme is present, and carbonic acid forms some 200 times faster than it does outside the cells. Carbonic acid within the red cells quickly dissociates to hydrogen ions (H^+) and bicarbonate ions (HCO_3^-), most of the hydrogen ions being taken up by reduced hemoglobin, a weak acid. The bicarbonate ions are matched by intracellular cations (positive ions), primarily potassium.

In the lung, the equilibrium shifts oppositely. As oxyhemoglobin, a more ionized acid, is formed, hydrogen ions are released, resulting in carbonic acid, which is dissociated within the red cell to carbon dioxide for diffusion into the plasma and then to alveolar gas.

Oxygen and carbon dioxide reciprocate in effecting changes in hemoglobin, each fostering the release and transport of the other. The change in affinity for hydrogen ions, characteristic of reduced and oxygenated hemoglobins, makes it possible for carbon dioxide transport to occur with minimal change in the hydrogen ion concentration of the blood.

Regulation. The movements of breathing continue independently of volition or consciousness and yet are responsive to the will and to changes in the organism or environment. Regulation of breathing, therefore, includes provision for automaticity, for optional volitional control, and for appropriate responsiveness.

Automaticity of rhythm and depth of breathing

Automaticity is incompletely understood. Cells in the brainstem in front of the fourth ventricle (a fluid-filled cavity near the base of the brain) are closely implicated in establishing the rhythm and depth of breathing. These cells are sensitive to fluctuations in carbon dioxide partial pressure and the hydrogen ion concentration of their surrounding fluid, producing changes in alveolar ventilation in keeping with the maintenance of normal carbon dioxide and hydrogen ion concentrations. The cells are also affected by impulses from higher stations in the central nervous system that mediate volitional and "psychogenic" respiratory drives.

Finally, the cells in the brainstem receive impulses from chemoreceptors (structures responding to chemical stimuli) sensitive to carbon dioxide, hydrogen ion concentrations, and oxygen pressures; these receptors are located above the heart (in the arch of the aorta) and at the base of the neck (in the fork, or bifurcation, of the common carotid artery). Impulses also come from other types of receptors: stretch receptors in the lung and chest that signal both stretch-inspiration and relaxation-expiration; receptors that are in the vicinity of joints and detect activity there; receptors variously scattered, as in the skin, that do not have specific relevance to respiration but that nevertheless influence breathing through medullary centres. Clearly, therefore, the system is designed to provide feedback to the centre from peripheral sensors responsive to a variety of changes.

The partial pressure of carbon dioxide in the tissues is the variable most delicately preserved by the regulatory mechanisms. This is assured primarily by the sensitivity of medullary cells themselves (the cells in the medulla, that part of the brainstem directly above the spinal cord) and secondarily through the aortic and carotid chemoreceptors. Alveolar ventilation is about doubled when arterial carbon dioxide pressure is increased from 40 to 43 millimetres of mercury and is quadrupled by an increase from 40 to 47 millimetres.

Increased acidity (hydrogen ion concentration) of either blood or medullary tissue fluid also increases alveolar ventilation. Indeed, evidence suggests that the effect of carbon dioxide on alveolar ventilation is indirect, through an attendant rise in hydrogen ion concentration.

A low oxygen level is a relatively ineffectual respiratory drive, a fall in arterial oxygen pressure all the way to 60 millimetres of mercury (from a normal of about 100 millimetres) being required to induce a ventilatory response. When the respiratory centre loses its sensitivity to carbon dioxide, and alveolar ventilation fails, however, stimulation through the chemoreceptors sensitive to oxygen becomes critical.

In summary, the regulation of breathing is one of the most impressive examples of complex physiologic regulation in the interest of preserving an optimal cellular environment.

BIBLIOGRAPHY. Textbooks of physiology are one important source of additional information. Three particularly recommended are: A.C. GUYTON, *Basic Human Physiology,* (1971); V.E. MOUNTCASTLE (ed.), *Medical Physiology,* 12th ed. (1968); and C.H. BEST and N.B. TAYLOR, *The Physiological Basis of Medical Practice,* 8th ed. (1966). Monographs devoted entirely to either the subject as a whole or specific subdivisions are: J.H. COMROE, *The Physiology of Respiration* (1965); J.E. COTES, *Lung Function,* 2nd ed. (1968); and E.J.M. CAMPBELL, E. AGOSTINI, and J. NEWSOM DAVIS, *The Respiratory Muscles,* 2nd ed. (1970). An annual review of developments in the field may be found in the *Annual Review of Physiology.*

Respiration and Respiratory Systems

Man failed to understand–the significance of his own breathing until late in the 18th century. In 1777 Lavoisier reported that the air in a closed jar containing a breathing bird showed an increasing amount of a gas that was absorbed by soda lime; that as the animal continued to respire there was a decrease in a life-sustaining gas he called *oxygdne.* The gas absorbed by soda lime was carbon dioxide.

The life processes of animals involve the expenditure of energy, and it is through the oxidation of molecules containing carbon that this energy, along with carbon dioxide, is released. Respiration is the process in which animal organisms consume oxygen and release carbon dioxide. This exchange of oxygen taken in for carbon dioxide given out stands in a remarkable relationship with plant life, for plants take in carbon dioxide and yield up oxygen, which can then enter once again into animal metabolism (see Figure 1). Although the acquisition of oxygen and elimination of carbon dioxide are essential requirements for all animals, the amounts vary according to the kind of animal and its state of activity. In relation to its weight, a butterfly requires more oxygen than a man, considerably more when it is flying. In Table 1 the oxygen consumption of various animals is expressed in terms of millilitres per kilogram of weight per hour. The butterfly of the genus *Vanessa,* for example, consumes 600 millilitres of oxygen per kilogram of weight per hour when resting, but during flight its consumption rises to 100,000 millilitres per kilogram of weight per hour—or 25 times as much, in relative terms, as a man doing hard physical work.

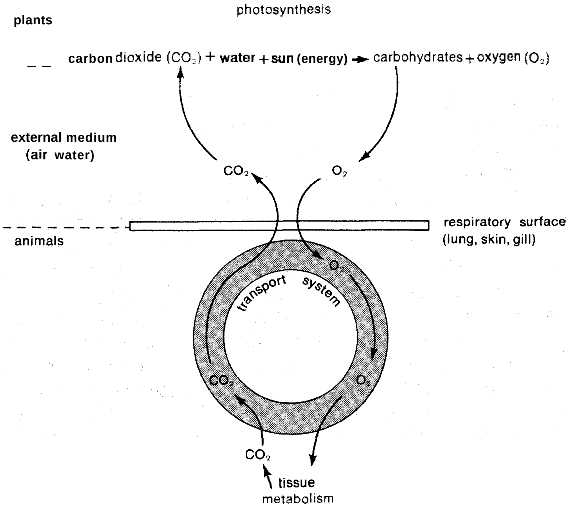

Figure 1: Relationship between photosynthesis and respiration (see text).

Table 1: Oxygen Consumption of Various Animals and Its Variation with Rest and Activity

	weight (grams)	oxygen consumption (millilitres per kilogram of weight per hour)
Paramecium	0.000001	500
Mussel (*Mytilus*)	25	22
Crayfish (*Astacus*)	32	47
Butterfly (Vanessa)	0.3

running		20,000
Man	70,000	
resting		200
maximal work		4,000

Source: A. Krogh, The Comparative Physiology of Respiratory Mechanisms (1959).

Very small organisms such as Protozoa require no special respiratory apparatus but rely on the diffusion of oxygen and carbon dioxide across the general surface area of their cell membranes. The evolution of larger animals has been accompanied by the development of specialized mechanisms for extracting oxygen from the environment and releasing carbon dioxide. These include gills, lungs, and various modifications of the outer surface of the body; all have in common the presentation to the external environment of a large surface area, often well-supplied with blood vessels, across which diffusion of the gases can occur. Since the tissues that ultimately consume oxygen may be quite remote from the gas-exchange surfaces, transport systems are employed to deliver gases across relatively great distances. The circulatory system in vertebrate animals is controlled by delicate mechanisms that regulate local blood flow in accordance with the needs of the various tissues. Many animals have specialized blood-borne pigments (hemoglobins in vertebrates, hemoglobins and other pigments in invertebrates) that convey most of the oxygen from the respiratory exchange surface to the tissues. The blood plasma itself is an aqueous fluid that holds only a limited quantity of oxygen.

Since an animal's requirements for oxygen vary over a wide range, its capacity for gas exchange with the environment must be adjusted accordingly. Increases in respiratory depth and rate result from strenuous exercise; quiet sleep or rest is correspondingly accompanied by a reduction in respiratory activity. In many animals the nervous system senses changes in the chemical composition of the body fluids reflecting the gas demands; the central nervous system then responds by exciting or depressing the machinery of external respiration.

The article is divided into the following sections:

I. General features

THE GASES IN THE ENVIRONMENT

Varying composition of air

The range of respiratory problems faced by aquatic and terrestrial animals can be seen from the varying composition and physical characteristics of water and air. Air contains about 20 times the amount of oxygen found in air-saturated water. In order to extract an equivalent amount of oxygen as an air breather, an aquatic animal may find it necessary to pass across the respiratory surfaces a relatively larger volume of the external medium. Moreover, the diffusion rate of oxygen is much lower in water than in air. The problem is further compounded by the higher density (1,000 times ail) and viscosity (100 times air) of water, which impose on the machinery of aquatic respiration a much greater work load. Thus it is not surprising to find that fish may expend about 20 percent of their total oxygen consumption in running the respiratory pump, as compared with about 1 to 2 percent in mammals, including man.

The carbon dioxide content of most natural waters is low compared to air, often almost nil. In contrast to oxygen, carbon dioxide is extremely soluble in water and diffuses rapidly. Most of the carbon dioxide entering water combines either with the water (to form carbonic acid) or with other substances (to form carbonates or bicarbonates). This buffering capacity maintains a low level of free carbon dioxide and facilitates the maintenance of a favourable diffusion gradient for carbon dioxide exchange by water breathers. In general, oxygen exchange, which is strongly dependent on the oxygen content of the water, is more critically limiting for aquatic forms than is the exchange of carbon dioxide.

Temperature exerts a profound effect on the solubility of gases in water. A change from 5° to 35° C (41" to 95" F) reduces the oxygen content of freshwater by nearly half. At the same time, a rise in body temperature produces an increase in oxygen consumption among animals that do not closely regulate their body temperatures (so-called cold-blooded animals). A fish experiencing both rising water and body temperatures is under a double handicap: more water must be pumped across its gill surfaces to extract the same amount of oxygen as was needed at the lower temperature; and the increased metabolism requires greater quantities of oxygen.

The amount of oxygen available in natural waters is also limited by the amount of dissolved salts. This factor is a determinant of oxygen availability in transitional zones between sea and freshwater. Pure water, when equilibrated with oxygen at 0° C, for example, contains about 50 millilitres of oxygen per litre; under the same conditions, a solution containing 2.9 percent of sodium chloride contains only 40 millilitres of oxygen per litre. Bodies of water may have oxygen-poor zones. Such zones are especially evident in swamps and at the lower levels of deep lakes. Many animals are excluded from such zones; others have become remarkably adapted to living in them.

The Earth's atmosphere extends to a height of many miles. It is composed of a mixture of gases held in an envelope around the globe by gravitational attraction. The atmosphere exerts a pressure proportional to the weight of a column of air above the surface of the Earth extending to the limit of the atmosphere: atmospheric pressure at sea level is sufficient to support a column of mercury 760 millimetres in height (abbreviated as 760 mm Hg—the latter being the chemical symbol for mercury). Dry air is composed chiefly of nitrogen (79.02 percent), oxygen (20.94 percent), and carbon dioxide (0.03 percent), each contributing porportionately to the total pressure. These percentages are relatively constant to about 50 miles in altitude. At sea level and a barometric pressure of 760 millimetres of mercury, the pressure of nitrogen is 79.02 percent of 760 millimetres of mercury, or 600.55 millimetres of mercury; that of oxygen is 159.16 millimetres of mercury; and that of carbon dioxide is 0.20 millimetres of mercury.

The existence of water vapour in a gas mixture reduces the partial pressures of the other component gases but does not alter the total pressure of the mixture. The importance of water-vapour pressure on gas composition can be appreciated from the fact that at the body temperature of man (37° C, or 98.6" F), the atmospheric air drawn into the lungs becomes saturated with water vapour. The water-vapour pressure at 37° C is 47 millimetres of mercury. To calculate the partial pressures of the respiratory gases, this value must be subtracted from the atmospheric pressure. For oxygen, 760 (the atmospheric pressure) —47 = 713 millimetres of mercury, and 713 × 0.209 (the percentage of oxygen in the atmosphere) = 149 millimetres of mercury; this amounts to some ten millimetres of mercury lower than the partial pressure of oxygen in dry air at 760 millimetres of mercury total pressure.

Atmospheric pressures fall at higher altitudes, but the composition of the atmosphere remains unchanged, At 25,000 feet the atmospheric pressure is 282 millimetres of mercury and the partial pressure of oxygen about 59 millimetres of mercury. Oxygen continues to be only 20.94 percent of the total gas present. The rarefaction of the air at high altitudes not only limits the availability of oxygen for the air breather, it also limits its availability for aquatic forms, since the amount of dissolved gas in water decreases in parallel with the decline in atmospheric pressure. Lake Titicaca in Peru is at an altitude of about 12,500 feet (3,810 metres); one litre of lake water at this altitude (and at 20° C, or 68° F) holds 4 millilitres of oxygen in solution; at sea level, it would hold 6.4.

These variations in the characteristics of air and water suggest the many problems with which the respiratory systems of animals must cope in procuring enough oxygen to sustain life.

BASIC TYPES OF RESPIRATORY STRUCTURES

Absence of respiratory organs in some small animals

The first step in respiration takes place at surfaces or interfaces between the organism and an environmental medium that contains oxygen. Small forms, such as protozoans, utilize their entire surface. Multicellular animals of considerably greater bulk than the protozoans may also utilize their general body surface for gas exchange. Flatworms, for example, have no specialized respiratory structures; because of their flatness, the distance between the surface and the interior fall well within the range in which diffusion alone is sufficient to meet oxygen requirements so that no specialized internal transport system is required for delivery. Among other animals the respiratory exchange sites may take the form of gills, lungs, specialized areas of the intestine or pharynx (in certain fishes), or tracheae (air tubes penetrating the body wall, as in insects).

Respiratory structures typically have an attenuated shape with a semipermeable surface that is large in relation to the volume of the structure. Within them there is usually a circulation of body fluids (blood through the lungs, for example). Two sorts of pumping mechanisms are frequently encountered: one to renew the external oxygen-containing medium, the other to insure circulation of the body fluids through the respiratory structure. In air-breathing vertebrates, alternately contracting sets of muscles create the pressure differences needed to expand or deflate the lungs, while the heart pumps blood through the respiratory surfaces within the lungs.

Respiratory organs of invertebrates. ***Tracheal** respiration.* The principal device for external respiration in insects is a system of tubes (tracheae) opening by pores (spiracles) to the outside and branching into smaller units (tracheoles) as they penetrate deeply into the tissues (see Figure 2). There are typically two pairs of spiracles in the thorax and eight in the abdomen. The spiracles may open and close periodically, and it is thought that spiracular closure is a means of preventing excess water loss through evaporation. The rate of opening and closing and the number of spiracles utilized appear to depend on the oxygen demands of the animal. Ventilation of the tracheal system, especially in large insects, may be augmented by muscular pumping motions of the abdomen.

A number of insects spend their larval existence or a good portion of their adult life submerged in water. Some of the adaptations, involving the use of the tracheal system for underwater exchange, are shown in Figure 2. Of special interest are those that might be termed bubble breathers, which, as in the case of the water boatman, take on a gas supply before submerging. The boatman traps an air bubble under its wing surfaces next to its spiracles. The beetles swim down from the surface and cling to algal filaments or other material on the bottom. As oxygen is consumed from the bubble, the partial pressure of oxygen within the bubble falls below that in the water; consequently oxygen diffuses from the water into the bubble to replace that consumed. The carbon dioxide produced by the insect diffuses through the tracheal system into the bubble and on into the water. The bubble thus behaves like a gill. There is one major limitation to this adaptation: as oxygen is removed from the bubble, the partial pressure of the nitrogen rises, and this gas then diffuses outward into the water, The consequence of outward nitrogen diffusion is that the bubble shrinks and must be replaced by another trip to the surface. A partial solution to the problem of bubble renewal has been achieved by small aquatic beetles of the family Elmidae (*e.g., Elmis,* Riolus) that capture bubbles containing oxygen produced by algae and incorporate this gas into the bubble gill. A number of aquatic beetles also augment gas exchange by stirring the surrounding water with their posterior legs.

This figure first appeared in New *Scientist,* the weekly review of science and technology, 128 Long Acre London W C 2

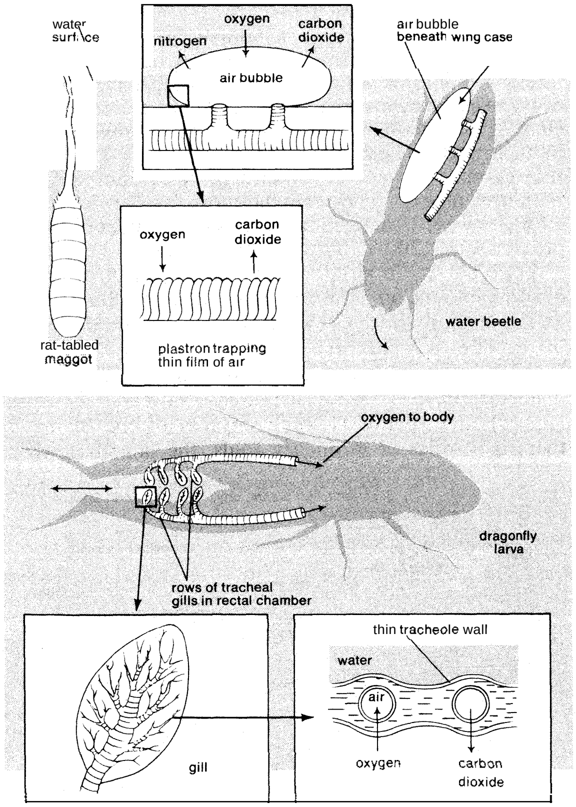

Figure 2: Ways by which aquatic insects obtain oxygen.

An elegant solution to the problem of bubble exhaustion during submergence has been achieved by certain beetles that have a high density of cuticular hair over much of the surface of the abdomen and thorax. The hair pile is so dense that it resists wetting, and an air space is formed below it, creating a plastron, or air shell, into which the tracheae open. As respiration proceeds, the outward diffusion of nitrogen and consequent shrinkage of the gas space are prevented by the surface tension—a condition manifested by properties that resemble those of an elastic skin under tension—between the closely packed hairs and the water. The plastron becomes "permanent" in the sense that further bubble trapping at the surface is no longer necessary, and the beetles may remain submerged indefinitely. Since the plastron hairs tend to resist deformation, the beetles can live at considerable depths without compression of the plastron gas.

The "book lungs" of spiders

The respiratory structures of spiders consist of peculiar "book lungs," leaflike plates over which air circulates through slits on the abdomen. The book lungs contain blood vessels that bring the blood into close contact with the surface exposed to the air and where gas exchange between blood and air occurs. In addition to these structures, there may also be abdominal spiracles and a tracheal system like that of insects.

Since spiders are air breathers, they are mostly restricted to terrestrial situations, although some of them regularly hunt aquatic creatures at stream or pond edges and may actually travel about on the surface film as easily as on land. The water spider Argyroneta aquatica, the frogman of the spider world, utilizes the water-beetle method of capturing air bubbles at the surface. The bubble is pressed against the respiratory openings on the abdomen, but, because there is no permanent plastron, trips must be made to the surface for bubble renewal. Most of the life cycle, however, including courtship and breeding, prey capture and feeding, and development of eggs and embryos, occurs below the water surface. Many of these activities take place in a kind of diving bell formed by silk. The spider weaves an inverted basket-like web that is anchored to underwater plants or other objects. Bubbles captured at the surface are ejected into the interior, inflating the underwater house with air. The combination of bubble trapping and web building has given Argyroneta aquatica access to an environment denied most of its relatives.

Among many immature insects are special adaptations for an aquatic existence. Thin-walled protrusions of the integument, containing tracheal networks, form a series of gills (tracheal gills) serving to bring water into close contact with the closed tracheal tubes (see Figure 2). The nymphs of mayflies and dragonflies have external tracheal gills attached to their abdominal segments, and certain of the gill plates may move in a way that sets up water currents over the exchange surfaces. Dragonfly nymphs possess a series of tracheal gills enclosed within the rectum. Periodic pumping of the rectal chamber serves to renew water flow over the gills. Removing the gills or plugging the rectum results in lower oxygen consumption. A considerable gas exchange also occurs across the general body surface in immature aquatic insects.

The insect tracheal system has inherent limitations. Gases diffuse slowly in long narrow tubes, and effective gas transport can occur only if the tubes do not exceed a certain length. It is generally thought that this has imposed a size limit upon insects.

Varieties of gill-like structures

Gills of invertebrates. Numerous groups of animals, including invertebrates, utilize gills as a major avenue of gas exchange. Almost any thin-walled extension of the body surface that comes in contact with the environmental medium and across which gas exchange occurs can be viewed as a gill. Gills usually have a large surface area in relation to their mass; pumping devices are often employed to renew the external medium.

The marine polychaete worms utilize the general body surface for gas exchange, but they also have a variety of gill-like structures: segmental flaplike parapodia (in *Nereis*) or elaborate branchial tufts (among the families Terebellidae and Sabellidae). The tufts, used to create both feeding and respiratory currents, offer a large surface area for gas exchange.

Although most of the respiratory exchange in echinoderms (starfish, sea urchins, brittle stars) occurs across their tube feet (a series of suction-cup extensions used for locomotion), this exchange is supplemented by extensions of the coelomic, or body-fluid, cavity into thin-walled "gills" or dermal branchiae that bring the coelomic fluid into close contact with seawater. Sea cucumbers (Holothuroidea), soft-bodied, sausage-shaped echinoderms that carry on some respiration through their tube feet, also have an elaborate "respiratory tree" consisting of branched hollow outpouchings off the cloaca (hindgut). Water is pumped in and out of this system by the action of the muscular cloaca, and it is probable that a large fraction of the animals' respiratory gas is exchanged across this system.

Among mollusks gills have a relatively elaborate blood supply, although respiration across the mantle, or general epidermis, also occurs. Clams possess gills across which water circulates, impelled by the movements of millions of microscopic whips called cilia. In the few forms studied, the extraction of oxygen from the water has been found to be low, on the order of 2 to 10 percent. The currents produced, which constitute ventilation, are also utilized for bringing in and extracting food. At low tide or during a dry period, clams and mussels close their shells and thus prevent dehydration. Metabolism then shifts from oxygen-consuming (aerobic) pathways to others in which an accumulation of acid products occurs; when normal conditions are restored, the animals increase their ventilation and oxygen extraction in order to rid themselves of the acid products. Snails have a feeding mechanism that is independent of the respiratory surface. A portion of the mantle cavity in the form of a gill or "lung" serves as a gas-exchange site. In air-breathing snails, the "lung" may be protected from drying out through contact with the air by having only a pore in the mantle as an opening to the outside. Cephalopod mollusks, such as squid and octopus, actively ventilate a protected chamber lined with feathery gills that contain small blood vessels (capillaries); their gills are quite effective, extracting 60 to 80 percent of the oxygen passing through the chamber. In oxygen-poor water, the octopus may increase its ventilation tenfold, indicating a more active control of respiration than appears to be present in other classes of mollusks.

Gills of crustaceans

Many crustaceans (crabs, shrimps, crayfish) are very dependent on their gills; these are often enclosed in protected chambers, and ventilation is provided by specialized appendages that create the respiratory current. As in cephalopod mollusks, oxygen utilization is relatively high —up to 70 percent in the European crayfish Astacus. When the partial pressure of oxygen in the water falls, there is a marked increase in ventilation (the volume of water passing over the gills); at the same time, the rate of oxygen utilization declines somewhat. Although more oxygen is extracted per unit of time, the increased ventilation is not without metabolic cost, since the work of operating the crustacean's respiratory apparatus itself requires oxygen; together with the decrease in extraction per unit of volume, it probably limits aquatic forms of crustaceans to levels of oxidative metabolism lower than those found in many air-breathing forms. Not all crustaceans meet a reduction in oxygen with increased ventilation and metabolism. The square-backed crabs (*Sesarma)* become less active, reducing their oxidative metabolism until more favourable conditions prevail.

Respiratory organs of vertebrates. The organs of external respiration of most vertebrates are usually thin-walled structures well supplied with blood vessels. Such structures bring blood into close association with the external medium so that the exchange of gases takes place across relatively small distances. There are three major types of respiratory structures in the vertebrates: gills, integumentary exchange areas, and lungs. The gills are totally external in a few forms (as in *Necturus*, a neotenic salamander), but in most they are composed of filamentous leaflets protected by bony plates (as in fish). Some fishes and numerous amphibians also use the body integument, or skin, as a gas-exchange structure. Both gills and lungs are formed during the animal's development from outpouchings of the gut wall. Such structures have the advantage of a protected internal location, but this requires some sort of pumping mechanism to move the external gas-containing medium in and out.

The quantity of air or water passing through the lungs or gills each minute is known as the ventilation volume. The rate or depth of respiration may be altered to bring about adjustments in ventilation volume. The ventilation volume of man at rest is approximately six litres per minute. This may increase to more than 100 litres per minute with increases in the rate of respiration and the quantity of air breathed in during each respiratory cycle (tidal volume). Certain portions of the airways (trachea, bronchi, bronchioles) do not participate in respiratory exchange, and the gas that fills these structures occupies an anatomical dead space of about 150 millilitres in volume. Of a tidal volume of 500 millilitres, only 350 millilitres ventilate the gas-exchange sites.

The maximum capacity of human lungs is about six litres. During normal quiet respiration, some 500 millilitres, the tidal volume, is inspired and expired during every respiratory cycle. The lungs are not collapsed at the close of expiration; a certain volume of gas remains within them. At the close of the expiratory act, a normal subject may, by additional effort, expel another 1,200 millilitres of gas. Even after the most forceful expiratory effort, however, there remains a residual volume of approximately 1,200 millilitres. By the same token, at the end of a normal inspiration, further effort may succeed in drawing into the lungs an additional 3,000 millilitres.

Fish gills

Gills of vertebmtes. The gills of fishes are supported by a series of gill arches encased within a chamber formed by bony plates (the operculum). A pair of gill filaments projects from each arch; between the dorsal (upper) and ventral (lower) surfaces of the filaments, there is a series of secondary folds, the lamellae, where the gas exchange takes place (Figure 3). The blood vessels passing through the gill arches branch into the filaments and then into still smaller vessels (capillaries) in the lamellae. Deoxygenated blood from the heart flows in the lamellae in a direction counter to that of the water flow across the exchange surfaces. Microscopic observation has shown that in a number of fishes the water-to-blood distance across which gases must diffuse is from 0.0003 to 0.003 millimetres, or about the same distance as the air-to-blood pathway in the mamm'alian lung.

This diagram first appeared in *New Scientist*, the weekly review of science and technology, 128 Long Acre, London W.C. 2

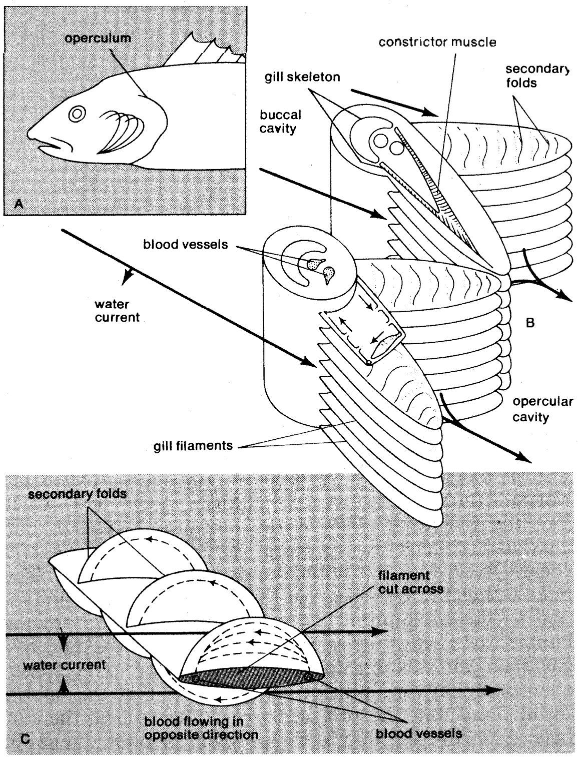

Figure 3: (A) Position of four gill arches beneath operculum on left side of fish. (B) Part of two gill arches with filaments of adjacent rows touching at their tips and the blood vessels that carry the blood before and after its passage over the gills. (C) Part of a single filament with three secondary folds on each side.

The fact that blood flows through the lamellae in a direction counter to that of water has much to do with the efficiency of gas exchange. Laboratory experiments in which the direction of water flow across fish gills was reversed showed that about 80 percent of the oxygen was extracted in the normal situation, while only 10 percent was extracted when water flow was reversed. The uptake of oxygen from water to blood is thus facilitated by countercurrent flow; in this way, greater efficiency of oxygen uptake is achieved by an anatomical arrangement that is free of energy expenditure by the organism. Countercurrent flow is a feature of elasmobranchs (sharks, skates) and cyclostomes (hagfishes, lampreys) as well as bony fishes.

A number of vertebrates use externalized gill structures. Some larval fishes have external gills that are lost with the appearance of the adult structures. A curious example of external gills is found in the male lungfish (Lepidosiren). At the time the male begins to care for the nest, a mass of vascular filaments (a system of blood vessels) develops as an outgrowth of the pelvic fins. The fish meets its own needs by refilling its lungs with air during periodic excursions to the water surface. When it returns to the nest, its pelvic-gill filaments are perfused with well-oxygenated blood, providing an oxygen supply for the eggs, which are more or less enveloped by the gill filaments.

It is theoretically possible for a skin that is well supplied with blood vessels to serve as a major or even the only respiratory surface. This requires a thin, moist, and heavily vascular skin that increases the animal's vulnerability to enemies. In terrestrial animals a moist integument also provides a major avenue of water loss. A number of fishes and amphibians rely on the skin for much of their respiratory ge hibernating frogs utilize the ski for practically all their gas exchanges.

Characteristics of vertebrate lungs

***The** lung.* The lungs of vertebrates range from simple sacklike structures found in the Dipnoi (lungfishes) to the complexly subdivided organs of mammals and birds. An increasing subdivision of the airways and the development of greater surface area at the exchange surfaces appear to be the general evolutionary trend among the higher vertebrates.

In the embryo, lungs develop as an outgrowth of the forward portion of the gut. The lung proper is connected to the outside through a series of tubes; the main tube, known as the trachea (windpipe), exits in the throat through a controllable orifice, the glottis. At the other end the trachea subdivides into secondary tubes (bronchi), in varying degree among different vertebrate groups.

The trachea of amphibians is not divided into secondary tubes but ends abruptly at the lungs. The relatively simple lungs of frogs are subdivided by incomplete walls (septa), and between the larger septa are secondary septa that surround the air spaces where gas exchange occurs. The diameter of these air spaces (alveoli) in lower vertebrates is larger than that in mammals. The alveolus in the frog is about ten times the diameter of that found in humans. The smaller alveoli in mammals are associated with a greater surface for gas exchange: although the respiratory surface of the frog (Rana) is about 20 square centimetres for each cubic centimetre of air, that of man is about 300 square centimetres (46 square inches).

An important characteristic of lungs is their elasticity. An elastic material is one that tends to return to its initial state after the removal of a deforming force. Elastic tissues behave like springs. As the lungs are inflated, there is an accompanying increase in the energy stored within the elastic tissues of the lungs, just as energy is stored in a stretched rubber band. The conversion of this stored, or potential, energy into kinetic, or active, energy during the deflation process supplies part of the force needed for the expulsion of gases. A portion of the energy put into expansion is thus recovered during deflation. The elastic properties of the lungs have been studied by inflating them with air or liquid and measuring the resulting pressures. Muscular effort supplies the motive power for expanding the lungs, and this is translated into the pressure required to produce lung inflation. It must be great enough to overcome (1) the elasticity of the lung and its surface lining; *(2)* the frictional resistance of the lungs; (3) the elasticity of the thorax or thoraco-abdominal cavity; (4) frictional resistance in the body-wall structures; (5) resistance inherent in the contracting muscles; and (6) the airway resistance. The laboured breathing of the asthmatic serves as an example of the added muscular effort necessary to achieve adequate lung inflation when the airway resistance is high, owing to narrowing of the tubes of the airways.

Studies of the pressure-volume relationship of lungs filled with salt solution or air have shown that the pressure required to inflate the lungs to a given volume is less when the lungs are filled with liquid than when they are filled with air. The differences in the two circumstances have been thought to result from the nature of the environment-alveolar interface, that interface being liquid–liquid in the fluid-filled lung and gas–liquid in the air-filled lung. In the case of the latter, the pressure–volume relationship represents the combined effects of the elastic properties of the lung wall plus the surface tension—the property, resulting from molecular forces, that exists in the surface film of all liquids and tends to contract the volume into a form with the least surface area; the particles in the surface are inwardly attracted, thus resulting in tension—of the film, or surface coating, lining the lungs (surface tension being nearly zero in the fluid-filled lung.).

The alveoli of the lungs are elastic bodies of nonuniform size. If their surfaces had a uniform surface tension, small alveoli would tend to collapse into large ones. The result in the lungs would be an unstable condition in which some populations of alveoli would collapse and others would overexpand. This does not normally occur in the lung because of the properties of its surface coating (surfactant), a complex substance composed of lipid and protein. This material causes the surface tension to change in a nonlinear way with surface area. As a result, when the lungs fill with air, the surface tensions of the inflated alveoli are greater than those of the relatively undistended alveoli. This results in a stabilization of alveoli of differing sizes and prevents the emptying of small alveoli into larger ones. It has been suggested that compression wrinkles of the surface coating and attractive forces between adjacent wrinkles inhibit expansion. Surfactants have been reported to be present in the lungs of birds, reptiles, and amphibians.

II. Dynamics of respiratory mechanisms

RESPIRATION IN FISHES

Among the most primitive of present-day vertebrates are the cyclostomes (lampreys and hagfishes), the gill structures of which are in the form of pouches that connect internally with the pharynx (throat) and open outward through slits, either by a fusion of the excurrent gill ducts into a single tube (in Myxine) or individually by separate gill slits (in *Petromyzon*). The gill lamellae of cyclostomes form a ring around the margins of the gill sac, and the series of sacs is supported in a flexible branchial skeleton. The number of paired pouches varies in different forms from six to 14. The pharynx of lampreys divides into an esophagus above and a blind tube below, from which the gill pouches arise. The upper pharynx of hagfishes communicates to the exterior through a nostril, a structure absent in lampreys. When the parasitic lampreys are embedded in the flesh of fish, upon which they live, they maintain a flow of water through the gills by alternate contractions of the gill pouches. When the gill-pouch muscles relax, the pouches expand, and water is sucked in. The water is forced out through the gills by muscular contraction; the branchial musculature apparently prevents reflux of the water into the pharynx while the head of the lamprey is embedded in the flesh of its prey.

In the hagfish Myxine *glutinosa,* the major oxygen supply is derived from water drawn in through the nostril that opens into the pharynx. The velum, a peculiar respiratory structure, lies just behind the nostril opening, where it is suspended from the upper midline of the pharynx by a membrane (the velar frenulum) from which a horizontal bar extends; the structure resembles an inverted T. Membranous scrolls attached to this horizontal bar can extend downward and then roll upward like window shades. During the upward motion, they scoop up water and direct it upward toward the frenulum and backward toward the gill pouches. Muscular sphincters on the inflow and outflow orifices of the gill ducts help to control the directional flow of water through the gill pouches. When the fish exhales, the inflow sphincters contract and the gill-pouch volume decreases; contraction of muscle elements within the gill pouches contributes to the expulsion of water. When the fish inhales, contraction of the outflow and relaxation of the inflow sphincters coupled with the elastic rebound of the gill pouches probably create a favourable pressure gradient for filling. The degree to which velar contractions are coordinated with these gill-pouch contractions is not known. When suspended particles are introduced into the nostril, they produce a violent "sneeze," and the foreign material is expelled from both the mouth and the nostril. This reaction is probably important to an animal having common respiratory and alimentary ducts, in preventing the smothering of respiratory surfaces. Blood flow in the gills of cyclostomes, as in those of bony fishes, is in a direction counter to that of water flow—an arrangement that increases the efficiency of gas exchange across the respiratory surface (Figure 4).

Sharks, rays, and bony fishes

Cartilaginous fishes (sharks and rays) and bony fishes employ a double-pumping mechanism to maintain a relatively constant flow of water over the gill exchange surfaces. The mouth, or buccal, cavity is employed as a positive-pressure pump and the gill cavity as a suction pump. Depression of the buccal cavity produces a pressure below that of the surrounding water, thus promoting flow into the cavity. The gill flaps are closed during this phase of respiration. The gill cavity expands as the opercular muscles relax, and the pressure on the back side of the gill filaments is reduced below the pressure on the buccal cavity. This pressure differential produces flow across the gill surfaces. Following this initial inspiratory phase, the buccal floor is actively elevated, thus creating a positive pressure within the mouth cavity. This produces accelerated flow to the gill cavity, in which the pressure is still negative. As pressure in the gill cavity rises above that of the external medium, the gill flaps are forced open, and water is discharged. This sequence of events has been worked out from studies of the pressures in the buccal (mouth) and opercular (gill) cavities during various phases of the respiratory cycle. In sharks and rays, a small forward gill slit, the spiracle, also provides a channel of water flow into the gill chamber. The importance of the spiracle seems to be correlated with habitat: bottom-dwelling forms (rays and skates) have relatively larger spiracles, and the major portion of the water flow passes through them rather than through the downward-oriented mouth.

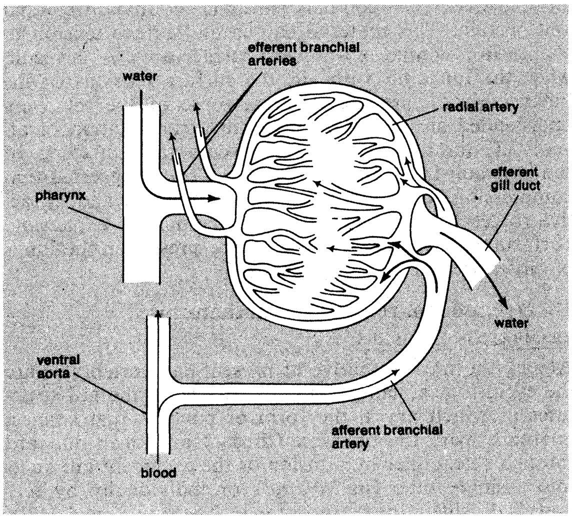

Figure 4: Blood and water flow through gill body of hagfish. Note that water flow is counter to blood flow, an arrangement facilitating gas exchange.

The pumping mechanism is not the only method of ventilation; sharks have been observed to keep both mouth and gill flaps open while swimming, assuring a constant water flow across the gill surfaces. When they slow down or settle to the bottom, the pumping activity is resumed. Tunas and mackerel cannot stop swimming: they have no active respiratory mechanism and are dependent for their gill ventilation on the current that results from their forward motion through the water.

A number of fishes depend in varying degree on aerial respiration. The ability to breathe air enables them to live in places where the oxygen content of water may be low or nil. Two general means of acquiring oxygen are employed. Some fishes stay near the surface of the water where the oxygen pressure resulting from surface diffusion is highest. Others have developed ancillary respiratory structures in the pharynx or the stomach; the gulping of air at the surface is a means of charging these respiratory surfaces (such as the pharyngeal epithelium in Electrophorus or the stomach in Plecostomus); the frequency with which these fishes rise to the surface to gulp air corresponds to their current need for oxygen.

The swamp-dwelling yarrow of Guyana (Erythrinus) uses both aquatic and aerial respiration, varying them according to the gaseous composition of the water. When the oxygen content is low, respiration through the gills ceases; when the oxygen content of the water is high, the fish relies primarily upon its gills except when the carbon dioxide content is also high—when, again, aerial respiration predominates. In other conditions it uses both modes of respiration. This apparently extends the range of conditions in which Erythrinus can survive.

Eels and lungfishes

Eels (*Anguilla*) use their skin as a major respiratory surface in addition to their gills. In water, about 15 percent of their oxygen uptake is across the skin, and this rises to around 50 percent when in air. They are capable of making extensive overland migrations during which, in the first few hours, they draw upon oxygen in the swim bladder. Like most fishes, eels when out of water exhibit a reduced heart rate and less oxygen consumption. When they return to water, their heart rate rises, and both oxygen consumption and blood lactic-acid levels rise. Lactic-acid production results from metabolism without oxygen, and such acid products must themselves be metabolized through higher oxygen consumption. Such patterns have been observed in grunions of the California coast that come ashore to breed and even in flying fishes during their brief aerial excursions.

Lungfishes, which have fossil relatives as far back as Devonian times, are considered closely related to the early amphibians. They extract oxygen from outpouchings of the gut that are biologically similar to the lungs of the higher vertebrates. Lepidosiren, the South American lungfish, has a poorly developed gill circulation and suffocates if denied access to air. But the African form Protopterus is less dependent upon aerial respiration, and the Australian lungfish Neoceratodus has well-developed gills and cannot survive out of water for long periods. Lungfishes inflate their lungs by rising to the surface and gulping a large bubble of air that they force into the lung by compressing the mouth and throat region. The mechanism is thought to be similar to that in many amphibians. Each breath is accompanied by increased heart activity and by a regional shift in blood flow from the body circuit to the lungs. The capacity to maintain a relatively efficient double circulation is an important evolutionary step toward a terrestrial life.

During long periods of drought, both Protopterus and Lepidosiren enter into a state of aestivation, during which metabolism and respiration fall to a low level. *Protopterus* secretes a protective mucous tube around itself with an opening entering the oral cavity. After it builds this cocoon, its oxygen consumption may fall to 10 percent of normal, its respiratory rate to one or two cycles per minute, and its heartbeat to around three per minute. It can survive in this state up to five years.

The bowfin, Amia *calva*, possesses both gills and an air bladder that may be used for respiration. It is almost exclusively a water breather at 10° C (50° F), a temperature at which it shows low physical activity. Its air-breathing rate increases with temperature and activity, and, at around 30° C (86" F), it draws about three times as much oxygen from air as from water. As in lungfishes, carbon dioxide elimination is predominantly across the gills. The bowfin's air-breathing frequency varies inversely with the oxygen content of the water; when oxygen tensions in water decline below 40 or 50 millimetres of mercury at 20° C (68" F), air breathing largely replaces water breathing. When an exchange surface (gill or air bladder) is not being utilized as the primary oxygen-exchange site, there is a tendency for blood to bypass it.

The so-called electric eel of South America (*Electrophorus electricus)* inhabits muddy streams that may become severely oxygen deficient. It is an obligatory air breather that depends upon the exchange of oxygen across the membranes of its mouth, expelling the air through its gill slits. Its blood has a high percentage of red corpuscles, is high in hemoglobin, and has an oxygen-absorbing capacity similar to that of mammals: Carbon dioxide elimination is primarily across the skin and, to a lesser extent, through the vestigial gills.

RESPIRATION IN AMPHIBIANS AND TERRESTRIAL VERTEBRATES

Amphibians. Frogs, toads, salamanders, and caecilians show a varying degree of dependence upon the aquatic habitat. Respiratory surfaces include the skin, the mouth cavity, and the lungs, the dependence on each varying within different groups and with the habitat and the season. The lungless salamanders (Plethodontidae) respire across the skin and to a smaller degree across the membranes of the mouth. Simultaneous use of mouth, skin, and lung respiration occurs in frogs. There is a well-developed blood supply to the lungs in all lunged amphibians; among frogs and toads (Anura) the pulmonary artery supplies not only the lungs but portions of the skin. Blood returns from the lungs directly to the left atrium of the heart; the drainage from the skin combines with the general circulation of blood in the veins.

At some time in their life cycle, frogs use all of the respiratory surfaces seen in other amphibians. In their tadpole stage, they breathe with the skin and the gills. During metamorphosis, they lose their gills and develop lungs. The large tail fins of tadpoles contain blood vessels and are important respiratory structures, but, like the external gills, they are lost during metamorphosis.

The dominant mode of lung inflation in adult frogs is the mouth–throat pumping mechanism seen in lungfishes. The seauence of respiratory movements is shown in Figure 5. The gas sampling probe leading to the respiratory mass spectrometer (a measuring device) is supported by a plastic collar in the rubber mask. Just preceding an expiration, the floor of the mouth is depressed (A), and air is drawn in through the nostrils to the floor of the mouth, where it remains during expiration. The expiratory act (B) is driven by muscles of the body wall and the elastic recoil of the lungs; during this phase the glottis is open and a high-velocity jet of air passes out through the nostrils, without mixing with that inhaled into the floor of the mouth. In the next phase (C), the floor of the mouth is elevated, creating a positive pressure in the mouth cavity and making air flow into the lungs through the open glottis. During this phase the nostrils are closed. After inflation a sequence of pumping actions follows with the glottis closed and the nostrils open (D). This serves to wash out residual expired gas and recharges the buccopharyngeal (mouth–throat) cavity with air.

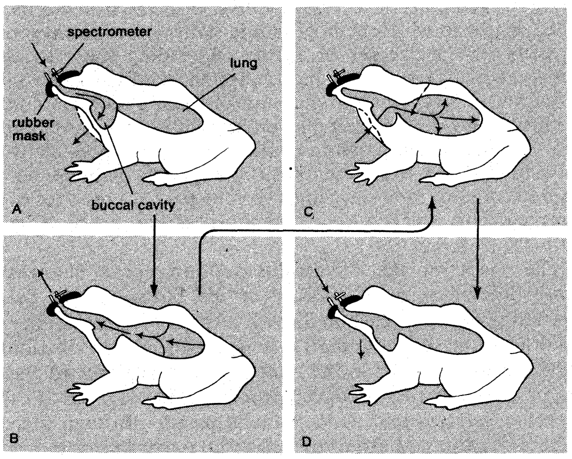

Figure 5: Successive stages of flow during the ventilatory cycle in the American bullfrog, Rana catesbeiana, The arrows indicate the approxirnate sequence of gas flow into and out of buccal cavity and lung (see text).

In frogs, the skin of the back and thighs (the areas exposed to air) contains a richer capillary network than the skin of the underparts. The capillary surface area of the mouth membranes is small compared with that of other respiratory surfaces. The aquatic newt ***Triton*** utilizes both lung and skin respiration, the skin containing about 75 percent of the respiratory capillaries. At the other extreme, the tree frog ***Hyla arborea*** is much less aquatic, and its lungs contain over 75 percent of the respiratory capillary surface area. similar-differences are found even in closely related forms: in the relatively more terrestrial frog, ***Rana** temporaria,* uptake of oxygen across the lung is about three times greater than across the skin; in ***Rana** esculenta,* which is more restricted to water, the lungs are about equal with the skin in the uptake of oxygen. Carbon dioxide is excreted mainly through the skin in both these forms; in fact, the skin appears to be a major avenue for carbon dioxide exchange in amphibians generally.

Reptiles. In becoming land animals, the reptiles had to develop a skin relatively impermeable to water and hence not well suited for respiration. This meant an almost complete dependence upon the lungs. The principal mechanism for lung inflation among reptiles is a suction pump. The power is derived from a muscular expansion of the rib cage and body wall, creating a subatmospheric pressure within the lungs and causing air to flow in.

The respiratory frequency of most reptiles is not regular, the pattern usually consisting of a series of active inspirations and expirations followed by relatively long pauses. As the inspiratory phase ends, the glottis closes, and there is a pause during which the lungs remain inflated. The respiratory muscles relax during this period. As a consequence of their relaxation and of the potential energy stored within the body wall and the stretched lung, the pressures within the abdomen and lungs rise. Expiration may then be largely passive, following upon the opening of the glottis.

Specialized muscles in turtles

The adoption of a rigid shell by turtles necessitated the development of highly specialized muscles to inflate the lungs, which are situated in a frame located between the internal organs and the domed upper shell. In the tortoise ***Testudo graeca,*** lung ventilation is accomplished by changing the volume of the body cavity. Expiration is brought about by the activity of muscles that draw the shoulder girdle back into the shell, compressing the abdominal viscera. The increased pressure in the body cavity is transmitted to the lungs. Inspiration involves opposite muscular actions that produce an increase in the volume of the body cavity and a reduction of lung pressure below that of the atmosphere. Because of the rigidity of the shell, it is not possible to use the potential energy of abdominal wall structures as in other reptiles, and hence for the tortoise both expiration and inspiration are active energy-consuming events.

Birds. Birds must be capable of high rates of gas exchange because their oxygen consumption at rest is relatively high, and it increases severalfold during flight. The gas volume of the bird lung is small compared with that of mammals, but the lung is connected to voluminous air sacs by a series of tubes, making the total volume of the respiratory system about twice that of mammals of comparable size (see Figure 6). The trachea divides into primary bronchi, each of which passes through a lung and onward to the paired abdominal air sacs; they also give rise to secondary bronchi supplying the other air sacs. Tertiary bronchi penetrate the lung mass, and, from

the walls of the tertiary bronchi, rather fine air capillaries arise. These have a large surface area; their walls contain blood capillaries connected with the heart. Gas exchange takes place between the air capillaries and blood capillaries. This surface is analogous to the alveolar surface in mammals.

Complex breathing of birds

The lungs are inflated by enlargement of the chest and abdominal cavity. The sternum (breastbone) swings forward and downward, while the ribs and chest wall move laterally. The pathway of airflow within the lungs and air sacs is not clear. A probable airflow scheme has been developed by inserting small devices into various parts of the airway. Airflow through the lung occurs during both inspiration and expiration, but in expiration it comes from the posterior air sacs. Apparently the anterior air sacs receive the gas after it has traversed the lung during the inflation phase. Fresh air comes into the lung by way of the primary and caudal secondary bronchi. The manner in which gas flow is controlled is not yet clear.

The lungs of birds undergo more complete ventilation than do those of mammals. They show a relatively low partial pressure of carbon dioxide. The ventilation of pigeons increases around 20-fold during flight, brought about by more rapid breathing and not by taking in more air at a breath. There is a precise synchrony between breathing and wing motion: the peak of expiration occurs at the downstroke of the wingbeat. The pigeon's in-flight ventilation is about two and one-half times that needed to support metabolism; around 17 percent of the heat production during flight is lost through evaporative cooling, suggesting that the excess ventilation is for regulating body heat. Studies of evening grosbeaks and ring-billed gulls show that their ventilation, in contrast to that of pigeons, increases in proportion to oxygen consumption. The increased ventilation in these birds is brought about by deeper as well as by more rapid breathing.

The respiratory system of birds is also used for communication through song. The "voice box" is the syrinx, a membranous structure at the lower end of the trachea. Sound is produced only when air flows outward across the syrinx. In canaries, notes or pulses are synchronous with chest movements; the trills, however, are made with a series of shallow breaths. The song of many small birds is of long duration relative to their breathing frequencies.

Mammals. Breathing in mammals is powered by a negative-pressure pump. Expansion of the chest lowers the pressure between the lungs and the chest wall, as well as the pressure within the lungs. This causes atmospheric air to flow into the lungs. The chief muscles of inspiration are the diaphragm and the external intercostal muscles. The diaphragm is a domelike sheet of muscle separating the abdominal and chest cavities that moves downward as it contracts. The downward motion enlarges the chest cavity and depresses the organs below. As the external intercostal muscles contract, the ribs rotate upward and laterally, increasing the chest circumference. During severe exercise other muscles may also be used. Inspiration ends with the closing of the glottis.

In expiration, the glottis opens, and the inspiratory muscles relax; the stored energy of the chest wall and lungs generates the motive power for expiration. During exercise or when respiration is laboured, the internal intercostal muscles and the abdominal muscles are activated. The internal intercostals produce a depression of the rib cage and a decrease in chest circumference.

The membranes surrounding the lungs (visceral pleura) and the membranes of the chest wall (parietal pleura) tend to be held together by the adhesive forces of the fluids between the two membranes. When lung pressure falls below atmospheric pressure, air enters the lungs. A still greater subatmospheric pressure develops in the space between the parietal and visceral pleura, of the order of —6 millimetres of mercury during quiet inspiration. During expiration this pressure rises to about —4 millimetres of mercury. Lung pressure at the beginning of inspiration is subatmospheric (—1 to —2 millimetres of mercury), rising to atmospheric pressure at the close of inspiration; during quiet expiration, lung pressures reach about three millimetres of mercury, returning to atmospheric pressure toward the close. Pressure fluctuations of great magnitude may occur with laboured respiration: intrapleural inspiratory pressure may be as low as —30 millimetres of mercury, while lung pressure may approach 100 millimetres of mercury when active expiratory efforts are made against a closed glottis. The pressure fluctuations within the chest cavity have an important influence on the flow of blood in the large veins that return blood to the heart. Negative pressures tend to create a more favourable gradient for blood flow into the chest cavity, whereas positive pressures tend to impede return of blood to the heart.

GAS TRANSPORT

Respiratory gases move between the air and the blood across the respiratory exchange surfaces in the lungs. The gases are transported in the blood mainly by the red blood cells, which make up about 40 percent of the volume of the blood in most mammals.

Hemoglobin

Transport of oxygen. Most of the oxygen is carried in association with the pigment hemoglobin, which is found in many unrelated groups of animals, including all classes of vertebrates. Other respiratory pigments found in animals include the green chlorocruorins (found in a number of polychaete worms), the violet hemerythrins (found in corpuscles of certain polychaete worms and brachiopods), and the copper-containing hemocyanins (in some arthropods and mollusks).

Hemoglobins have been the most thoroughly studied of the respiratory pigments. The hemoglobins of vertebrates consist of four iron-containing molecules (hemes) chemically bonded to a large "carrier" protein called the globin. Oxygen joins in reversible union with the iron atoms. The degree to which hemoglobin is saturated with oxygen depends on a number of factors, including the partial pressure of oxygen in the blood plasma, the hydrogen-ion concentration, the partial pressure of carbon dioxide, and temperature. By keeping the other factors constant and varying the partial pressure of the oxygen, it is possible to construct a curve representing the capacity of hemoglobin to combine with oxygen at various partial pressures of oxygen. This is called the oxygen-dissociation curve (Figure 7).

The shape of the oxygen-dissociation curve changes with differences in the acidity of the blood and in the partial pressure of carbon dioxide. An increase in acidity and an increase in the partial pressure of carbon dioxide both produce a shift in the dissociation curve toward the right. Active tissues produce carbon dioxide as a result of metabolism, and the capillary blood passing through such tissues is exposed both to this elevated partial pressure of carbon dioxide and to a greater acidity. The shift of the oxygen-dissociation curve to the right shows how this facilitates the unloading of oxygen in the metabolizing

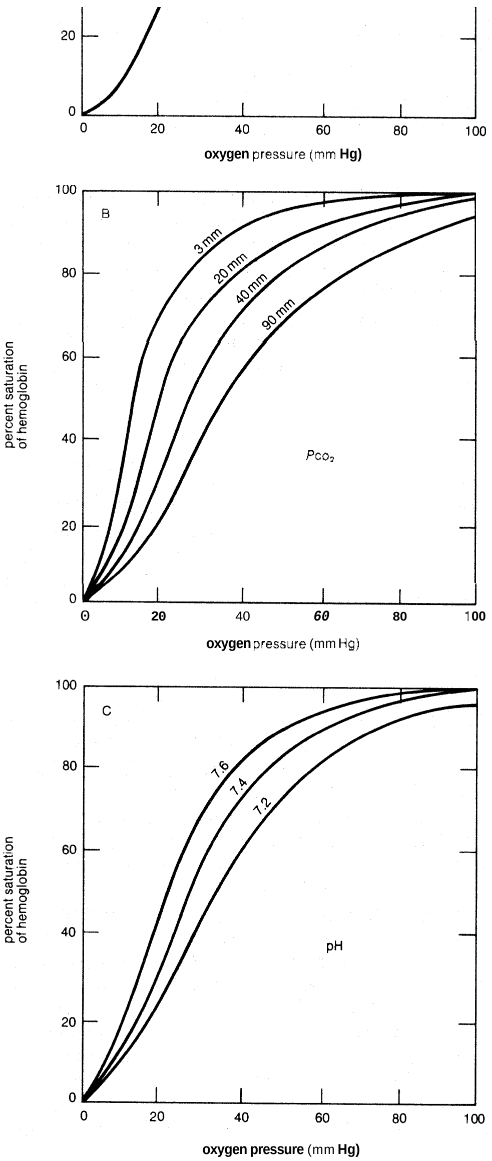

Figure 7: The combination of hemoglobin with oxygen. (A)Oxygen dissociation curve. (B,C) Effects of variation in P_{CO_2} and pH on the dissociation curve (see text).

tissues. Since the tissue cells consume oxygen, there is a favourable gradient for diffusion of oxygen from the capillary blood to the tissue cells. In short, the combination of high partial pressure of carbon dioxide and low oxygen pressure in the tissues facilitates the unloading and delivery of oxygen at the site where it is consumed. The steep part of the dissociation curve in the range of 40 millimetres of mercury for the partial pressure of oxygen, close to that found in many tissues, is of great physiological interest: it means that a relatively small decline in the partial pressure of oxygen is associated with a relatively large release of bound oxygen.

Temperature differences also affect the **oxygen-dissociation** curve. In so-called cold-blooded animals, the loading and unloading of oxygen can be carried on at adequate levels only between certain temperature limits. For example, even though octopus blood becomes fully saturated with oxygen at temperatures near 0° C (32" F), the animal will be starved of oxygen because significant unloading at the tissues cannot occur. At 20° *C* (68" F) human hemoglobin is saturated with oxygen, but little oxygen is delivered to the tissues—setting a natural limit to the possibility of lowering body temperature during certain surgical procedures (such as open-heart surgery). The lack of dissociation of oxyhemoglobin at low temperatures also accounts for the red colour of very cold ears.

The hemoglobin associated with many skeletal muscles (myoglobin) has a much higher oxygen affinity at low partial pressures of oxygen than does the circulating hemoglobin. Myoglobin contains only a single heme group. When a comparison of the dissociation curves of mammalian myoglobin and hemoglobin is made, it is found that at the normal partial pressure of oxygen found in venous blood (about 40 millimetres of mercury) the hemoglobin is about 60 percent saturated, whereas myoglobin is over 90 percent saturated. The dissociation curve of myoglobin is far to the left of that for hemoglobin and has a different shape. Since myoglobin unloads oxygen at low oxygen partial pressures, it has been suggested that this molecule facilitates transport of oxygen from the hemoglobin to the intracellular site, where those partial pressures are normally much lower than that associated with the unloading of hemoglobin.

Buffering of hydrogen ions by hemoglobin

Transport of carbon dioxide. Metabolizing tissues produce carbon dioxide, which must be transported to the lungs, gills, or skin where it is exchanged for oxygen. Most of the carbon dioxide (CO_2) transported by the blood is found in reversible chemical combinations in plasma or red blood cells. As carbon dioxide enters the plasma from tissues, it combines with water to yield carbonic acid (CO_2 .+ H_2O e H_2CO_3). This reaction is followed by the dissociation of carbonic acid into hydrogen and bicarbonate ions (H_2CO_3 + H^+ + HCO_3^-). This would result in greater acidification of the plasma (free H+) were it not for the presence of buffering agents such as protein (A–) that combine with the free hydrogen ion (H+ + *A*- + HA). A buffer solution resists change in acidity by combining with added hydrogen ions and, essentially, inactivating them. The formation of carbonic acid from carbon dioxide and water is much too slow to account for the actual rate at which carbon dioxide is taken up by the plasma. The actual rate is explained by the buffering effect of the hemoglobin: as hemoglobin gives up its oxygen to the tissues, it becomes less acid and can therefore take up most of the hydrogen ions. About 80 percent of the increased carbon dioxide content of the blood returning from the tissues is accounted for by the buffering capacity of hemoglobin. The role of hemoglobin buffering in this set of reactions may be summarized as follows: (1) carbon dioxide enters the red blood cell from the plasma by diffusion; (2) once in the red cell, it combines with water to form carbonic acid in the same way as in the plasma. In the red cell, this reaction is extraordinarily rapid because it is speeded up by an enzyme, carbonic anhydrase; (3) carbonic acid dissociates into hydrogen ions and bicarbonate ions; (4) hemoglobin, after giving up oxygen, enters into a complex with the hydrogen ions. The last reaction is of great importance in stabilizing the acidity of the red blood cell.

As carbon dioxide enters the red blood cell, it is accompanied by a shift of the chloride ion, C1-, from the plasma to the interior of the cell. Bicarbonate ions are formed at a very high rate because of the presence of carbonic acid, and they diffuse into the plasma. This inward diffusion of chloride in exchange for bicarbonate maintains the electrical balance across the red-cell membrane, a phenomenon known as the chloride shift.

Hemoglobin also acts in another way to facilitate the transport of carbon dioxide. Amino groups of the hemoglobin molecule react reversibly with carbon dioxide in solution to yield a carbamino compound. About 20 percent of the carbon dioxide is transported in the form of carbamino hemoglobin, about 5 percent in physical solution, and the remaining 75 percent in the form of bicarbonate ions. A reverse sequence of reactions occurs during oxygenation in the lungs, during which the carbon dioxide is unloaded into the alveolar gas to be expired.

Blood pigments and environment. The oxygen-dissociation curves vary widely among different kinds of animals. These variations appear to be related to differences in the chemical structures of the blood pigments. Curves to the extreme right of the range indicate pigments that require relatively high oxygen tensions for loading. Animals possessing such pigments would not flourish in zones of low oxygen tension. Vertebrate animals shows rather striking correlations between their distribution and their oxygen-dissociation curves.

Hemocyanin in mollusks

Among invertebrates, the cephalopod mollusks employ hemocyanin as an oxygen carrier. In the squid *Loligo* and in *Octopus,* the oxygen content of arterial blood is about 25 percent of that found in man. The extraction of oxygen by the tissues, however, is approximately 92 percent, or more than three times the percentage in man. Although such a system transfers a large amount of oxygen to the tissues, it fails to provide a reserve against oxygen scarcity. The oxygen-dissociation curves are affected by carbon dioxide, increased acidity, and increased temperature in much the same manner as in animals with hemoglobin. The cuttlefish of the genus *Sepia* and *Octopus* exhibit oxygen-dissociation curves to the left of that found in squid—a characteristic that correlates with their capacity to survive in waters of lower oxygen concentration.

Comparison of the dissociation curves of fishes reveals that those forms that are inhabitants of water containing a high partial pressure of oxygen (such as trout) exhibit curves to the right of forms living in stagnant waters (carp, catfish). The affinity of hemoglobin for oxygen is thus an important determinant of environmental distributions. A comparison of the behaviour of hemoglobins of trout and carp at 15° C (59" F) and a partial pressure of carbon dioxide of two millimetres of mercury reveals that it requires a partial pressure of oxygen of about five millimetres of mercury to bring about 50 percent saturation of the hemoglobin of the carp, as compared to 18 millimetres of mercury for the trout. Carp can range into waters of low partial pressure of oxygen denied to trout because of the loading characteristics of their hemoglobin. Furthermore, the effect of elevated carbon dioxide pressure is less on the blood of stagnant-water forms than on that of those inhabiting highly oxygenated waters. An elevation in the partial pressure of carbon dioxide from one to ten millimetres of mercury induces a shift to the right in the dissociation curve of the trout, such that only partial saturation with oxygen may be attained, and the fish may suffocate even in an abundance of oxygen.

Comparisons of a variety of animals inhabiting zones of varying oxygen availability indicate that aquatic forms saturate their hemoglobin with oxygen at lower oxygen pressures than do those that live on land. The greater oxygen affinity of their hemoglobins allows extraction of oxygen from environments poor in oxygen relative to air. The more terrestrial amphibians and reptiles require much higher environmental oxygen pressure than do the aquatic forms.

Mammals native to high altitudes (such as the llama and the vicuña) have hemoglobins of greater oxygen affinity than do low-altitude forms. Their hematocrits (percentages of red cells in the blood) and red-blood-cell counts are similar to those of their sea-level relatives. When low-altitude animals ascend to high altitudes, there are increases in their hematocrits, red-cell counts, and total hemoglobin. The net effect is an increase in oxygen capacity, although the dissociation curve does not shift appreciably. Similar responses have been observed in fishes; goldfish exposed to reduced oxygen pressures increase their hemoglobin levels. When mammals are exposed to low-oxygen conditions, they release a hormone, erythropoietin, that accelerates the production of red blood cells and hemoglobin.

Fetal hemoglobin

Similar differences appear in the fetal stage of vertebrates. The oxygen-dissociation curve of the fetus in both sheep and man is considerably to the left of that seen in the adult. This allows for a more efficient transferral of oxygen from the maternal to the fetal blood across the placenta. After birth the fetal hemoglobin is replaced by the adult pigment. Viviparous fishes such as the dogfish shark exhibit fetal hemoglobins having greater oxygen affinity than the adults, and similar pigments have been discovered in viviparous snakes. The dissociation curve of the frog tadpole is to the left of that of the adult, a relationship that seems appropriate in the transition from an aquatic to **a** terrestrial life. The hemoglobin of birds also exhibits a high oxygen affinity during the fetal period.

III. The control of respiration

Because respiration involves the acquisition of oxygen and the elimination of carbon dioxide, it is reasonable to suppose that respiratory activity must be controlled by mechanisms that adjust external respiration to changes in the concentrations of these gases. This was suspected as long ago as 1796, when it was speculated that the increase in respiratory activity at high altitudes was a response to the low partial pressure of oxygen. By the latter part of the 19th century, it had been demonstrated that low oxygen and elevated carbon dioxide pressures were respiratory stimulants. Such observations formed the framework for most of the subsequent work on respiratory control.

NEURALREFLEXES

The ancient Greek physician Galen knew that cutting the spinal cord at a level near the brain brought about a cessation of respiratory activity. A French physiologist, J.J.C. Legallois, located the "respiration centres" in 1812 by demonstrating that cutting the brainstem just behind a mass of nerve fibres called the pons did not abolish respiration but that, as the transections were moved backward through the medulla a few rnillimetres at a time, respiration finally ceased. These observations indicated that the medulla is a major central-nervous-system area in the control of respiration. An English physiologist, Marshall Hall, demonstrated in 1850 that the vagus nerves were involved in reflexes that modify respiration. The observation that cutting off the blood supply to the brain induced respiratory stimulation led other workers to suggest that the chemical composition of the blood circulating in the brain had an important influence on respiration. Taken together, these early observations suggested that respiration adjusts to changes in the environmental-gas composition or to chemical alterations of the body fluids; that the central nervous system is essential for the control of respiration; and that chemical alterations may either directly or by reflex modify the movements of respiration.

Two types of respiratory neurons have been located in the lower portion of the brain (the medulla oblongata) in all vertebrates. One set of neurons activates inspiratory activity; the other activates expiratory activity. Because electrical stimulation of either the expiratory or the inspiratory neurons produces an appropriate respiratory act, these neurons are sometimes thought of as "centres." It is not likely that discrete centres exist, and in fact there is considerable intermingling and overlap of these two neuronal types. When the sensory nerves coming to the respiratory areas are eliminated, it is still possible to produce alternating bursts of expiratory and inspiratory activity in the medulla. The system behaves as if mutual inhibitory and excitatory nerve links exist between the two sets of neurons. As the inspiratory neurons discharge, there is an increase in neural activity not only to the muscles of inspiration but also to the expiratory neurons; their discharge excites the expiratory muscles and also activates inhibitory pathways to the inspiratory centre; inhibition of the inspiratory neurons then decreases the excitation going to the expiratory neurons, leading to a diminution in expiratory-discharge rate and the removal of inhibition of the inspiratory areas. Although speculative, this system is in accord with observed facts. Whatever the case, respiratory activity is not solely under the control of the medulla, since the medullary site is also influenced by sensory input from the body as well as from connections in the higher centres of the brain. Sensory stimuli such as pain, heat, and cold applied to various body areas modify respiratory activity in higher vertebrates; visual or olfactory stimuli alter the respiratory rhythm of fishes. In mammals, at least two additional centres in the area of the pons have important respiratory connections. Experiments in which the brainstem is sectioned at various levels show that, although the medullary centre is capable of producing sequences of respiratory inspiration and expiration, these are of an abnormal character when the medulla is disconnected from higher levels of the brain. In the lower pons, an area known as the apneustic centre governs cessation of respiration during inspiration. When disconnected from the medulla, prolonged inspiratory spasm may occur. In the higher pons, the pneumotaxic centre functions to restrain periodically the apneustic centre; furthermore, fibres in the vagus nerve converge on the apneustic centre to produce inhibition.

MUSCULAR FEEDBACK

Stretch receptors

The behaviour of the respiratory centres in the brain is also modified by neural feedback from various parts of the body. The lungs send sensory information to the brain that alters the activity of the respiratory centres. This type of relationship was studied experimentally in 1868 in Vienna by two physiologists, Ewald Hering and Josef Breuer; they found that, if the airways were blocked following inspiration, the activity of the expiratory muscles (acting against the blocked airways) was prolonged. Moreover, subsequent inspiratory activity was prolonged far beyond the normal length of time. Clamping of the airways after expiration was followed by a prolongation of inspiratory activity. Taken together, their observations indicated that expiratory and inspiratory neural activity was linked to the degree of chest expansion. When they severed the vagus nerve to the brain, they obtained a deeper and slower ventilation pattern; blockade of the airways at the end of inspiration was then followed by expiratory effort of a duration similar to that seen prior to cutting the vagus nerve. It was concluded from these observations that, during inspiration, mechanical receptors were stimulated, which, through their linkage via the vagus nerve to the respiratory centres, augmented the expiratory act. This reflex is known as the Hering-Breuer reflex. The mechanical receptors are in the walls of the bronchioles and their branches. During inspiration these receptors are stretched as the lung is filled; the electrical activity of the vagus nerve has been shown to increase as the lung volume is increased. The receptors differ in their sensitivity to stretch: at the end of a normal inspiration, many of them are stimulated, but others remain quiescent unless further inflation occurs. Other vagal pathways are activated at the end of an expiration. Their activation terminates expiration at a point earlier than normal, as would occur during the deep breathing associated with exercise. During quiet respiration these receptors are apparently not brought into play, but, as breathing volume increases, they institute, bv their action on the respiratory centres, strong inspiratory activity. It requires greater muscular effort to increase the inspiratory volume above a certain level, this effort increasing disproportionately with changes in volume. By setting a limit on inspiratory volume during quiet breathing, respiration is maintained at a more efficient level. Although the inflation reflexes described above were discovered in mammals, they have also been found in birds. In the dogfish shark, intiation of the pharynx inhibits inspiratory activity, an effect that disappears after cutting the spiracular branches of nerves VII, IX, and X. The receptors involved in this reflex are located at the junction of the pharynx and the gill pouches.

Other stretch receptors exist in the skeletal muscles that provide the motive power for respiration, including the diaphragm. (Figure 8 shows the organization of these receptors and their relationship to the main muscle mass.) These are similar to the receptors that produce the knee-jerk reflex. Contraction of the extrafusal muscles powers inspiration. These muscles may be activated as a result of annulospiral receptor activity; the receptors discharge when stretched by intrafusal fibres. This produces a train of impulses over the nerves that run to the spinal cord and interconnect with motor nerves to the muscle; motor-nerve activity is set off that causes the muscle to contract and shorten; secondarily this produces shortening of the annulospiral stretch receptors in the muscle and reduces the frequency of the impulses they send to the spinal cord. Recent evidence suggests that these stretch receptors have muscle fibres (intrafusal fibres) at each end in series with the receptor. The complex of annulospiral endings and associated intrafusal fibres is in parallel with the major muscle fibres (extrafusal fibres). Two types of motor neurons have been differentiated: gamma neurons, which innervate the intrafusal fibres, and alpha neurons, which innervate the major muscle mass. Activation of gamma neurons, producing contraction of the intrafusal fibres, has the effect of stretching the annulospiral endings and thus producing impulses that reach the spinal cord and there synapse with the alpha motor neurons.

gamma neurons
alpha neurons
extrafusal (main) respiratory muscle fibres
annulospiral (stretch) receptors
intrafusal respiratory muscle fibres

Figure 8: Control of respiratory muscle shortening by stretch receptor mechanism (see text).

The gamma neurons in the respiratory muscles are thought to receive impulses arising in the respiratory centres. The magnitude of gamma activation thus depends upon the intensity of discharge of the respiratory centres in the brain, and the intensity of respiratory-centre discharge is dependent upon the type of sensory information brought in from chemoreceptors and stretch receptors. In order for the annulospiral sensory endings to reduce their discharge rate, the major muscle mass must now shorten, to the extent that the stretch induced by intrafusal contraction is now reduced. This system would appear to give the muscles of respiration a means of matching their activity with the sensory information being received; shortening of the intrafusal fibres would govern the extent of extrafusal-fibre activity necessary to attain a desired breathing volume.

CHEMICALLY SENSITIVE CONTROLS

Breathing is also controlled by specialized nerve cells that are sensitive to chemical changes in the blood. The carotid arteries, which convey the major blood supply to the head and brain, branch near the skull into internal and external carotid arteries. Small vascular spherules, the carotid bodies, are located at this point. The Belgian physiologist Comeille Heymans received the Nobel Prize in 1938 for his demonstration that the carotid bodies and similar structures on the aorta (the artery arising from the heart) are chemosensitive. When he perfused these bodies with blood of low partial pressure of oxygen, he observed increases in the volume and frequency of respiration. In mammals, the nerve fibres from the carotid bodies (cranial nerve IX) and aortic bodies (nerve X) form the afferent limb of a chemically induced reflex. There is some variation in other vertebrates. The blood

The carotid and aortic bodies

flow to the carotid and aortic bodies is of the highest order of magnitude known for any tissue.

Studies of the electrical activity of the nerves of the carotid bodies indicate that reductions in the level of arterial oxygen pressure are associated with increases in the rate of firing of the carotid-body receptors. Arterial carbon dioxide pressure also plays an important role in the activity of these receptors; when the partial pressure of carbon dioxide is elevated, the response to low partial pressure of oxygen is heightened. The firing rate of the sensory nerves of the carotid body reaches a maximum under conditions of asphyxia, in which the partial pressure of oxygen is low and the partial pressure of carbon dioxide is high. The activity of the carotid-body receptors also influences blood circulation; an increase in their firing rate leads to an increased heart rate and to a rise in arterial blood pressure. These receptors are also indirectly sensitive to blood flow. Low blood pressure reduces the blood flow to these bodies and may result in oxygen deficiency to them even in the presence of a normal arterial partial pressure of oxygen—apparently because of the high oxygen extraction associated with the high rate of metabolism of these bodies. A combination of low arterial partial pressure of oxygen and reduced blood flow is a more effective stimulus for the receptors than either is alone.

It had long been supposed that the respiratory centres of the brain were directly sensitive to small changes in partial pressure of carbon dioxide (P_{CO_2}), since perfusion of the brain with blood of very moderately elevated arterial partial pressure of carbon dioxide elicits increased ventilation. More recently it has been found that this response is brought about indirectly through the cerebrospinal fluid. Areas on the surface of the medulla that are normally bathed with cerebrospinal fluid have been shown to be sensitive to solutions of high partial pressure of carbon dioxide or elevated hydrogen-ion concentration; these receptors apparently have connections with the respiratory centres. Cerebrospinal fluid is characterized by a low protein content compared with that of blood and thus a low capacity for absorbing hydrogen ions. Carbon dioxide diffuses rapidly from blood and interstitial fluid to the cerebrospinal fluid; the medullary receptors are well situated for detecting slight changes in hydrogen-ion concentration. It is likely that this sensitivity provides for a critical monitoring of blood partial pressure of carbon dioxide and cerebrospinal-fluid acidity. An elevation in arterial partial pressure of carbon dioxide, through its effects on cerebrospinal-fluid acidity, will lead to increased ventilation of the lungs and expiration of carbon dioxide. Representatives of all the major vertebrate groups respond to elevated partial pressure of carbon dioxide or low partial pressure of oxygen with increased ventilation.

IV. Adaptation to special conditions

ADAPTATION TO DIVING

Many air-breathing vertebrates are able to remain submerged in water for a long period of time (Table 2).

Table 2: Duration and Depth of Diving in Some Mammals

species	duration (in minutes)	depth (in metres)
Platypus	10	
Mink, ***Mustela vison***	3	
Harbour seal, ***Phoca vitulina***	20	
Walrus. ***Odobenus rosmarus***	10	***80***
Steller's sea lion, ***Eumetopias jubata***		146
Gray seal, ***Halichoerus grypus***	20	100
Weddell seal, ***Leptonychotes weddelli***	43	600
Bottle-nosed whale, ***Hyperoodon ampullatus***	120	deep
Sperm whale, ***Physeter catodon***	75	900
Blue whale, ***Sibbaldus musculus***	49	100
Harbour porpoise, ***Phocaena phocaena***	12	20
Bottle-nosed porpoise, ***Tursiops truncatus***	5	
Beaver, ***Castor canadensis***	15	
Muskrat, ***Ondatra zibethicus***	12

One of the most striking physiological alterations observed in such diving animals is a marked reduction in the heart rate. This has been shown to result from the action of the vagus nerve.

Lactic-acid concentration in the blood may rise slightly during diving; immediately after emerging, it rises precipitously. This has been observed in a wide variety of divers, including ducks, the alligator, and many mammals. Lactic acid is produced by metabolism occurring in the absence of oxygen. During diving the blood flow is greatly reduced or temporarily eliminated in muscle, kidney, and intestinal tissue. Blood vessels going to many of the tissues are constricted, and, as a result, most of the body's oxygen stores are distributed toward the brain and the heart. The lactate produced during the dive is oxidized afterward and excreted.

The constriction of the blood vessels during diving is controlled by the sympathetic nervous system. Diving animals differ from others in that the sympathetic nerves terminate in the muscular walls of the major supply arteries. In nondiving mammals such as the cat, the sympathetic nerves terminate primarily in the arterioles, the blood vessels just prior to the capillaries where metabolic exchange takes place. During sympathetic stimulation, the reduction of blood flow in the cat is associated with an accumulation of local metabolic materials (vasodilator metabolites) that tend to diffuse to the arterioles, at which place these metabolic materials compete with the sympathetic nerves and ultimately cause the vessels to dilate. The diving animals avoid this by utilizing sympathetic nerves, which cause constriction of main supply arteries that are far enough away from the capillaries so as to be unaffected by vasodilator metabolites produced in the tissues.

Lung volumes

The lung volumes of diving animals do not appear to be different from those of nondiving forms, with the exception of whales, which have a smaller relative lung volume than nondivers. It has been suggested that the small lung volume of whales (about 50 percent less than other mammals per unit of weight) enables them to descend to great depths without danger of nitrogen bubbles forming in the blood (caisson disease). The lungs may actually collapse during descent to great depths. It has been calculated that, at a depth of 100 metres (330 feet), all of the lung gas could be contained in the nonexchange respiratory components (dead space), the exchange surfaces being collapsed. The effect of such a redistribution of the lung gases under pressure would be a decrease in nitrogen diffusion into the blood. On ascent, only a relatively small load of dissolved nitrogen would have to be disposed of, thus reducing the danger of bubble formation. Most diving animals actually exhale before or shortly after diving. Observation of trained porpoises with underwater television cameras has shown that the thorax becomes increasingly compressed as the animal reaches greater depth.

Turtles, despite their heavy shells, manoeuvre easily through the water, floating near the surface at one moment or quietly sinking to the bottom the next. In the red-eared turtle ***Pseudemys scripta***, this depends on the animal's ability to change the relative volumes of lung air and stored water. The water storage is done through the cloacal bursae, outpouchings from the terminal portion of the hindgut; the mechanism closely resembles that used in ballasting submarines.

The tidal volume (that is, the volume of air drawn in) of mammalian divers is greater than that of nondivers, and the lungs are also more completely emptied during expiration.

Many diving animals have a larger blood volume than nondivers. The relative blood volumes of the porpoise and seal are approximately twice that found in dog and man, and diving birds may have about a 60 percent greater blood volume than their nondiving relatives. Ducks seem to store considerable oxygen reserves in their venous system. Diving mammals may also store a considerable supply of oxygen in the form of oxymyoglobin. Myoglobin unloads oxygen at much lower tensions than does hemoglobin. It has been calculated that nearly 50 percent of the oxygen reserves of diving seals is in the form of oxymyoglobin.

A set of responses that may be called a "diving reflex" is found in all the vertebrate groups. Fish "dive" when removed from water, exhibiting a slowing of the heart rate. Reduced cardiac output and heart rate are also characteristic of diving frogs. The cardiac response to diving is exhibited even in nondivers such as man, although to an extent much smaller than in specialists such as seals, porpoises, or whales.

ADAPTATION TO HIGH ALTITUDES

Ascent from sea level to a high altitude has well-known effects upon respiration. The decline in barometric pressure is accompanied by a fall in the partial pressure of oxygen, and it is this that imposes the major respiratory challenge to man at higher altitudes. At moderate elevations, the decline in alveolar partial pressure of oxygen is partially offset by increased ventilation. On ascent to higher levels, however, the alveolar partial pressure of oxygen declines even more than does the ambient partial pressure of oxygen. Since the air entering the respiratory system is saturated with water vapour before reaching the alveolar exchange surfaces, the gases are "diluted" by the presence of water vapour (which has a partial pressure of around 47 millimetres of mercury [mm Hg] at body temperature). At 30,000 feet (9,000 metres), for example, the barometric pressure is 226 millimetres of mercury and the gases are partitioned in the alveoli as follows: $P_{CO_2} = 24$ mm Hg; $P_{N_2} = 134$ mm Hg; $P_{H_2O} = 47$ mm Hg; and $P_{O_2} = 21$ mm Hg. The ambient partial pressure of oxygen is around 47 millimetres of mercury at this altitude, and it is apparent that water vapour is responsible for diluting both oxygen and nitrogen in the lungs. Alveolar partial pressure of carbon dioxide remains at 24 millimetres of mercury at altitudes exceeding 20,000 feet (6,000 metres). This is because breathing approaches its upper limit, and therefore maximum ventilation capacity is reached at this altitude. Since carbon dioxide production is relatively constant, a relatively constant alveolar partial pressure of carbon dioxide results.

The decline in the partial pressure of oxygen is offset to some extent by greater ventilation. On first arriving at high altitude, the declining arterial oxygen saturation causes the chemoreceptors to induce greater respiratory activity; ventilation increases to about one and one-half times normal. This is far below the ventilation level associated with exercise at sea level. This limitation on ventilation is associated with lower partial pressure of carbon dioxide in the blood and decreasing acidity, which cause the receptors in the medulla to suppress respiration and limit the level of ventilation. Gradually the blood acidity is corrected toward normal by kidney mechanisms. As the blood becomes less alkalotic, the medullary receptors begin again to augment respiratory activity, and ventilation may increase around sevenfold.

Hemoglobin production at high altitudes

The scarcity of oxygen at high altitude stimulates increased production of hemoglobin and red blood cells. At altitudes of around 17,000 feet (5,000 metres), the red-cell count may ultimately rise from the sea-level value of 5,000,000 per cubic millimetre to 7,000,000, and hemoglobin levels may rise from 15 to 22 grams per 100 millilitres of blood. ·The proportion of red cells in the total blood supply rises from 40 percent to as high as 70 percent. The result is a marked increase in oxygen-carrying capacity.

Upon initial exposure to high altitude, the cardiac output at rest increases by 20 to 50 percent; as adjustments in oxygen-carrying capacity are made, the cardiac output returns to near-normal levels. Exercise produces a smaller increase in cardiac output at high altitude than it does at sea level. The higher blood viscosity because of the increase in red cells imposes an additional work load on the heart. It is thought that the pacemaker tissue of the heart may also be suppressed because less oxygen is available.

The flow of blood to the brain, heart, and skeletal muscles increases during the initial adjustments to high altitude, but the flow to the kidneys and skin is reduced because of constriction of the blood vessels. On longer exposure to low barometric pressure, the tissues develop more blood vessels, and, as capillary density is increased, the length of the diffusion path along which gases must pass is decreased—a factor augmenting gas exchange.

Men climbing to heights above 20,000 feet reach the upper limit of chemoreceptor-driven ventilation. As the oxygen saturation of the arterial blood falls to 50 percent, faintness or unconsciousness follow. The critical height for 50 percent saturation is about 23,000 feet (7,000 metres). Even at 12,000 feet (4,000 metres), hypoxia may be severe enough to induce mental fatigue, drowsiness, headache, or euphoria. The journals of mountain climbers offer interesting testimony to this fact: often the handwriting becomes unintelligible, and phrases are repeated or appear out of context. Night vision is impaired because of lack of oxygen at the retina. Above 23,000 feet, suppression of central nervous system functions leads to convulsions, coma, and death.

Mammals that live at high altitudes, such as the llama and vicuña, have hemoglobin of high oxygen affinity. The oxygen-dissociation curves of these animals are to the left of lower altitude mammals; *i.e.*, full saturation of the blood with oxygen occurs at lower partial pressures of oxygen. Although their hemoglobin levels are relatively high, the proportion of red blood cells to the total volume of blood is not: at a partial pressure of oxygen of 40 millimetres of mercury, the blood of man holds about 14 millilitres of oxygen to each 100 millilitres of blood, while that of the vicuiia holds 18. The hematocrit (proportion of blood represented by red blood cells) in the high-altitude cameloids does not vary much at various altitudes, and moreover, it is rather low (30 percent) by comparison with that of man at sea level (40 percent). These mammals of high altitude are adapted to low oxygen pressures by their possession of hemoglobin of high oxygen affinity.

BIBLIOGRAPHY. JULIUS H. COMROE, *Physiology of Respiration* (1965), covers the basic aspects of respiration in mammals. PIERRE DEJOURS, *Physiologie*, vol. 3, ch. 1 (1963; Eng. trans., *Respiration*, 1966), is a concisely written introduction (for medical students) to mammalian and human respiration. ERNEST FLOREY, *An Introduction to General and Comparative Animal Physiology* (1966), contains sections on gases in the environment and on how various animals, invertebrates as well as vertebrates, extract and transport oxygen and carbon dioxide. M.S. GORDON *et al.*, *Animal Function: Principles and Adaptations* (1968), presents the mechanisms by which various groups of vertebrates deal with gas acquisition and transport. GEORGE M. HUGHES, *Comparative Physiology of Vertebrate Respiration* (1963; reprinted with corrections, 1965), is a brief introductory text. L. IRVING, "Comparative Anatomy and Physiology of Gas Transport Mechanisms," in W.O. FENN and H. RAHN (eds.), *Respiration*, sect. 3, vol. 1 of the *Handbook of Physiology* (1964), reviews invertebrate and vertebrate respiratory mechanisms including those of diving vertebrates. AUGUST KROGH, *The Comparative Physiology of Respiratory Mechanisms*, new ed. (1959), is a classic for those interested in comparative aspects of respiration. F.H. MCCUTCHEON, "Organ Systems in Adaptation: The Respiratory System," in D.B. DILL, E.F. ADOLPH, and C.G. WILBER (eds.), *Adaptation to the Eitvironment*, sect. 4 of the *Handbook of Physiology* (1964), discusses respiratory mechanisms in relation to the environment, with sections on chemical regulation, gas transport, and evolutionary patterns of respiratory adaptations. J.F. PERKINS, "Historical Development of Respiratory Physiology," in *Respiration (op. cit.)*, traces the chronology of the discoveries leading to modern respiratory physiology. C. LADD PROSSER and FRANK A. BROWN, JR., *Comparative Animal Physiology*, 2nd ed. (1961), has numerous examples of blood pigment behaviour as related to external and internal environments. H. RAHN, "Aquatic Gas Exchange Theory," in N. BALFOUR SLONIM and J.L. CHAPIN (eds.), *Respiratory Physiology* (1967), is a technical discussion of the application of gas laws to problems of gas transport in aqueous media. F.J.W. ROUGHTON, "Transport of Oxygen and Carbon Dioxide," in *Respiration (op. cit.)*, treats gas transport in the body fluids from a physicochemical point of view. P.F. SCHOLANDER, "Animals in Aquatic Environments: Diving Mammals and Birds," in *Adaptation fothe Environment (op. cit.)*, is a fundamental article for those interested in diving physiology.

(F.N.W.)

Respiratory System, Human

The respiratory system in man consists of the nasal cavity, the throat (or pharynx), the voice box (or larynx), the windpipe (or trachea), the bronchi, and the lungs, all of which are involved in the act of breathing.

Other bodily systems involved in breathing

Other parts of the body sharing in the process of moving air into, and out of, the lungs are ordinarily given membership in other body systems. The diaphragm—the muscular structure that separates the chest from the abdominal cavity—and the ribs and muscles of the chest walls play a necessary role in expanding and contracting the lungs so as to bring air in and push it out, but the ribs are viewed as part of the skeleton rather than the respiratory system and the muscles as part of the body's system of voluntary muscles.

If breathing is thought of as the process of instilling oxygen into the blood and bringing it to the tissues and of carrying carbon dioxide from the tissues out of the body, the elements of the respiratory system listed in the first paragraph above consist essentially of the organs in which the exchange of oxygen for carbon dioxide takes place—the lungs, and more particularly the pulmonary alveoli, or tiny air sacs, and the minute blood vessels around them—and the elaborate system of passageways through which air travels on its way to the alveoli and from them back into the external world. If breathing is the exchange of oxygen for carbon dioxide, it is clear that other parts of the body are involved: the blood itself, which transports the gases between the tissues and the lungs, and the cardiovascular system, consisting of the vessels through which the blood travels, and the heart, which provides the power by which the blood is driven.

The present article is focussed on the structure of the elements listed in the first paragraph: the nasal cavity, the pharynx, the larynx, the trachea, the bronchi, and the lungs (Figure 1). The functioning of the respiratory system is dealt with in RESPIRATION, HUMAN; its disorders are dealt with in RESPIRATORY SYSTEM DISEASES.

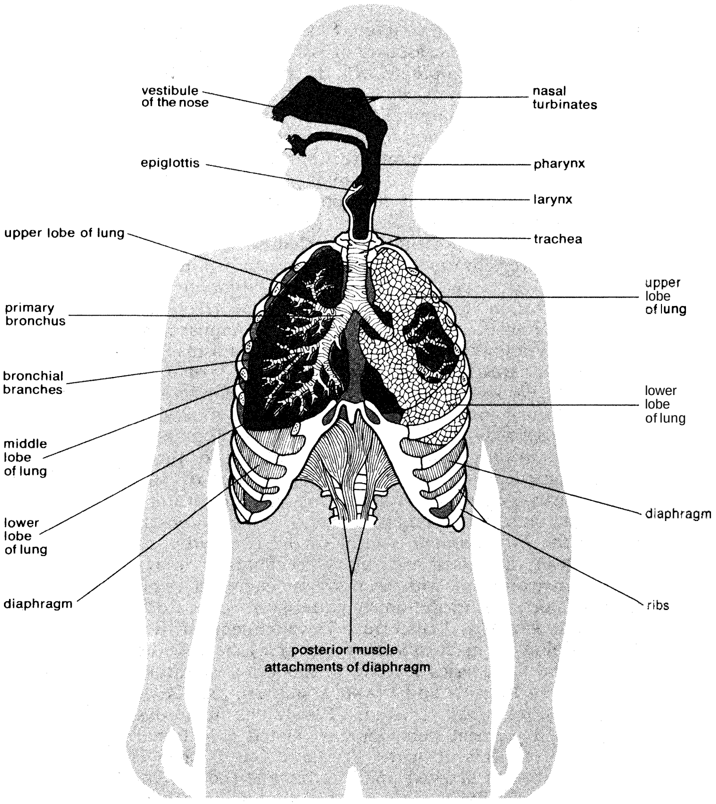

Figure 1: Respiratory system and its location.

THE UPPER PORTION OF THE RESPIRATORY TRACT

The nasal cavity. The nasal cavity is a space of complex shape, lined with mucous membrane and bounded below by the mouth and above by two air-filled cavities, the frontal and sphenoidal sinuses, and by a third cavity, the cranial cavity, which encloses the brain. **A** bony and cartilaginous partition, the nasal septum, divides the nasal cavity into right and left sides. Into the cavity's outer walls three ridges project, formed by the lower, middle, and superior turbinate bones. The air passageways with open inner side thus formed below each ridge are called the inferior, middle, and superior meatuses. (The configuration of the nasal cavity is described in SPEECH, PHYSIOLOGY OF.)

Divisions and passageways

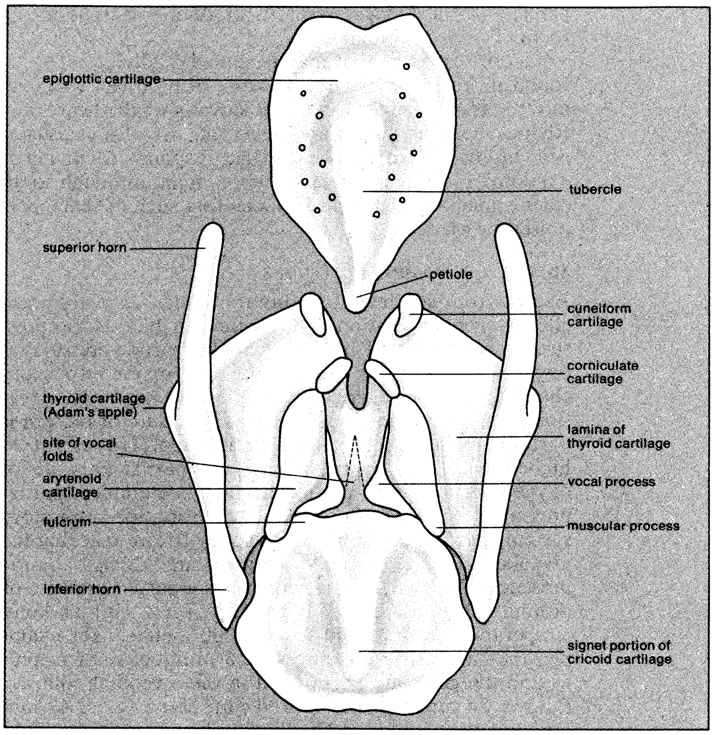

Figure 2: Cartilages of larynx seen from behind.

The uppermost portion of each nasal cavity contains an area highly specialized for olfactory sensation. Here are located the sensory cells that are the receptors for the sense of smell (see SENSORY RECEPTION, HUMAN).

The pharynx. The upper portion of the pharynx, the nasopharynx, is separated from the rest of the pharynx by the soft palate, which roofs the back of the mouth and terminates in the uvula. The nasopharynx is traversed exclusively by air and by nasal secretions. The nasopharynx and the mouth open into the oral pharynx, a common passageway, like the mouth, for air and food. By means of the epiglottis, which serves as a cap for the voice box, the latter is ordinarily closed during the process of swallowing, so that food is routed from the oral pharynx into the laryngeal pharynx, the portion of the pharynx behind the epiglottis and the voice box, and into the esophagus, the passage to the stomach.

The larynx. The larynx, a structure at the upper end of the trachea, or windpipe, serves a dual purpose, as one section of the airway to the lungs and as an important part of the apparatus by which voiced sounds are made. The outer framework of the larynx is made up of cartilage joined together by ligaments and membranes.

The thyroid cartilage, the largest of the cartilages in the larynx, consists of two plates joined at the front midline. Toward the top of this juncture is a notch, the thyroid notch, and just below the notch is the forward projection of the larynx, known as the Adam's apple. To the notch, on its inner side, is attached the epiglottis, the leaf-shaped plate of cartilage that serves as the lid for the larynx.

At the bottom of the larynx and forming a joint with the thyroid cartilage at one point on either side is a ringlike cartilage, the cricoid, which has a wider section, like the signet of a signet ring, in back (Figure 2).

Dividing the larynx into an upper and a lower compartment are the vocal folds, white folds of mucous membrane that, at their inner edges, enclose the vocal ligaments, or vocal cords. A slit between the vocal cords, called the rima glottidis, is closed or opened wider by the swinging inward or outward of the arytenoid cartilages. These cartilages, attached to the vocal cords near the rear end of the rima glottidis, are pyramid-like in form and rest upright on the cricoid cartilage.

Vocal cords

Above the vocal folds are the vestibular folds, or false vocal cords, formed of mucous membrane that is a continuation of the membrane lining the larynx. The gap between the false vocal cords is wider than that between the true ones; thus, the true cords may be seen if the inside of the larynx is inspected with an instrument called a laryngoscope. The recess between the true vocal cords and the false ones is called the ventricle of the larynx.

The muscles of the larynx are classified as either extrinsic or intrinsic. The extrinsic muscles are those that extend between the larynx and adjacent structures, such as the hyoid bone and the breastbone, and move the larynx upward, as in swallowing, and downward. The intrinsic muscles have two functions, to bring the vocal cords together and to tense them.

The trachea. The trachea, or windpipe, is a tube consisting of a number of cartilages shaped like horseshoes or like **Y's** that are bent in a curve and lie on one side; these cartilages are enclosed in an inner and an outer layer of elastic fibrous membrane. In back, where the trachea lies next to the esophagus, there is a layer of smooth muscle that can draw the open ends of the cartilages together and so diminish the calibre of the tube. The trachea, like the larynx, is lined with mucous membrane. Its length, from the cricoid cartilage of the larynx to the fork at the juncture with the rieht and left main bronchi, the air passages directly into the lungs, is about four to 4.5 inches (ten to 11 centimetres) in the adult, and its diameter is about one inch (about 2.5 centimetres). The fork at the bottom of the trachea, which has a ridge, or keel, on its inner side, has developed into a vocal organ, the syrinx, in birds.

THE LUNGS AND BRONCHI

Structure of the bronchi. The right and left main bronchi, the stretches of bronchus between the lower end of the trachea and the lungs, have the same construction as the trachea, with cartilages shaped like broken rings or bent Y's and with tough covering membranes. The larger bronchi within the lungs have, instead of broken rings, irregularly shaped plates of cartilage completely around the wall, so that the intrapulmonary bronchi are cylindrical, rather than D-shaped like the trachea and the extrapulmonary bronchi.

Cartilages in bronchi

The layer of muscle, instead of being concentrated in the rear wall, as in the trachea and the extrapulmonary bronchi, completely encircles the intrapulmonary bronchi. There are blood vessels outside this smooth-muscle tissue and penetrating into it. On the outside of the bronchi and penetrating into the surrounding lung tissue is a tough, dense layer of connective tissue.

As the bronchi divide and subdivide and become increasingly smaller, the walls become thinner. Bronchioles (small bronchi), of a diameter of only a few millimetres, no longer have plates of cartilage in their walls. The smooth muscle is present, however, through the whole range of bronchial sizes, even down to the extremely fine alveolar ducts (see below Respiratory substance).

Shape, size, and location of the lungs. The two lungs rest against the outer walls of the chest cavity. Between them is the mediastinum, a thick group of structures that includes the heart, the major blood vessels, the trachea, and the esophagus. The lungs are roughly conical in shape, with pointed apexes jutting slightly above the collarbone, outer sides convex because of the rib cage, against which they rest, obliquely concave below because of the arching diaphragm beneath them, and deeply indented on their medial surface—the surface toward the centre of the body—by the heart and the other structures between them. Within the indentation in the medial surface of each lung is the hilus, the entrance point for the bronchi, blood vessels, and nerves.

The right lung is ordinarily somewhat larger than the left; together their average weight is about 600 grams (about 1.3 pounds). Each lung is enveloped in pulmonary (visceral) pleura, a tough membrane that exudes a small amount of lubricating fluid, as does the parietal pleura—the membrane lining the chest cavity—of which it is a continuation. Deep fissures in the lungs mark the outlines of their main divisions, the lobes. The right lung is divided by a horizontal fissure and an oblique one into three lobes; the left lung is divided by an oblique fissure into two.

The lobes

Bronchopulmonary segments, or lobules. Each lobe of the lungs is served by a lobar bronchus, one of the first branchings of the main bronchi. The three lobar bronchi in the right lung and the two in the left divide into segmental bronchi, ten in the right lung and nine in the left (Figure 4). The section of lung tissue served by a segmental bronchus and its many subdivisions is known as a bronchopulmonary segment, or lobule. The segments are separated by veins and thin membranes of connective tissue.

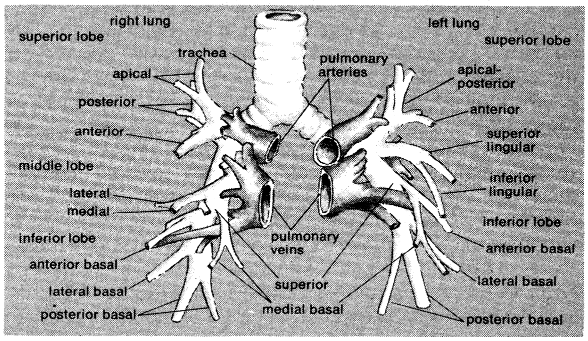

Figure 4: Segmental bronchi and pulmonary vessels (see text).

The bronchopulmonary segments are significant divisions of the lungs because such a segment or a group of such segments may represent the limit of involvement by a disease process, such as bronchiectasis. Thus, when surgical removal of diseased lung tissue proves necessary, it

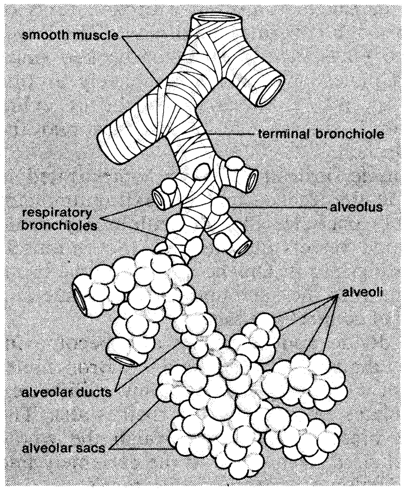

Figure 5: Terminal respiratory units of bronchial tree.

may be possible to confine the surgery to one or more segments and save most of the lobe.

Subdivisions of segmental bronchi. Each of the segmental bronchi divides and subdivides until there are 20 or more generations of branchings before the tiny bronchi called terminal bronchioles are reached. The first ten generations of bronchi are widely spaced divisions and occupy two-thirds of the distance from the hilus to the periphery of the bronchial apparatus. The remaining ten to 15 generations of branches are bronchioles, distinguished from the larger bronchi by not having cartilages. These bronchioles are more closely spaced and have a fairly uniform diameter, from about three millimetres down to about one (from about 0.12 to 0.04 inch).

Alveoli and alveolar sacs

Respiratory substance. The last bronchioles to be lined by cuboidal epithelium are called terminal bronchioles. There are an estimated 20,000–80,000 of these. Each gives rise to an acinus, a "berry"-shaped terminal group of air-filled respiratory bronchioles, alveolar ducts, and terminal sacs (Figure 5). It has been estimated that there are 300,000,000–400,000,000 alveoli in the lung. They are the functional units of respiration. In the walls of an alveolus is a dense network of capillaries, the smallest of the blood vessels. A network of fibres forms a scaffold on which the capillaries rest. Through the capillary walls oxygen from the air in the alveolus is exchanged for carbon dioxide in the blood. The respiratory substance of the lungs consists of the respiratory bronchioles, the alveolar ducts, alveolar sacs, and alveoli, together with the accompanying blood vessels, lymph channels, nerves, and connective tissue.

Blood vessels, lymph channels, and nerves. Blood laden with carbon dioxide and low in oxygen is carried from the right side of the heart through the pulmonary arteries to the lungs. Shortly after entering the lung at the hilus, the pulmonary artery divides into central arteries for the individual bronchopulmonary segments. These branches further divide and subdivide; a vessel to each alveolar duct breaks up into a capillary network for all the alveoli that open directly or indirectly into the duct. The bronchopulmonary segments are compartmentalized with respect to arteries but not veins; an intersegmental vein, lying in the membrane that separates adjacent segments, drains both. The oxygenated blood from the capillary networks is gathered into veins running through the bronchopulmonary segments and in the connective tissue between them. Near the hilus, the veins merge into about ten large veins that follow the course of the bronchi. The blood leaves the lungs in the pulmonary veins and is delivered to the atrium of the left side of the heart.

There are two sets of lymphatic vessels in the lungs. The lymphatic capillaries of one set lie under the pulmonary, or visceral, pleura, the membrane enveloping the lung, which they drain. These vessels converge at the borders of the lungs and at the edges of the fissures between lobes and end in the bronchopulmonary lymph nodes, at the hilus of each lung. The other set of lymphatics begins as a network of capillaries in the walls of the alveolar ducts; the capillaries converge into vessels that accompany the bronchi and blood vessels. They drain, as do the lymphatics of the first set, into the bronchopulmonary nodes. From these nodes the lymph drains into the tracheobronchial nodes, at the fork of the trachea and the two main bronchi, and from there into the major lymph channels, called the bronchomediastinal trunks.

Sympathetic and parasympathetic nerve fibres

The blood vessels and bronchi of the lungs are controlled by sympathetic and parasympathetic nerve fibres from the vagus, or tenth cranial nerve, and the sympathetic nerve trunk. It is believed that the parasympathetic fibres constrict the bronchi and that the sympathetic fibres constfict the blood vessels. Sensory fibres from the lung are thought to join the vagus nerve.

Development of lungs. The rudiment of the tracheobronchial tree—the treelike formation consisting of the trachea and the many branchings of the bronchi—appears as early as the 25th day of intrauterine life in the form of a groove, called the laryngeotracheal groove, on the ventral (or forward) side of the tubular foregut just below the pharynx. A day or so later, two lung buds push out from the lower end of this groove. These become primitive lung sacs, or primary bronchi. This period is a critical one, and, occasionally, one lung may fail to appear. By the 31st day each bronchus has developed secondary buds, which become the lobar bronchi. Meanwhile, the laryngotracheal groove is being separated from the esophageal portion of the gut by a wall that moves progressively upward from the level of the bronchial buds to the larynx. As each lobar bronchus continues to grow, it divides. By the 36th day all ten segmental buds have appeared, giving the exterior of the lung a scalloped appearance. By the 40th day several additional generations of branchings have appeared, so that a model of the bronchial tree resembles great clusters of grapes.

This period of branching (pseudoglandular period) continues through the fourth month. About 16–26 generations of branching are then established. Between the fourth and sixth fetal months (canalicular period) the surface epithelium is flattened out from below by invading capillaries. Two adherent cellular membranes for exchange of gases thus form. Between the sixth month and birth (terminal sac period) this double membrane invades the surrounding connective tissue, forming clusters of sacs in the walls of which primitive alveoli develop just before birth. Cells secrete a lipoprotein substance (surfactant) that facilitates expansion of the air–fluid interface at birth. From this time on the premature infant is viable.

The first respirations after birth expand only a limited area. Full expansion may require weeks. Portions of the lung may never dilate (a condition called congenital atelectasis). In premature infants and those delivered by cesarean section, a proteinaceous membrane, probably derived from leaking adjacent capillaries, sometimes lines the alveoli, preventing respiration.

It has been estimated that from birth to maturity the lung volume increases from 0.2 to 5.5 litres, that the number of alveoli increase from 24,000,000 to 296,000,000, and that the air-tissue interface (for exchange of gases) increases from 2.8 to 75 square metres (30 to 810 square feet). At birth the only alveoli present are located in the very end branches of the tree, in tiny clusters of alveolar sacs one millimetre in diameter. Within two months, new alveoli appear along the bronchioles in a centripetal direction so that what were clusters of saccules become alveolar ducts, and what were smooth respiratory bronchioles bulge with new alveoli.

Respiratory System Diseases

The respiratory system includes the structures and organs that have to do with breathing—the nasal cavities, the throat or pharynx, the larynx, the trachea, the bronchi, and the lungs. The lungs are the site of an exceptionally large range of disorders. The main reasons for this are three: first, they are exposed to the environment in which man lives and are therefore affected by dust or other substances in the air that he breathes; second, they possess a large capillary network through which the entire output of the heart has to flow every minute, and this means that diseases with a general effect on small blood vessels are likely to affect the lung; and third, they may be the site of "sensitivity," or allergic phenomena that may profoundly affect their function.

General considerations

SIGNS AND SYMPTOMS OF RESPIRATORY DISEASES

By contrast, the symptoms of lung disease are relatively few. Diseases of the major airways, of which chronic bronchitis is an example, cause a cough productive of sputum as their most important manifestation. In more severe degrees of involvement of the bronchial tree, in which there may be considerable enlargement of the mucous glands and excessive mucus production, as much as half a pint of sputum may be produced in a day. Much more commonly, however, an ounce or two of sputum is produced in a 24-hour period, and particularly during the first two hours of the morning. The presence of blood in the sputum (hemoptysis) is an important sign and one that can never be disregarded. Although it may have been caused only by an exacerbation of an existing chronic infection, it may indicate the presence of a serious pathological process such as malignant disease. Bloodstaining of the sputum is a classical symptom of pulmonary tuberculosis but may also occur when there is congestion of the lungs as a result of heart disease. Cough is a particularly important sign of all diseases that affect any part of the bronchial tree, and an irritative cough may be caused by involvement of the bronchial tree by extension of malignant disease or cancer from nearby organs.

The second most important indication of lung disease is shortness of breath. This sensation, known as dyspnea, may be insidious in onset and slowly progressive in some lung diseases, or it may occur acutely, as in the case of spasmodic asthma, in which the airway obstruction may be sudden in onset and equally swift in remission. Diseases such as pulmonary emphysema, in which there may be extensive lung destruction, are associated with unremitting shortness of breath, which may become so severe as more or less to immobilize the victim. Such dyspnea leads to a life of invalidism and may be one of the most distressing features of chronic lung disease. The slow development of diffuse interstitial fibrosis of the lung—widespread growth of fibrous tissue in the walls of the air sacs or alveoli—leads to slowly worsening dyspnea, and it is commonly this symptom which first causes the patient to seek advice from a physician. The absence of shortness of breath, however, may mislead someone into thinking that a given lung condition is necesssarily not a serious one. Actually, a small lung cancer, if it is not obstructing a major airway, will not produce shortness of breath. Though chest pain may be an early symptom of chest disease, it is most often associated with an attack of acute pneumonia or an embolus to the lung and in both of these situations is part of the symptom complex produced by these conditions. When an acute inflammatory process involves the external covering of the lung (the pleura), the pain is characteristically felt when a deep breath is taken, and it is often severe enough to limit the deep breathing of the patient. In some episodes of pneumonia, the chest pain may be very severe and disturb the afflicted by preventing sleep. Usually fluid soon collects in the intrapleural space and the pain of the pleurisy disappears. Severe chest pain may be occasioned by the spread of malignant disease outward from the lung to involve the pleura and even to extend to the chest cage. The intractable pain caused by this condition may require surgery to cut the nerves supplying the affected segment and give permanent relief from what is otherwise a severe and incapacitating symptom. Fortunately, however, this occurrence is the rare exception rather than the general rule.

Lesser signs and symptoms

To these major symptoms may be added a few more that are of less importance. The ailing person may observe a wheeziness in the chest, or this may be noticed by others. The cause of the wheeziness is airway obstruction. Some diseases of the lung are associated with the development of swelling of the tips of the fingers (clubbing of the fingers), and this may be a feature of bronchiectasis (chronic dilation of the bronchial tubes), diffuse interstitial fibrosis, and lung cancer. In the latter case, this unusual sign has been observed to disappear after removal of the tumour. In some diseases of the lung, the first symptom may be swelling of the lymph nodes that drain the affected area. Most particularly these may be small nodes situated above the collarbone in the neck, and enlargement of lymph nodes in these regions should always lead to a suspicion that the primary disease may be in the lungs. The biopsy of nodes in this region constitutes an important diagnostic technique in some types of lung disease, particularly sarcoidosis (a chronic disease characterized by the formation of many nodules or small lumps) and lung cancer. As noted in a later section, lung cancer may produce a wide variety of symptoms that may be mistaken for primary disease in other organs.

Debilitation from chronic lung disease

The generally debilitating effect of chronic lung disease is well recognized. The person with primary lung tuberculosis or with lung cancer, for example, may be conscious only of a general feeling of malaise, of unusual fatigue, and of apparently rather minor symptoms as the major indicators of his disease. Loss of appetite and loss of weight, a disinclination for physical activity, some general psychological depression, and some symptoms apparently unrelated to the lung such as mild indigestion or occasional headaches may be diverse indicators of these diseases. Not infrequently, he may feel as if he were still convalescent from an attack of influenza, and he may not realize that the primary cause of his malaise is the development of a serious lung condition. It is for this reason that the examination of the chest and the taking of a chest X-ray are regarded as basic to any general physical examination of a patient.

The development of X-rays and pulmonary function tests has diminished the importance of the stethoscope in making a definitive diagnosis, but in spite of this its convenience and usefulness in diagnosing airway obstruction and pulmonary congestion ensure that it will continue to be used. Skilled clinical diagnosis of chest disease depends upon the proper deployment of many methods of investigation, and the skilled integration of the resulting information. Great advances have been made in the treatment of lung disease. The one condition that was synonymous with lung disease for many years, pulmonary tuberculosis, is much less of a problem in civilized countries than it used to be. However, the alarming increase in the incidence of cancer, chronic bronchitis, and emphysema, and the increasing recognition of industrial lung disease, have been prominent features of the last 20 years.

Lung disease may be caused by physical factors such as dust, by bacteria and viruses, by sensitivity phenomena such as occur in asthma, or by disorders in the circulating blood, and the lungs may be involved in primary malignant disease and are commonly the site of secondary deposits from malignant disease elsewhere.

In the article, a general description of most of the important diseases affecting the respiratory system will be given. Details of medical treatment and specific drug therapy have in general not been included, but particular attention has been directed to the wider aspects of lung disease as these affect the community. The bibliography has been carefully selected to provide the reader with the answers to particular technical questions, and in them will be found elaboration of most aspects of lung disease.

MORPHOLOGICAL CLASSIFICATION OF RESPIRATORY DISEASE

Structure of lungs

It is helpful to recall the main divisions of the lung as a basis for the morphological distribution of respiratory system disease. Broadly speaking, the lungs may be visualized as consisting of the upper airway, the trachea or windpipe, and of progressive divisions of that airway system into progressively smaller tubes, until finally the terminal bronchioles, which are about one millimetre (mm) in diameter, are reached. Approximately 16 generations of division occur between these bronchioles and the trachea. Although there is one airway at the beginning, namely the trachea, there are approximately 650,000 terminal bronchioles. The cross-sectional area of the bronchial tree in fact increases with increasing subdivision, although the diameter of each individual bronchus is decreasing. The end of the terminal bronchioles opens into the "acinus," so called because the structure resembles a cluster of grapes, and from this point onward the gas-exchange portion of the lung is reached. The alveoli or air sacs, which are divided into groups or "lobules" by fibrous partitions or septae, are small hexagonal structures forming a blind end to the acinus. The wall of the alveolus consists almost entirely of blood capillaries, and the remaining structures are extremely thin, only providing supporting tissue for the rich blood capillary bed that constitutes the parenchyma, or the essential tissue of the lung itself. The blood is distributed to the lung through the pulmonary artery, which subdivides with the bronchial tree and which accompanies the smaller bronchioles into the region of the acinus to supply the capillaries of the alveolar wall. The pulmonary veins drain the oxygenated blood from the alveoli and run at some little distance from the bronchioles. An interstitial space exists around the alveoli and around the bronchioles and blood vessels, and this connects with lymph nodes (the small masses of lymphatic tissue that occur along the course of the lymph vessels) situated in the midline of the lung and extending up in a chain into the neck and down into the abdomen. The lung is covered by a protective membrane, the pleura, and the inner lining of the chest wall is comprised of a similar membrane. The "intrapleural space," which exists between these two fibrous coverings, normally contains no air, and only a few millilitres of liquid for lubrication purposes. The pleurae may, however, become involved with inflammatory disease, in which case an effusion of fluid may occur between the two layers of the pleura.

Morphologic categories of respiratory tract disease

From this general description, the diseases of the respiratory tract may be broadly grouped into the following categories.

Diseases of major bronchi. These become the seat usually of chronic inflammation as in chronic bronchitis or bronchiectasis, or they may be the common site of primary malignant disease or lung cancer.

Diseases of smaller bronchi and bronchioles. It is in the smaller bronchi that major obstruction commonly occurs in asthma, since these bronchioles are supplied with smooth muscle and this may contract to obstruct the airway in this disease. The small radicles of the bronchial tree, the bronchioles, are commonly involved in infective processes and are the primary site of dust deposition in particular occupations.

The alveolar ducts and alveoli. These are the site of primary involvement in many infections, including pneumonia, and it is on the parenchyma of the lung that the main effects occur when the primary artery is obstructed by a blood clot. The capillary bed surrounding the alveoli is subject to damage, and it is through the alveolar capillaries that leakage of fluid leading to its accumulation in the lungs (pulmonary edema) may occur. The alveolar walls themselves may be involved with diffuse interstitial thickening, and this is a prominent part of the diseases grouped under the general heading of "diffuse interstitial fibrosis."

The lymphatic system. The system of channels draining the lung may be involved in primary disease of the lungs, and some diseases may first show themselves by enlargement of the lymph nodes in this area at a time when the essential tissue of the lung is still minimally or inconspicuously involved.

The pleura. The pleura is commonly involved in acute inflammatory processes; this gives rise to the symptom of pleurisy. The intrapleural space may also be the site of the collection of fluid forming a "pleural effusion." This most commonly occurs either as a result of acute or chronic lung infection, or as a result of lung cancer.

Although these divisions give a general outline of the ways in which diseases may affect the lung, they are by no means rigid. It is common for more than one part of the system to be involved in any particular disease process, and disease in one area not infrequently leads to involvement of other parts of the system. Thus, obstruction or blockage of a branch of the pulmonary artery leads to extensive congestion, hemorrhage, and pathological change in the capillaries and alveoli beyond the obstruction. The process of pneumonia may simultaneously involve the pleura and the pulmonary parenchyma. And the disease complex of chronic bronchitis and emphysema most often simultaneously involves chronic inflammatory change in the major bronchi, obliterative chronic inflammatory change in bronchioles, and, finally, destruction of pulmonary alveoli, commonly the alveoli situated in the middle of the lobule. Involvement therefore of different parts of the lung may be synchronous, and a rigid classification is consequently not possible.

THE EFFECT OF RESPIRATORY DISEASE ON PULMONARY FUNCTION

Normal function and symptoms of abnormality. The primary purpose and function of the lung is to fully oxygenate the blood and enable carbon dioxide (CO_2) to be eliminated. In many conditions, the lungs are unable to accomplish these tasks and there is therefore a fall in the oxygen content and oxygen pressure of arterial blood, and there may be an increase in carbon dioxide as a manifestation of lung disease. These disorders most commonly occur when there is inefficient ventilation and perfusion within the lung, or when there is a gross decrease in effective ventilation. There may, however, be severe physiological abnormalities detectable long before the gases dissolved in the blood have changed. In some diseases, the primary defect is in an increase in the resistance to airflow through the bronchial tree. This is the primary manifestation of the airway narrowing that occurs in bronchial asthma, and it is also a prominent feature of chronic bronchitis. The abnormality may be detected by the retardation in airflow that occurs when a subject makes a maximal expiration. Extensive and diffuse involvement of the alveolar tissue of the lung may lead to a severe increase in the "stiffness" of the lung tissue, which may be measured as a reduction in pulmonary compliance. In very serious examples of this disorder there may be a severe defect of gas transfer across the alveolar wall of the lung. In many respiratory diseases, the lesions are not uniform and, in many situations, complex patterns of pulmonary dysfunction may be observed.

Causes of shortness of breath

The sensation of shortness of breath is one of the common symptoms of pulmonary abnormality. During normal exercise, there is a considerable increase in pulmonary ventilation, and the lungs are so constructed that this can normally take place without any consciousness of major effort. In moderately severe exercise, the lung ventilation may increase from a resting value of about 10 litres (1) a minute to as much as 50 or 60 litres a minute. Any obstruction to airflow, however, will lead immediately to a consciousness that more effort is needed to shift these volumes of gas in and out of the lungs. Thus, although a person may be comfortable sitting at rest, as soon as his ventilation demand increases on exercise he may become aware of difficulty in breathing. In some chronic conditions such as chronic bronchitis and pulmonary emphysema, there may be severe airway obstruction, and this is the prime cause of the shortness of breath that the ill person notices and the main reason why his exercise may become severely limited. Many factors contribute to this airway obstruction, including changes in the major bronchi themselves, inflammatory changes in small airways, and the development of pulmonary emphysema, which involves destruction of pulmonary alveoli with a consequent loss of the normal elastic recoil of the lung. The loss of this recoil means that the airways are more likely to collapse and obstruct airflow when expiration is occurring.

The normal lung is capable of a more or less normal distribution of ventilation within it, which is to say that the gas being inspired is distributed more or less uniformly to all parts of the lung. The presence of lung disease, or the presence of obstruction in one airway, means that this will no longer occur and the distribution of ventilation may become nonuniform. Gross disturbance of the lung architecture will also cause abnormalities of ventilation distribution and may contribute to the dysfunction of the lung.

The transfer of oxygen across the lung is dependent on the maintenance of good ventilation of the alveoli and hence a high pressure of oxygen in the alveoli at all times. Transfer of oxygen from gas to blood occurs by diffusion from alveolar gas into the blood. Oxygen, being a relatively insoluble gas, does not move quickly through biological membranes and thus takes a finite time to saturate the blood in the alveolus. Normally, the red cells of the blood are only in contact with gas for about 0.7 second in a normal subject at rest, and on moderately severe exercise this time may be reduced to 0.3 second. In normal people at sea level, full saturation of the blood occurs in all circumstances within these time limits. Ascent to altitude, where the alveolar tension is reduced, may limit the attainment of full equilibrium, and the same thing may occasionally occur if the alveolar wall is extensively involved by disease even when the subject is at sea level.

An important cause of failure of lung function is diminution in ventilation of the lung. Occasionally, this may be the result of some defect in the regulatory system and may be caused by lesions in the brain. More commonly, there is general underventilation of large parts of the lung as a result of some disease process, and this may cause failure of gas exchange. The normal maintenance of arterial oxygen tension and elimination of carbon dioxide is very much dependent on the uniform distribution of ventilation and perfusion within the lung, and if these are mismatched or if there is a decrease in effective ventilation, the gas pressures are changed, leading to deficient oxygenation of arterial blood and deficient elimination of carbon dioxide. It is important, however, to realize that there may be considerable airway obstruction with shortness of breath and troublesome symptoms of lung disease before any change may be noted in the arterial blood gases, and it is for this reason that simple measurement of the arterial blood is not the sole pulmonary function test of importance in the understanding of chest disease.

Tests useful in diagnosis of lung disease

The measurement of capability with respect to pulmonary ventilation, the precise ascertainment of the oxygen and carbon dioxide pressures of the arterial blood, measurements of the efficiency of distribution of ventilation and perfusion in the lung, measurements of gas transfer across the alveolar bed, and finally measurements of the lung stiffness and airway resistance by simultaneous recording of esophageal pressure and airflow have contributed immeasurably to the understanding of lung-disease processes. Many of these techniques are in routine use in hospitals, and some of them have proved important in survey work in relation to chronic respiratory disease within a given population. In particular, for the study of chronic bronchitis, which is one of the most important contemporary disease problems, particularly in a population with heavy cigarette consumption, the surveys making use of measurements of ventilatory capability have proved of exceptional value in indicating, in a quantitative manner, the ventilatory capability of the subjects. This may be very hard to gauge from clinical examination or questioning, and since the plain chest film in this condition is commonly normal, this kind of survey has become very dependent on field laboratory measurements.

Not uncommonly, it is necessary to be able to measure the function of the two lungs separately. This is usually done by passing into the trachea a rubber tube that divides the air coming from the two lungs. More recently, radioactive gases and particularly xenon-133 have proved invaluable in measuring relative efficiency, both in terms of ventilation and blood flow, of different parts of the lung.

The respiratory system presents a number of effective protective mechanisms. The nasal mucosa acts as an air-conditioner and traps large dust particles. The major bronchi are equipped with ciliated cells and lined by a layer of mucus to which particles and bacteria may adhere, to be moved continuously upward by the action of the cilia. The act of coughing is an important protective mechanism, and this powerful reflex is trigged by irritation in the major bronchial tree. The forcible airflow that results is extremely effective in moving large pieces of material upward. The lung is equipped with major healing capability particularly after infections, but the damage caused by some disorders such as emphysema seems to be generally beyond repair. At the alveolar level there are wandering macrophages, cells with the ability to ingest particles, and it is likely that the surface-active lining of the alveoli may have an important protective function. Particles that have been breathed in and that reach the alveolar wall may be removed to lymphatic channels and stored in lymph nodes to which these drain.

Characteristics and course of respiratory failure

Respiratory failure. In many of the conditions described below, but particularly in chronic conditions such as pulmonary emphysema and conditions involving the pulmonary musculature, respiratory failure may occur. In this condition there is a failure to oxygenate the blood normally and to eliminate sufficient carbon dioxide to keep the tension of this gas in the blood at its normal value of 40 millimetres of mercury (mm Hg). In some conditions, particularly acute asthma, there may be a dangerous drop in arterial oxygen tension before much retention of carbon dioxide has occurred, and this may also be seen as a result of injury to the chest or in certain postoperative situations. The commonest cause of this reduction in arterial oxygen tension is the continued perfusion of parts of the lung with blood, although the ventilation to these regions has been greatly reduced. Reduction of arterial oxygen tension may in turn produce a fall in systemic blood pressure, which aggravates the oxygen lack existing at the tissue level. Although easily reversed, this stiuation may be difficult to diagnose clinically in its early stages. Later, often when the patient is fatigued or exhausted, the arterial carbon dioxide tension begins to rise. At levels of 80 to 90 millimetres of mercury, carbon dioxide produces a narcotic effect; this state is called carbon dioxide narcosis. The rise in carbon dioxide is accompanied by increasing acidity of the blood. If untreated, these changes combined with hypoxemia lead to failure of the heart and circulation, and death. The introduction of modern methods of analyzing the arterial blood for its gas content and tension have revolutionized the management of this condition in hospitals. The provision of medical staff and nurses specially trained in the technique of suction of secretions from the bronchial tree, the administration of enriched percentages of oxygen in a controlled manner, and, if necessary, the protracted artificial ventilation of the ill person either through a tube passed through the nose into the trachea, or through an opening made in the trachea, have resulted in the successful treatment of many persons with acute respiratory failure who would previously have certainly died. The maintenance of respiration when muscle disease has led to respiratory weakness may be necessary for several weeks until the disease spontaneously improves. The person with some degree of chronic lung disease may be thrown into respiratory failure by an acute infection, and if he can be brought through this successfully, he may have useful activity for years afterward. Sufferers from spasmodic asthma may, and commonly do, recover completely normal pulmonary function although an acute episode of status asthmaticus may be life threatening (see above). The prompt and careful management of these patients is required for successful therapy.

RELATIONSHIP OF RESPIRATORY DISEASE TO AIR POLLUTION

Although the influence of cigarette smoking and of certain industrial occupations on the prevalence of different kinds of lung disease has been established, the general influence of air pollution is much more difficult to define. Air pollutants commonly measured consist of sulfur dioxide and general particulate pollution. It has been clearly shown that in most cities where the levels of these pollutants are high, the general incidence of chronic bronchitis and emphysema and acute respiratory infections bears some relationship to the level of the pollutants. It has also been demonstrated that the incidence of respiratory infections in children under the age of two years is related to the general level of air pollution as indicated by these two measurements. In large industrial areas, it has been shown that there is a general relationship between morbidity from respiratory disease in people who already have some respiratory condition and peaks of worsening air pollution as measured by smoke and sulfur dioxide concentration. However, it is far from proved that all these effects should be attributed directly to sulfur dioxide. It is not clear what other aspects of city living, such as overcrowding, exposure to other people with respiratory infections, or even potentiation of the growth of respiratory viruses in the atmosphere as a consequence of the presence of air pollutants, may play in producing these results. The influence of other pollutants such as oxides of nitrogen, which are produced by automobile exhausts, and ozone, which may be produced by the action of sunlight on automobile exhaust, is not well defined. One of the reasons for the difficulty in clarifying the influence of air pollution on respiratory disease has been the concomitant increase of cigarette smoking and of the diseases which have been shown to be closely related to this. Indeed, only if the noncigarette-smoking population is studied can reliable statistics be obtained. If different populations are to be compared, it is essential that the cigarette-smoking habits of each group be most carefully analyzed. It may be said, however, that the evidence linking air pollution with exacerbations of respiratory disease is solid enough to form a basis for legislative action to limit the deteriorating environment of most industrial regions.

Diseases of the respiratory system

DISEASES CAUSED BY VIRUSES AND SIMILAR ORGANISMS

A wide variety of viruses is responsible for respiratory disease. It is a common experience that the common cold may extend to involve the trachea and to cause laryngitis, and there is little doubt that these processes may extend to involve the lower bronchial tree. After such episodes the ciliary lining of the bronchial tree may be damaged, but the repair processes are usually rapid.

Infections with the rhinovirus and adenovirus groups of viruses are particularly important in children, in which they may cause an acute febrile illness sometimes with a severe degree of bronchial tree involvement. Recovery from all these processes is usually rapid. In exceptionally severe infections there may be involvement of the pulmonary parenchyma, or an effusion into the intrapleural space with pleurisy, and in rare instances concomitant involvement of the pericardium—the protective membrane enclosing the heart—and even of the heart muscle itself. Isolated severe examples of these diseases may occur during an epidemic.

By contrast, influenza and parainfluenza may commonly cause more severe respiratory illness. The influenza virus attacks many systems of the body simultaneously, but it appears likely that its primary site of reproduction is in the alveolar cells of the lung. Tremendous multiplication of the virus occurs in these cells within a 24-hour period, and the pulmonary involvement may begin at the parenchyma and cause considerable consolidation and inflammation of lung tissue. It is common for there to be severe bronchitis and tracheitis at the same time. A less severe example of the disorder is that described as viral pneumonia, in which a distinguishing feature is the presence of patchy areas of atelectasis, or partial collapse of lung tissue, without very widespread bronchial-tree involvement. These conditions may be particularly dangerous in elderly people and in small children, and the lung that has been the seat of a severe attack of influenza may quickly become secondarily infected with streptococci or staphylococci.

Influenza epidemic of 1918–19

The severe epidemic of influenza of 1918 and 1919 was one of the worst human catastrophes on record. It has been estimated that more than 20,000,000 people died around the world as a result of this epidemic, and of the 20,000,000 persons who suffered from the illness in the United States, approximately 850,000 died. It was a characteristic of this epidemic that young people were commonly severely affected, and in them the virus illness was complicated by addition of a bacterial pneumonia to the original virus infection. At that time there was no effective chemotherapy for the secondary bacterial invasion. There are three immunologically distinct types of influenza virus, designated A, B, and C, and there is also a group designated by the letter D, known as the parainfluenza viruses. However, within type A there are now known to be at least four strains. The "Asian" strain of type A was responsible for the 1957 epidemic. Epidemic influenza tends to go in two- or three-year cycles, and the careful study of epidemics has enabled some predictions to be made concerning their future occurrence. Although there is lasting immunity to a particular strain following an attack of influenza, the immunity is highly specific as to type and no protection is afforded even against closely related strains. Artificial immunization with high-potency vaccines is of value in protecting against previous strains, and the vaccines have been shown to ameliorate the infection in the general population. They are particularly indicated for use in elderly people or those with pre-existing lung disease.

Mycoplasma, the organism identified in 1944 as responsible for a group of pneumonias, is an organism having many forms and capable of passing through filters, and for this reason it was originally regarded erroneously as a virus. It is a member of a group of organisms known as the pleuropneumonia-like organisms (PPLO) and has also been called the "Eaton agent" after the scientist who first described it. It is commonly responsible for what used to be known as "viral pneumonia." It produces characteristic soft shadows on the X-ray and relatively few signs that are observed in clinical examination. Usually a nonproductive cough and a fever persist for a few days. The disease is common in children and particularly occurs in epidemic form in young people brought together as into an army recruiting centre. Normally, it is a self-limiting disease of short duration.

Psittacosis and ornithosis, primarily infections of birds and particularly common among parakeets and parrots, are transmitted to human beings by inhalation as dust from the droppings of infective birds. The onset of psittacosis may be quite severe with headache, insomnia, and even delirium. Gastrointestinal symptoms such as vomiting and abdominal pain are frequent, and a cough with production of clear sputum usually develops after a few days. The areas of pulmonary consolidation ("solidification" with white blood cells, which shows in X-rays) may change over the course of the illness, and mild attacks of the condition are probably often unrecognized or dismissed as influenza. Recovery is usually complete, but convalescence may be slow. The diagnosis may be made by concurrent X-ray evidence of consolidation of the lung, and identification of the micro-organism in the sputum or in the blood. The greatest epidemic of this disease occurred in 1929 and 1930, when a pandemic was caused by the shipment of 5,000 parrots into Argentina from Brazil for auction. Many of the birds died, and there was a considerable human mortality from this particular episode. This disease is to be distinguished from the sensitivity diseases that may result from contact with birds.

Q fever

Q fever is an infection with *Coxiella **burnetii.*** The disease gets its name from the fact that it was first described in Queensland, Australia, though it is now known to be widely prevalent in North America and Europe. It is probably a common disease of cattle, and transmission is believed to occur between mammals through ticks and mice. Slaughterhouse workers are particularly susceptible to the disease, but the method by which humans contract it is often not clear. It may be transmitted through milk, particularly if this has not been pasteurized, and in the past this has probably been an important method of transmission. Q fever is usually a self-limited disease and calls only for symptomatic treatment; the pulmonary aspect of the condition is usually confined to temporary inflammation and accumulation of white blood cells with no later complications.

The disease chicken pox (varicella), particularly when it occurs in adults, may affect the lung. Acute lesions may occur at the alveolar level, leading to a transient, but significant, fall in arterial oxygen tension and occasionally necessitating oxygen therapy. Recovery from this condition seems to be slow but complete, but radiological shadows may be left as a result of it.

It seems clear from recent information that the reparative processes occurring in the lung after viral attack may be quite slow. Apparent clinical recovery may occur relatively quickly and the X-ray may show no remaining shadows, yet at the level of the alveolar wall the process of repair and restitution may take several further weeks.

Whooping cough occurs in epidemic form, particularly among children, and is important not because of its immediate effects but because there is evidence linking it with the later development of the chronic infective process known as bronchiectasis.

BACTERIAL DISEASES

Bacterial pneumonia. Until the development of effective antibiotics, pneumonia was the respiratory disease responsible for the greatest mortality and was one of the most feared of all diseases. The commonest form of this disease was caused by the "pneurnococcus" (Diplococcus pneumoniae). This organism characteristically caused an acute illness of sudden onset with high fever, consolidation of a whole lobe or more than one lobe of the lung, followed either by such complications as a lung abscess or pleurisy or heart failure, but naturally terminating after about seven days in a high peak of fever and then a sudden crisis followed by a sharp fall in temperature and slow resolution. This dramatic illness, so often fatal in older people, came to be known as the "old man's friend." The classical form of the illness is now rarely seen by the medical student, since prompt antibiotic therapy controls the acute process within 24 hours. The streptococcus causes a diffuse type of bronchopneumonia and it is this condition that is most likely to occur as a consequence of forced recumbency in old people—sluggish venous circulation results in accumulation of fluid in the lungs—or as a complication of a severe attack of influenzal pneumonia. This disease has also been largely controlled by antibiotics. Staphylococcal pneumonia now occurs as an acute illness of small children and of adults whose resistance has been lowered. In small children it may lead to rapid destruction of lung tissue with abscess formation, but from which the lung fully recovers if the acute state is survived (as it usually is with modern therapy). The development of antibiotic-resistant staphylococci has meant that this form of pneumonia has become a problem in the hospital environment and may complicate other lung disease or lung damage and may particularly be a problem in the postoperative period in those who are debilitated and weak. Pneumonia due to infection with *Klebsiella* pneumoniae may be particularly difficult to treat and characteristically may occur as a repetitive series of episodes of pneumonia each running a rather long course with slow resolution.

Resistant staphylococci

In all these bacterial pneumonias the diagnosis may be made by characteristic X-ray patterns combined with the isolation of the bacteria primarily responsible from the sputum. The organism *Haemophilus influenzae* is commonly isolated from the sputum of patients with chronic bronchitis (see below) and may be associated with acute exacerbations of that condition, though its exact role as a cause of disease is not well understood.

Pulmonary tuberculosis. Of all the lung diseases caused by bacteria, historically, pulmonary tuberculosis is by far the most important. Particular features of this condition, to which many writers and novelists of the last hundred years have turned for dramatic material, include the severe general debilitation and weakness that it may cause; the insidious nature of the onset of its initial symptoms, which may not be primarily pulmonary in nature; the fact that certain families are particularly prone to it; the long, drawn-out nature of the course of the disease and the distressing nature of many of its manifestations—particularly, severe hemorrhage of the lung, involvement of other organs, especially the brain in fatal meningitis, and the hopelessness of all medical attempts to control it until the development of effective antibiotic treatment. These compounds have largely displaced traditional methods of treatment such as collapsing the lung by pneumothorax (the injection of gas into the chest cavity), and they have greatly reduced the mortality from this disease in all civilized countries. In countries in which medical programs have not yet been applied to any major extent to rural populations, and particularly tropical countries in which this disease may take a heavy toll, pulmonary tuberculosis remains a major public-health problem. Diagnosis within a population may be greatly assisted by a survey of the population by taking miniature X-rays of large numbers of people; this method has contributed much to the control of the disease. The much more effective treatment and control of this condition has had the beneficial effect of reducing people's fear of it and has also resulted in the necessary reorientation of large numbers of sanatoriums and pulmonary-tuberculosis hospitals that are no longer required for long-term care.

In its classic form, pulmonary tuberculosis occurs principally at the apexes (upper portions) of the lung and may slowly progress to form a chronic cavity within the lobe affected. The cavity develops a fibrous wall, and once the disease has reached this stage complete healing may be difficult even with antibiotic therapy. Secondary infection of the cavity may occur and be difficult to eradicate. Pulmonary tuberculosis, when still active, is a constant threat to the patient because blood-borne spread to many organs may occur at any time and the disease may become more active or extend to other parts of the lung. The diffuse spread of tuberculosis may occur as its first manifestation, and this condition, known as miliary tuberculosis, usually begins as a generalized illness of unknown cause. The diagnosis may be suspected when the chest X-ray reveals diffuse small shadows, and when other causes of fever have been excluded. The exact sequence of events that leads to this disseminated type of tuberculosis is not understood, but prompt treatment is essential if spread to the brain is to be avoided. Tuberculous meningitis, in which spread to the brain has occurred, is one of the most dreaded complications of pulmonary tuberculosis and, before antibiotic therapy, was almost uniformly fatal. Tuberculous involvement of the adrenal glands leads to the syndrome of adrenal insufficiency called Addison's disease, a condition that comvounds the general debilitating effects of the pulmonary disease alone.

Treatment of pulmonary tuberculosis

The treatment of pulmonary tuberculosis has been revolutionized by the introduction of effective chemotherapy. Streptomycin was the first clinically successful antituberculosis drug and has remained important. It is now used mostly in conjunction with other antituberculosis drugs, isonicotinic acid hydrazide (isoniazid) or para-aminosalicylic acid (PAS), and, although originally toxic effects of streptomycin were commonly seen as a consequence of heavy dosage, it is now used in a dose well below that causing toxic symptoms. The symptoms of toxicity are selective on the nervous system and produce unsteadiness and attacks of giddiness with abnormalities and deficiency in hearing. Isoniazid has considerable potency against tuberculosis but has the disadvantage that the tubercle bacilli may rapidly acquire resistance to the drug. This drug is consequently never given alone but in combination with PAS or streptomycin. The drug diffuses well into the cerebrospinal fluid, and it is particularly valuable in treating tuberculous meningitis or miliary tuberculosis. It has few serious toxic effects, but it has been suspected of occasionally causing rheumatic symptoms in patients under long-term treatment for tuberculosis. PAS is usually given in combination with isoniazid. Although it is valuable in the treatment of tuberculosis, it is a difficult drug to administer because it produces side reactions. These are mainly gastrointestinal irritation, with impairment of appetite and some dyspepsia and diarrhea. Although these are not indications of serious toxicity, the symptoms are troublesome and make patients reluctant to take the drug if they are being affected by them. Viomycin sulfate is also used in the treatment of tuberculosis; it is now most commonly prescribed in doses lower than those usually responsible for its neurotoxic side effects. Pyrazinamide is not used alone in the treatment of tuberculosis but may be valuable in conjunction with other drugs. It should not be used in patients with a history of gout because it has a secondary effect of causing elevation of the level of uric acid in the blood. Ethionamide and ethambutol hydrochloride are both occasionally used in the treatment of tuberculosis, particularly when resistant strains of the organism have developed.

It is important to stress that there is no one "best" regimen superior in all circumstances to every other, in the treatment of pulmonary tuberculosis. Tubercle bacilli are able to acquire resistance to most of the antituberculous drugs, and skillful treatment consists in combining antibiotics so that resistant bacilli are less likely to be produced. The resistance to antibiotics may be delayed by the concomitant use of two or more drugs, by continuous treatment without significant interruption until bacterial growth ceases, and, thirdly, by the use of bed rest or surgery in selected cases in addition to antibiotic therapy. Clinical improvement of most patients with symptom-producing pulmonary tuberculosis is rapid if the bacilli are sensitive to the specific drug given. The general symptoms of the illness diminish, and radiological regression begins within a few weeks and may be complete within a few months. New shadows almost never appear on X-rays during treatment with antibiotics. One of the problems of treating pulmonary tuberculosis is that of ensuring that therapy is maintained and that the victim is continuously supervised. For this reason the treatment of pulmonary tuberculosis in undeveloped parts of the world or in remote village communities poses severe problems for the public-health authorities. Effective programs of control in the village environment have been initiated in India, but it is recognized that major pools of infection may be hard to eradicate in some of these isolated communities without continuing medical care. Effective treatment of pulmonary tuberculosis in the environment of the Western city may be equally complicated by the difficulty of ensuring that elderly, unemployed, and possibly alcoholic patients are kept on a proper regimen of treatment. It may be difficult to ensure continued supervision and treatment of such patients particularly if they drift from one city to another. Although the death rate from respiratory tuberculosis has diminished greatly in western Europe and in the United States since 1950, it remains an extremely serious problem in some underprivileged communities, in various tropical countries, and in any circumstances in which the medical supervision of the population is difficult or inadequate.

ALLERGIC LUNG DISEASES

There are at least four reasons why the lungs are particularly liable to involvement in "allergic" responses to proteins. They are exposed to the outside environment and hence particles of foreign protein—*e.g.*, in pollen—may be deposited directly in the lung; the walls of the bronchial tree contain a considerable amount of smooth muscle that is very likely to be stimulated to contract if histamine is released by cells affected by the allergic reaction; the lung contains a large vascular bed and therefore, in general responses causing diffuse inflammation of blood vessels, it is likely to be involved; and, finally, the lung has biochemical functions (at present very poorly understood), which mean that it is a store of histamine, has the task of denaturing circulating substances such as serotonin and bradykinin, and may well have important biochemical functions relating to proteins and allergins. It is therefore not surprising to find that sensitivity phenomena are common and represent an important aspect of pulmonary disease as a whole. The commonest and most important of these is asthma. This word is occasionally misused to indicate all kinds of conditions in which there is airflow obstruction in the lungs, but it is better reserved for those conditions in which an allergic component of the bronchial obstruction is likely to be present.

Causes and course of asthma

Asthma. Spasmodic asthma is a disease characterized by contraction of the smooth muscle of the airway, and later by airway obstruction as a result of failure of mucus clearance. This results in a greater or lesser degree of difficulty in breathing, which is often of fairly acute onset and equally rapid disappearance. Asthma generally develops in childhood or at least is present during adolescence if it is going to develop at all, and it poses a threat to life only when it is so severe that ventilation is grossly reduced. The acute asthmatic attack is alarming both for the sufferer and the onlooker. There may be extreme difficulty in breathing out, and the chest assumes a more and more inspiratory position. In spite of the severe respiratory difficulty, the patient remains fully conscious and, because oxygen in the arterial blood is initially not depleted, appears of a normal colour. In some patients an acute asthmatic attack may be precipitated by psychological factors, but it seems clear that an organic mechanism underlies this disorder in all patients, and, although the reactivity of the bronchial tree may be affected by fatigue and anxiety, this disease is not to be regarded as primarily psychogenic in origin. In some patients a sensitivity to particular foodstuffs plays some part in this disorder, and this is probably particuarly true of children. In others, sensitivity to animals or to dust of all kinds may be a feature, but it may be said that the condition is characterized by a generally increased reactivity of the bronchial tree to any stimulus, and in many patients these stimuli need not be highly specific.

Status asthmaticus

The most dangerous form of the condition is known as status asthmaticus. In this situation, the severe bronchial spasm lasts for several days and finally the bronchi become obstructed by plugs of mucus, which completely fills the passages in the bronchial tree. This causes severe ventilatory difficulty and, by the time this stage is reached, the administration of epinephrine, which in the early stages usually relieves the attack, becomes ineffective. At this stage of the disease, the arterial oxygen tension begins to fall to dangerously low levels, and terminally the arterial carbon dioxide tension begins to rise. When this severe state of respiratory insufficiency is reached, artificial assistance may have to be given to ventilation, and close supervision is obligatory. If the condition progresses, the victim becomes unable to make the enormous respiratory effort needed to overcome the resyiratory obstruction., and with increasing failure to eliminate carbon dioxide and with increasing ;depletion of oxygen, the heart stops beating. As a result of recent work, it has become clear that occasionally heart stoppage may occur at a somewhat earlier stage of the condition before the ventilatory obstruction has been established for very long. There has recently been considerable anxiety that deaths from status asthmaticus, particularly in younger people, have been increasing, and it is not at all clear why this should be so. The management of patients with asthma calls for considerable skill and patience on the part of the physicians and may be materially assisted or made much more difficult by the psychological and domestic circumstances of the patient.

Rarely this disease may interrupt normal schooling and interfere with normal activities to such an extent that it casts a shadow over the psychological development of the individual personality. Much more commonly, it tends to diminish in severity with age and assisted by therapy may be quite compatible with an active life. So-called asthma developing in the middle age is much more commonly the occurrence of considerable bronchial obstruction as a consequence of chronic bronchitis, the latter disease usually resulting from cigarette smoking and other environmental factors. In such instances, although there may be some sensitivity to *Haemophilus influenzae*, which complicates chronic bronchitis, a true familial allergic spasmodic asthma is not present. The patient with spasmodic asthma commonly has a normal chest X-ray, and this condition does not lead to the development of lung destruction or emphysema unless it is associated with chronic bronchitis.

Characteristically, in asthmatic persons, even though physical evidence of pulmonary abnormality may not be found, it is possible to demonstrate that there are abnormalities of pulmonary function, particularly an abnormal distribution of inspired gas, indicating that there is a failure of uniform ventilation of different parts of the lung. These findings indicate that the lung of the asthmatic patient is not infrequently abnormal at a time when he feels well and is free of symptoms.

Hay fever

Hay fever and farmer's lung. Hay fever is an allergic condition affecting the nasal mucosa and sometimes associated with asthma or with other allergic conditions. It is commonly familial and occurs in its most severe form as an allergic response to the inhalation of pollens, particularly the pollen of ragweed. It may cause the nose to run with attacks of sneezing and may be associated with uncomfortable conjunctivitis. It commonly has a seasonal variation and is closely associated with the exposure of the patient to the pollen. Allergic inflammation of the nasal passages is a more severe and more chronic form and is mole commonly associated with asthma.

Farmer's lung

In recent years much attention has been given to the important disease farmer's lung. It is now known that this is a sensitivity reaction to the inhalation of spores that germinate in mouldy hay. In most farming areas of the Western world in which careful studies have been made, the disease has been shown to be much more common than hitherto supposed. In Wisconsin and the New England states, and in the west of England, as well as in France, it is not unusual in farming communities. Characteristically, the victim notices shortness of breath after he has been exposed to hay that has been stored over the winter, and that he may be putting out for feed for horses. The dyspnea may become more severe and he may develop a febrile illness with increasing shortness of breath. The X-ray shows a finely mottled appearance. At this stage of the disease, there is not only considerable airway obstruction but in addition interference with gas transport in the lung leading to a reduced arterial oxygen tension. Spontaneous resolution of this condition may occur, and its treatment is facilitated by the administration of adrenocorticosteroid compounds. It seems likely, however, that, if untreated, the disease may assume a more chronic form and may lead to permanent changes in the lung, causing considerable chronic interference with pulmonary function. A somewhat similar group of diseases have recently been described occurring in those with close contact with birds. Variously known as pigeon breeder's lung and bird fancier's lung, these represent different kinds of allergic response to proteins from birds, and particularly, probably, proteins contained in the excreta of pigeons, budgerigars, and canaries. The allergic response may be primarily in the bronchial tree, but it not uncommonly involves the lung parenchyma, and the patient may complain of shortness of breath and wheezing. It seems unlikely that this group of disorders leads to any permanent pulmonary damage, but removal of the ailing person from contact with birds is essential if he has developed a sensitivity to them.

Pigeon breeder's lung

In a number of other diseases an allergic response or sensitivity phenomenon plays an important part in determining the disease. This is true of byssinosis (see below ***Industrial lung disease)*** and it is also probably true of response to infection with some organisms. It is not known to what extent a sensitivity phenomenon may determine the bronchial spasms that result from an acute exacerbation of infection with ***Haemophilus influenzae*** in chronic bronchitis. There may be a sensitivity phenomenon associated with infection with the fungus ***Aspergillus,*** and it is possible that some of the respiratory disorders described in grain handlers may be based on a sensitivity phenomenon occurring in response to inhalation of dust from this material.

BRONCHITIS

Acute bronchitis. Acute bronchitis most commonly occurs as a consequence of virus infection. It may also be precipitated, however, by acute exposure to harmful gases, as for example chlorine and sulfur dioxide, and perhaps most commonly it occurs as an exacerbation of chronic bronchitis. The bronchial tree may be reddened and congested, and minor blood streaking of the sputum may occur in this condition. In most instances resolution is reasonably quick and full recovery occurs. If there is extensive chronic lung disease present, however, the additional acute inflammatory reaction occurring in large and smaller segments of the bronchial tree may be dangerous, and this sequence of events is not uncommonly observed in patients with chronic bronchitis and emphysema. Similarly, persons suffering from bronchiectasis—chronic dilation of the bronchial tubes—may suffer from acute exacerbations of infection, and this chronic disease may well be characterized by a sequence of such acute events.

Bronchiolitis obliterans is an acute disease of small airways. It probably occurs to some extent in acute viral disorders, and acute bronchiolitis is a well-recognized clinical syndrome in children between the ages of one and two years. In these infants, the cause is most commonly a virus, which gives rise to a syndrome of respiratory obstruction with gross enlargement of the chest and considerable difficulty in breathing. In severe instances it may threaten life, but it normally clears spontaneously and leaves the lung apparently undamaged. In adults acute bronchiolitis of this kind is not a well-recognized clinical syndrome, though there is little doubt that in most patients with chronic bronchitis acute exacerbations of infection are associated with further damage to small airways. Acute bronchiolitis obliterans in adults occurs most characteristically as a result of inhaling gas fumes. These may be oxides of nitrogen, which cause specific damage at the level of the small bronchioles. Workers may be exposed to this gas in a number of different situations. Oxides of nitrogen are generated in grain-filled silos, and a farmhand, being unaware of the danger, may be inadvertently exposed to this gas at the top of a silo. Oxides of nitrogen are generated as a result of underground explosions, and cases of acute bronchiolitis obliterans have occurred when workers have moved too quickly into an area where a dynamite charge has been set off below ground. The combustion of some plastic materials, particularly in enclosed spaces, may lead to the generation of oxides of nitrogen to a damaging concentration, and thus this syndrome may be seen in firemen or those who have been exposed to the fumes from fires. The syndrome is characterized by dyspnea, and resolution may be slow. The extent to which inflammation of the terminal bronchioles and its slow resolution occur in virus diseases is not fully understood, since the recognition of this condition in the absence of distinctive radiological change is not easy.

Industrial hazards

The syndrome of spasmodic asthma may in rare instances be difficult to control, and the obstruction it causes may become chronic. Spasmodic asthma is however not, on balance, a common cause of generalized obstructive lung disease, since it is most commonly remittent and periodic.

Chronic bronchitis and emphysema. The diseases chronic bronchitis and pulmonary emphysema, on the other hand, are much less liable to be remittent and much harder to relieve once they have become established. There is much concern about the incidence of these two diseases in modern industrial society because there is evidence that they have increased considerably over the past 20 years. In the United States, chronic bronchitis and emphysema appear to have increased as a cause of mortality and morbidity by a factor of 12 over the decade of the 1960s, and the rate of increase appears still to be unchecked. Similar increases have been noted in western Europe and in Canada, and there is much discussion of the relative importance of cigarette smoking, air pollution, and climate in determining their increasing incidence. There is general agreement that the major increase is most closely related to cigarette smoking, and the general incidence of these conditions in any population appears to correlate most closely with cigarette smoking. Other factors such as climate, industrial environment, air pollution, and even genetic factors may be responsible for some additional increase. Chronic bronchitis is characterized by changes in major bronchi, particularly hypertrophy of the mucous glands in the wall, changes in smaller bronchioles leading to obliteration and obstruction, and, finally, alterations in the distribution of ventilation and perfusion within the lung that may lead to altered tensions of carbon dioxide and oxygen in the blood. Chronic production of sputum is a feature, and this may occasionally be blood-stained. The relatively normal chest X-ray gives little indication of the severity of these changes until a late stage has been reached. Careful radiologic studies, however, using contrast material in the bronchial tree, may reveal the extent of the changes that have occurred at a relatively early stage.

Chronic bronchitis gives rise to a progressive fall in the ventilatory capability of the patient and leads to a progressive shortness of breath. Initially, this may only be noted during winter months or during times when the acute infection is worse than usual, but later the shortness of breath becomes chronic. Chronic bronchitis may continue to be a mild disorder for many years, and there is little doubt that in some victims chronic hypertrophy of the mucous glands may be productive of a blob of morning sputum, but the disease may progress little from that stage. In other cases, however, chronic bronchitis is complicated by more severe changes in the bronchial tree and the gradual destruction of the lung parenchyma of pulmonary emphysema. The disordered blood-gas tensions to which chronic bronchitis of itself may give rise and the development of pulmonary emphysema represent the two most severe complications of this condition. Even if chronic bronchitis does not advance to these more serious stages, the repetitive chest infections and periods away from work with fever and cough, the general ill health that may result from the chronic bronchial infection, and the susceptibility of such individuals to more severe chest infections cause considerable morbidity in the normal working population. The statistical data linking these events and the changes in the bronchial tree to cigarette smoking seem to be beyond dispute. It is not at all clear what determines the severity of the condition in different persons; it is evident that the relationship, like most other biological relationships, exhibits considerable individual variation. It is only in the last 20 years that the general features of chronic bronchitis have come to be recognized for what they are. Previously, a slight cough in the early morning would be dismissed as a smoker's cough, and physicians and the general public had little understanding of the potential severity of this condition if allowed to continue its progress uncontrolled.

Pulmonary emphysema

There has been a striking increase in the mortality rate from pulmonary emphyrema in North America during the decade of the 1960s. This disease exists in two distinct pathological forms. The first is called centrilobular emphysema; in this form a hole appears in the centre of each pulmonary lobule. Alveoli in this situation are apparently destroyed, and there are also inflammatory changes of a chronic nature in many of the terminal bronchioles. There is reason to suppose that this form of the disease is preponderantly found in cigarette smokers. Persons with this generalized type of disorder almost invariably have moderately severe chronic bronchitis, and it is not precisely known how much of the abnormality of arterial blood-gas tensions found in this condition is to be attributed to the bronchitis and how much to the pathological lesions of centrilobular emphysema. The second main type of pulmonary emphysema is known as panlobular. In this condition there appears to be a generalized loss of alveoli throughout the lobule and there is no selective destruction of the alveoli at the centre. This type of emphysema is commonly seen in older people and is the pathological type of the disease that has been shown to be associated with a deficiency in the blood of antitrypsin, which counteracts the activity of the digestive agent trypsin. Other types of emphysema are of less importance than these major varieties, but emphysema may occur along the dividing walls of the lung (septal emphysema) and in association with scars from other lesions. It is an essential feature of emphysema as now defined that it should involve evident destruction of lung parenchyma.

The exact cause of pulmonary emphysema is not yet fully understood. It is clear that multiple factors are involved, but its common association with chronic bronchitis suggests that chronic infection may well be important. Earlier theories that the lung destruction could be produced by blowing wind instruments or as a consequence of spasmodic asthma have now been shown to be incorrect. There is a general loss of lung elasticity as the normal lung ages, but it is not clear that this observation is relevant to the pathological lesions that may be found. Once emphysema of any variety is well established, there is severe ventilatory defect, and constant breathlessness is a feature of this condition. Since there is usually associated chronic bronchitis, there is often a productive cough, but in some instances this may not be a prominent feature of the condition. It is now known that emphysema in relatively young non-cigarette-smoking adults may occur as a consequence of a deficiency of antitrypsin in the serum, but it is not yet understood why the deficiency of this enzyme should lead to the development of panlobular emphysema.

Once the arterial blood–oxygen tension has become abnormally low and the carbon dioxide pressure elevated, an increased pressure in the pulmonary artery results and in this way the pulmonary lesion leads to heart failure. The average age of incapacity from emphysema, however, is in the mid-50s, and it is incorrect to describe this disease as a disease of advanced old age. Differentiating pulmonary emphysema from chronicbronchitis during life presents considerable difficulty. A combination of tests of pulmonary function, detailed radiological examination, together with a carefully taken history of shortness of breath usually enable a reasonably accurate diagnosis to be made. Before these methods were fully understood and developed, older physicians placed much reliance on the shape of the chest, but this can be seriously misleading, and little reliance can be placed on a visual inspection of the individual's chest as indicative of the change within the lung.

Unusual forms of pulmonary emphysema are occasionally reported. In one of these the disease may apparently involve one lung only. It is believed that this form of the disease is most commonly caused by an infection, probably of virus origin, occurring during childhood and preventing normal maturation of the lung on one side. "Congenital lobar emphysema" of infants is misnamed because there is no alveolar destruction. It is caused by overinflation of the lobe of the lung because of maldevelopment of cartilages in the wall of the major bronchus. Accurate descriptions of the structure of the lung with specimens of the organ taken in the inflated state have led to a much more accurate classification of this disorder than was hitherto possible, and many of the advances of understanding of this disease have occurred because of a quantitative approach to its pathology.

Bronchiectasis

Bronchiectasis is a disease believed usually to begin in childhood. As a consequence of whooping cough, some damage to the bronchial tree may occur; it reveals itself in adult life as a localized area of dilatation of major bronchi. These become chronically infected, and production of sputum and episodes of chest infection may become common. Apparently, the disease may also be caused by localized obstruction to the airway, and bronchiectasis may be a feature of congenital conditions or of inherited defects. The most important of these is the condition known as mucoviscidosis (or cystic fibrosis), an inherited genetic disorder characterized by deficiency of pancreatic excretion, abnormality of chloride secretion in the sweat, and pulmonary changes, particularly bronchiectasis and bronchiolar abnormality. This condition does not progress to lead to pulmonary emphysema but rather causes obliteration and fibrosis of small airways, and dilatation and infection of large bronchi. Thick viscid secretions found in the bronchial tree resist treatment. Bronchiectasis may also result from acute inhalation of irritants such as sulfur dioxide, and it may also occur as a result of other infections in the lung, particularly pulmonary tuberculosis of chronic form. In many of these conditions the treatment has been much improved by the use of antibiotics, but when lung damage is severe and recurrent infection cannot be controlled, surgical resection of the region may have to be undertaken.

GENERALIZED NONOBSTRUCTIVE LUNG DISEASE

The lung may be involved in generalized changes particularly involving the alveolar walls and not associated with chronic infection. These diseases primarily involve the alveoli of the lung and the capillary bed; they may progress to pulmonary fibrosis of considerable severity. One form of this group of disorders, known as diffuse interstitial fibrosis, is of unknown cause. A diffuse and progressive thickening of the alveolar walls occurs, associated with marked disturbances of pulmonary function and progressive X-ray change. This condition may occur in association with diseases of the connective tissue, such as scleroderma, and it may run a short or very protracted clinical course. Pulmonary alveolar proteinosis is another generalized lung disorder, in which characteristic protein-rich material accumulates within the alveolar spaces. It is not usually associated with irreversible changes in the lung and is a disease that may run a remittent course and finally resolve completely. It produces characteristic radiological change and is unassociated with any other changes in any other organs of the body. Its cause is unknown. Some diseases characterized by the formation of granulomas—nodules of chronically inflamed tissue—of unknown origin are important in relation to the lung. Boeck's sarcoid, the commonest of these, is a disorder usually involving many systems of the body in which small granulomas may be found. Very commonly the lungs are the primary source of involvement, and the disorder may involve predominantly the lymph nodes in the chest, or the lung parenchyma. When this is affected, small granulomatous lesions are found, particularly around small blood vessels in the lung, and they may be of sufficient number to cause change visible in X-rays. Spontaneous resolution of this condition is the most likely clinical outcome, but some residual lung damage is not unusual. Exceptionally severe pulmonary fibrosis may occur, leading to incapacitating lung disease; in such instances there are usually severe changes in other organ systems. Eosinophilic granuloma (also known as histiocytosis X) is a disease in which the lungs may become infiltrated with eosinophil cells—white blood cells that stain readily with eosin. Progressive fibrosis may occur as a consequence of this, leading eventually to formation of small cysts in the lung and considerable fibrotic change. This disorder tends to be self-terminating but may leave the lung substantially damaged.

Diseases that affect blood vesselsin lungs

In rare instances, the lung may be involved as part of the generalized rheumatoid process, and pulmonary changes in association with rheumatoid arthritis have been described. It is clear, however, that this is a rare event. When it occurs, the changes in the lung appear to be similar to those occurring in diffuse interstitial fibrosis, but on a patchy and uneven basis. Certain diseases that attack the vascular system and which are believed to be related to abnormalities of sensitization and immune response are prominent in the lung. Among these, the acute inflammatory disease periarteritis nodosa is an important cause of varying degrees of blood-vessel inflammation within the lung. Acute hemorrhagic pneumonitis may occur in association with changes in the kidney (Goodpasture's syndrome), and pulmonary hemorrhage occur as part of the clinical condition of pulmonary hemosiderosis, the accumulation of the iron-containing substance hemosiderin in the tissues. In most of these conditions it seems likely that the primary basis for lung involvement is an abnormality of the normal immune mechanism affecting the small vessels and capillaries of the lung. In some of these syndromes the pulmonary involvement may be so severe as to threaten life, but usually it is part of general system involvement, and the outcome may be determined by the extent of involvement in other organs.

This group of disorders is of relatively recent general recognition. Accurate diagnosis of them has been much improved by the development of pulmonary function tests, refinements in X-ray technique, and the improvements in thoracic surgery and anesthesia that have made a biopsy of the lung a much less dangerous procedure than formerly. In the past, many of these diseases were confused with each other, and accurate understanding of some of them has only been possible with the advances in understanding of immunological processes that have occurred in the past ten years.

PULMONARY RESPONSE TO CHEMICAL AND PHYSICAL IRRITANTS

Industrial lung disease. It has been known for many years that silica has a particularly irritant effect on the lung. The dangers of silicosis are generally well recognized, and the problems caused by this dust have been reduced by better engineering techniques in underground mining. Silica produces a distinctive reaction in the lung that leads eventually to masses of fibrous tissue and distinctive nodules of thick fibrosis, which, by contracting, distort and damage the lung. Silica is to be regarded as a hazard of any occupation in which dust containing this compound is free in the atmosphere. Hard-rock drilling underground, various industrial processes involving grinding and molding, and sandblasting are all examples of such potentially hazardous occupations. Silicosis is usually fairly easily detectable on a chest X-ray; it causes considerable impairment of lung function with shortness of breath as its characteristic feature. Coal dust alone, even if its silica content is very low, causes a distinctive pattern of lung change known as coal-worker's pneumoconiosis. Initially the dust is deposited in the terminal bronchioles, and it may lead to a fibrotic reaction around these. Later the disorder progresses to a more generalized form (lung disease caused by dust), and in some instances may progress to a stage known as progressive massive fibrosis. It is not clear whether this stage may be reached by dust alone or by some interaction between the dust and pulmonary tuberculosis. In both silicosis and coal-worker's pneumoconiosis, it is known that the disease may progress after the man has left the working environment in which exposure occurred, probably as a result of progressive fibrosis occurring within the lung.

The dangers of exposure to asbestos consist of the development of a diffuse fibrosis of the lung in response to inhalation of asbestos fibres, and secondarily some increased risk of development of lung cancer as a result of asbestos inhalation. This mineral is being increasingly used in modern industry and has proved valuable in the manufacture of such things as acoustic ceiling tiles and in all kinds of insulating work. The reason why this particular fibre causes a considerable reaction within the lung is not understood, but increasing attkntion is being paid to the proper engineering techniques in its manufacture and processing to avoid any major exposure to airborne fibres.

Organic dust has been shown to be responsible for various syndromes involving the lung. The dust produced when raw cotton is being processed causes a reversible airway obstruction, but continued exposure may lead to some permanent impairment of lung function. This disorder, known as byssinosis, has been shown to be present in cotton workers in several different countries. Workers in sugar cane may be affected by a somewhat similar syndrome (bagassosis) and sisal workers are also exposed to fibres that may cause a sensitivity reaction and considerable airway obstruction. In most of these diseases, the recognition of the cause and the modification of the industrial process or removal of the worker from the environment produces amelioration of symptoms.

There are many chemical irritants that are exceedingly damaging to the lung in high concentration. These include oxides of nitrogen, ammonia, oxides of sulfur, chlorine, ozone, gasoline vapour, and benzene. Acute episodes of poisoning by these gases are well documented, but relatively little is known of the long-term chronic effects of exposure to very low concentrations of them. In industrial processes involving their use, the hazard is well recognized. They mostly produce an inflammatory reaction in the bronchial tree coupled with accumulation of fluid in the lungs. If the patient survives the acute episode, there may be residual damage to the bronchial tree leading to bronchiectasis, there may be obliteration of small radicles of the bronchial tree, and in certain other instances there may be some degree of pulmonary fibrosis.

Radiation damage

The lung may be damaged by excessive radiation. Radiation therapy for malignant disease of the breast may cause transient pneumonitis in the lung lying within the irradiated area, and in the majority of such instances the lung heals completely and without any fibrotic change. In a small minority of patients, the pulmonary reaction may be more severe and may result in extensive pulmonary fibrosis and contraction and shrinkage of the lung with concomitant dyspnea. There is considerable individual variation in reaction to the same radiation dose, and there is still much to be learned as to what determines the radiation sensitivity of a particular organ in a given individual.

The prompt recognition of the dangers of beryllium, which causes severe pulmonary disease, led to the discontinuance of its use in the manufacture of fluorescent light tubes. Although the dangers of many classical materials such as silica and asbestos are well understood, the industrial physician and toxicologist is continuously confronted with new compounds that may have a deleterious effect on the lung and bas to be alert to detect these. One such substance, toluene diisocyanate, used in the manufacture of polystyrene foam (an expanded plastic used for insulation and packing), caused a transient flulike syndrome associated with considerable reversible airway obstruction. Prompt recognition of this syndrome led to modifications in the process and discontinuance of exposure of men to these particular fumes. Although the acute effects of many of these substances in high concentration are well documented, there is very little information, indeed, concerning the importance or unimportance of regular exposure to very low concentrations of gases such as oxides of nitrogen and sulfur dioxide, and of airborne metals such as lead, which occur as part of the polluted urban environment in modern Western nations.

Localized obstructive **lung** disease. Acute laryngeal obstruction and asphyxiation may be caused by the accidental inhalation of food, which sometimes happens when an anesthetic has to be administered for emergency surgery shortly after a meal has been taken, or which may occur accidentally during a meal, particularly if aperson is elderly. More common aspiration is into a bronchus, and classically this occurs in children, often when they are eating peanuts or other food of this kind. Such obstruction may cause overinflation of the lung supplied by the bronchi, or in other circumstances may cause a collapse of the affected region, which may be a quite small segment. It is likely that small regions of atelectasis or collapse precipitate the pneumonia of old people who have to be recumbent for several days. Occasionally the aspiration of a foreign body is followed by acute infection in the lung; in these circumstances a lung abscess may result. In the past, this was a much feared complication of pneumonia because it was difficult to treat and often extended to produce inflammation in the pleural cavity leading to empyema. In the absence of effective chemotherapy, these were dangerous complications. Abscess formation in the lung may occur rapidly in infants with staphylococcal pneumonia, but complete healing normally occurs and the acute infection can be well controlled by antibiotics. Abscesses now occur more commonly in association with cancer of the lung, as a consequence of pulmonary infarction (death of a section of lung tissue), or as a result of long-standing inflammatory processes such as tuberculosis and histoplasmosis, infection with the fungus *Histoplasma capsulatum.*

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES

A wide variety of malformations occur in the lung. These include congenital absence of the whole lung, failure of different parts of the pulmonary artery to develop, anomalies in drainage of pulmonary veins, and failure of the cartilages to develop in a lobar bronchus, giving rise to infantile emphysema. **A** generalized cystic condition of the lung may occur as a congenital defect, but it is a very rare condition and many of the cases previously described under this heading are now considered to be instances of acquired cystic bronchiectasis. A remarkable inherited condition is that of microlithiasis alveolaris in which the alveoli are filled with small concretions. This gives rise to a spectacular chest X-ray that may be mistaken for other conditions. In general, this defect produces little interference with pulmonary function though a later pulmonary fibrosis has been described in association with it. The recent description of a syndrome of panlobular pulmonary emphysema in association with deficiency of serum α_1-antitrypsin has been noted above in the section on emphysema.

Respiratory-distress syndrome of newborn

Respiratory-distress syndrome, an important disorder of the newborn infant, appears to be either a failure to produce the surfactant lining of the lung at the time of birth, or a destruction of this factor. Whichever of these processes is fundamental to the condition, the infant born with a deficiency of this substance suffers from progressively severe atelectasis—collapse—of the lung. Failure of the lung to re-expand normally may lead within a few hours to a condition of acute respiratory failure. This condition is an important cause of neonatal mortality; although great advances have been made in understanding its essential nature, methods of preventing its development are still unknown.

OTHER CAUSES OF BRONCHOPULMONARY DISEASE

Circulatory disorders. The lung is commonly involved in disorders that are primarily those of the circulation. An instance of this is the pulmonary disease associated with failure of the left ventricle. The left ventricle is responsible for the pumping of blood into the main circulation. If the action of this ventricle becomes deficient—*e.g.*, as a result of disease of the coronary arteries or as a consequence of high blood pressure, the lungs may be subjected to an elevated pressure, because the right ventricle continues to put blood into the pulmonary artery but the outflow from the lung into the left atrium is impeded by the failing function of the left ventricle. This gives rise to pulmonary congestion. If the congestion becomes sufficiently severe, fluid passes through the alveolar wall, leading to pulmonary edema, and this may be a fatal complication of an acute heart attack. The shortness of breath that may accompany systemic hypertension is believed to be mainly due to pulmonary congestion, causing an increased stiffness of the lung and, perhaps in addition, obstructing airflow through the collection of edema fluid around small airways.

Acute pulmonary embolism

The lung is by its nature particularly susceptible to blockage of its blood vessels by circulating blood clots. These originate either in the veins of the legs or in the veins of the pelvis; such emboli classically may become detached a week or ten days after a major surgical operation or injury, and be carried to the lung, where they acutely block some part of the pulmonary vasculature. This condition of acute pulmonary embolism may be immediately fatal, or it may give rise to infarction of part of the lung, which may be accompanied by acute pleuritic pain and spitting of blood from the lungs. In most instances full recovery of lung function occurs after such an event. Similarly, fat emboli to the lung may occur after fractures to major bones; these may cause a deficiency of arterial blood oxygenation for a few days but usually full recovery occurs. In some uersons, either a process of progressive thrombosis or unresolved embolization leads to a chronic state of severe increased blood vressure in the pulmonary circuit. This may be so severe as to eventually cause heart failure. A variant of this condition occurs in schistosomiasis, a tropical disease common in Egypt and parts of West Africa in which the pulmonary arterial tree becomes blocked by ova of the parasite.

In some patients with chronic lung disease, both of the fibrotic and the destructive type, there may be a considerable rise of pressure in the pulmonary artery. The pulmonary vessels are reactive to deficiency of oxygen, and it seems likely that it is the abnormal gas concentrations in the alveoli that play the major part in determining this response. The presence of pulmonary hypertension in normal subjects occurs at altitude when there is alveolar hypoxia, and the development of cor pulmonale — heart failure consequent upon lung disease—appears to be an extension of this naturally occurring phenomenon in many cases.

Lung cancer. Cancer of the lung 40 years ago was a relatively rare condition. The increase in its incidence noted after World War II was at first ascribed to better diagnostic technique, but by 1952 it had become clear that the rate of increase of the condition was too great to be accounted for in this way. At that time the first evidence was obtained that indicated that a heavy cigarette smoker was more likely to develop lung cancer than a nonsmoker. In recent years there has been a tremendous volume of epidemiological work covering many different populations in many different countries that has clearly shown that a heavy cigarette smoker is more likely to develop lung cancer than a nonsmoker, and that the risk of developing this disease depends on the duration and intensity of cigarette smoking. By contrast, cigar smoking and pipe smoking seem to carry very little additional risk of lung cancer.

Cigarette smoking and cancer

By 1965, cancer of the lung and bronchus accounted for 43 percent of all cancers in United States men, an incidence nearly three times greater than that of the second commonest cancer (cancer of the prostate) in men, which accounted for 16.7 percent of total incidence.

The ***Report of the Advisory Committee to the Surgeon General of the Public*** *Health* ***Service*** (1964), stated:

> (1) Cigarette smoking is causally related to lung cancer in men; the magnitude of the effect of cigarette smoking far outweighs all other factors. The data for women, though less extensive, point in the same direction. (2) The risk of developing lung cancer increases with duration of smoking and the number of cigarettes smoked per day, and is diminished by discontinuing smoking. (3) The risk of developing cancer of the lung for the combined group of pipe smokers, cigar smokers, and pipe and cigar smokers is greater than for nonsmokers, but much less than for cigarette smokers.

The data in the third section are insufficient to warrant a conclusion for each group individually.

The reason for the carcinogenicity of tobacco smoke from cigarettes is not known. Tobacco and tobacco smoke contain a large number of carcinogenic materials and, although it is presumed that the "tars" in cigarette smoke probably contain a substantial fraction of the cancer-causing condensate, it is far from being established which of these is responsible. Although the tobacco industry has concentrated its efforts on removing the tar content as much as possible from cigarette smoke, it is too early to know whether or not this has had any effect on the carcinogenicity of cigarettes. There is a presumption that cigarette smoking may be additive to other factors, but the possible role of air pollution or of exposure to industrial irritants remains in general unclear. In spite of some advances in diagnostic technique and general advances in pulmonary surgery, the outlook for a person found to have this condition is still severely limited. It is a characteristic of lung cancer that, by virtue of its site, it may disseminate generally in the body at a time when the primary tumour is still too small to cause local symptoms. Thus the first manifestation of a lung cancer may be the development of a secondary tumour in the brain, in the bones, or in the liver. Usually the lymph nodes draining the affected area of lung are involved relatively early, and the diagnosis may first be suggested by the presence of enlarged nodes in the neck or mediastinum, the partition of membrane that divides the chest into right and left compartments. Lung cancer not infrequently occurs in patients with chronic bronchitis who already have a productive cough. If any cigarette smoker suddenly develops a cough and this does not clear up within a few days, an investigation should be made; in some patients it is the first appearance of hemoptysis added to chronic production of sputum that indicates the presence of lung cancer. The condition may also begin by causing a pneumonia that proves difficult to treat, or, if the tumour is situated peripherally in the lung, the first evidence of it may be a pleural effusion. The diagnosis essentially depends on securing tissue for pathological examination. Routine chest X-rays in the cigarette-smoking population have been advised for early detection of lung cancer, and increasing use has been made of a careful study of the sputum for the presence of malignant cells. Examination of the bronchial tree by bronchoscopy may make the diagnosis possible, but in some instances a lesion visible on the chest X-ray must be removed from the lung directly before the diagnosis can be established.

It is largely because of the demonstrated increase in lung cancer that many countries have begun to limit cigarette advertising and have insisted that cigarette packages be labelled with a warning to the smoker. In spite of advances in radiation therapy and a much lower generalized risk from operations on the lung, the mortality from the condition remains high even if it is diagnosed early. Long-term cure is unfortunately the exception rather than the rule, and, if all cases of lung cancer are considered, the five-year survival rate from the first time the disease is diagnosed is, in most reported series, less than 20 percent of the total. Although in the vast majority of cases of lung cancer the tumours consist of scalelike cells such as those in squamous epithelium, there are other types of lung cancer probably not related to the cigarette in their etiology. Alveolar cell cancer is a slowly spreading condition that seems to affect men and women in equal proportion and does not seem to be related to cigarette smoking. Pulmonary adenocarcinoma (a type of cancer with gland-like structures) of the lung also has a more equal sex incidence, and its relationship to cigarette smoking is much less well established than in the case of the squamous-cell type of cancer.

DISEASES OF THE NONPULMONARY STRUCTURES

Diseases of the pleura. The lungs move in an airtight space, the thorax lined on its inner side with a layer of smooth fibrous tissue. The external surface of the lung itself is covered by another layer of pleura and the space between these two membranes is occupied by only a small volume of fluid for lubrication purposes under normal circumstances. Rupture of the pleura covering the lung means that this space communicates with the airway and the lung, by virtue of its intrinsic recoil, consequently collapses. In some individuals the lung, particularly at its apex, contains some small bullae, or blisters, and it is not uncommon for one of these to rupture causing a spontaneous pneumothorax, a disease particularly of people in their second and third decade of life. Most commonly, this condition resolves spontaneously, but it may cause acute onset of chest pain and some shortness of breath and necessitate several weeks of rest while the lung re-expands. It usually does not indicate the presence of any underlying lung disease, but if recurrences occur, it may be necessary to seal the pleura or to remove the few blebs, or small liquid-filled blisters, at the top of the lung, which are responsible for the trouble. The primary diseases of the pleura are almost all inflammatory in nature. A pleurisy with an effusion may be the presenting symptom of pulmonary tuberculosis and pleurisy may accompany any kind of pneumonia. Acute inflammation of the-pleura normally produces pain when the patient attempts to take a deep breath, but once the effusion has developed, the pain disappears. Pleural effusions may also accompany pulmonary embolization and pulmonary infarction. The pleura may be attacked by primary or secondary malignant disease, and rarely it may be invaded by direct extension of processes from the abdominal cavity. When a pleural effusion in pneumonia becomes secondarily infected, a condition of empyema results with pus in the pleural cavity. This complication, dreaded before the antibiotic era, gave rise to drainage of affected material from a sinus in the chest for months or even years after the acute event. Such episodes are now rarely seen as a result of acute infections, but draining sinuses still may occur as a consequence of tuberculosis or of fungus disease. Infection of the lung and later the pleural cavity by the fungus ***Actinornyces*** was particularly prone to produce a draining empyema and sinus.

Diseases of the mediastinum and diaphragm. Important structures in the thorax run through the mediastinum, and disease in them may produce changes within the mediastinum. Perforation of the esophagus by a foreign body such as a fish bone may give rise to a mediastinitis, and this may be a life-threatening condition. Cancer of the esophagus not uncommonly spreads to involve the mediastinum, and enlargement of lymph glands in the mediastinum commonly occurs in a wide variety of conditions involving the lung. A mediastinitis may also be caused by radiation therapy aimed at the chain of lymph glands in the mediastinum and this may lead to some residual fibrosis with involvement of structures within.

Diseases affecting diaphragm

There may be congenital abnormalities of the diaphragm, but the commonest disease that involves it is paralysis caused by interruption of the motor nerve of the diaphragm, the phrenic nerve, at some point in the neck or in the mediastinum. Accidental injury to this nerve during operations on the neck, or involvement of the nerve in disease in the mediastinum, may cause paralysis of one side of the diaphragm. This does not cause severe effects and may be demonstrated only by X-ray. A bilateral paralysis of the diaphragm causes some impairment of pulmonary function but is a relatively rare condition. Herniation of the diaphragm is an important development defect that may require reparative surgery. In extreme cases the stomach may be mostly within the thorax, and there are many variations of abnormality that may occur, but they all lead to considerable impairment of function of the affected side.

Restaurant

The public dining room that came ultimately to be known as the restaurant originated in France, and the French have continued to make major contributions to the restaurant's development. The first restaurant proprietor is believed to have been one A. Boulanger, a soup vendor, who opened his business in Paris in 1765. The sign above his door advertised restoratives, or *restaurants*, referring to the soups and broths available within. The institution took its name from that sign, and "restaurant" now denotes a public eating place in the English, French, Dutch, Danish, Norwegian, Romanian, and many other languages with some variations. For example, in Spanish and Portuguese the word becomes *restaurante*; in Italian it is *ristorante;* in Swedish, *restaurang*; and Russian, *restoran*; in Polish, *restauracia.*

Although inns and hostelries often served paying guests meals from the host's table, or table d'hôte, and beverages were sold in cafés, Boulanger's restaurant was probably the first public place where any diner might order a meal from a menu offering a choice of dishes.

The first luxury restaurant

Development of the restaurant. Boulanger operated a modest establishment; it was not until 1782 that La Grande Taverne de Londres, the first luxury restaurant, was founded in Paris. The owner Antoine Beauvilliers, a leading culinary writer and gastronomic authority, later wrote *L'Art du cuisirzier* (1814) a cookbook that became a standard work on French culinary art. Beauvilliers achieved a reputation as an accomplished restaurateur and host, and the French aphorist and gastronomic chronicler, Jean-Athelme Brillat-Savarin, a frequent guest, credited Beauvilliers with being

> the first to combine the four essentials of an elegant loom, smart waiters, a choice cellar, and superior cooking.

Brillat-Savarin also noted that Beauvilliers would

> point out here a dish to be avoided, there one to be ordered instantly . . . ; and send, at the same time, for wine from the cellar, the key of which he produced from his own pocket; in a word, he assumed so gracious and engaging a tone, that all these *extra* articles seemed so many favours conferred by him.

Before the French Revolution, aristocratic French households maintained elaborate culinary establishments, but when the revolution reduced the number of private households offering employment, many chefs and cooks found employment in restaurant kitchens or opened their own eating establishments. By 1804 Paris had over 500 restaurants, producing most of the great chefs of history and creating many famous dishes.

French restaurants of the 19th century. During the Napoleonic era the Palais-Royal, the colonnaded, tree-lined area adjacent to the Louvre, became the location of many of the finest restaurants in Paris. The Véry, a leading restaurant of the era, was lavishly decorated and frequented by beautiful women escorted by dashing officers. The menu listed a dozen soups, two dozen fish dishes, 15 beef entrees, 20 mutton entrees, and scores of side dishes. The novelist Honor6 de Balzac often dined at the Véry, consuming prodigious quantities of oysters, fish, meat dishes, fruits, wines, and liqueurs. It was a favourite haunt of gourmet-author, Grimod de la Reynière, who considered it the finest restaurant in France.

The Véry was absorbed in 1869 by the neighbouring Le Grand Véfour. This restaurant was still in business in the early 1970s and is regarded as one of the finest eating places in France. Another outstanding Paris establishment of the 19th century was the Café Foy, later called Chez Bignon, a favourite dining place of the English novelist William Makepeace Thackeray and of the Italian composer Gioacchino Rossini, who lived in the same building. The Café de Paris, on the Boulevard des Italiens, was the first of many restaurants in Paris and elsewhere that have operated under this name. Other favourite eating places were the Rocher de Concale, on the rue Montorgueil, famous for its oysters and fish, and the Restaurant Durand, at the comer of the Place de la Madeleine and the rue Royale, a favourite gathering place of politicians, artists, and writers, including the authors Anatole France and Émile Zola.

The most illustrious of all 19th-century Paris restaurants was the Café Anglais, on the Boulevard des Italiens at the comer of the rue Marivaux, where the chef, Adolphe Dugléré, created classic dishes such as *sole Dugléré* (filets poached with tomatoes and served with a cream sauce having a fish stock base) and the famous soup *potage Germiny.* On June 7, 1867, the Café Anglais served the now-famous "Three Emperors Dinner" for three royal guests visiting Paris to attend the Universal Exposition. The diners included Tsar Alexander II of Russia; his son the tsarevich (later the tsar Alexander III); and King William I of Prussia, later the first emperor of Germany. The meal included soufflés with creamed chicken (d *la reine*), fillets of sole, escalloped turbot, chicken *à la portugaise* (cooked with tomatoes, onions, and garlic), lobster *à la parisienne* (round, flat medallions glazed with a gelatin-mayonnaise mixture and elaborately decorated), ducklings *à la rouerznaise* (the carcasses stuffed with liver and pressed, presented on a platter with boned slices of the breast and the grilled legs, and served with a red wine sauce containing pureed liver), ortolans (small game birds) on toast, and eight different wines.

Although the Café Anglais closed in 1913, when the building was demolished, the table setting for this dinner is now displayed at La Tour d'Argent, the oldest surviving restaurant in Paris.

Toward the end of the 19th century, in the gaudy and extravagant era known as *la belle époque,* the luxurious Maxim's, on the rue Royale, became the social and culinary centre of Paris. The restaurant temporarily declined after World War I but recovered under new management, to become an outstanding gastronomic shrine.

Kitchen teams

France produced many of the world's finest chefs, including Georges-Auguste Escoffier, who organized the kitchens for the luxury hotels owned by César Ritz, developing the so-called *brigade de cuisine,* or kitchen team, consisting of highly trained experts each with clearly defined duties. These teams included a chef, or *gros bonnet,* in charge of the kitchen; a sauce chef, or deputy; an *entremettier,* in charge of preparation of soups, vegetables, and sweet courses; a *rôtisseur* to prepare roasts and fried or grilled meats; and the *garde manger,* in charge of all supplies and cold dishes. In Escoffier's time, the duties and responsibilities of each functionary were sharply defined, but in modern times the rising labour costs and the need for faster service have broken down such rigidly defined duties. In the kitchens of even the leading modern restaurants, duties at the peak of the dinner-hour preparations are likely to overlap widely, with efiiciency maintained amid seeming chaos and confusion.

French restaurants in the 20th century. In the 20th century, with the development of the automobile, country dining became popular in France, and a number of fine provincial restaurants were established. The Restaurant de la Pyramide, in Vienne, regarded by many as the world's finest restaurant, was founded by Fernand Point and after his death, in 1955, retained its high standing under the direction of his widow, Madame "Mado" Point. Other leading French provincial restaurants have included the Troisgros in Roanne; the Paul Bocuse Restaurant near Lyons; the Auberge de I'll in Illhaeusern, Alsace; and the hotel Cote d'Or, at Saulieu.

Restaurants throughout France are evaluated annually by the *Guide Michelin,* a publication devoted to surveying eating establishments and hotels in more than 3,400 towns and cities, and awarding one, two, or three stars, based upon quality. One star denotes, "a good restaurant in its class"; two stars mean "excellent cuisine, worth a detour"; three stars, the top rating, signify "one of the best tables in France, well worth the journey."

French restaurants today are usually in one of three categories: the bistro, or brasserie, a simple, informal, and inexpensive establishment; the medium-priced restaurant; and the more elegant grand restaurant, where the most intricate dishes are executed and served in luxurious surroundings.

Restaurants of other countries. Other nations have also made many significant contributions to the development of the restaurant.

European restaurants. In Italy the *botteghe* (coffee shop) of Venice originated in the 16th century, at first serving coffee only, later adding snacks. The modern *trattorie,* or taverns, feature local specialities. The *osterie,* or hostelries, aie informal restaurants offering homelike cooking. In Florence small restaurants below street level, known as the *buca,* serve whatever foods the host may choose to cook on a particular day.

Austrian coffeehouses offer leisurely, complete meals, and the diner may linger to sip coffee, read a newspaper, or even to write an article. Many Austrians frequent their own "steady restaurants," known as *Stammbeissl.*

In Hungary the *csárda,* a country highway restaurant, offers menus usually limited to meat courses and fish stews.

The beer halls of Czechoslovakia, especially in Prague, are similar to coffeehouses elsewhere. Food is served, with beer replacing coffee.

The German *Weinstube* is an informal restaurant featuring a large wine selection, and the *Weinhaus,* a food and wine shop where customers may also dine, offers a selection of foods ranging from delicatessen fare to full restaurant menus. The *Schenke* is an estate-tavern or cottage pub serving wine and food. In the cities a similar establishment is called the *Stadtschenke.*

In Spain the bars and cafes of Madrid offer widely varied appetizers, called tapas, including such items as shrimp cooked in olive oil with garlic, meatballs with gravy and peas, salt cod, eels, squid, mushrooms, and tuna fish. The tapas are taken with sherry, and it is a popular custom to go on a *chateo,* or tour of bars, consuming large quantities of tapas and sherry at each bar. Spain also features the *marisco* bar, or *marisqueria,* a seafood bar; the *asadoro,* a Catalan rotisserie; and the *tasca,* or pub-wineshop.

In Portugal, *cervejarias* are popular beer parlors also offering shellfish. Fado taverns serve grilled sausages and wine, accompanied by the plaintive Portuguese songs called *fados* (meaning "fate").

The smörgåsbord

In Scandinavia sandwich shops offer open-faced, artfully garnished sandwiches called *smørrebrød.* Swedish restaurants feature the *smorgdsbord,* which literally means "bread and butter table," but actually is a lavish, beautifully arranged feast of herring, shrimp, pickles, meatballs, fish, salads, cold cuts, and hot dishes. The food is taken with aquavit or beer.

The Netherlands has sandwich shops, called *broodjeswinkels,* serving open-faced sandwiches, seafoods, hot and cold dishes, and cheeses from a huge table.

English city and country pubs have three kinds of bars: the public bar, the saloon, and the private bar. Everyone is welcome in the public bar or saloon, but the private bar is restricted to habitues of the pub. The food served in pubs varies widely through England, ranging from sandwiches and soups, to pork pies, veal and ham pies, and steak and kidney pies, bangers (sausages) and a pint (beer), bangers and mash (potatoes), toad in the hole (sausage in a Yorkshire pudding crust), and Cornish pasties, or pies filled with meat and vegetables.

Middle Eastern restaurants. In the *tavérnas* of Greece, customers are served such beverages as retsina, a resinated wine, and ouzo, an anise-flavoured aperitif, while they listen to the music of the *bouzouki.* Like other Mediterranean countries, Greece has the grocery-tavtrna where one can buy food or eat.

The Turkish *işkembeci* is a restaurant featuring tripe soup and other tripe dishes; *muhallebici* shops serve boiled chicken and rice in a soup and milk pudding.

Asian restaurants. In Japan, *tempura* bars offer fried shrimp at a counter. Other food bars serve *sushi,* raw fish fillets or other ingredients rolled in vinegared rice, and *sashimi,* raw fish slices. *Yu-dōfa* restaurants build their meals around a variety of bean curds, and the elegant tea houses serve formal Kaiseki table d'hôte meals that amount to a Japanese haute cuisine.

In China, restaurants serving the local cuisine are found, and noodle shops offer a wide variety of noodles and soups. The *dim-sum* shops provide a never-ending supply of assorted steamed, stuffed dumplings and other steamed delicacies.

A common sight in most parts of Asia is a kind of portable restaurant, operated by a single person or family from a wagon or litter set up at a particular street location, where specialties are cooked on the spot. Depending upon the country, the food and cooking utensils vary widely.

The cafeteria

U.S. sontributions to restaurant development. The cafeteria, a U.S. contribution to the restaurant's development, originated in San Francisco during the gold rush. Featuring self-service, it offers a wide variety of foods displayed on counters. The customer makes his selections, paying for each item as he chooses it or paying for the entire meal at the end of the line. Other types of quick-eating places originating in the U.S. are the drugstore counter, serving sandwiches or other snacks, and the lunch counter, where the diner is served a limited quick-order menu at the counter. Coin-operated vending machines also offer snacks and beverages.

The specialty restaurant, serving one or two special kinds of food, such as seafood or steak, is another distinctive U.S. establishment.

The Pullman car diner, serving full-course meals to long distance railroad passengers, and the riverboat steamers, renowned as floating gourmet palaces, were original American conceptions. They belong to an earlier age, when dining out was a principal social diversion, and restaurants tended to become increasingly lavish in food preparation, decor, and service.

In many modern restaurants customers now prefer informal but pleasant atmosphere and fast service. The number of dishes available, and the elaborateness of their preparation, has been increasingly curtailed as labour costs have risen and the availability of skilled labour decreased. The trend is toward such fast and efficient food operations as snack bars, cafeterias, coffee shops, and drive-ins. The trend in elegant and expensive restaurants is toward smaller rooms and intimate atmosphere, with authentic, highly specialized and limited menus.

Reticuloendothelial System, Human

The term reticuloendothelial system (RES) denotes certain tissue cells that occur in widely separated parts of the body and have the specific ability to take up particulate substances. Should these substances be noxious, as are some bacteria, they can be destroyed by the cells of the reticuloendothelial system by enzymatic action. RES cells are thus an important part of the defense system of the body. When the substances are chemically inert, as are carbon particles, they are stored in the cell body and are in this way removed from the circulation or other extracellular spaces.

Names of the cells

Reticuloendothelial cells have a variety of names. Histiocytes are stationary cells located in loose connective tissue; together with leukocytes, or white blood cells, they are an important factor in cellular defense. The cells in the liver that belong to the reticuloendothelial system are called von Kupffer cells or stellate cells of von Kupffer. Those in nervous tissue are called microglial cells, or microglia, while those in the air spaces of the lung are called alveolar macrophages, or dust cells (a name derived from their ability to ingest inhaled dust particles). As part of the framework, or reticulum, of lymph nodes, bone marrow, and spleen, they may be called reticulum cells.

The cellular process by which RES cells take in substances has been termed phagocytosis (eating by cells) or pinocytosis (drinking by cells). Since a sharp distinction cannot always be made, and since fundamentally the same cellular activity may be involved, the term endocytosis is often used to encompass both processes. The designation endocytosis, however, when interpreted in its broadest sense, encompasses cellular internalizations not strictly belonging to the functions of the reticuloendothelial system.

Elie Metchnikoff, a Russian zoologist, first called attention to the importance of phagocytic activity. He called the white blood cells microphages ("small -eaters^w) because of their relatively small size, and he called larger cells that are also phagocytic macrophages ("large eaters").

The pathologists K.A.L. Aschoff and K. Kiyono found that when colloidal dyes are injected into the bloodstream they are taken up by certain types of cells. The cells that take up the greatest amount of dye are the von Kupffer cells; the special endothelial lining cells of the sinuses (channels) of the lymph nodes, spleen, bone marrow, and liver; the cells forming a reticulum in the stroma, or pulp, of these organs; and widely scattered wandering cells (also called histiocytes, though they are not stationary) in the connective tissues. The similarity of phagocytic activity of these cells suggested that they be grouped together as a system, named the reticuloendothelial system by Aschoff and Kiyono. This term, while still the most popular, is somewhat misleading because it appears to include the nonphagocytic endothelia of somatic vessels, as well as the phagocytic endothelium of the liver, bone marrow, spleen, and lymph nodes. From time to time suggestions have been made to return to the earlier term "macrophage system," while the name "mononuclear phagocyte system" has also been proposed. The latter term is, in part, based on the fact that macrophages have common precursor cells that are located in the bone marrow and that are deposited through intravascular transport at various places in the body and then transformed into macrophages.

While typical macrophages and the endothelial cells lining the sinuses of the liver, bone marrow, spleen, and lymph nodes can take up particulate substances, they do so in different ways. Macrophages engulf by extending processes from their cell bodies around the particulates and are capable of ingesting relatively large particles, such as red blood cells, or large aggregates of small particles. The sinus endothelial cells of the liver and bone marrow ingest particles by small indentations ("coated pits") at their surfaces that then pinch off and are found in the cytoplasm as small vesicles. These latter cells are not able to interiorize larger objects or large aggregates of particles.

While the modes of endocytosis of these two cell types are different, the eventual intracellular disposition of the ingested material is, in principle, the same in both cases. The endocytosed material is sequestered in the phagocytic cell in membrane-enclosed vesicles, termed phagosomes. These phagosomes fuse with other vesicles, called lysosomes, that contain hydrolytic enzymes that break down digestible material.

Control of the RES cells

Immune phagocytosis by macrophages may be mediated by the association of extracellular material with two types of receptors on the plasma membrane. The first, the F$_c$ receptor, binds the F$_c$ portion of IgG antibodies (immunoglobulin), with which bacteria may be coated, and thereby causes these antibodies and the bacteria to be adhesive to the phagocytic cell. The second receptor binds a complement cleavage product (C3b), which is bound by antigen-antibody complexes attached to bacteria. In addition to phagocytosis by these immunologically modified materials, macrophages are capable of ingesting materials independently of such factors in a manner that is not yet known.

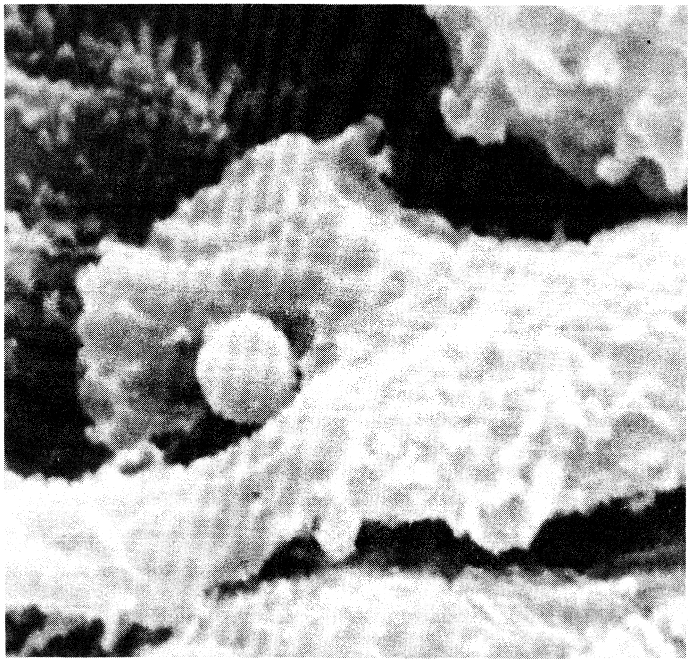
In the present article primary attention is paid to the functions of the reticuloendothelial cells and to the places where they are found in greatest numbers. The microglia are not discussed; they receive attention in the article NERVOUS SYSTEM, HUMAN.

ORGANS AND TISSUES OF THE SYSTEM

General morphology. In the spleen and bone marrow are thin-walled venous blood channels called sinuses or sinusoids; in the lymph nodes, lymphatic sinuses are interposed between the incoming and outgoing lymph streams. The cells forming the walls of both types of sinuses are elongated and resemble endothelial cells. The tissue around the sinuses is composed of spindle-shaped or branching cells that form a network, or reticulum, of reticulum cells and supporting reticulum fibres. The reticulum cells are actively phagocytic. The spaces of the reticulum contain many free, rounded cells, including large mononuclear (single-nucleus) reticulum cells that have become free and mobile and that have retained their phagocytic capacity. These are the macrophages described by Metchnikoff. The endothelial cells lining the sinuses are also phagocytic, a property not shared by the endothelial cells lining blood and lymph vessels elsewhere.

The walls of the sinuses of the liver have endothelial cells similar in function to those of the bone marrow and splenic sinuses. In addition, special macrophages that have a stellate shape occupy the sinus passages to a variable extent. These are the so-called von Kupffer cells.

There are also macrophages in the connective tissue, particularly in the loose connective tissue, throughout the body. They are called histiocytes or, less frequently, clasmatocytes or histoid wandering cells.



A macrophage engulfing a foreign particle.

Spleen. The spleen is an important phagocytic organ; its phagocytic capacity per unit weight exceeds that of other organs or tissues of the reticuloendothelial system. The small arteries entering the substance of the spleen are for some distance surrounded by masses of lymphocytes—called splenic lymph follicles or Malpighian corpuscles—that form the so-called white pulp of the spleen. Interspersed between these lymphocytes are reticulum cells that are phagocytic. Within the tissue surrounding the white pulp—called red pulp because it contains a large amount of blood—are thin-walled venous sinuses that contain the cellular elements of peripheral blood and free macrophages. Around the sinuses is a network of reticulum cells and reticulum fibres; in the meshes of this network are blood cells and free macrophages. The lining of the sinuses differs from the endothelium of ordinary blood vessels elsewhere in that it is phagocytic.

Endocytosis in the spleen

Particulate material present in the circulation enters the splenic tissue proper through small capillaries. The material is endocytosed by the reticulum cells in white and red pulp, by the free macrophages outside and inside the venous sinuses, and by the endothelial lining cells of the venous sinuses. In this way the spleen functions as a reticuloendothelial organ inserted into the bloodstream. Sometimes red corpuscles that are old, damaged, or abnormal are segregated in the pulp spaces. The circulation in the pulp is slow, and the contained cells are subjected to influences that cause their destruction. Macrophages ingest the liberated hemoglobin and metabolize it, forming hemosiderin, the presence of increased amounts of which may cause bronzing of the skin, a condition known as hemosiderosis.

(P.P.H. De B.)

There are many conditions in which destruction of blood results in anemia. In some of these the spleen is involved only to the extent that its reticulum cells participate in the removal of cell debris and in the metabolism of iron pigments, An example is malaria, in which the malarial parasite destroys erythrocytes (red cells), resulting in the deposition of blood-derived pigments in thc reticuloendothelial cells,

In other cases the role of the spleen is not as obvious. In congenital spherocytic anemia, also called congenital hemolytic jaundice, for example, some of the red cells are spherical instead of being biconcave disks, as is normal. It has been postulated that their spherical shape prevents them from passing through the narrow openings in the walls of the splenic sinuses and thus entering the venous circulation. These spherical cells are more fragile than normal ones and, as they remain in the pulp spaces in contact with reticulum cells, undergo hemolysis (liberation of hemoglobin) and are thus eliminated. The importance of the spleen in this condition is evident from the effect of its surgical removal (spienectomy), which usually ends the excess blood destruction of the disease, presumably because of the removal of a large source of reticuloendothelial cells. It is notable that if accessory spleens are present, they may enlarge after removal of the primary spleen and resume the excessive destruction of blood cells.

In hemolytic anemias, caused by the presence of antibodies on the red cells, the presence of the antibody so alters the cells that they are treated as objects foreign to the body and are segregated and disposed of in the splenic pulp. In this condition, splenectomy is often of little value.

There are other conditions in which the number of circulating blood elements is low and in which splenectomy may be beneficial. Idiopathic thrombocytopenic purpura is a condition associated with coagulation defects and tendencies toward bleeding in which there is an inadequate number of blood platelets. The number of platelets usually promptly increases upon removal of the spleen, a result suggesting an action similar to that in hemolytic anemia, especially since immune bodies have been found in the blood serum.

(M.N.R.)

Lymph nodes. The substance of the lymph nodes is composed of a network of phagocytic reticulum cells and supporting reticulum fibres. In the meshes of this network are lymphocytes and free macrophages. This reticulum is traversed by lymphatic sinuses that receive lymph from incoming lymphatic vessels and are drained by outgoing lymphatics. The lining of the lymphatic sinuses is continuous and consists of phagocytic endothelial cells. The lumen (interior passage) of a lymphatic sinus is spanned by trabeculae (bundles of fibres) comprised of reticular fibres and adhering reticulum cells to which macrophages are attached. Free macrophages may occur in the lumina of the lymphatic sinuses. The endothelial lymphatic sinus lining cells, reticulum cells of the trabeculae, free intraluminal macrophages, and macrophages adhering to the trabeculae are all phagocytic and form—together with the reticulum cells and free macrophages outside the sinuses—the reticuloendothelial components of the lymph nodes. The lymph nodes thus function as phagocytic organs inserted in the lymph stream. Bacteria, cell fragments, and pigments that originate within and outside of the body (*e.g.*, hemosiderin, melanin, coal dust) all may be found in these reticuloendothelial elements. (See also LYMPHATIC SYSTEM, HUMAN; LYMPHATIC SYSTEM DISEASES.)

Bone Marrow. In addition to having an important blood-forming function, the bone marrow plays a significant role in the function of the reticuloendothelial system.

Structure of the bone marrow

Bone marrow consists of a network of phagocytic reticulum cells and some supporting reticulum fibres. In the meshes of this reticulum are immature and mature red and white blood cells, blood-platelet-forming cells (megakaryocytes), fat cells, and free macrophages. The major blood vascular components in bone marrow are the venous sinuses, into which the mature blood cells are deposited and from which they reach the peripheral blood circulation. The walls of these sinuses are composed of a continuous lining of endothelial cells that remove particulate material from the bloodstream by capturing it in pitlike indentations (bristle-coated pits) in the endothelial cell surface. The pits pinch off from the cell surface and the phagocytosed material is thereby sequestered in small intracellular vesicles. These endothelial cells, as well as the extravascular reticulum cells and macrophages, are the essential components of the reticuloendothelial system in the bone marrow. Since phagocytosis by the endothelia! lining cells is through small pits and small vesicles, the particulate uptake of these cells is restricted to small particles and small aggregates of such particles. The macrophages that engulf by pseudopodial extensions are capable of the uptake of large particles or larger aggregates of small particles. (For the blood-forming functions of the bone marrow, see BLOOD, HUMAN.)

Liver. The liver, while per unit weight less phagocytic than the spleen, is the most phagocytic organ of the human body because of its size. Its phagocytic activity is intercalated in the bloodstream. The substance of the liver is traversed by venous sinuses that—unlike the sinuses of the spleen, lymph nodes, and bone marrow—have no network of reticulum cells or fibres and no free macrophages around them. The sinus endothelium is separated from the liver cells proper by a narrow space, called the space of Disse. These endothelial lining cells have small open apertures that directly link the lumina of the venous sinuses with the space of Disse.

In addition to the endothelial lining cells, there are in the walls of the sinuses typically large macrophages, the cells of von Kupffer. Their cell bodies may protrude into the sinus lumina and carry pseudopodial extensions that may reach the opposite sinus wall. The endothelial cells and the von Kupffer cells are the essential components of the reticuloendothelial system of the liver. The endothelial cells phagocytose by means of small bristle-coated pits at the cell surfaces, while the von Kupffer cells can engulf large particles through their pseudopodial extensions.

(P.P.H. De B.)

As in other parts of the reticuloendothelial system, several kinds of pigment may be found in the von Kupffer cells, the most common of which is hemosiderin. Although only small amounts are found normally, increased blood destruction results in extensive hemosiderosis. Hemosiderin may be found in both liver and von Kupffer cells, but this apparently common site probably represents the passage of hemosiderin to the liver cells by von Kupffer cells in which it is formed.

The malarial parasite forms a pigment, hematin, from hemoglobin that resembles hemosiderin in appearance but does not give chemical reactions for iron as hemosiderin does. Hematin may be found in von Kupffer cells. Occasionally malarial parasites are also present, but only in small numbers. (See also LIVER, HUMAN.)

(M.N.R.)

FUNCTIONS OF THE SYSTEM

Metabolism of iron

The reticuloendothelial system in metabolism. The metabolism of iron starts with its absorption in the intestinal tract and continues through its utilization in the formation of hemoglobin and its final degradation. The part played by the reticuloendothelial system in this sequence has been mentioned briefly in connection with the presence of hemosiderin in phagocytes. This process is the visible and therefore the most obvious functional activity in this connection. The role of reticulum cells in hemoglobin synthesis is not readily observed. It has been shown that in the sites of early red-cell formation, nucleated precursors of red cells, or normoblasts, may be seen in small groups with a reticulum cell in the centre. It is here that reticulum cells function directly in hemoglobin synthesis by transferring iron-containing material in the form of ferritin, an amber-coloured protein, directly to the surrounding normoblasts.

When hemosiderin is formed after disintegration of red cells, the reticuloendothelial system has the additional function of storage. The hemosiderin contained in the reticulum cells is available for further use in the formation of more hemoglobin. There is, thus, an important difference between the loss of hemoglobin and its contained iron from the body by bleeding and the loss of hemoglobin, with retention of iron, in hemolytic disorders. The implications for therapy in the latter case are obvious, for storage makes the administration of additional iron unnecessary.

The reticuloendothelial system also plays a role in the formation of bile. It has been shown experimentally in animals that bile formation may occur in the absence of a liver. In human beings this function can be observed in the vicinity of hemorrhages. Non-iron-containing fragments of hemoglobin, as well as hemosiderin, may be found in local phagocytes. Hematoidin, which is one of these fragments, has been identified as bilirubin.

The metabolism of lipids (fats) is also an important function of the reticuloendothelial system as is evidenced by its prominent involvement in disturbances of lipid metabolism. The foam cells characteristic of Niemann-Pick disease, for example, are reticuloendothelial cells, as are the Gaucher's cells of Gaucher's disease.

The reticuloendothelial system in defense. The reticuloendothelial system plays an important part in the body's defense against disease in two ways: first, by the phagocytic activity of its cells; second, by the apparent necessity of the presence of macrophages for the effective interactions and activities of immunologically competent cells, such as stimulated lymphocytes.

Phagocytosis of microorganisms has already been described. The process may also be directed to insoluble foreign bodies; examples of the activity are the reactions to splinter fragments or to surgical sutures. If a fragment is small enough, it may be ingested by a single cell. If the object is too large, several macrophages collect around it, and their cell bodies coalesce to form a single giant cell. These large cells may contain from a few to two or three dozen nuclei, indicating the number of macrophages involved in their formation. The foreign substance may often be identified in the cytoplasm (the cell substance outside the nuclei).

In chronic reactions (*e.g.*, granulomas) and in the healing stages of acute inflammation, the cellular response is predominantly by mononuclear cells from the connective tissue mingled with cells from the blood. The result is the production of a tissue referred to as granulation tissue. The process is described in the article INFLAMMATION. Here only the part played by the reticuloendothelial system is considered.

(M.N.R./P.P.H. De B.)

As a response to a local noxious stimulus, such as the entry of bacteria into the connective tissue, white blood cells leave the circulation through capillaries and small veins and arrive at the site where the stimulus occurs. The granulocytes immediately phagocytose bacteria or other particulate material, and they can destroy digestible foreign material by enzymes present in their granules (lysosome~).Nongranulocytic cells (monocytes) also leave the circulation and, once arrived in the extravascular connective tissue, transform into macrophages. In addition to these macrophages derived from the peripheral blood (hematogenous macrophages), the histiocytes present in the connective tissue become actively phagocytic and thus form a pool of histogenous macrophages.

(P.P.H. De B.)

The second method by which the reticuloendothelial system participates in body defense is through immune reactions. (The complex mechanism of this participation is discussed in detail in the article IMMUNITY.) In brief, one class of lymphocytes (B-cells, believed to be derived from bone marrow) can synthesize and secrete antibody molecules (immunoglobulin) with the help of another class of lymphocytes (T-cells, derived from the thymus.) The T-cells are also capable of other immunological reactions not involving antibody production. In these immunological responses of lymphocytes, the presence of macrophages appears to be a required factor, although their precise function is not entirely clear.

METHODS FOR STUDY OF RETICULOENDOTHELIAL FUNCTION

Tests of phagocytosis

The classical method of identifying the cells of the reticuloendothelial system is the injection of colloidal dyes or carbon particles. Quantitative measurements of functional activity can be obtained. The general principle is to utilize the phagocytic capacity of the cells by determining the rate at which substances are removed from the circulation after injection into a vein.

Besides the dyes and carbon particles, the substances used in animal experiments have included materials such as radioactive chromium phosphate and thorium dioxide (Thorotrast) and other materials. Quantitative studies of reticuloendothelial function have been based on the theory that functioning of the cells can be blocked by saturating them with such harmless substances as lipids, albumin, and gelatin. The assumption is that cells already filled cannot ingest additional material. This "blockade" of the reticuloendothelial system is only partially successful. Cells filled with one substance may still take up another; the presence of ingested material may influence the rate of phagocytosis, phagocytized substances may be disposed of, or new phagocytes may be mobilized.

Nevertheless, a number of factors are known to influence the rate of phagocytosis, such as the chemical nature of the material, the size and number of the injected particles, and the state of the cells themselves. The species and condition of the animal used in the experiment affect the results because there are differences in the amount of reticuloendothelial tissue available, especially in the spleen and liver.

The metabolic activity of the cells is less readily measured. Inert substances remain within the tissues indefinitely, but others undergo metabolic changes within the cells. Serum albumin labelled with radioactive iodine is an example. The iodine portion is released by the reticuloendothelial cells and eliminated, so that reduction of radioactivity in an organ is an indication of the rate of metabolism.

NEOPLASMS

Tumours of the reticuloendothelial system are common. They may be relatively localized or widespread, and are nearly always malignant.

Reticulum-cell sarcoma

Reticulum-cell sarcoma is a malignant tumour composed of reticulum cells. Theoretically it may arise wherever reticulum cells occur, but the most common primary site is in lymph nodes. When tumours of lymph nodes are grouped together as lymphomas, reticulum-cell sarcoma is referred to as malignant lymphoma of the reticulum cell (or histiocytic) type. The tumour may metastasize (spread) either by blood or by lymph and thus appear in other locations in the body.

The different appearances of reticulum cells are reflected in differences among the tumours derived from them. The sarcoma cells may be round and little larger than lymphocytes, thus suggesting lymphosarcoma; the formation of tumour giant cells may give the appearance of Hodgkin's disease, the cells of which are also of reticuloendothelial origin.

Although the tumours metastasize readily, their cells are not ordinarily found on blood examination. Occasionally, however, cases of leukemia occur in which the leukemic cells in the blood have been identified as circulating reticulum cells. As noted before, there has been a controversy over the origin of the neoplastic cells in monocytic leukemia.

It is notable that the cells of reticulum-cell sarcoma seldom contain ingested material. There is, however, a condition that can readily be confused with reticulum-cell sarcoma or with Hodgkin's disease, and in which phagocytosis of red cells is a conspicuous feature. The condition, called histiocytic medullary reticulosis, is one of a group of diffuse proliferations of cells described under the general terms reticuloendotheliosis or reticulosis.

BIBLIOGRAPHY. For a historical review by the author of the concept of the reticuloendothelial system see L. ASCHOFF, *Reticuloendothelial System: Lectures in Pathology* (1924). Experimental studies are reported in the *Journal of the Reticuloendothelial Society* (1963–). Additional information on this subject is given in W. BLOOM and D.W. FAWCETT, *A Textbook of Histology,* 9th ed. (1968); R.H. JAFFE, "The Reticuloendothelial System," in H. DOWNEY (ed.), *Handbook of Hematology,* vol. 2 (1965); M.N. RICHTER, "Blood and Bone Marrow" and "Lymph Nodes, Spleen and Reticuloendothelial System," in W.A.D. ANDERSON (ed.), *Pathology,* 5th ed. (1966). A variety of aspects of the reticuloendothelial system are presented in R. VAN FURTH (ed.), *Mononuclear Phagocytes* (1970). and *Mononuclear Phagocytes in Immunity, Infection, and Pathology* (1975). The most comprehensive treatment of the reticuloendothelial system is found in a series of books by H. FRIEDMAN, M. ESCOBAR, and S.M. REICHARD (eds.), *The Reticuloendothelial System* (1980–).

Revelation

Revelation is a religious term that designates the disclosure of divine or sacred reality or purpose to human beings. In the religious view, such disclosure may come through mystical insights, historical events, or spiritual experiences that transform the lives of individuals and groups.

NATURE AND SIGNIFICANCE

Every great religion acknowledges revelation in the wide sense that its followers are dependent on the privileged insights of its founder or of the original group or individuals with which the faith began. These profound insights into the ultimate meaning of life and the universe, which have been handed down in religious traditions, are arrived at, it is believed, not so much through logical inference as through sudden, unexpected illuminations that invade and transform the human spirit. Those religions that look upon God as a free and personal spirit distinct from the world accept revelation in the more specific sense of a divine self-disclosure, which is commonly depicted on the model of human intersubjective relationships. In the "prophetic" religions (Judaism, Christianity, Islām, and Zoroastrianism), revelation is conceived as a message communicated by God to an accredited spokesman, who is charged to herald the content of that message to an entire people. Revelations received on behalf of the whole community of the faithful are often called "public" (as opposed to "private" revelations, which are given for the guidance or edification of the recipient himself).

The media of revelation

The ways by which revelation occurs are variously conceived. Most religions refer to signs, such as auditory phenomena, subjective visions, dreams, and ecstasies. In so-called primitive religions, revelation is often associated with magical techniques of divination. In the prophetic religions, revelation is primarily understood as the "Word of God," enabling the prophet to speak with certainty about God's actions and intentions. In mystical religions (*e.g.*, Islamic Ṣūfism, Tantric Buddhism), revelation is viewed as an ineffable experience of the transcendent or the divine.

TYPES AND VARIATIONS

Primitive religions. In so-called primitive cultures, revelation is frequently identified with the experience of supernatural power (mana) in connection with particular physical objects, such as stones, amulets, bones of the dead, and unusual animals. The sacred or holy is likewise believed to be present in sacred trees, groves, shrines, and the like and in elemental realities such as earth, water, sky, and the heavenly bodies. Once specified as holy, such objects take on symbolic value and become capable of mediating numinous (spiritual) experiences to the adherents of a cult. Certain charismatic individuals, such as shamans, who are believed to be in communion with the sacred or holy, perform functions akin to those of the prophet and the mystic in more developed religions.

Religions of the East. Eastern religions are concerned with man's struggle to understand and cope with the predicament of his existence in the world and to achieve emancipation, enlightenment, and unity with the Absolute. Western religions, on the other hand, lay more stress on man's obedient response to the sovereign Word of God. The notion of revelation in the specific sense of a divine self-communication is more apparent in Western than in Eastern religions.

Hinduism. In Hinduism, the dominant religion of India, revelation is generally viewed as a process whereby the religious seeker, actuating his deeper spiritual powers, escapes from the world of change and illusion and comes into contact with ultimate reality. The sacred books are held to embody revelation insofar as they reflect the eternal and necessary order of things.

A major form of Hindu thought, Vedānta, includes two main tendencies: the monistic (advaitn) and the theistic (*bhakti*). The leading sage of Advaita Vedanta, Śaṅkara (early 9th century), while acknowledging in principle the possibility of coming to a knowledge of the Supreme Reality (Brahman) through inner experience and contemplation of the grades of being, held that in practice a vivid apprehension of the divine arises from meditation on the sacred books, especially the *Upaniṣads*. In Bhakti, systematized by the philosopher Rāmānuja (*c.* 1050–1137), the Absolute is regarded as personal and compassionate. Revelation, consequently, is viewed as the gracious self-manifestation of the divine to those who open themselves in loving contemplation. The devotional theism of Bhakti, very influential in modern India, resembles the pietism and mysticism of the Western religions.

Buddhism. Buddhism, the other great religion originating on Indian soil, conceives of revelation not as a personal intervention of the Absolute into the worldly realm of relativities but as an enlightenment gained through discipline and meditation. Gautama the Buddha (6th to 5th century BC), after a striking experience of human transitoriness and a period of ascetical contemplation, received an illumination that enabled him to become the supreme teacher for all his followers. Although Buddhists do not speak of supernatural revelation, they regard the Buddha as a uniquely eminent discoverer of liberating truth. Some venerate him, some worship him, and all Buddhists seek to imitate him as the most perfect embodiment of ideal manhood — an ideal that he in some way "reveals."

Role of the Buddha

Chinese religions. Chinese wisdom, more world-affirming than the ascetical religions of India, accords little or no place to revelation as this term is understood in the Western religions, though Chinese traditions do speak of the necessity of following a natural harmony in the universe. Taoism, perhaps the most characteristic Chinese form of practical mysticism, finds revelation only in the transparency of the immanent divine principle or way (Tao). Confucianism, while not incompatible with Taoism, is oriented less toward natural mysticism and more toward social ethics and decorum, though it too is concerned with accommodating life to a balance in the natural flow of existence. Confucius (551–479 BC), who refined the best moral teachings that had come down in the tradition, was neither a prophet appealing to divine revelation nor a philosopher seeking to give reasons for his doctrine.

Religions of the West. In the three great religions of the West — Judaism, Christianity, and Islām—revelation is the basic category of religious knowledge. Man knows God and his will because God has freely revealed himself —his qualities, purpose, or instructions.

Judaism. The Israelite faith looked back to the Pentateuch (the first five books of the Old Testament) for its fundamental revelation of God. God was believed to have revealed himself to the patriarchs and prophets by various means not unlike those known to the primitive religions —theophanies (visible manifestations of the divine), dreams, visions, auditions, and ecstasies — and also, more significantly, by his mighty deeds, such as his bringing the Israelites out of Egypt and enabling them to conquer the Holy Land. Moses and the prophets were viewed as the chosen spokesmen who interpreted God's will and purposes to the nation. Their inspired words were to be accepted in loving obedience as the Word of God.

Revelation through events

Rabbinic Judaism, which probably originated during the Babylonian Exile and became organized after the destruction of the Temple by the Romans, concerned itself primarily with the solution of legal and ethical problems. It gradually developed an elaborate system of casuistry resting upon the Torah (the Law, or the Pentateuch) and its approved commentaries, especially the Talmud (commentaries on the Torah), which was regarded by many as equal to the Bible in authority. Orthodox Judaism still recognizes these authoritative sources and insists on the verbal inspiration of the Bible, or at least of the Pentateuch.

Christianity. The New Testament took its basic notions of revelation from the contemporary forms of Judaism (1st century BC and 1st century AD)—*i.e.*, from both normative rabbinic Judaism and the esoteric doctrines current in Jewish apocalyptic circles in the Hellenistic world. Accepting the Hebrew Scriptures as preparatory revelation, Christianity maintains that revelation is brought to its unsurpassable climax in the person of Jesus Christ, who is God's own Son (Heb. 1:1–2), his eternal Word (John 1:1), and the perfect image of the Father (Col. 1:15). The Christian revelation is viewed as occurring primarily in the life, teaching, death, and Resurrection of Jesus, all interpreted by the apostolic witnesses under the illumination of the Holy Spirit. Commissioned by Jesus and empowered by the divine spirit, the apostles, as the primary heralds, hold a position in Christianity analogous to that of the prophets in ancient Israel.

The Apostle Paul, though not personally a witness to the public life of Jesus, is ranked with the Apostles by reason of his special vision of the risen Christ and of his special call to carry the Gospel to the Gentiles. In his letters, Paul emphasized the indispensability of missionary preaching in order that God's revelation in Christ be communicated to all the nations of the world (Rom. 10:11–21).

Christianity has traditionally viewed God's revelation as being complete in Jesus Christ, or at least in the lifetime of the Apostles. Further development is understood to be a deeper penetration of what was already revealed, in some sense, in the 1st century. Periodically, in the course of Christian history, there have been sectarian movements that have attributed binding force to new revelations occurring in the community, such as the 2nd-century Montanists (a heretical group that believed they were of the Age of the Holy Spirit), the 13th century Joachimites (a mystical group that held a similar view), the 16th-century Anabaptists (radical Protestant sects), and the 17th-century Quakers. In the 19th century the Church of Jesus Christ of Latter–day Saints (popularly known as Mormons) recognized, alongside the Bible, additional canonical scriptures (notably, the Book of Mormon) containing revelations made to the founder, Joseph Smith.

Islām. Islām, the third great prophetic religion of the West, has its basis in revelations received by Muhammad (*c.* 7th century AD). These were collected shortly after his death into the Qur'ān (Koran), which is regarded by Muslims as the final, perfect revelation — a human copy of the eternal book, dictated to the Prophet. While Islām accords prophetic status to Moses and Jesus, it looks upon the Qur'ān as a correction and completion of all that went before. More than either Judaism or Christianity, Islrim is a religion of the Book. Revelation is understood to be a declaration of God's will rather than his personal self-disclosure. Insisting as it does on the absolute sovereignty of God, on man's passivity in relation to the divine, and on the infinite distance between creator and creature, Islām has sometimes been inhospitable to philosophical speculation and mystical experience. Yet in medieval Islām there was both a remarkable flowering of Arabic philosophy and the intense piety of the mystical Siifis. The rational-

Revelation through a sacred book

ism of some philosophers and the theosophical tendencies of some of the Ṣūfīs came into conflict with official orthodoxy.

Zoroastrianism. A fourth great prophetic religion, which should be mentioned for its historic importance, is Zoroastrianism, once the national faith of the Persian Empire. Zoroaster (Zarathushtra), a prophetic reformer of *c.* 7th century BC, apparently professed a monotheistic faith and a stern devotion to truth and righteousness. At the age of 30 he experienced a revelation from Ahura Mazdā (The Wise) and chose to follow him in the battle against the forces of evil. This revelation enabled Zoroaster and his followers to comprehend the difference between good (Truth) and evil (The Lie) and to know the one true God. Later forms of Zoroastrianism apparently had an impact on Judaism, from the time of the Babylonian Exile, and, through Judaism, on Christianity.

THEMES AND FUNCTIONS

Recurrent questions concerning revelation include the relationship between general and special revelation; the relationship between word and deed as media of special revelation; the authority of the sacred books; the revelatory value of tradition; the nonverbal component in revelation; the interpersonal dimension of revelation; and the relationship between faith and reason.

General revelation: the role of nature. The Eastern religions, on the whole, differ from Western religions in that they place less emphasis on a special or exclusive revelation received by a "chosen people" and rather speak of the manifestation of the Absolute through the general order of nature. There is, however, no irreconcilable opposition between general and special revelation. Vedanta Hinduism and Buddhism, even if they do not speak of special revelation, believe that their religious books and traditions have unique value for imparting a saving knowledge of the truth. The Bible and the Qurʾān, conversely, proclaim that although God has specially manifested himself to the biblical peoples, he also makes himself known through the order of nature. The failure of some nations to acknowledge the one true God is attributed not to God's failure to disclose himself but rather to the debilitating effects of sin on the perceptive powers of man.

Special revelation: the role of history. The Western religions differ somewhat among themselves in the ways in which they understand how special revelation occurs. Some focus simply on the direct inspiration of the divinely chosen prophets. The Judeo-Christian tradition, however, characteristically looks upon the prophets as witnesses and interpreters of what God is doing in history. Revelation through deeds is conceived to be more fundamental than revelation through words, though the words of the prophets are regarded as necessary to clarify the meaning of the events. Since the Old Testament term for "word" (davar) signifies also "deed" or "thing," there is no clear line of demarcation between word-revelation and deed-revelation in the Bible. The biblical authors look upon the national fortunes of Israel as revelations of God's merciful love, his fidelity to his promises, his unfailing power, his exacting justice, and his readiness to forgive the penitent sinner. The full disclosure of the meaning of history, for many of the biblical writers, will occur only at the end of time, when revelation will be given to all peoples in full clarity. The Judeo-Christian notion of history as progressive revelation has given rise to a variety of theological interpretations of world history, from St. Augustine (AD 354–430) to G.W.F. Hegel (1770–1831) and other modern thinkers.

The importance of canons of scriptures

Revelation and sacred scriptures. In those religions that look for guidance to the ancient past, great importance is attached to sacred books. Theravāda Buddhism, while it professes no doctrine of inspiration, has drawn up a strict canon (standard or authoritative scriptures)—the "Pāli canon'—in order to keep alive what is believed to be the most original and reliable traditions concerning the Buddha. Mahāyāna Buddhism, while it has no such strict canon, considers that all its adherents must accept the authority of the *sūtras* (basic teachings written in aphorisms). Zen Buddhism, in many ways the broadest development of Mahāyāna thought, sometimes goes to the point of rejecting any such written authority. Many religions view their holy books as inspired and inerrant. According to a very ancient Hindu tradition, the sages of old composed the Vedas by means of an impersonal type of inspiration through cosmic vibrations. Judaism, on the other hand, looks upon the Bible as divinely inspired. The idea of verbal dictation from God, which occurs here and there in the Bible, was applied by some rabbis to the Pentateuch, which was believed to have been written by Moses under verbal inspiration, and even to the whole Bible. Christianity, which generally accepts both the Old and New Testaments as in some sense inspired, has at times countenanced theories of verbal dictation. According to the Mormons, the Book of Mormon was composed in heaven and delivered on tablets of gold to Joseph Smith. Islām holds that the Qurʾān, an eternal heavenly book, was dictated verbatim to Muhammad. The Prophet's companions testified that he would often turn red or livid, sweat profusely, and fall into trances while receiving revelations.

Apostolic tradition

Revelation and tradition. The great religions frequently make a distinction between those scriptures that contain the initial revelation and others, at the outer fringe of the canon, that contain authoritative commentaries. In Hinduism, the four Vedas and three other ancient collections—the *Brāhmaṇas,* Aranyakas, and *Upaniṣads*—are *Śruti* ("that which has been heard"; *i.e.*, constitutive revelation); the other sacred writings (the *sūtras*, the lawbooks, *Purāṇas*, and the Bhagavadgītā and the *Rāmā*yana, the two great epics) are *Smṛti* ("that which has been remembered"; *i.e.,* tradition). Later Judaism, while recognizing the unique place of the Bible as the written source of revelation, accords equal authority to the Talmud as traditional commentary. Among Christians, Roman Catholics and the Eastern Orthodox believe that revelation is to be found not only in the Bible but also, by equal right, in the apostolic tradition. Protestants emphasize the objective sufficiency of Scripture as a source of revelation, but many Protestants today are careful to add that Scripture must always be read in the light of church tradition in order that its true message be rightly understood. Islām holds that the Qurʾān alone contains revelation in the strict sense (wahy), but it accepts tradition (Hadith) as a supplementary source of Islāmic law. Special significance is attached to the practice (sunnah) of the Prophet himself and to the traditions handed down by his immediate companions.

Revelation and experience. In most religions nonverbal communication plays an important part in the transmission of revelation. This can occur in art (notably in icons, statues, and idols), in sacred music, in the liturgy, and in popular dramas, such as the mystery plays common in medieval Europe or those still performed in Indian villages. For a deeper initiation into the revelation, it is believed necessary to live under the tutelage of a guru (teacher), monk, or holy man. To the extent that revelation is identified with a profound and transforming personal experience, the spiritual preparation of the subject by prayer and asceticism is stressed. Among the great living religions of the world, there is wide agreement that revelation cannot be fully communicated by books and sermons but only by an ineffable, suprarational experience. In Hinduism the *Upaniṣads* emphasize the hiddenness of God. Leaving behind all created analogies, the adept is led to the point where he comes to praise God in an adoring silence more exalted than speech. Buddhism of the Mahāyāna, especially its Zen varieties, likewise advocates ecstatic contemplation. The Eastern mystics are here in close agreement with the Jewish Hasidim (mystical pietists), with the Islāmic Ṣūfīs, and with the great Christian mystics, such as Pseudo-Dionysius, the Areopagite, Meister Eckehart, and St. John of the Cross. Many theologians within Judaism (*e.g.*, Maimonides) and Eastern Christianity (*e.g.*, St. John Chrysostom, St. John of Damascus) have contended that God is best known through a negative, or "apophatic," theology that makes no positive statements about God. This idea, never absent from the medieval scholastic (intellectualist) tradition, was newly emphasized by Martin Luther, who insisted that the revealed God ***(Deus revelatus)*** remains the hidden God ***(Deus absconditus)***, before whom man must stand in reverent awe. Contemporary Roman Catholic theologians, such as Karl Rahner, maintain that even in heaven God will not cease to be, for man's finite mind, an unfathomable mystery. Revelation makes man constantly more aware of the depths of the divine incomprehensibility.

The revealed God as the hidden God

Revelatory relationships. In certain forms of mysticism, particularly prevalent in the Eastern religions, the envisioned goal is an absorption into the divine, involving the loss of individual consciousness. In the Western religions and in Bhakti Hinduism the abiding distinctness of the individual personality is affirmed. Islāmic orthodoxy, looking upon revelation as a declaration of the divine will, stresses not so much the communion of man with God as rather man's obedient submission to the creator. Islāmic Ṣūfīsm, however, resembles Hasidic Judaism and Christianity in its aspiration for personal union with God. For many contemporary religious thinkers, such as the Jewish philosopher Martin Buber and the Roman Catholic philosopher Gabriel Marcel, revelation involves a mutual self-giving of the revealer and the believer in personal intercommunion. According to Karl Rahner, revelation consists primarily and essentially in God's gracious communication of his own divine life to man as a personal spirit. In his view, the articulation of revelation in the scriptures and creeds is a secondary stage, presupposing an experiential encounter with the divine. This secondary phase, however, is viewed as necessary in order that man may realize himself in his humanity as a believer and achieve solidarity with his fellow believers. In general, the Western religions tend to attach more importance to the idea of a community of faith than do the Eastern religions. Revelation in the biblical and Islāmic view is addressed not to individuals as such but to a whole people, which achieves its identity, in part, by articulating its faith in writings that are approved as authentic expressions of what God has revealed.

Revelation and reason. The problem of the relationship between revelation and reason arises, on the one hand, because revelation transcends the categories of ordinary rational thought and, on the other hand, because revelation is commonly transmitted by means of authoritative records, the contents of which cannot be verified by the believer. Buddhism, since it does not attribute inspiration or inerrancy to its canonical sources, allows some scope for individual reason to criticize the authoritative writings, but, like other religions, it has to face the charge that the illumination to which it aspires may be illusory. Orthodox Hindus, giving full authority to the Veda, hold that human reason errs whenever, on the grounds of perceptual experience, it takes issue with the sacred writings. Hinduism, however, allows for great freedom in the exegesis (interpretation) of its sacred books, some of which are more poetic than doctrinal.

Tension between faith and reason

The tension between faith and reason has been particularly acute in the Western religions, which find revelation not simply in holy books but in prophetic words that call for definite assent and frequently command a precise course of action. The ambiguities of scripture in these religions are frequently cleared up by creeds and dogmas of the community, calling for the assent of true believers. Judaism, Christianity, and Islām, moreover, came into close contact with Hellenistic culture, which held up the ideal of rationally certified knowledge as the basis for the good life. They, therefore, had to face the problem: could assent to an authoritative revelation be justified before the bar of reason? Some theologians took a "fideist" (faith-based) position, maintaining that reason must in all things submit to the demands of revelation. Others, such as the Arabic philosopher Averroës and his followers (both Muslim and Christian), accepted the primacy of reason. They reinterpreted the content of revelation so as to bring it into line with science and philosophy. A third school, in which the medieval Jewish philosopher Maimonides and the medieval Christian scholastic theologian Thomas Aquinas may be included, sought to maintain the primacy of faith without sacrificing the dignity of reason. According to the Thomist theory, human reason can discern the credibility of revelation because of the external signs by which God has authenticated it (especially prophecies and miracles). Reason, moreover, makes it possible for the believer to understand, in some measure, the revealed mysteries. This intellectualist position continues to appeal to many Christians; but some maintain that it overlooks the qualitative differences between faith—as a transrational assent to mystery—and scientific knowledge, which operates within the categories of objectivizing reason.

CONCLUSION

In some theological circles the concept of revelation is rejected on the ground that it is bound up with mythological and anthropomorphic conceptions and introduces an unassimilable element into the history of religions. It would seem, however, that the concept can be purified of these mythical elements and still be usefully employed. In the sphere of religion, wisdom is often best sought through privileged moments of ecstatic experience and through the testimony of those who have perceived the sacred or holy with unusual purity and power. The self-disclosure of the divine through extraordinary experiences and symbols is fittingly called revelation. Because of the pervasiveness of the idea of revelation in the world's religions and because the various religions have had to cope with similar theological problems concerning revealed knowledge, revelation has become a primary theme for dialogue among the great religions of mankind.

Perception of the sacred or holy

Revolution, Political

"Revolution," its connotations in astronomy apart, has in political and social thought come to mean a sudden, major, and hence typically violent alteration in government and in related associations and structures. It is used by analogy in such expressions as the industrial revolution, where it refers to a radical and profound change in economic relationships and technological conditions.

DEFINITIONS OF "REVOLUTION"

Though the idea was originally related to the notion of cyclical alterations in the forms of government, it now connotes a novel departure, as epitomized in Leon Trotsky's assertion that "revolutions are the mad inspiration of history." It is the idea of a "new order," which predominates since the American and French revolutions, rather than that of a return to an old one, as suggested by the cosmic revolution of heavenly bodies. An early use of the word around 1450, toward the end of the Middle Ages, has been noted; but it came into more general use after 1600, first meaning a return to the old order, but afterward in the modern sense. These dates show that revolution as a major political term parallels the emergence of the modern state around 1600. Hence in its core meaning a revolution constitutes a challenge to the established political order and the eventual establishment of a new order radically different from the preceding one. One recent writer defines it in its most common sense as "an attempt to make a radical change in the system of government." It might be added that a successful revolution is more than an attempt; it does radically change such a system. The great revolutions of European history, especially the Reformation and the English, French, and Russian revolutions changed not only the system of government but also the social system in all its ramifications, economic, social, and cultural.

THEORIES OF REVOLUTION

Classical theories of revolution

Ancient and medieval theories. In light of such a definition, it is hardly surprising that the history of political thought consists of a series of theories of revolution. In classical antiquity the preoccupation of Plato, Aristotle, and later writers was profoundly antirevolutionary, even though in point of fact Plato's (and Socrates') thought was revolutionary in its implications, or perhaps more correctly it was counter-revolutionary, in that it sought to recapture the old order and rejected the democratic order that prevailed in the Athens of their day. The Sophistic revolution, opposed by Plato, was seen to have destroyed the old *nomos,* or tradition, of right and law. It has been persuasively argued that Plato saw history as a regress and combatted the "liberal temper in Greek politics." Surely Socrates' sharp criticism of Pericles as the corrupter of the people (reported by Plato in the Gorgias) was counter-revolutionary in sentiment and intent. The implicit theory of revolution among the Greeks is that it results from the development of *anomia,* a disintegration of the traditional values and beliefs, founded in religious convictions, as to what is right and wrong. In a sense Plato's Republic seeks to show that only a fixed and unalterable system of values, based upon the rule of guardians who have learned philosophical truth through the cognition of eternal ideas, can hope to escape from the revolutionary turmoil that unstable values cause.

Aristotle, in his Constitution of Athens, displays a concrete insight into what appears as a sequence of revolutions and counter-revolutions in the political order of that great city. He generalized from that story, and presumably from similar (but now lost) studies of comparable stories of other Greek cities, and distilled what is commonly believed to be the first general theory of revolution. Empirical material of great interest is also contained in the History of the *Peloponnesian* War of Thucydides, who, although sophistical in his philosophical outlook, is also anti-revolutionary. The constant oscillation between oligarchic and democratic regimes in the Greek cities, bound up with the rivalry of Athens and Sparta, seemed to him an important cause of the lethal conflict of the Peloponnesian War, and he gives some highly critical descriptions of revolutionary upheavals—*e.g.,* "And so there fell upon the cities on account of revolutions many grievious calamities. . . ." Aristotle, writing after these calamities, formulated his theory of revolution in light of these experiences (Book V of Politics). Aristotle relates the causes of revolutions to his typology of forms of government and their cyclical sequence, which Plato had hinted at before him. He stresses a fourfold set of conditions, in keeping with his general theory of causation. The material conditions he recognizes are in the distribution of wealth and the related class structure, simplistically seen as the division between rich and poor. The ideological aspect (to use a modern term) he sees provided by the ideas of justice that mold party divisions. The efficient cause consists of the makers of revolutions, that is to say the leaders of the movements that are seeking power and, therefore, the transformation of the political order. This latter is itself the fourth "cause": the end or purpose of a revolution is a radically altered political order. Aristotle's theory can be stated more generally by saying that any radical alteration in basic value or beliefs provides the ground for a revolutionary upheaval.

From this it can be seen that Aristotle's was an elaboration of the Platonic view, and it is not surprising that Cicero too should have shared this outlook. In his fragmentary De *republica* he says that "a disagreement among the citizens is termed a breaking up because the citizens divide into several factions." He introduces the term sedition at this point, further emphasizing his distrust of revolution and the importance of avoiding it. It is the task of the statesman to be "always armed to meet emergencies which unsettle the constitution," he argues.

Revolution in medieval thought

This preoccupation with stability continued into the Middle Ages. Political thinkers, however, were concerned over the problem of resistance to revolution, and more particularly the right to resist, which was seen in the perspective of the division of medieval authority between the two swords of secular and priestly office and the related question of tyranny and monarchy. Accepting the latter as the natural and good form of government, in the image of God's rule over the universe, they had to face the issue of the abuse of power and the possibility of a usurper. These were the two kinds of tyranny medieval thinkers saw as perversions that the church had to prevent—if need be, by excommunicating the offending prince and calling for the resistance of his feudal vassals. The actual revolutionary in the medieval sense was, thus, the offending prince himself; and it was the task of his subjects to redress the balance with all available means, including tyrannicide. Even as conservative a thinker as St. Thomas Aquinas could, therefore, justify the killing of a tyrant when sanctioned by the ecclesiastical authorities. Part of his commentary on the fifth book of Aristotle's Politics is characteristically entitled "For what causes tyrannies and kingdoms are dissolved," and he asserts that injustice is the main cause. In keeping with Aristotle's theory of justice as expressed in his Ethics, Aquinas holds that seditions are caused by inequality. Revolution is seen as sedition and is understood to spring from the corruption that outrages the sentiment of justice and equality. Other medieval thinkers, such as Marsilius of Padua, leaned in the same direction. This theory of revolution was reinforced by the Augustinian indifference to the worldly city and the general belief that its iniquities must be endured by the good Christian. It is clear that the antirevolutionary tendency had become even more pronounced in the Middle Ages than it was in classical thought. Even the conciliar movement of the 15th century, though in many ways subversive of the medieval tradition in church and state, did not develop any theory of revolution.

The beginning of the modern view

Renaissance and early modern theories. Such a theory only became possible in the secular thought of humanism, with its Renaissance interest in classical antiquity. Niccolb Machiavelli especially, but others before and after him as well, were inclined to see revolution in a new light. In general, Machiavelli, like Plato, expounded revolutionary thoughts without theorizing about revolution. The term does not appear in his writings; he speaks of rebellion *(seditio)*, as the Middle Ages had done, and of changes of political order—Cicero's *mutatio rerum*—because like the ancients he was primarily interested in stability. He sought the means to found a lasting and stable political order, as Plato and Aristotle had, and as Polybius believed the Romans had succeeded in doing. But in Machiavelli's writings there is no evolutionary notion of a meaningful historical progress of which a revolution might be a crucial step. As Hannah Arendt has said, "the specific revolutionary pathos of the absolutely new . . . was entirely alien to him." Even so, he was, if not "the spiritual father of revolution," then at any rate the thinker who cleared the road for its appearance by the stress he laid upon the founding process, and the willingness to condone the violence associated with it.

The radical recognition of the creative potential of revolution first appears in the course of the English Revolution, and more particularly in the writings of John Milton, later popularized by John Locke. Milton, in his defense of what the Puritans had done, proclaimed the "right of revolution." This was no longer merely the right of resisting a tyrannous ruler, but the right to "choose" their own form of government. In ***The Tenure of Kings and Magistrates (1649)*** Milton speaks of the right of a free nation "as oft as they judge it for the best, either to choose or reject" a ruler, "though he be no tyrant," "merely by the liberty and right of free-born men to be governed as seems to them best." Milton's is the decisive breakthrough to the modern position, which asserts that revolution is vitally linked to the realization of freedom. Milton mocks those who think that a nation can be free which does not claim this right, those "whose government, though not illegal, or intolerable, hangs over them as a lordly scourge. . . ." Milton's contemporary, the political philosopher, James Harrington, shared this belief in the right of a free people to organize itself, and John Locke expresses the core idea of the right of revolution in what he calls an "appeal to heaven." But Locke did not maintain Milton's vigorously libertarian view. In his ***Second Treatise of Government,*** though he rejects the critics of the revolutionary doctrine of Milton and Harrington, he resumes the old argument about the "ill usage of arbitrary power" and suggests that "such ***revolutions happen"*** not "upon every little mismanagement in publick affairs." He argues about "illegal attempts made upon their [the people's] Liberties and Properties," and about "unlawful violence" and "tyranny."

Revolution as the agent of freedom was, of course, the concept behind both the American and French revolutions. Not the defense of old and established liberties but the conquest of new and fuller ones was seen as the essence of the revolutionary thrust. In order to argue thus, the doctrine of natural rights was developed out of the old natural-law notions and given fuller scope than it had hitherto possessed. Jean-Jacques Rousseau, though by no means an advocate of revolution, which, he tells us in his ***Confessions,*** he had come to detest, nonetheless became the revolutionary thinker par excellence. For what he sketched was a republican and democratic ideal, rooted in Swiss tradition, but with profoundly revolutionary implications for France and other European monarchies. Rousseau himself argued that only some people in some historical constellations were capable of genuine republican freedom, but if so, a revolution to achieve it was natural. The German philosopher Immanuel Kant, dubbed the "red Jacobin of Konigsberg" by his contemporaries, went a step further and argued that though a revolution may be accompanied by "miseries and atrocities" (as in the French Revolution) it was still a "sign" of the "moral propensity in man," and hence related to human progress. In spite of all its excesses, he saw the French (as well as the American) Revolution as an attempt "to secure freedom under law through the establishment of a republican constitution." For Kant, a revolution was a fact of nature, not morally or legally allowable as such but to be accepted as "natural" if directed toward a higher moral goal.

The 19th-century theories. The French and American revolutions, so vitally related to the progress of freedom, raised the question that has dominated political theory ever since, namely that of the ***historical meaning*** of a revolution. The broad cultural implications of these revolutions eventually led to a new definition of "revolution" as a spiritual upheaval through which a group seeks to establish a new foundation for its existence, no longer a merely political process but part of the unfolding of human potentiality. Though Kant and the Marquis de Condorcet had suggested this possibility, the decisive philosophical turn toward this view was G.W.F. Hegel's philosophy of history. The Hegelian metaphysics, which saw the progressive unfolding of human history as a manifestation of the world spirit and as such as the realization of freedom, though it did not explicitly employ the term revolution as a key concept, was in fact a great revolutionary interpretation of mankind's progress. The idea of world revolutionary individuals, who fulfill the destiny of nations by bringing about a new and broader freedom, is linked to this revolutionary interpretation. Hegel therefore interpreted the Reformation as a revolution using such language as this: "The ancient and ever-preserved inwardness of the German people had to effect this revolution out of the simple, modest heart." The political results are incidental to this spiritual revolution, and as such they are not of primary importance.

Revolution and historical progress

Passing over the English Revolution, as do so many continental thinkers, Hegel then concentrates on the French Revolution, which he saw as a manifestation of the French genius for abstraction. The revolution is "world-historical" in its significance, "the principle of the French Revolution permeated almost all modern states" and particularly all the Latin nations "fell under the dominion of liberalism." "Thus liberalism traversed the Latin world as an abstraction emanating from France." Regarding England, Hegel claims: "Abstract and general principles consequently have no attraction for Englishmen." A close student of Edmund Burke and his famous ***Reflections on the Revolution in France,*** he echoes here a notion that has persisted, namely that English people are resistant to revolutionary upheavals and prefer gradual and evolutionary development. At the end of his life Hegel sharply condemned the reform movement in England and expressed the view that it would destroy the English constitution's basic freedom. In the case of England he did not perceive the revolutionary thrust in positive terms.

The Hegelian theory of revolution as part of an evolutionary process of world-historical dimensions was made the basis of what is unquestionably the most dominant modern theory of revolution, the Marxian. By focussing attention upon the material factor of the control of the means of production and the class that exercises such control, Karl Marx believed he had given the Hegelian notions a scientific basis. He saw history as proceeding according to ascertainable and regular laws, and revolutions as serving a decisive function in this process: a new and ascendant class overthrows an obsolete one and a new social order replaces the outworn one. The productive forces of a certain stage clash with the prevailing "relations of production." That is, the existing social order hinders the further development of these relations, and, as tensions increase, a revolutionary situation develops. In Marx's view power and politics are crucial; the seizure of power by the revolutionaries is the first step that determines all the rest. The struggle of the classes culminates in civil war and revolution. But unlike Hegel's, Marx's vision is eschatological. The process is not conceived as continuing indefinitely; rather, the revolution of the class-conscious Communist elite of the proletariat is seen as achieving a final stage which puts an end to all class rule and exploitation. The class struggle has then come to an end, and with it the chance of further revolutionary upheavals.

Marxian theory

Marx thought that this final stage would be reached in the most advanced industrial nations at the end of their period of bourgeois class rule. In fact, the Communist revolution has succeeded in preindustrial and backward countries, and this success did not bring the classless society. It has been argued with persuasive insight that a new class has arisen: the ***apparat,*** that is to say the managerial bureaucracy, controlling the means of production in the name of the Communist Party. Nor did the industrial proletariat play a decisive role in these revolutions, which hardly represented a greater realization of freedom. In the former colonial regions, freedom from foreign dominion was achieved in this way, but usually at the price of a reduction in civil liberties.

THE CAUSES OF REVOLUTION

Unlimited revolutions

The processes of revolution. The problem of what causes a revolution, first explicitly stated by Aristotle, has had considerable vogue. The sharp contrast between strictly governmental revolutions, bordering on the coup d'etat, and the great revolutions of European history make it desirable to separate the two in a discussion of causation. For the great revolutions, in view of their culturally global character, it seems futile to search for definite causes, since the entire preceding state of a society is involved, and all one can hope to do is to describe the phases in the unfolding of the revolutionary process. A number of attempts have been made to sketch this pattern of revolution. One impressive attempt at overall interpretation, in the Hegelian tradition of seeing the great revolutions as part of the march of history, was made by Eugen Rosenstock-Huessy. He links the unlimited revolutions to the development of Western culture and the formation of nations. According to him, each of these revolutions was made by one of the major nations of Europe in the course of becoming a nation and discovering its own style of life, a particular version of Western culture.

This interpretation fits the English and French experience reasonably well, but becomes less tenable when applied to other revolutions, and it has been bitterly criticized for its historical inaccuracies. Yet Rosenstock-Huessy has contributed some important insights; he has shown how each of these total revolutions came to see itself as a "world revolution" whose makers expected that its values and beliefs would become universal throughout Europe. This bold theory of Europe's great revolutions treats the Russian Revolution as the last of its kind, after which the world is moving "out of revolution." The theory contains many fascinating details, such as the widening group of active revolutionaries, culminating in the one or two million proletarians of the Soviet Revolution. Rosenstock-Huessy sees each revolution as in a sense directed against the preceding one, echoing to some extent Marxian thought patterns in this respect. This striking synthesis of Hegelian and Marxian elements in terms of an autonomous process of nation forming is primarily a cultural theory of revolution, but the political element occupies the centre of the analysis, for in its violence and suddenness the political revolution epitomizes all the rest. Yet, it must be distinguished from the limited type of political revolution (such as the coup d'etat) that signifies little more than overthrow of the government.

Limited revolutions

Some contexts seem especially favourable to this kind of revolution. According to one count, there have been 68 revolutions during 65 years of Bolivian history. Actually many of these were mere coups d'etat. But even after discounting these, enough remain in Bolivia and other Latin American countries to conclude that Latin America, like ancient Greece, is favourable to revolutionary change. By contrast, Britain and the United States, Switzerland, and the Scandinavian countries have been rather free of it. These, in turn, form a striking contrast to France and a number of other European countries. The experience of France would suggest that if a regime represses much needed change and is overthrown, it may become very difficult to reestablish a political order that will last, unless provisions are made for its recurrent change. It may be necessary, as in Switzerland, to go as far as to allow a total revision of the constitution, but even more limited amending arrangements may accomplish the required flexibility.

Turning now to the process of limited political revolution, one modern historian (Crane Brinton) has constructed what he considers an "anatomy" of revolutions by abstracting the political from the broader cultural and social context. This political pattern, taken by itself, appears rather uniform. Brinton based his tentative generalizations upon some of the great, "unlimited" revolutions—the English, the French, and the Russian. We may summarize his findings as follows: The signs of an approaching revolution are not very distinctive. There are more and more stresses and strains, some of which are endemic in any society, but whose multiplications eventually leads to a breakdown of the political order. Both legitimacy and authority disintegrate; such power as is still effectively wielded depends more and more upon coercive means and is thereby limited. At the same time, hitherto unrecognized groups gain power and influence. Such groups eventually fan out into revolutionary movements with the openly declared goal of destroying the existing order and replacing it by another.

The phases of revolution

There is a definite sequence of stages or phases to the revolutionary process, but it appears doubtful that what holds of the unlimited revolutions necessarily applies to the limited ones. Brinton noted that in the first stage utopian expectations run high, and the revolutionaries engage in much perfectionist rhetoric. But this phase does not last very long. The practical tasks of governing have to be faced, and a split develops between moderates and radicals. It ends in the defeat of the moderates, the rise of extremists and the concentration of all power in their hands. This is the second stage. Such extreme concentration of power is followed by the "terror," and the ever more radical deployment of violence. The third stage is the desperate effort to realize the revolutionary goals at all costs. This overextension engenders a reaction, after the French case often called the Thermidorean reaction (from Thermidor, French name of the month in which the reaction took place), bringing a period of convalescence during which the revolutionary fervour subsides. This period of resignation and dissension then leads to the setting up of a dictator who is still animated by some of the revolutionary aspirations; his rule constitutes the fifth stage. Gradually, the practical problems of governing gain the upper hand and old habits of life reappear. The revolutionary symbols lose their hold and the dictatorship appears as naked power. At this point, the time is ripe for a restoration, an attempt to reestablish the old regime. But the restoration never succeeds in restoring what has been; new institutions are designed for the changed social structure the revolution has brought into being. Brinton concludes that the overall result of such a revolution is the achievement of greater governmental efficiency. He notes that, of the countries upon which his generalizations are based, all "emerged from their revolutions with more efficient and more centralized governments."

Only the last of these aspects of the revolutionary process, and possibly the first, are to be observed in the American Revolution. That this strengthening of government is a common result of revolutions is understandable enough in light of the fact that revolutions are made against weak governments. A good many other political revolutions do not run through the phases Brinton abstracted from the unlimited revolutions of European history. The explanation may lie in the absence of a sharp clash between moderates and radicals that in turn is related to the absence or weakness of the ideological factor. The Roman revolution by which the Republic was replaced by the empire illustrates the point. Like the Roman revolution, many political revolutions result from the breakdown of an established system.

If there is no ideological ferment, what are the causes of revolution? No particular useful analysis results from listing abstract general values such as freedom, security, equality, or justice as causes of revolution, on the ground that they provide a basis for revolutionary sentiment. Such general motivations will enter the thinking of revolutionaries as of other political leaders; they may be real motivations or mere rationalizations. It has already been noted that a multiplication of stresses and strains, resulting from a structure that is too rigid, is the most usual cause of revolutionary sentiment. George Pettee called these stresses and strains "cramps," implying a "maladjustment with accompanying strain." He then proceeded to analyze the prerevolutionary situation in terms of economic, ideological, social, and political cramps, resulting from institutional decay and the decadence of the elite. Pettee insists that only a cumulation of such stresses and strains will produce a revolutionary outbreak. A clash of loyalties develops which in due course produces a revolutionary crisis.

The collapse of the state

In the prerevolutionary situation, ever larger groups of people are alienated from the established political order. Existing law loses its legitimacy and seems arbitrary and its enforcement unjustified. The old established sense of right that the Greeks called ***nomos*** fades, and the resulting state of affairs is one without *nomos*; and the Greek word *anomia* has once again become fashionable: anomie, though often used rather vaguely, is meant to describe the present-day moral confusion and lack of a firm sense of values. In such a prerevolutionary period, usually efforts at reforming the political and social order are attempted, but they often fail and thus enhance the sense of frustration and alienation. Each such period has produced one or more striking figures who try hard: Strafford in England under Charles I, Turgot and Necker in France under Louis XVI, and Stolypin in Russia under Nicholas II were genuine reformers, but their very ability and dedication having produced no success served to prove that the system was beyond reform. These reformers highlight its rottenness and corruption. Not long after this sort of effort, the political order (the state) collapses. It is often some minor matter that serves to demonstrate that the system has ceased to function, but it may be a major policy that helps to make manifest the breakdown, such as France's Algeria policy before Charles de Gaulle.

If one considers these facts and compares a large number of revolutions, both unlimited and limited, it is striking how often they have been precipitated by an unsuccessful war. In fact, losing a war is dangerous for any political regime, but especially for one with prerevolutionary tensions. It would be superficial, however, to consider the war the cause of the revolution. The war is itself the result of the deeper strains that produced the prerevolutionary situation. It has often been remarked that autocratic regimes when confronted with internal conflict and restlessness have sought to assuage the aggressive elements by engaging in attacks upon other states. Mussolini's aggression against Ethiopia, Hitler's against Poland, and Stalin's against Finland are merely recent examples of a propensity that has prevailed through the ages. If the aggression is successful, it may serve as the safety valve for the regime, but if it is not, it may precipitate a revolution.

The medieval doctrine of tyrannicide, with its stress on the abuse of power, pointed to another "cause" of revolutionary overthrow. But as in the case of war, one must ask further what caused such abuse. The old answer that power tends to corrupt, while not without some value, is inadequate. The tyrant may be a self-seeking bully; more probably he is a man afraid who is trying to master an unmanageable situation resulting from failure of the regime to adapt to changing circumstances.

The place of ideology

The aims of revolutionaries. So far, the discussion of causation has been largely in terms of the "efficient cause^{w}—the so-called scientific and value-free analysis of antecedents. But there is also the teleological causation, which we reach by inquiring about the end or purpose of the revolutionaries. For it is not merely a matter of considering the antecedents but also of analyzing the revolution's thrust. A radical alteration of the political and social order may occur, and appear in retrospect to have brought about a revolution, but more typically, the revolutionaries have a global goal, such as a "free" society or a constitutional order or a socialist community. Such goal definitions usually contain a utopian element, and the more unlimited the revolution, the more utopian the goal. The utopianism, often eschatological, that is to say, conceived as a final state in mankind's evolution, usually occasions the excesses of violence, not only because superhuman efforts are required to achieve the unattainable and the ineffable, but also because such goals beyond rational communication become a fertile ground for factionalism among the revolutionaries themselves. It has been said that "the revolution devours its children," because the attempt to achieve the utopian goal brings on the fanaticism of violence. It is a collective frustration-aggression psychosis that causes these self-destructive propensities. Even so, the goal, end, or purpose of the revolution, unattainable as it may be, has been a powerful factor in the etiology of revolutions. The goal predominant in the minds of the leaders may be the *goût* de ***pouvoir,*** but such love of power is usually reinforced by ideological fixations. To the scientific observer, the English, American, and French revolutions, as well as many postcolonial revolutions, are unusual in that their goal of establishing a constitutional order called for a considerable degree of self-denial on the part of the leaders of the revolution. The drama and the tragedy of this situation is epitomized in Oliver Cromwell's bitter struggles with parliament to make and abide by a constitution that they had made at his dictatorial demand.

A particular kind of constitutional revolution has occurred in recent times, the so-called negative revolutions in France, Italy, and Germany following World War II. In these cases constitutional orders were fashioned by people who had no great enthusiasm for or belief in constitutionalism but preferred it to the dictatorial regimes that had been overthrown. The same might be said of the quasi-revolution that brought de Gaulle to power in 19.58. While approved in a referendum, the constitution of the Fifth Republic was the work of legal technicians and has evolved quite differently from what its engineers intended. It unquestionably revolutionized the French government, and to some extent French society; but it was a "revolution from above," imposed by the imperious will of a leader who was not the maker but the beneficiary of the revolutionary ferment.

Revolutions, whatever their immediate occasion, would seem to be the result of deep-rooted and slowly evolving political and social malformations rather than the sudden outbreak that they appear to be at the surface. But in their last, culminating phase they are sudden and violent. And after the seizure of power by the revolutionaries, revolutions tend to run through certain phases, especially the unlimited, global revolutions of modern Europe. The more limited political revolutions do not exhibit all or even part of the phases; some of them closely resemble a coup d'etat. Such a coup is a stroke at the particular persons wielding power, but it is made merely for the purpose of replacing them by others, without any intended or actual change in the system. It is the violent substitute for what an election normally accomplishes, and many an overturn (stasis) discussed by Aristotle in his writing on revolution is merely such a coup. Coups often occur in the succession of revolutionary leaders: the replacement of Soviet Premier Nikita Sergeyevich Krushchev, for example, was clearly a coup d'etat. Before a new political order becomes established, a coup is the only way of changing the leadership, and much revolutionary violence occurs in connection with such coups and their prevention.

THE STAGES OF REVOLUTIONARY CONFLICT

It has been noted that there is an interlude of good feeling immediately after the outbreak of a revolution. For a time enthusiasm and optimism reign supreme, but this is a short-lived period that cannot last. The practical task of realizing the revolutionary program and attending to the everyday business of government leads eventually to sharp controversy and in turn to power struggles.

In the next phase the ideological issues come to the fore. The programmatic certainty of the early days vanishes and is replaced by strife and disagreement. Many possible avenues of implementation are explored, advocated, and discarded. All the French revolutionaries may have been followers of Rousseau; still they guillotined each other. Intertwined with this ideological phase is a succession of coups d'etat, which eventually leads to an exhaustion, after having precipitated one or more civil wars. In some cases, such a civil war constitutes a separate phase, but in many others it remains latent or overlaps with the succession struggles. It is true that in the French Revolution the radicals won in these wars and succession crises, but this is by no means generally true. Neither in England (Crom-

The phase of exhaustion

well) nor in America nor in Russia did the radicals triumph; Trotsky had to yield to the more conservative Stalin. The exhaustion from internecine conflict also may be preceded by foreign intervention as a separate phase; but this again depends upon circumstances. The greater the threat the revolution poses for other states, the more likely is such intervention, provided that the neighbouring states are not preoccupied with other matters, as they were in the case of the English Revolution, or weakened from a long war, as in 1917.

It is arguable whether the phase of exhaustion, the Thermidorean reaction, is still part of the revolutionary cycle. It was out of this period in the French Revolution that the dictatorship of Napoleon emerged. The Soviet leadership, for example, having determined to avoid the Thermidorean reaction and consequent dictatorship and restoration, declared that their regime was a permanent revolution. Some critical observers of the Soviet scene were inclined to doubt their success and to interpret Stalin's regime as a typical Thermidorean phase. This interpretation seems in retrospect rather doubtful, since the terror culminated during his leadership. Although Stalin may have had the chance of becoming the Napoleon of the Russian Revolution, and though he did in fact build a new system of autocracy, he appears to have been the executioner of the revolution. Like Napoleon, he excused the violence of his rule by reference to external threats. But it remains to be seen how close the evolution of the Russian Revolution will come to the pattern of phases deduced from the French revolution.

Revolutions of the limited kind often have not had a period of exhaustion and hence no Thermidor. After achieving the new order, the revolutionaries were able to continue it without any restoration. Thus Hitler's revolution led to a new Fascist regime in Germany, as had Mussolini's before him in Italy, and then on into war and destruction of the new order. No period of this kind seems in sight in China, though the death of Mao Tse-tung may initiate one.

CONCLUSION

In conclusion, one might say that the phenomena of political revolution and resistance are endemic in any political order, and that they are closely related. To avoid them or reduce their menace to a minimum, effective change by means of gradual transformation has to be organized to make possible recurrent adaptations of the institutions and processes of a political order to evolving values, interests, and beliefs. Otherwise violence will spread, sporadically as resistance at first, globally and all-engulfing as revolution afterward. Political orders resemble forests and families. They contain the potentiality of self-renewal, but this potentiality does not exclude the chance of failure and ultimate death. Revolution, when successful, signalizes the passing of such a political order. It is not in itself a good, as contemporary political romantics are inclined to feel, but it is better than the death of the society that such an order is intended to serve. The old Roman adage still holds: *Videant consules ne respublica detrimentum capiat* ("Let the consuls see that the republic suffer no harm").

BIBLIOGRAPHY. Two classic statements on the subject of revolution are JOHN LOCKE, *Second Treatise on Government* (1689), on the right of revolution; and EDMUND BURKE, *Reflections on the Revolution in France* (1790), *a* famous criticism of revolutionary violence. Attempts to define the concept of revolution may be found in the essays of HANNAH ARENDT, *On Revolution* (1963); in a collection of articles edited by C.J. FRIEDRICH, *Revolution* (1966); and in C.A. JOHNSON, *Revolutionary Change* (1966). L.S. FEUER (ed.), *Mars and Engels: Basic Writings on Politics and Philosophy* (1959), contains excerpts from the writings of Marx and Engels that are essential to an understanding of the Marxist theory of revolution. V.I. LENIN, *The State and Revolution: The Marxist Theory of the State and the Tasks of the Proletariat in the Revolution* (1917), presents a significant extension of the thought of Marx and Engels. Comparative studies of revolutions include C.C. BRINTON, *The Anatomy of Revolution,* rev. ed. (1952), an analysis of the process of revolution as exemplified by the French, American, English, and Russian Revolutions; and R.B. MERRIMAN, *Six Contemporaneous Revolutions* (1938), an historian's comparative description and evaluation of a revolutionary age. C. MALAPARTE, *Coup d'Etat: The Technique of Revolution,* trans. by S. SAUNDERS (1932), is concerned primarily with the lessons of Fascism. An interesting study of the interaction between revolution and the relation between states is G.A. KELLY and L.B. MILLER, *Internal War and International Systems* (1969). Other contemporary theoretical discussions include: B. MOORE, *Social Origins of Dictatorships and Democracy* (1966); N.R.C. COHN, *The Pursuit of the Millennium: Revoiutionary Messianism in Medieval and Reformation Europe and its Bearing on Modern Totalitarian Movements,* 2nd ed. (1961; rev. paperback ed., 1970), a general study with stress on Utopian objectives; S.P. HUNTINGTON, *Political Order in Changing Societies* (1968), a study of contemporary political development; H.J. LASKI, *Reflections on the Revolution of Our Time* (1943); H.D. Reynolds, Sir Joshua

The British art world of the middle and late 18th century was dominated by Sir Joshua Reynolds, one of England's greatest portrait painters and artistic theorists. Through his art and teaching, he attempted to lead British painting away from the indigenous anecdotal pictures of the early 18th century toward the grandiloquent formal rhetoric of the continental tradition of the "Grand Manner." In the *Discourses,* among the most important art critical writings of the time, he outlined the essence of grandeur in art and suggested the means of achieving it through rigorous academic training and study of the old masters of art.

Reynolds, self-portrait, oil painting. 1773. In the Royal Academy of Arts, London.

Joshua Reynolds was born on July 16, 1723, at Plympton in Devonshire. He was educated at the Plympton grammar school of which his father, a clergyman, was master. The young Reynolds became well read in the writing of classical antiquity and throughout his life was to be much interested in literature, counting many of the finest British authors of the 18th century among his closest friends. Influenced by the essays of the prominent English portrait painter Jonathan Richardson, Reynolds early aspired to become an artist, and in 1740 he was apprenticed for four years in London to Richardson's pupil and son-in-law, a conventional portraitist named Thomas Hudson. In 1743, he returned to Devon and began painting at Plymouth naval portraits that reveal his inexperience. Returning to London for two years in 1744, he began to acquire a knowledge of the old masters and an independent style characterized by bold brushwork and the use of impasto, a thick surface texture of paint, such as in his portrait of "Capt, the Hon. John Hamilton."

Italian influence

Back in Devon in 1746 he painted a large group portrait of the "Eliot Family" (c. 1746/47; Earl of St. Germans, Port Eliot, Cornwall), which clearly indicates that he had studied the large-scale portrait of the "Pembroke Family" (1634–35; Wilton House, Wiltshire) by the Flemish Baroque painter Sir Anthony Van Dyck (1599–1641), whose style of portrait painting influenced English portraiture throughout the 18th century. In 1749 he sailed with a friend to Minorca, one of the Balearic Islands off the Mediterranean coast of Spain. A fall from a horse detained him for five months and permanently scarred his lip—the scar being a prominent feature in his subsequent self-portraits. From Minorca he went to Rome, where he remained for two years, devoting himself to studying Italian art from ancient to his own times. Returning to England via Florence, Bologna, and Venice, he became absorbed by the compositions and colour of the great Renaissance Venetian painters of the 16th century: Titian, Jacopo Tintoretto, and Paolo Veronese. The Venetian tradition of atmospheric painting with its emphasis on colour and the effect of light and shading had a lasting influence on Reynolds, and, although all his life he preached the need for young artists to study the sculptural definition of form characteristic of Florentine and Roman painters, his own works are redolent of the Venetian style.

In 1753 Reynolds settled in London, where he was to live for the rest of his life. His success was assured, from the very first, and by 1755 he was employing studio assistants to help him execute the numerous portrait commissions he received. The early London portraits have a vigour and naturalness about them that is perhaps best exemplified in a likeness of "Hon. Augustus Keppel." The pose is not original, being a reversal of the "Apollo Belvedere," an ancient Roman copy of a mid-4th-century-BC Hellenistic statue he had seen in the Vatican. But the fact that the subject is shown striding along the seashore introduces a new kind of vigour into the tradition of English portraiture. In these first years in London, his knowledge of Venetian painting is very apparent in such works as the portraits of "Lord Cathcart" (1753/54; Trustees of Earl Cathcart, on loan to Manchester City Art Gallery, Lancashire) and "Lord Ludlow" (1755; Woburn Abbey, Bedfordshire). Of his domestic portraits those of "Nelly O'Brien" and of "Georgiana, Countess Spencer, and Her Daughter" (1761; Earl Spencer, Althorp, Northamptonshire) are especially notable for their tender charm and careful observation.

After 1760 Reynolds' style became increasingly classical and self-conscious. Falling under the influence of the classical Baroque painters of the Bolognese school of the 17th century and the archaeological interest in Greco-Roman antiquity that was sweeping Europe at the time, the pose and clothes of his sitters took on a more rigidly antique pattern, in consequence losing much of the sympathy and understanding of his earlier works.

Presidency of the Royal Academy

There were no public exhibitions of contemporary artists in London before 1760, when Reynolds helped found the Society of Artists and the first of many successful exhibitions were held. The patronage of King George III was sought, and in 1768 the Royal Academy was founded. Although Reynolds' painting had found no favour at court, he was the obvious candidate for the presidency, and the King confirmed his election and knighted him. Reynolds guided the policy of the academy with such skill that the pattern he set has been followed with little variation ever since. His yearly Discourses clearly mirrored many of his own thoughts and aspirations, as well as his own problems of line versus colour and public and private portraiture, and gave advice to those beginning their artistic careers.

From 1769 nearly all of Reynolds' most important works appeared in the academy. In certain exhibitions he included historical pieces, such as "Ugolino" (1773; Knole House, Kent), which were perhaps his least successful works. Many of his child studies are tender and even amusing, though now and again the sentiment tends to be excessive. Two of the most enchanting are "Master Crewe as Henry VIII" (1775–76; Lord O'Neil, London) and "Lady Caroline Scott as 'Winter' " (1778; Duke of Buccleuch, London). His most ambitious portrait commission was the "Family of the Duke of Marlborough (1777; Blenheim Palace, Oxfordshire).

In 1781 Reynolds visited Flanders and Holland, where he studied the work of the great Flemish painter of the Baroque style Peter Paul Rubens. This seems to have affected his own style, for in the manner of Rubens' later works the texture of his picture surface becomes far richer. This is particularly true of his portrait of the "Duchess of Devonshire and Her Daughter" (1786; Chatsworth House, Derbyshire). Reynolds was never a mere society painter or flatterer. It has been suggested that his deafness gave him a clearer insight into the character of his sitters, the lack of one faculty sharpening the use of his eyes. His vast learning allowed him continually to vary his poses and style. In 1782 Reynolds had a paralytic stroke and about the same time he was saddened by bickering within the Royal Academy. Seven years later his eyesight began to fail, and he delivered his last Discourse at the academy in 1790. On February 23, 1792, he died in London and was buried in St. Paul's Cathedral.

Social life

Reynolds preferred the company of men of letters to that of his fellow artists. Although his 14th Discourse (1788) is a tender and moving appreciation of his rival, the painter Thomas Gainsborough, who stood for so much that he himself disliked in painting, it was in the company of the lexicographer and author Dr. Samuel Johnson, the statesman and philosopher Edmund Burke, and the dramatist, novelist, and poet Oliver Goldsmith that Reynolds was happiest. When Goldsmith died, Reynolds could not bring himself to paint for a whole day, and a moving essay he wrote on his friend showed that he could write a portrait as well as he could paint one. Reynolds and his friends were members of The Club, which he established in 1764. He never married, and his house was kept for him by his sister Frances.

Reynolds' state portraits of the King and Queen were never considered a success, and he seldom painted for them; but the Prince of Wales patronized him extensively, and there were few distinguished families or individuals who did not sit for him. Nonetheless, some of his finest portraits are those of his intimate friends and of fashionable women of questionable reputation.

Unfortunately, Reynolds' technique was not always entirely sound, and many of his paintings have suffered as a result. After his visit to Italy, he tried to produce the effects of Tintoretto and Titian by using transparent glazes over a monochrome underpainting, but the pigment he used for his flesh tones was not permanent and even in his lifetime began to fade, causing the overpale faces of many surviving portraits. An example of this can be seen in the "Roffey Family" (1765; City of Birmingham Museum and Art Gallery). This paleness often has been increased by injudicious cleaning. In the 1760s Reynolds began to use more extensively bitumen or coal substances added to pigments. This practice proved to be detrimental to the paint surface. Though a keen collector of old master drawings, Reynolds was never a draftsman, and indeed few of his drawings have any merit.

MAJOR WORKS

"Captain the Honourable John Hamilton" (1746; Duke of Abercorn Collection, Ireland); "Lady Chambers" (1752; Iveagh Bequest, Kenwood House, London); "Honourable Augustus Keppel" (1753–54; National Maritime Museum, Greenwich, London); "Anne, Countess of Albemarle" (1757–59; National Gallery, London); "Nelly O'Brien" (1760–62; Wallace Collection, London); "Lord Ligonier" (1760; Tate Gallery, London); "Garrick Between Comedy and Tragedy" (1760–61; Lord Rothschild Collection, Rushbrooke, West Suffolk); "Mrs. Abingdon As 'The Comic Muse' " (1764–65; Waddesdon Manor, Buckinghamshire); "The Honourable Henry Fane with His Guardians, Inigo Jones and Charles Blair" (1766; Metropolitan Museum of Art, New York); "Mrs. Richard Hoare with Her Son" (1767–68; Wallace Collection, London); "Dr. Samuel Johnson" (1770–80; Tate Gallery, London); "William Robertson" (1772; Scottish National Portrait Gallery, Edinburgh); "Three Ladies Adorning a Term of Hymen" (1773–74; National Gallery, London); "Self-Portrait" (1773; Royal Academy, London); "St. John in the Wilderness" (1776; Wallace Collection, London); "The Infant Samuel" (1776; Tate Gallery, London); "Lady Bamfylde" (1776–77; Tate Gallery, London); "The Society of Dilettanti I & II" (1777–79; Society of Dilettanti, London): "Lady Elizabeth Delmé and Children" (1777; National Gallery of Art, Washington, D.C.): "John Musters" (1777–80; Museum of Fine Arts, Boston); "Colonel George Cousssmaker" (1782; Metropolitan Museum of Art, New York); "Sarah Siddons As the Tragic Muse" (1784; Huntington Art Gallery, San Marino, California); "Heads of Angels" (1787; Tate Gallery, London); "Selina, Lady Skipwith" (1787; Frick Collection, New York); "Lady Gertrude Fitzpatrick As 'Sylvia' " (1787; Museum of Fine Arts, Boston); "Lord Hcathfield, Governor of Gibraltar" (1788; National Gallery, London); "The Age of Innocence" (1788; Tate Gallery, London); "Mrs. Abbingdon As 'Roxalana' " (1788; Peter Vaughan Collection, London).

Reza Shah Pahlavi of Iran

An officer of the Iranian Army, who rose from the rank of private to that of general and finally became the sovereign of Iran, Reza Shah Pahlavi (name at birth Reza Khan) is regarded as having begun the regeneration of his country. He was officially granted the title of the "the Great."

Keystone

Reza Shah Pahlavi.

Reza Khan was born in 1878 in the village of Alasht in the Savadkuh district of Mazanderan province. He was of a family of chiefs of a clan named Pahlevan. After the death of his father, Col. Abbas Ali Khan, Reza's mother took him to Teheran, where he eventually enlisted as a private in an Iranian military unit under Russian instructors. Tall and powerfully built, the young soldier, from the beginning, showed an uncommonly strong will, remarkable intelligence, and a capacity for leadership. He was highly regarded by his seniors.

After centuries of misrule by its former rulers and the ravages of the war waged by foreign belligerents on its soil from 1914 to 1919, Iran in 1921 was prostrate, ruined, and on the verge of disintegration. The last of the *shāhs* of the Qājār dynasty, Ahmad Shah, was young and incompetent, and the Cabinet was weak and corrupt. Patriotic and nationalist elements had long been outraged at the domination of Iran by foreign powers, especially Great Britain and Russia, both of which had strong commercial and strategic interest in the country. This situation led Reza Khan to decide on an attempt at putting an end to the chaos by taking over power and forming a strong government, bolstered by an effective and disciplined military force. He contacted some young, progressive elements and on February 21, 1921, occupied Teheran at the head of 1,200 men. A young journalist, Sayyid Zia od-Din Tabatab'ai, became prime minister, while Reza Khan took command of all the military forces and was appointed minister of war a few weeks after.

Coup of February 1921

Reza Khan cherished the idea of regenerating the Iranian nation and leading it on the path of progress. Many had imagined that Reza Khan, whom they took to be an unsophisticated regimental officer, would be content with a high-sounding title and a sword of honour given by the Shah. But he was not about to step aside to allow a mixed group of inexperienced though sincere idealists and foreign-influenced opportunists to rule the country. His progress toward supreme power was extraordinarily rapid. Of a forbidding appearance, he talked very little and never revealed his intentions. Displaying great political talent against his opponents, he divided and weakened them. He also understood that to reach his ultimate objective he had to have complete control over a military force and that. that required money. Able to levy some taxes, he built up the army with the proceeds and then used the army to collect more taxes, until finally he had gained control over the entire country. As war minister, he was the real power behind several prime ministers in succession until 1923, when he became prime minister himself.

The sovereign, Ahmad Shah Qājār, was ill and undergoing a lengthy cure in Europe. In spite of the entreaties of Reza Khan and the speaker of the Majles (Iranian parliament), the Shah refused to return to Iran. Reza Khan then considered proclaiming a republic but was dissuaded by the strong opposition to the idea by the majority of the people. In 1925 the Majles deposed the absentee monarch, and a constituent assembly elected Reza Khan as *shdh*, vesting sovereignty *in* the new Pahlavi dynasty.

Policies as *shāh*

After his coronation in April 1926, Reza Shah continued the radical reforms he had embarked on while prime minister. He broke the power of the tribes, which had been a turbulent element in the nation, disarming and partly settling them. In 1928 he put an end to the one-sided agreements and treaties with foreign powers, abolishing all special privileges. He built the Trans-Iranian Railway and started branch lines toward the principal cities (1927–38). He emancipated women and required them to discard their veils (1935). He took control of the country's finances and communications, which up to then had been virtually in foreign hands. He built roads, schools, and hospitals and opened the first university (1934). His measures were directed at the same time toward the democratization of the country and its emancipation from foreign interference.

His foreign policy, which had consisted essentially of playing the Soviet Union off against Great Britain, failed when those two powers joined together in 1941 to fight the Germans. In order to be able to supply the Soviet forces with war material through Iran, the two allies jointly occupied the country in August 1941.

Reza Shah then decided to abdicate, to allow his son and heir, Mohammed Reza Shah, to adopt a policy appropriate to the new situation, and to preserve his dynasty. He wanted to go to Canada, but the British government sent him first to Mauritius and then to Johannesburg, South Africa, where he died in July 1944.

Rhamnales

The Rhamnales, or buckthorn order, is an order of flowering plants containing about 1,550 species in three families. General interest in this group rests primarily on the cultivated grape and the fruits known as jujubes. Both products have been consumed since prehistoric times in the Mediterranean countries. Tradition has it that Jesus' crown of thorns was fashioned from jujube twigs.

Bitropical distribution of Rhamnales plants

Scientific interest in the group is especially piqued by the number of genera (but no species) native to both Old World and New World tropics or subtropics. This kind of distribution is by no means rare, but the Rhamnaceae (buckthorn) and Vitaceae (grape) families are among the dozen families of flowering plants with the highest proportion of genera to be found in both tropical regions. Distributions such as these have yet to be satisfactorily explained, but at least they seem to give some evidence of great antiquity, perhaps 150,000,000 years or more according to some writers. It has been conjectured that such families probably arose before Cretaceous times (*i.e.*, more than 136,000,000 years ago), but there is no fossil evidence either to support or to undermine this opinion. In contrast to the Rhamnaceae and Vitaceae families, which are widely distributed in temperate and tropical regions, the Leeaceae family, comprising a single genus of about 100 species, is restricted to tropical areas from southern Asia to Africa.

General features. *Size range and diversity of structure.* Trees, shrubs, and woody vines predominate in the buckthorn order, herbaceous plants being extremely rare. Climbing plants are common. Perhaps the most bizarre forms encountered are the nearly leafless shrubs of *Colletia paradoxa* (Rhamnaceae family) of South America, whose short, opposite green twigs are modified to thick, laterally flattened thorns; this species is widely planted as a curiosity. The one notable tendency in the Rhamnaceae family is that of xeromorphism, meaning adaptation to a dry climate, which encompasses a syndrome of adaptations including reduced size of leaves, crowding of leaves, shortening of some branch axes, thorniness or spininess; and a low, shrubby, intricately branched habit. In the Vitaceae family the most notable tendency is that toward trailing and twining, in general a vine-like habit. There are no true aquatics, epiphytes, or parasites in the order.

Economic uses. Two important members of the buckthorn order that furnish edible products are the grape and the jujube. The grape (genus *Vitis,* family Vitaceae) has been a source of fresh and dried fruit and has been used in wine making in Mediterranean lands since prehistoric times. The jujubes (genus *Ziziphus,* family Rhamnaceae), spiny shrubs that abound in arid areas from the Mediterranean region eastward, also furnish fresh and dried fruit and their culture probably dates as far back as that of grape culture. Other species furnishing edible products include *Hovenia dulcis* (Rhamnaceae), widely grown in China and neighbouring countries; the stalks of the flower clusters are succulent and raisin-like. The fruits of species of *Sageretia* (Rhamnaceae) are eaten fresh in parts of India and China. The leaves of *Sageretia thea* furnish a substitute for tea in southern China.

Green and yellow dyes are obtained from the fruits of various Old World species of *Rhamnus* (Rhamnaceae). Two species of *Rhamnus* furnish the famous "Chinese green" or lokao dye, which is the only natural plant dye giving a green colour in cotton.

Laxatives are obtained from the berries and bark of species of *Rhamnus,* including the famous cascara sagrada from the North American *Rhamnus purshiana.*

The fruits of *Colubrina asiatica* (Rhamnaceae) of tropical shores and of the Mexican *Ziziphus amole* are used as soap.

Ornamental plants, other than shade trees, are rare in this order, owing to the usually small size and scattering of the flowers. But a number of species of the North and Central American genus *Ceanothus* (Rharnnaceae) are cultivated for their showy flower clusters and are sometimes called "wild lilac" or "French lilac." The Virginia creeper *(Parthenocissus quinquefolia,* family Vitaceae) is widely planted as a wall and ground cover.

Wood products

A number of kinds of plants from the Rhamnaceae family furnish useful timber. Perhaps the most important economically is the tropical African *Maesopsis eminii,* which is now widely planted in Indonesia and Malaya as well as Africa; the lumber is used in building houses and boats. The wood of the genus *Ziziphus* is often hard and dense. Among the Old World species the wood of *Ziziphus mauritiana* is used for houses and for furniture; that of *Z. spina-christi* and of *Z. jujuba* for cabinetmaking; of *Z. xylopyra* and *Z. mucronata* for making wagons, agricultural implements, etc. Two Jamaican species, *Z. sarcomphalus* and *Z. chloroxylon* yield good wood, the former for construction and the latter a hard, heavy, elastic wood excellent for all purposes. The wood of *Hovenia dulcis* is valuable for furniture and musical instruments. *Pomaderris apetala* of southern Australia is especially used in cooperage. Some West Indian species have such dense, strong wood that it is often called "ironwood" in the trade—for example, *Reynosia latifolia* and *Krugiodendron ferreum;* the latter, air-dried, has a specific gravity of about 1.42 and is, thus, one of the densest woods known. The wood of *Colubrina arborescens* is used in the West Indies; that of the related *Colubrina oppositifolia* is so dense and durable that it was used as money by the ancient Hawaiians. *Rhamnus cathartica* and *R. frangula* of Europe furnish limited quantities of high-quality wood for various small objects, lathework, and furniture, as do *Berchemia zeyheri* of Africa and the North American *Condalia hookeri.*

Representative plant structures of the order Rhamnales.

Natural history. Little is known of the natural history of the Rhamnales order. Of the few species that have been intensively studied in culture, it can only be said that their vital success seems to be related, at least in part, to a lack of specialization. Seed germination is rarely checked, but in those species widely cultivated it seems to be prompt and easily achieved. Seed dispersal is usually by means of animals attracted to the fruits, although some genera have winged fruits adapted to wind dispersal. Reproduction is primarily by sexual means, although root sprouting is not uncommon. Pollination, in spite of the drabness and small size of the flowers, is accomplished by insects, which apparently are attracted to the nectar of the flowers. Extraordinarily little is known of the identity of the pollinators. Various small wasps, flies, bugs, bees, beetles, butterflies, and moths have been observed to visit the flowers of various species of the Rhamnaceae and Vitaceae families, but the extent to which any one species accomplishes pollination is unknown. In contrast to the situation in some groups, birds, ants, bats, and wind and water currents apparently are never involved in the pollination process in the buckthorn order. Special soil characteristics or other environmental requirements, such as a dependency upon fires, have not been found in the Rhamnales order. In fact, the members of the order are apparently so diverse as to their habitat requirements or at least their preferences that no cogent generalization is possible on this subject, though it can be said that, on the average, tropical forested areas are favoured. Many members of the order occur in forests and many in low forests or scrubby vegetation or desertic scrub. Few occur in grasslands. Certain spiny jnjubes abound in some desertic and semidesertic scrub formations in the Old and New Worlds, but apparently nowhere does any member of the buckthorn order so dominate the vegetation that species of other groups are essentially excluded. While each species of the order seems to have a narrower range of habitat tolerances and preferences, the order, as a whole, ranges from exceedingly arid areas to rain forests and from sea level to elevations and latitudes near the perpetual snow line. Perhaps the most specialized habitat requirements are exhibited by *Colubrina* asiatica, which is restricted to tropical beaches. The seeds of this species are known to float unharmed in seawater for long intervals, and this apparently accounts for its dispersal to numerous islands scattered in a vast expanse of the Pacific Ocean.

Wide range of habitats

Form and function. Members of the buckthorn order share the distinction that the stamens, which are the male flower parts that produce the pollen, are exactly as numerous as the flower petals and, even more important, are attached opposite (just toward the floral axis from) the petal attachments. The number and placement of stamens as found in the buckthorn order, known as obstemony, is a relatively rare condition among flowering plants. This is another reason for the considerable botanical interest in these plants. In most groups in which the stamens are just as numerous as the petals, they are attached alternate to the petals; *i.e.*, nearly between them. Other characteristics that these plants share include a disk (a ring-shaped structure of several distinct masses of tissue) that is located toward the central axis from the stamen attachments (intrastaminal) and usually produces nectar. The ovules (immature seeds) are anatropous (*i.e.*, the micropyle or depression through which the pollen tube bearing the male sexual cells enters for fertilization is at the same end of the ovule as the stalk by which the ovule is attached), bitegmic (the micropyle is defined by a double flange of seed-wall tissue), and erect (they are attached at the bottom of the seed cavities of the ovary). Each of the cavities of the ovary has only one or two ovules.

Evolution. Fossil record. Numerous fossil leaf impressions and a lesser number of fossil woods, fruits, and seeds have been referred to this order. The oldest such remains are from Cretaceous Period beds (about 100,000,000 years old), but the most numerous are from younger beds, especially those of the Miocene and Pliocene Epochs (about 10,000,000 to 20,000,000 years old). Unfortunately, there is no single character or set of characters of the foliage that, beyond a shadow of a doubt, distinguishes leaves of this order from those of some other orders. None of the leaves has been found in organic connection with flowers or fruits. Thus, the assignments of fossils to the Rhamnaceae or Vitaceae families range in probability of correctness from high to infinitesimal. In general, the oldest fossils are of the most dubious identity, but even some of the most recent fossils are not certainly referred to the Rhamnales order. Numerous Cretaceous and early Tertiary leaf impressions (about 30,000,000 to 100,000,000 years old) previously referred to the genus *Ziziphus* have more recently been referred to *Cercidiphyllum*, which is not a close relative of the Rhamnales order. This illustrates the pitfalls of hasty assignment of fossil leaf impressions to modern kinds of plants. Fossils that are assignable to this order with a higher degree of probability have been found in Oligocene or younger beds (about 30,000,000 years old or less). By Miocene times (about 20,000,000 years ago), apparently both the Rhamnaceae and the Vitaceae families were large and diverse. This seems to indicate a much greater antiquity for both families, but it is impossible to trace them further back through the fossil record with any certainty. Evaluation and correlation of the fossil wood, fossil pollen, and fossil leaf evidence is not yet in a sufficiently advanced state to permit the presentation of a coherent evolutionary story.

Phylogeny. The idea that the buckthorns and the grapes are closely related dates at least as far back as 1671 and continues to be accepted by present-day botanists. The gathering consensus that the buckthorn and grape families have an especially close affinity by now amounts to a botanical act of faith. There have been important dissenters but relatively few. The placing together of the buchthorn and grape families (the latter including the genus Leea as a subfamily) as the narrowly construed order Rhamnales dates from 1892. Previously, these families had been associated at the ordinal level with families now placed variously in the Celastrales, Sapindales, Rutales, and Cornales orders. The assumption implicit in the close modern taxonomic placement of the families Rhamnaceae, Vitaceae, and Leeaceae is that they represent the products of a single ancestral population that was not the same as those from which plants of neighbouring taxonomic groups arose, though it may in turn, further back in time, have sprung from a population from which plants of neighbouring taxonomic groups also arose. This is thought by many to be a reasonable assumption, and, if it is accepted, then the relationships of such presumably closely related groups as the Sapindales and Celastrales orders can only be described as collateral to the Rhamnales order.

Relation of the buckthorn and grape families

Classification. *Distinguishing taxonomic* features. The following characters are especially useful to delineate groups within the order: the degree of lobing of the leaves; the presence or absence of a floral cup; the degree of bud closure by the calyx (sepals) or corolla (petals); the number of ovules per ovary cavity and the dorsal, lateral, or ventral placement of the raphe (a ridge along the ovule); the formation of the micropyle either by the inner or outer integument; the nature of the fruit, and, especially, whether the endocarp is soft or indurated; and the relative size of the embryo to the seed.

The classification below is generally acceptable as a reflection of current taxonomic thought (see, however, the remarks at the end). None of the families is of doubtful affinity except insofar as the question of the mutual affinity of the two suborders is concerned.

Annotated classification.

ORDER RHAMNALES

Giant trees, large woody vines or lianas to subshrubs or weak vines, rarely herbs (annual herbs in only 1 species, the Guatemalan *Crumenaria steyermarkii* of the Rhamnaceae family); tendrils often present. Leaves simple or palmately compound or rarely twice or thrice pinnately compound; stipules usually present. Inflorescence (the arrangement of the flowers) basically cymose, but the cymes commonly aggregated into 2nd-order inflorescences of various shapes, and these usually leafless or nearly so, occasionally the cymes so reduced that the flowers are merely fasciculate (clustered) or even solitary. Flowers small, rarely more than 5 mm in diameter, rarely brightly coloured (exceptions in *Ceanothus* and Leea), radially symmetrical, 4- or 5-merous (parted, lobed), hypogynous, perigynous, or epigynous (*i.e.*, the floral parts arise at the base of, from a cuplike organ around, or from the top of the ovary, respectively), perfect, polygamous, or dioecious (*i.e.*, flowers have both sexes in 1 flow-er, or on 1 plant there are separate flowers of either sex, or there are separate plants containing flowers all of 1 sex or the other). Sepals free or less commonly joined in the lower part and never overlapping even in bud. Petals rarely any other colour than white, pale yellow, or cream colour, as numerous as sepals and alternate with them, free or uncommonly joined to each other along the margins in the distal moiety (in which case the corolla falls as a unit just before anthesis) or (in *Leea*) forming a short tubular corolla, or petals rarely absent. Stamens as numerous as sepals and alternate with them; anthers minute, usually opening toward the central axis of the flower (introrse), filaments thin, usually inbowed in bud and rarely exceeding the petals in length; pollen production not copious, the pollen binucleate (rarely trinucleate) when shed, usually tricolporate (having 3 equidistant germinal grooves) and angulapertuate, the outer wall being usually, perhaps always, reticulate. Intrastaminal disk present, usually producing nectar, either lining or filling the cup in perigynous flowers or usually lobed and closely associated with the ovary or along with the filaments forming a tube. Gynoecium (female flower parts) of a single pistil (ovary, style, and stigma, the female structure) of 2 or 3, less commonly 4, rarely up to 8 carpels; locules (chambers) as numerous as carpels or fewer by abortion; each locule with 1 or 2 basal, erect, anatropous, bitegmic ovules; the dicotyledonous embryo straight, flat or nearly so, embedded in abundant, firm to corneous endosperm; fruit various, never very large, averaging from a few millimetres to a few centimetres in maximum dimensions. Two suborders, 3 families, about 59 genera and 1,550 species in tropical and temperate regions.

Suborder Rhamnineae

Leaves simple and unlobed; flowers with a floral cup at the rim of which are borne the sepals, petals, and stamens, this floral cup either free (and the flower then perigynous) or its lower part joined to the gynoecium and the flower then epigynous; calyx (sepals) valvate and enclosing the corolla (petals) in bud; petals never exposed in bud, never valvate, smaller than the sepals, occasionally absent; disc never deeply lobed and always intimately associated with or lining the floral cup; anthers usually introrse, rarely extrorse (opening outwards, away from floral axis); ovule usually 1 per locule with a dorsal or lateral raphe; micropyle usually formed by the outer integument; fruit a schizocarpous (splitting apart into 1-seeded units) capsule or dry or fleshy drupe (a "stone-seeded" fruit), with the endocarp always indurated or at least cartilaginous, never a berry; embryo of seeds usually large, the endosperm very rarely lobed or ruminate.

Family Rhamnaceae

Trees, shrubs, seldom vines, rarely herbs, with monopodial (having a main axis) growth and with the subordinal characters given above; distributed in all temperate and tropical regions. About 45 genera and 850 species.

Suborder Vitineae

Leaves simple and deeply lobed or commonly palmately or pinnately compound; flowers hypogynous (floral cup absent); calyx reduced, never valvate and never enclosing the bud; petals never absent, much larger than the calyx, valvate, and closed over the stamens, disc, and pistil in bud; disc usually deeply lobed (the lobes alternate with the petals) and intimately associated with the basal part of the ovary; anthers introrse or extrorse; ovules 1 or 2 in each locule, with a ventral raphe; micropyle formed by the inner integument; fruit always a berry, usually soft, seldom firm, rarely hard, and with the endocarp of the same texture as the rest; embryo of seeds usually comparatively small and embedded in the endosperm near the rnicropyle; endosperm lobed or in a few members even ruminate.

Family Vitaceae

Woody vines or lianas, seldom shrubby or treelike; tendrils usually present; growth sympodial (with an apparent main axis not produced from a terminal bud but from one fork of a dichotomy, the other being suppressed); stipules present; petioles never winged in the lower part; leaves simple and deeply lobed or commonly palmately compound, rarely pinnate; inflorescences often "lateral" (*i.e.*, terminal on the short axes that appear lateral because of the sympodial habit); petals either free and persistent or else joined marginally in their upper moieties in which case the corolla falls as a unit just prior to anthesis; filaments free; lobes of disc never equalling filaments in length; anthers introrse; locules of ovary 2 (rarely 3), each with 2 ovules; endosperm lobed, rarely ruminate. About 12 genera and 600 species, widely distributed in temperate and tropical regions.

Family Leeaceae

Shrubs or subshrubs, rarely small trees, never lianas; tendrils absent; growth monopodial; stipules absent; petioles winged in their lower part; leaves simple or twice or thrice pinnately compound; inflorescences always terminal; petals joined marginally in their lower moieties, the corolla persistent at least until after pollination; a tube or corona formed partially by the lower parts of the filaments and apparently partially by disc-lobe tissue is united to the corolla tube at base, becoming free and prolonged above, approximately equalling the anthers in elevation, and adaxially bearing an annular flange; upper parts of filaments free; anthers at first appearing introrse because of inbowing of filaments over the corona, but later erect and definitely extrorse; locules of ovary 3 to 8, rarely 2, each with 1 ovule; endosperm ruminate. One genus (Leea) and about 100 species, in tropical areas from Africa to southern Asia.

Critical appraisal. The internal coherence and assumed origin from a single ancestral population of each of the three families circumscribed above is unquestioned. Also, most authorities consider the Vitaceae and Leeaceae families to be naturally and closely associated, although it has been recently suggested that the family Leeaceae has as much in common with the Rhamnaceae family as it has with the Vitaceae family. The Leeaceae family, however, is probably a specialized derivative of the Vitaceae.

The internal coherence of the Rhamnales order as a whole, however, is not such as to convince all taxonomists that their close association at the ordinal level, and their segregation from other orders such as Sapindales, are required. Nor will the careful phylogenist find it necessary to postulate a common origin short of that which is common to various other orders such as Sapindales, Rutales, etc. Erect ovules and tricolporate pollen (pollen with three equidistant germinal grooves) are scarcely rare in such other orders, and obstemony could easily have arisen in two or more diplostemonous ancestors (*i.e.*, ancestors with two series of stamens, one series opposite, and one series alternate with, the petals).

The true measure of the interrelatedness of Rhamnaceae, Vitaceae, and Leeaceae families and the various groups with which they have been associated in the last 200 years is perhaps indicated by the gathering consensus that all these plants were derived ultimately from plants similar to some of the more primitive members of the Rosidae subclass. The character combinations by which families of the loosely coherent Celastrales, Sapindales, and Rutales orders are distinguished from one another are often of about the same magnitude and diversity as those which distinguish the Rhamnaceae family from the Vitaceae and from the Leeaceae families.

In fact, the suggestion is not at all far fetched that the ancestors of the Rhamnaceae may be found in the vicinity of the Rosales order, whereas those of the suborder Vitineae (including Vitaceae and Leeaceae families) may be found, as suggested by some authorities, in the neighbourhood of the ancestors of the Sapindales and Celastrales orders, that is to say, near Saxifragales order.

If this suggestion is accepted as having greater probability of correctness than the widespread assumption of a rather approximate common ancestry of the families here included in the Rhamnales order, then the taxonomic action indicated is the dismemberment of the traditional Rhamnales group. The Rhamnaceae family would then be referred to the Rosales order, and the suborder Vitineae either to the Saxifragales or to the Sapindales or, more likely, placed near these two orders as a distinct order, Vitales.

Rheinland-Pfalz

Rheinland-Pfalz, in English Rhineland-Palatinate, the sixth largest *Land*, or state, of the Federal Republic of Germany, has had a long history of division and possession by foreign powers. The modern state was created only after World War II and is therefore still reworking its economy. industry has overtaken agriculture as the primary wage earner, and trade links with the rest of West Germany have been forged and strengthened.

The state is bordered by the states of Nordrhein-Westfalen to the north, Hessen and Baden-Württemberg to the east, and Saarland to the southwest, and by the countries of France, Luxembourg, and Belgium to the south and west. It covers 7,659 square miles (19,838 square kilometres), an area about the size of Israel. The population of 3,645,000 represents 6 percent of the inhabitants of West Germany. its capital is Mainz, one of the oldest German cities.

The border of Rome

History. The oldest archaeological remains of the region are tools from the Stone Age that are at leas? 100,000, and may be as much as 300,000, years old. During the Neolithic Period between 3000 and 1800 BC, large areas along the Rhine were settled by Celts and Germanic peoples. Incorporated into the Roman Empire in the 1st century BC, the Rhineland formed the northeastern border region of the Gallic Provinces for about 500 years. The cities of Moguntiacum (Mainz), Augusta Treverorum (Trier), and Colonia Agrippinensis (Cologne) were founded during the Roman period. From the 5th to the 9th centuries AD, the Rhineland belonged to the frankish kingdom of the Merovingians and later the Carolingians. In 843 the kingdom was divided in half, and the Rhineland became the western border region of the East Frankish or German kingdom. During this period, the region was fractured into a large number of small independent states with temporal and religious governments. The most powerful of these states were the archdioceses of Trier, Cologne, and Mainz and the Rhenish Palatinate, which was ruled from the 13th century by the Bavarian Wittelsbach dynasty.

Incorporation into the French Rhine

The Reformation of the 16th and 17th centuries saw further territorial division that originated in the religious conflicts of Protestantism, Catholicism, and Calvinism and led to the Thirty Years' War (1618–48). Foreign nations—particularly Bavaria, Spain, Austria, Sweden, and France—determined the political development of the Rhineland. In the 17th and 18th centuries the Palatinate had close political and cultural ties with France. According to the truce of Campo Formio on October 17, 1797, the lands to the west of the Rhine were incorporated into the French territories, the individual states were dissolved, and religious possessions were secularized. In 1815 the Rhineland became a part of the newly founded German Confederation, and the region was divided by the Congress of Vienna of 1815 among Prussia, Bavaria, Hesse-Darmstadt, and Hesse-Nassau. After World War II, the region was again divided by order of the American, French, and English military governments, and the Rhineland-Pfalz was created.

The landscape. ***Relief.*** The northern portion of the state consists of woodlands and cultivated fields that are crossed by deeply eroded river valleys. Part of the Rhine Massif, its average elevation lies between 1,300 and 1,900 feet. The Rhine River crosses the region from the southwest to the northeast and receives the Moselle from the southwest and the Lahn from the northeast. The rivers effectively create four distinct regions—the Hunsriick, Eifel, Westerwald, and Taunus.

The southwestern region, bordered on the north by the Nahe River, is broken by the Saar-Nahe Mountains and the escarpments of the Pfalzer Wald, a national forest. Open cultivated areas of heavy clay and marl (loose clay containing calcium carbonate) soils alternate with large wooded areas of porphyry (dark-red, mineral-bearing rocks) and sandstone. In contrast, the southeast contains the treeless Rhein-Hesse Plateau and the Rhine Rivet Valley. The plateau is composed of limestone that is covered by loess (a brownish mixture of clay, silt, and sand deposited by the wind), while the valley contains fertile alluvial soils.

Climate. At Mainz the average annual temperature is 50° F (10" C) and the average yearly rainfall is 20 inches. Regional variations occur, however: the northwestern part of the Eifel has an average annual temperature of 42" F (5.6" C) and an average yearly rainfall of 31 inches.

Settlement. The settlement pattern is characterized by very old, irregularly structured villages with mostly consolidated fields in the regions of favourable soil and climate, and by villages and hamlets in the mountains. In the mid-20th century, the function of the rural settlements changed from that of purely agrarian communities to dormitory towns containing a large number of commuters. The most important cities are Mainz, Ludwigshafen, Koblenz, Trier, Kaiserslautern, Worms, Pirmasens, and Neustadt an der Weinstrasse.

A changing population

The people. Although the majority of the population is of Frankish descent, the turbulent history of the Rhineland has produced a complex social structure that has also been influenced by Romanic (*i.e.*, French and Italian) origins. The latest influence has been that of the 403,000 refugees who have migrated from middle and east Germany since 1945 and comprise about 12 percent of the total population of 3,645,000. Over 56 percent of the people are Roman Catholic and about 42 percent are Protestant. The population has an annual rate of increase of 0.7 percent that is due to both natural increase and immigration. The immigrants are primarily foreign workers from Italy, France, Turkey, Spain, Yugoslavia, and Greece who enter Rheinland-Pfalz through the surrounding German states. The average population density of 480 persons per square mile is considerably lower than that for the entire nation; the greatest—over 800 persons per square mile—is in the large river valleys where the main cities are located, while the sparsely populated highlands support under 150 persons per square mile. There is a constant emigration from the rural areas to the urban regions, but this rural exodus is on a much smaller scale than in the rest of western Germany. In the early 1970s half the people lived in communities of under 5,000, and only 18 percent lived in cities of over 100,000.

Economy. Rheinland-Pfalz is one of the poorest of West German states. In the late 1960s, however, the rate of increase of the economy was higher than that of the rest of the country. The total gross national product of 30,000,000,000 Deutsche Marks (DM. 3.22 = $1 U.S.; DM 8.37 = £1 sterling, on December 31, 1971) in 1969 derived from several sources—50 percent came from secondary industry, 28 percent from services, 16 percent from commerce and transportation, and 6 percent from agriculture.

Agriculture. In the early 1970s about 17 percent of the employed population was engaged in agriculture. The number of farm workers and of small farms was constantly decreasing, while the number of large farms was growing steadily. In the most fertile agricultural regions of the Neuwied Basin, Bitburg, Rhinehessen, and the eastern Palatinate, potatoes, cereals, and sugar beets are the primary crops. In the less fertile highlands, however, stock farming is more important. The state is known for the many specialized crops of the river valleys. Besides the growing of fruit and tobacco, viticulture occupies a predominate place in the agriculture of the state, and the famous vineyards along the Rhine, Moselle, and Nahe rivers produce over 75 percent of West Germany's wines.

New industries

Industry. The pumice quarries of the Neuwied Basin represent the state's only important natural resource. The largest activities are the chemical industry in Ludwigshafen, Ingelheim, and Mainz and the engineering industry in Bad Kreuznach, Frankenthal, and Kaiserslautern. Over one-third of the nation's shoes are produced in Pirmasens, and 88 percent of West Germany's trade in precious stones is carried on in the town of Idar-Oberstein. An important tourist industry has developed in the middle Rhiie area.

In 1970 over 40 percent of the gross national product, or GNP, derived from commerce and services, and about 50 percent of the employed population was thus engaged. The centres of industry and administration are also the most important places for such activities.

Transportation. The most important transportation routes are the navigable waterways of the Rhine and the Moselle. In order to meet increasing demands, the Rhine is to be deepened in the 1970s. All of the main railways follow the Rhine Valley, and most of the less important junctions are to be discontinued. The primary highways also run from north to south. Roads, existing or planned, from Ludwigshafen to Saarbrucken, from Koblenz to Trier, and the Hunsriick Highway all join the primary routes.

Administration and social conditions. The state is divided into the three *Regierungsbezirke* (administrative districts) of Koblenz, Trier, and Rheinhessen-Pfalz. The legislative body, the Landtag, is composed of 100 deputies elected by the people every four years. The Landtag appoints a prime minister, who in turn appoints seven ministers. Under the state's judicial system, civil and criminal cases are tried by the provincial court of appeal and the county courts. There are also special courts for social, financial, and administrative problems, while the constitutional court deals with the legality of laws and administrative measures. Education is also subject to the sovereignty of the state. All children from six years of age are obliged to attend grammar school for four years. The student may then choose to attend five more years of *Hauptschule*, or common school; six years of *Realschule*, which qualifies him to enter technical schools; or nine years of *Gymnasium*, where a classical and scientific education are offered. Only from this school is entrance to the University possible. There are universities at Mainz (Johannes Gutenberg-Universitat) and Trier and Kaiserslautern (Universitat Trier-Kaiserslautern). Teachers for the primary schools are educated in the departments of special education universities. There are several technical schools, a university for the science of administration at Speyer (Hochschule fur Verwaltungswissenschaften), and academies for arts and sports that are a part of the university in Mainz. There are about 240 public and private hospitals in the state.

Cathedrals and festivals

Culture. The state's rich cultural tradition is reflected in the cathedrals at Speyer, Worms, and Mainz. The many museums include the Historische Museum der Pfalz ("Historical Museum of the Palatinate") in Speyer, the Rheinisches Landesmuseum ("State Museum of the Rhine") in Trier, and the Romisch-Germanisches Zentralmuseum ("Roman-Germanic Central Museum") and the World Museum of the Art of Printing (Gutenberg-Museum) in Mainz. National traditional festivals take place annually, highlighted by the pre-Lenten carnival in Mainz. There are theatres in Mainz, Trier, Koblenz, and Kaiserslautern. The academy of sciences and the Rheinisch-Naturforschende Gesellschaft ("Natural Research Society of the Rhine") promote scientific research. The large cities contain printing offices for 26 daily papers, with a circulation of 630,000. Mainz is the seat of a studio of the Southwestern German Broadcasting and the Second German Television networks.

Prospects for the future. The future prosperity of the Rheinland-Pfalz depends on its growing strength as an industrial state. New businesses and manufacturers are needed to absorb the influx of foreign immigrants to the cities, while the growth of commercial farming prompts internal movements to the urban centres. Improved communications and transportation routes with the rest of the country will aid in the future success of the economy. Although federal plans exist for another redivision of the state, it is apparent that the region is becoming a viable political and economic unit.

(O.Ka.)

Rhetoric

The term rhetoric has traditionally applied to the principles of training communicators—those seeking to persuade or inform others; in the 20th century it has undergone a shift of emphasis from the speaker or writer to the auditor or reader. This article will deal with the subject of rhetoric in both its traditional and its modern forms. For related information on the techniques of language in poetical contexts, see the article PROSODY. Rhetorical techniques are also discussed in the articles ARTS, CRITICISM OF THE; LITERARY CRITICISM; and LITERATURE, NONFICTIONAL PROSE.

Rhetoric in literature

THE NATURE AND SCOPE OF RHETORIC

Function of rhetoric

Traditional and modern rhetoric. From the traditional point of view, rhetoric might be limited to the insights and terms developed by rhetors, or rhetoricians, in the Classical period of ancient Greece, about the 5th century nc, to teach the art of public speaking to their fellow citizens in the Greek republics and, later, to the children of the wealthy under the Roman Empire. Because some sort of public performance was regarded as the highest reach of education proper, rhetoric as a discipline or as a principle of pedagogy and learning was at the centre of the educational process in western Europe for some 2,000 years—until well into the 19th century, as a matter of fact. *Institutio oratoria* (before AD 96; "The Training of an Orator"), by the ancient Roman rhetorician Quintilian, perhaps the most influential textbook on education ever written, was in fact a book about rhetoric. Inevitably, there were minor shifts of emphasis in so long a tradition, and for a long time even letter writing fell within the purview of rhetoric; but it has consistently maintained its emphasis upon creation, upon instructing those wishing to initiate communication with other men.

The mark of modern rhetoric, on the other hand, is its shift of focus to the auditor or reader. From the beginning, of course, literary criticism borrowed from rhetoric—stylistic terms such as antithesis and metaphor were invented by Classical rhetoricians. When language became a subject of sustained scholarly concern, as it has in the 20th century, it was inevitable that scholars would turn back to Classical theories of rhetoric for help. But modern rhetoric is far more than a collection of terms borrowed from Classical rhetoricians. The perspective from which it views a text is different from that of other disciplines, History, philosophy, literary criticism, and the social sciences are very apt to view a text as though it were a kind of map of the author's mind on a particular subject. The rhetorician, accustomed by his traditional discipline to look at communication from the communicator's point of view, regards the text as the embodiment of an intention, a design—not as a map. He knows that that intention in its formulation is profoundly affected by its audience. He knows, also, that the structure of a piece of discourse, the way its major parts fit together, is profoundly a result of its intention. A concern for audience, for intention, and for structure is, then, the mark of modern rhetoric. As a study or discipline, educational principle, or body of theory, modern rhetoric is as involved with the process of interpretation, or analysis, as it is with the process of creation, or genesis.

The situations of a message

In these two processes, the perspectives are similar. Rhetorical analysis is actually an analogue of traditional rhetorical genesis: both view a message through situations—the situation of the auditor or reader as well as the situation of the speaker or writer. Both view the message itself as compounded of elements of time and place, motivation and response. **A** text must reveal its context—that insistence automatically makes a rhetorician of the literary critic or interpreter and distinguishes his approach from the other kinds of verbal analysis. A group of literary critics that came into prominence around World War 11—the "New Critics"—insisted upon isolating, or abstracting, the literary text from the mind of its creator and from the milieu of its creation, but they found themselves unable to abstract it from the situation of its reader. Certain modern critics have joined with rhetoricians in denouncing the folly of all such attempts at abstraction. When modern man interprets any text—say a speech by Elizabeth I of England at Tilbury, Essex, or a play by the great Hindu poet of the 5th century, Kālidāsa—he must imaginatively re-create the original situation of that text as well as endeavour to understand those factors that condition his present understanding.

Moreover, all discourse now falls within the rhetorician's purview. The traditional rhetorician, even when his efforts are directed toward interpretation, is primarily concerned with oratory or with those forms of nonfictional prose that might have a didactic or persuasive intent. But the modern rhetorician identifies rhetoric more with critical perspective than with artistic product. In part, he justifies expanding his concerns into other literary provinces on the basis of a striking change that has occurred in thinking about the very nature of man's reason itself. Modern philosophers of the Existentialist and Phenomenologist schools, while seeking a way out of the oftentimes false dilemmas posed by traditional philosophical approaches, have strongly challenged the assumptions whereby such dualities as knowledge and opinion, persuasion and conviction, reason and emotion, rhetoric and poetry, and even rhetoric and philosophy have in the past been distinguished. The old line between the demonstrable and the probable has become blurred. According to these modern philosophers, man's basic method of judgment is argumentation, whether in dialogue with others or with a text, and the results are necessarily relative and temporal. Such modern philosophers again and again use legal battles in a courtroom as basic models of the process every man goes through, or should go through, in acquiring knowledge or opinion of any phenomenon. For some, philosophy and rhetoric have become conflated, with rhetoric itself being a further conflation of the subject matter Aristotle discusses not only in his *Rhetoric* but also in his *Topics,* which he had designed for dialectics, for disputation among experts. According to this view, a philosopher, like any lawyer or giver of knowledge, is engaged in a rhetorical transaction seeking to persuade through a dialogic process first himself and then, by means of his utterance, others. It is in something like this "argumentative" light that a rhetorically trained reader or auditor interprets all texts—philosophical, oratorical, poetical—and justifies their inclusion within the province of rhetoric.

Thus, having shifted its focus from the communicator to the communicant and having been profoundly influenced by the temper of modern intellectual movements, rhetoric has come to be understood less as a body of theory or as certain types of artificial techniques and more as an integral component of all human discourse. As a body of discursive theory, rhetoric has traditionally offered rules that are merely articulations of contemporary attitudes toward certain kinds of prose—perhaps that is the most charitable interpretation of the 17th-century English satirist Samuel Butler's charge that "all a rhetorician's rules/ But teach him how to name his tools." In this view rhetoric has tended to be identified with orations in which the specific intent to persuade is most obvious. But modem rhetoric is limited neither to the offering of rules nor to studying topical and transient products of controversy. Rather, having linked its traditional focus upon creation with a focus upon interpretation, modern rhetoric offers a perspective for discovering the suffusion of text and content inhering within any discourse. And for its twin tasks, analysis and genesis, it offers a methodology as well: the uncovering of those strategies whereby the interest, values, or emotions of an audience are engaged by any speaker or writer through his discourse. The perspective has been denoted with the term situation; the methodology, after the manner of certain modern philosophers, may be denoted by the term argumentation. It should be noted at the outset that one may study not only the intent, audience, and structure of a discursive act but also the shaping effects of the medium itself on both the communicator and the communicant. Those rhetorical instruments that potentially work upon an audience in a certain way, it must be assumed, produce somewhat analogous effects within the writer or speaker as well, directing and shaping his discourse.

Figures of speech

Elements of rhetoric. For the tasks imposed by the rhetorical approach some of the most important tools inherited from antiquity are the figures of speech: for example, the metaphor, or comparison between two ostensibly dissimilar phenomena, as in the famous comparison by the 17th-century English poet John Donne of his soul and his mistress's to the legs on a geometer's compass in his "A Valediction: Forbidding Mourning"; another is the allegory, the extended metaphor, as in John Bunyan's classic of English prose *Pilgrim's Progress* (1678, 1684), wherein man's method of earning Christian salvation is compared to a road on which he journeys, and the comparison is maintained to such an extent that it becomes the central structural principle of the entire work. Such figures may be said to pertain either to the texture of the discourse, the local colour or details, or to the structure, the shape of the total argument. Ancient rhetoricians made a functional distinction between trope (like metaphor, a textural effect) and scheme (like allegory, a structural principle). To the former category belong such figures as metaphor, simile (a comparison announced by "like" or "as"), personification (attributing human qualities to a nonhuman being or object), irony (a discrepancy between a speaker's literal statement and his attitude or intent), hyperbole (overstatement or exaggeration) or understatement, and metonymy (substituting one word for another which it suggests or to which it is in some way related—as part to whole, sometimes known as synecdoche). To the latter category belonged such figures as allegory, parallelism (constructing sentences or phrases that resemble one another syntactically), antithesis (combining opposites into one statement—"To be or not to be, that is the question"), congeries (an accumulation of statements or phrases that say essentially the same thing), apostrophe (a turning from one's immediate audience to address another, who may be present only in the imagination), enthymeme (a loosely syllogistic form of reasoning in which the speaker assumes that any missing premises will be supplied by the audience), *interrogatio* (the "rhetorical" question, which is posed for argumentative effect and requires no answer), and *gradatio* (a progressive advance from one statement to another until a climax is achieved). However, a certain slippage in the categories trope and scheme became inevitable, not simply because rhetoricians were inconsistent in their use of terms but because well-constructed discourse reflects a fusion of structure and texture. One is virtually indistinguishable from the other. Donne's compass comparison, for example, creates a texture that is not isolable from other effects in the poem; rather, it is consonant with a structural principle that makes the comparison both appropriate and coherent. Above all, a modern rhetorician would insist that the figures, like all elements of rhetoric, reflect and determine not only the conceptualizing processes of the speaker's mind but also an audience's potential response. For all these reasons figures of speech are crucial means of examining the transactional nature of discourse.

Rhetoric of or in a discourse. In making a rhetorical approach to various discursive acts, one may speak of the rhetoric *of* a discourse—say, Robert Browning's poem "My Last Duchess" (1842)—and mean by that the strategies whereby the poet communicated with his contemporaries, in this case the Victorians, or with modern man, his present readers; or one may speak of the rhetoric *in* a

The three voices of discourse

discourse and mean by that the strategies whereby the persona, the Duke of Ferrara who speak's Browning's poem in dramatic-monologue fashion, communicates with his audience in the poem, in this case an emissary from the father of Ferrara's next duchess. The two kinds of rhetoric are not necessarily discrete: in oratory or in lyric poetry, for example, the creator and his persona are assumed to be identical. To a degree Aristotle's distinction between the three voices of discourse still holds. A poet, according to Aristotle, speaks in his own voice in lyric poetry, in his own voice and through the voices of his characters in epic (or narrative), and only through the voices of his characters in drama. Thus, the speaker of oratory or of most nonfictional prose is similar to the lyric speaker, with less freedom than the latter either to universalize or to create imaginatively his own audience.

RHETORICAL TRADITIONS

Although knowledge of rhetorical traditions is essential to the modern student's work, it must be borne in mind that he is nonetheless divorced from those traditions in two important ways. First, there is an almost exclusive emphasis upon the speaker or writer in traditional rhetoric; and, second, there is an implicit belief that the truth can be detached from the forms of discourse and can be divided into the demonstrable and the probable. In both of these respects, modern rhetorical practice differs.

Ancient Greece and **Rome.** Since the time of Plato it has been conventional to posit a correlative if not causal relationship between rhetoric and democracy. Plato located the wellsprings of rhetoric in the founding of democracy at Syracuse in the 5th century BC. Exiles returning to Syracuse entered into litigation for the return of their lands from which they had been dispossessed by the overthrown despotic government. In the absence of written records, claims were settled in a newly founded democratic legal system. To help litigants improve their persuasiveness, certain teachers began to offer something like systematic instruction in rhetoric.

In this experience at Syracuse, certain identifiable characteristics become prototypal: the rhetor, or speaker, is a pleader; his discourse is argumentative; and his audience are participants in and judges of a controversy. Later, in Athens, these characteristics began to aggregate to themselves some serious intellectual issues.

Role of the Sophists in Athens

In Athens early teachers of rhetoric were known as Sophists. These men did not simply teach methods of argumentation; rather, they offered rhetoric as a central educational discipline and, like modern rhetoricians, insisted upon its usefulness in both analysis and genesis. With the growth of Athenian democracy and higher systematized education, the Sophists became very powerful and influential. Today the word sophistic refers to a shabby display of learning or to specious reasoning; it refers, consequently, to an image of the Sophists that resulted from the attacks upon them led by such reformers as Plato. The ideal rhetoric proposed by Socrates in Plato's dialogue the *Phaedrus,* however, is itself not unlike the ideal sought by the Sophists in general, Isocrates in particular. Though the Platonic-Socratic ideal is more specialized in its focus on creating discourse, nonetheless, like the Sophistic ideal, it sought a union of verbal skills with learning and wisdom. Specifically, Platonic-Socratic rhetoric became a means of putting into practice the wisdom one acquires in philosophy. In this way Plato and Socrates resolved one of the most serious intellectual issues surrounding the subject: the relationship between truth and rhetorical effectiveness. The resolution, of course, presupposes and maintains a bifurcation between the two.

Aristotle's contributions to rhetoric

Aristotle, too, presupposed and maintained the same division between truth, which was knowable to varying degrees of certainty, and verbal skills, which for Aristotle were primarily useful in assisting truth to prevail in a controversy. But Aristotle lived in a world different from Plato's, one that was closer to the present in the premium it placed upon literacy and upon those patterns of thought that literacy encourages. The literate function of Aristotle's brilliance at recording and categorizing is well captured in Donne's phrase, "Nature's Secretary." Aristotle's *Rhetoric* both recorded contemporary practice and sought its reform through fitting it into its proper category among the arts. One of the masterstrokes of Aristotle's thought on the subject is his teaching that rhetoric itself is not a productive art of making but is an art of doing, embodying a power which is employed in certain kinds of speaking. Further evidence of his brilliance on the subject is his division of speaking into the forensic, the deliberative, and the epideictic and of persuasive appeals into the ethical, the emotional, and the logical. His division of speaking into three kinds reflects his efforts to distinguish rhetoric and its counterpart, dialectics, from philosophy and science. Rhetoric and dialectics, he felt, are concerned with probable matters, in which there are several roads to truth; philosophy and science, on the other hand, are concerned with demonstrable matters, in which the roads are fewer but the truth more certain. In dividing persuasive appeals into three kinds, Aristotle indicated an unmistakable preference for the logical. This preference has been interpreted variously as a result of Aristotle's naive assumption about the rationality of most audiences and as 'an attempt to reform the emotionally charged rhetoric of his contemporaries. In discussing elements of style, Aristotle treated metaphor, perhaps the major figure of speech, in a way that was to plague rhetoricians and poets for centuries. He describes it not as an instrument of thought but as an ornamentation, an adornment that at best serves the functions of clarity and vividness. The effect is further reflection of the principle noted earlier: for Aristotle the truth with which rhetoric is concerned is not demonstrable. It is, moreover, detachable from the forms of argument, and it can be tested by such analytical means as dialectics, which is the counterpart of rhetoric but which does not have what Aristotle viewed as rhetoric's cloying concerns with that beast of many heads, the heterogeneous audience composed of experts and laymen alike.

Rhetorical issues in the age of Quintilian

The Sophistic doctrine that rhetoric should be the central discipline in the educational scheme had a long history, rising to its fullest statement in the writings of Quintilian in Rome of the 1st century AD. By the age of Quintilian three intellectual issues had become firmly fixed within the orbit of rhetoric. Two of these were consciously faced: (1) the relationship between truth and verbal expression and (2) the difficulties of achieving intellectual or artistic integrity while communicating with a heterogeneous audience. In a sense, both of these issues were not faced at all but dodged, as they had been in the past, with the implicit assumption that wisdom and eloquence were not necessarily synonymous and that truth and integrity were ultimately dependent upon the character of the speaker. The orator, according to Cato the Elder, must be a good man skilled in speaking. Through the writings of Cicero, the ancient Roman orator of the 1st century BC whom later ages were to adulate both for his statesmanship and for his prose style, Cato's doctrine was spread in the Western world for centuries. Quintilian's tediously prescriptive *Institutes* is built on Cato's thesis: it offers an educational program for producing generations of Ciceronian statesmen. But for all its importance and influence, the work never found its time so far as being used as a text for political leaders to follow. Quintilian's program was impossible to achieve in the age of tyranny in which he lived, and it was impracticable in the Renaissance. Nevertheless, it was in the Renaissance that the *Institutes* began to be revered as the greatest educational treatise ever written.

A third issue arose in part as a consequence of literacy and in part as a consequence of social change: rhetoric became a productive art, but one whose role and status were unclear. The audience was no longer quite the full partner in the creative event that it had been in older days of freer public discussion; subsequently, from the classical period through the Middle Ages rhetoricians began to conceive of their art as a kind of methodical, solitary progress toward literary creation. Rhetoric was thought of less in terms of a power and more in terms of certain products of that power—orations; elaborate rules were given for distinguishing the kinds of orations and'for arranging the material in them. Accompanying this shift, the entire creative process taught by the rhetoricians became linear and sequential in concept, with some activities located at further and further removes from the serious operations of the mind. A certain linearity, or step-by-step procedure, is evident in Aristotle's *Rhetoric*, but the attendant dangers of compartmentalization and fragmentation into increasingly trivial matters did not make themselves felt for centuries. By the time of Cicero, rhetoric was considered to be a discipline that encompassed five "offices": invention, analyzing the speech topic and collecting the materials for it; disposition, arranging the material into an oration; elocution, fitting words to the topic, the speaker, the audience, and the occasion; pronunciation or action, delivering the speech orally; and memory, lodging ideas within the mind's storehouse. Not only orations but also poems, plays, and almost every kind of linguistic product except those belonging peculiarly to logic (or dialectics) fell within the rhetoricians' creative art. Thus, the function of rhetoric appeared to be the systematic production of certain kinds of discourse, but the significance of this now clearly productive art became increasingly dubious in ages when governments did not allow public deliberation on social or political issues or when the most significant speaking was done by church authorities whose training had been capped by logic and theology.

The five "offices" of rhetoric

The Middle Ages. The early Church Father St. Augustine made one of the earliest efforts to write a rhetoric for the Christian orator. Book IV of *On Christian Doctrine* is usually considered the first rhetorical theory specifically designed for the minister. Of course, the kind of truth to which Augustine sought to give verbal effectiveness was the "revealed" truth as contained in the Scriptures. The first three books of On *Christian Doctrine*, which describe procedures for a proper interpretation of the Bible, actually set forth the invention part of Augustine's rhetoric. There is no basis here for replacing either logic or theology with rhetoric as the capstone of professional training. The work does represent, however, one of the first theoretical efforts to bring together interpretation—that is, interpreting a text, as opposed to interpreting the facts of a case—and rhetoric.

Late in the 13th century, two students of the German philosopher Albertus Magnus produced a great impact upon the thought—particularly the educational thought—of succeeding generations. Thomas Aquinas, who became in effect the preceptor of the theological curriculum, and Peter of Spain, the preceptor of the general or "arts" curriculum, gave articulate force to the current educational practice of making logic the specialty toward which the professional student advanced beyond rhetoric. Thomas wrote on the logic of abstract, symbolic thought, and Peter wrote on the logic of dialectics, disputation among experts.

The Renaissance and after. In the 16th century, at a time marked by a tremendous growth of interest in creating vernacular rhetorics to satisfy a new self-consciousness in the use of native tongues, the French philosopher Petrus Ramus and his followers merely completed the incipient fragmentation of rhetorical theory by affirming the offices as discrete specialties. invention and disposition were assigned to dialectics, by now largely a silent art of disputation which in the Ramist system placed a premium upon self-evident, axiomatic statements. Memory was considered not a matter of creating sound effects to enhance the memorization of the orator's ideas but a matter of effective disposition, so that separate attention to memory disappeared. Elocution and pronunciation were considered the only two offices proper to rhetoric, and these fell under peculiar opprobrium.

The Ramist system

Elocution, or style, became the centre of rhetorical theory, and in Ramist hands it was almost solely concerned with figures of speech. Actually, a strong emphasis upon the figures of speech had been evolving since the late Middle Ages. When responsibly taught, as linguistic postures, stances, gestures of the mind in confrontation with external reality, the figures served a useful purpose; and in Renaissance education they were widely employed, as in the modern manner, in the interpretation or analysis of discourse. Less responsibly taught, the figures became merely an ornamentation, like the metaphor in Aristotle. In the Ramistic system, the figures ranged between serving as arguments and serving as extrinsic decorations. The figures of speech fell into greater disrepute in the new culture of the Renaissance, which was marked not only by an enthusiasm for printed vernacular discourse in a "plain" style but also by an increasing perplexity over doctrines of the passions. For centuries rhetoricians had taught figures of speech as means of "amplifying" ideas so that they would appeal to the passions in an audience. With Ramus, rhetoric discarded its principles of amplification, leaving the passions to be discussed primarily by "moral philosophers," who battled heatedly over which were ordinate and which were inordinate passions. Ultimately, the passions themselves became subjects, or objects, of the new scientists, who divorced them from moral or religious dogma. It was the end of the 18th century before doctrines of the passions fell once more within the rhetorician's purview; however, at that time the figures were regarded less as appeais to an audience's passions and more as manifestations of the author's or speaker's psychology—or, to use the metaphor employed earlier, as places on the map of his mind.

The other part of the fragmented Ramist rhetoric, pronunciation or action, was rarely mentioned in the Renaissance; it hath not yet been perfected, was the excuse the Ramists gave. The first real impetus for a scientizing of English oral delivery came at the beginning of the 17th century from Francis Bacon, who, in touching on rhetoric in his writings, called for a scientific approach to the study of gesture. The Ramists had created a context within which Bacon's call would have peculiar force and meaning. John Bulwer's *Chirologia* (1644) was the first work to respond, and in its wake came a host of studies of the physical, nonverbal expression of ideas and passions, including works by Charles Darwin and Alexander Melville Bell in the 19th century and modern writings on "silent language" by the American linguist Edward T. Hall.

The elocutionary movement

But, so far as rhetorical theory is concerned, even more significant attempts to specialize in the study of pronunciation or action came in the elocutionary movement of the 18th century, which was the first large-scale, systematic effort to teach reading aloud (oral interpretation). The elocutionists named their study for the third office of rhetoric partly because "pronunciation" was coming to refer solely to correct English phonation and partly because "elocution" had traditionally referred to the decorous expression of previously composed material. The most important elocutionists were actors or lexicographers, such as Thomas Sheridan and John Walker, both of whom acted in London and went on to write dictionaries in the late 18th century. At first glance, their efforts to describe or prescribe the oral delivery of written or printed discourse (poems, plays, as well as speeches) appear to operate on extremely inadequate theory: exactly how one discovered the meaning on the page seems mysterious, almost divinatory. Some of their efforts produced such absurdities as statue-like posing or a contempt for the verbal later associated in America with the 19th-century French teacher of dramatic and musical expression François Delsarte. Yet, their efforts may also be seen as attempts to restore the voice to that entire language process which the page abstracted—as attempts to bridge the gap left in concepts of "natural" meaning by the decay of the oral traditions. Moreover, it is most significant that of all theorists within the history of rhetoric, the elocutionists were the first to place an exclusive concern upon interpreting discourse. Indeed, it was through the elocutionary emphasis upon interpretation that something like a meaningful restoration of pronunciation occurred within the rhetorical tradition.

Sheridan had found within the teachings of the 17th-century English philosopher John Locke a foundation on which the study of elocution could be built: words are the signs of ideas, tones the signs of passions. A new, virtually irrevocable split had apparently occurred between spoken language and printed or written discourse. But the split did not produce in other rhetoricians quite the anxiety it produced in the elocutionists. Other rhetoricians began to discover faculty psychology (*i.e.*, the obsolete notion that supposed faculties of the mind such as will and reason account for all human behaviour) and associationism (*i.e.*, the philosophy expostulated by the 18th-century Scot David Hume and others that most mental activity is based on the association of ideas). In these concepts they found a fragmented, compartmentalized means whereby a fragmented, compartmentalized rhetorical theory could recover part of its earlier vast province, as, for example, doctrines of the passions. Pathetic appeals could simply become, as in Hugh Blair's Lectures on Rhetoric *and Belles Lettres* (1783), something like the sixth office of rhetoric. Besides Blair's, the most important rhetorical treatises of the period were George Campbell's *Philosophy* of *Rhetoric* (1776) and Richard Whately's Elements of *Rhetoric* (1828). All three books were written by Protestant clerics, and all reveal the pervasive assumptions of the Age of Reason. Though rhetoric may involve the whole man—indeed, that is the very reason Campbell believed rhetoric properly seen is naturally allied with a science of the mind—nonetheless, man was viewed as an animal with higher and lower faculties, whose intellect was susceptible to being disordered by his passions and whose noble achievement was the creation of rational, preferably written, discourse.

Theories of rhetorical invention of the 18th and 19th centuries seldom treated the exigencies of oral composition before live audiences or even involved an imaginative projection of oneself into a public situation. Rather, they posited an inventive process that was silent, solitary, meditative—a process of conducting solitary, or inward, dialogues. Imagination, that faculty by which man may potentially synthesize what faculty psychology termed his rational and sensory experiences, was not vindicated philosophically until the Romantic movement of the 19th century (and perhaps never effectively). By that time, rhetoric had fallen into discredit. Printed matter had proliferated to such an extent that traditional principles of invention had become antiquated. Eventually all traditional techniques of style and all organized rhetorical study were devalued by interest in experiments; in Switzerland, cultural historian Jacob Burckhardt described antiquity's interest in rhetoric as a "monstrous aberration." In America, the Delsarteans, who stressed gesture rather than words, spread an antirhetorical approach to imagination, the passions, sensory experience, and delivery. Thus, well into the 20th century, "elocution" in popular speech meant florid delivery and "rhetoric," because of its principal concern with oratory, meant purple prose. In academic circles, "rhetoric" referred largely to principles of "belles lettres" until "belletristic" became a pejorative; then "rhetoric" in a host of college "composition" courses referred to less philosophically troublesome principles of paragraph development and thematic arrangement. More than the medieval logicians, more than Ramus, more than all Rationalist philosophers, and more than even the new philosophies of science, it was probably the very momentum of the revolution begun by Johannes Gutenberg's invention of the printing press that caused traditional rhetoric, both as an educational principle and as a theory, to go under.

TOWARD A NEW RHETORIC

These extremely negative views toward rhetoric prevailed until the 1930s, when attention to the importance of studying how language is used was stimulated by Logical Positivism, the philosophical movement that insists that all statements be verifiable by observation or experiment, and that movement had ironically been stimulated in turn by the very scientism that had earlier disparaged rhetoric. Substantial attempts were made, particularly in the United States, to develop an art of discourse suitable for teaching in schools and universities.

In the opening decades of the 20th century, an attempt was made in American universities to restore rhetoric to the serious study of communication (that is, of creating discourse). Teachers of public speaking were the first to turn to rhetorical traditions for help, followed by teachers of writing. (The teaching of speaking had been divorced from the teaching of writing in America since the third quarter of the 19th century—a divorce that has been recognized by modern universities but challenged by the temper of modern life.) Appropriately, considering the impetus of Logical Positivism, the restored rhetoric was largely Aristotelian, an Aristotelianism that was filtered through centuries of faculty psychology, that was becoming part of a doctrinaire stance against the Romantics and the elocutionists, and that was interpreted in terms of lingering presuppositions of a typographical age. Nonetheless, the rhetoric offered through the tenets of a restored Aristotelianism was potentially more comprehensive—more inclusive of all the offices of rhetoric—than any in Western education since the Renaissance. The political facts of modern life, however, made the Rationalist proclivity of this rhetoric appear naïve. The new media—films, radio, and television—and the new orality of modern life was felt by those interested in rhetoric as a challenge to older linguistic notions, not simply those of the print-oriented teachers of written or spoken composition but those of the Aristotelian Positivists as well.

Restored Aristotelianism

Moreover, the restoration of traditional rhetoric was at first—within speech departments and then later within English departments—an attempt to serve as an emphasis upon training students in how to communicate. When modern rhetoricians shifted their emphasis to interpretation and shifted their concerns from the speaker or writer to the auditor or reader, traditional rhetoric was seen in a new perspective and the subject itself was given its strongest modern impetus and relevance. As noted earlier, the latter effect was the combined result of the work of modern philosophers and literary critics as well as educators.

The 20th century witnessed the publication of some highly provocative works on rhetoric, which potentially carry the subject beyond its Aristotelian confines and give it new relevance to an age dissatisfied with older epistemologies (or theories of knowledge) and their curious, divisive assumptions about truth and verbal expression or about oral and written discourse. Particular attention must be called to the work of the American critic and philosopher Kenneth Burke. A controversial writer, partly because of his extension of rhetoric into the study of nonverbal transactions and sensations, he has perhaps done more than anyone else to create a theoretical basis for the use of rhetoric in interpretation.

As noted at the opening of this essay, modern literary critics have helped to free rhetoric from its traditional emphasis by proving its instrumentality in literary analysis—"practical criticism," as the English critic I.A. Richards called his 1929 book on the subject. But in turn the practical critic has helped preserve traditional rhetoric for the analyses of traditional literature, and through his work on modern literature, he has stimulated the demand for a new rhetoric.

THE RHETORIC OF NON-WESTERN CULTURES

Freed, too, of the parochialism engendered by its Western traditions, rhetoric could undertake a variety of analytical endeavours, even "cross-cultural" studies—for example, the mingling of Malaysian and Western cultures in the political oratory of the Philippines, structure and intention in the oral literatures of Africa, or the communicative strategy of the Japanese verse form haiku.

The search for the rhetoric of non-Western cultures

Indeed, the search for the rhetoric of non-Western cultures has become a crucial scholarly and political endeavour, as men seek bases for understanding the politics as well as the poetry of other lands—and, hopefully, bases for dialogue across tribal and national boundaries. The avenues this search has taken thus far reveal a significant fact both about rhetoric and about the nature of its Western tradition: the true rhetoric of any age and of any people is to be found deep within what might be called attitudinizing conventions, precepts that condition one's stance toward experience, knowledge, tradition, language, and other people. Searching for those precepts, the scholar realizes the extent to which Western culture has become secularized and compartmentalized. In Western culture one may seek out a body of writing under such special rubrics as "rhetoric," "religion," "ethics." But in some Oriental or Middle Eastern cultures, the search may begin and end with religious thought and practices. The Talmudic rabbis, with their disputatious hermeneutics and their attitudes toward Oral Law, gave centuries of Jews a pattern of reasoning and communication. No less so did the *Tao-te-Ching*—the basic text of the Chinese religious system of Taoism—shape a mentality that is as inherent in certain Chinese poetry as in the oratory, dance, painting, architecture, and government of that ancient culture. And for all the Western studies one might encourage into the haiku, surely only one thoroughly grounded in the mysterious doctrines of Zen Buddhism can fully understand how that imagistic poetry itself "works." Moreover, as rhetorical doctrine, the form and function of the "sayings" of a modern, secular Oriental revolutionary may not be so far distant from the form and function of the ancient analects of the sage Confucius. Though rhetoric is to be found in every use of language, only Western man has attempted to divide its precepts discretely from the great body of ethical, moral, or religious precepts that condition the very nature of his culture.

In sum, the basic rhetorical perspective is simply this: all utterance, except perhaps the mathematical formula, is aimed at influencing a particular audience at a particular time and place, even if the only audience is the speaker or writer himself; any utterance may be interpreted rhetorically by being studied in terms of its situation—within its original milieu or even within its relationship to any reader or hearer—as if it were an argument. (T.O.S.)

Rhetoric in philosophy: the new rhetoric

There is nothing of philosophical interest in a rhetoric that is understood as an art of expression, whether literary or verbal. Rhetoric, for the proponents of the new rhetoric, is a practical discipline that aims not at producing a work of art but at exerting through speech a persuasive action on an audience.

NATURE OF THE NEW RHETORIC

Theory of argumentation

The new rhetoric is defined as a theory of argumentation that has as its object the study of discursive techniques and that aims to provoke or to increase the adherence of men's minds to the theses that are presented for their assent. It also examines the conditions that allow argumentation to begin and to be developed, as well as the effects produced by this development.

This definition indicates in what way the new rhetoric continues classical rhetoric and in what way it differs from it. The new rhetoric continues the rhetoric of Aristotle insofar as it is aimed at all types of hearers. It embraces what the ancients termed dialectics (the technique of discussion and debate by means of questions and answers, dealing especially with matters of opinion), which Aristotle analyzed in his Topics; it includes the reasoning that Aristotle qualified as dialectical, which he distinguished from the analytical reasoning of formal logic. This theory of argumentation is termed new rhetoric because Aristotle, although he recognized the relationship between rhetoric and dialectic, developed only the former in terms of the hearers.

It should be noted, moreover, that the new rhetoric is opposed to the tradition of modern, purely literary rhetoric, better called stylistic, which reduces rhetoric to a study of figures of style, because it is not concerned with the forms of discourse for their ornamental or aesthetic value but solely insofar as they are means of persuasion and, more especially, means of creating "presence" (*i.e.*, bringing to the mind of the hearer things that are not immediately present) through the techniques of presentation.

The elaboration of a rhetoric thus conceived has an undeniable philosophical interest because it constitutes a response to the challenge of Logical Empiricism. The Logical Empiricists proclaim the irrationality of all judgments of value—*i.e.*, those judgments that relate to the ends of men's actions—because such judgments can be grounded neither in experience nor in calculation, neither in deduction nor in induction. But it is not clearly necessary, after discarding the recourse to intuition as an insufficient basis for a judgment of value, to declare all such judgments equally arbitrary. This amounts to considering as futile the hopes of philosophers to elaborate a wisdom that would guide men in their public as well as their private lives. The alternative offered by the new rhetoric would furnish a complementary tool to traditional logic, which is limited to the technique of demonstration, or necessary proof according to the rules of deduction and induction; it would add the technique of argumentation. This would allow men not only to verify and to prove their beliefs but also to justify their decisions and their choices. Thus, the new rhetoric, elaborating a logic for judgments of value, is indispensable for the analysis of practical reasoning.

SYSTEMATIC PRESENTATION OF THE NEW RHETORIC

Adaptation to the audience

Personal relations with the audience. Argumentation, whether it be called rhetorical or dialectical, always aims at persuading or convincing the audience to whom it is addressed of the value of the theses for which it seeks assent. Because the purpose of all argumentation is to gain or reinforce the adherence of an audience, it must be prepared with this audience in mind. Unlike demonstration, it cannot be conceived in an impersonal manner. On the contrary, it is essential that it be adapted to the audience if it is to have any effectiveness. Consequently, the orator—the person who presents an argument either by speech or in writing to an audience of listeners or readers—must seek to build his argumentative discourse on theses already accepted by his audience. The principal fallacy in argumentation is the petitio principii ("begging of the question"), in which the speaker presupposes that the audience accepts a thesis that actually is contested by them, even implicitly.

Taken in a broad sense, the new rhetoric can treat the most varied questions and be addressed to the most diverse audiences. The audience may involve only the individual deliberating within himself or it may involve another person in a dialogue. The discourse may be addressed to various particular audiences or to the whole of mankind—to what may be called the universal audience —in which case the orator appeals directly to reason.

Classical rhetoric was traditionally addressed to an audience made up of a crowd of generally incompetent hearers gathered in a public place; argumentation, however, can be addressed to highly qualified audiences, such as the members of an academy or some learned society. As a result, effectiveness is not the only means of testing the value of an argument, for this value also depends on the quality and competence of the minds whose adherence is sought. An argument may persuade an audience of less informed persons and remain without effect on a more critical audience. For Plato, the argumentation worthy of a philosopher should convince the gods themselves.

Basis of agreement and types of argumentation. The orator, in order to succeed in his undertaking, must start from theses accepted by his audience and eventually reinforce this adherence by techniques of presentation that render the facts and values on which his argument rests present to the listener. Thus, the orator can have recourse to literary devices, using figures of rhetoric and other techniques of style and composition that are well-known to writers.

If the discourse is addressed to a nonspecialized audience, its appeal will be to common sense and common principles, common values, and common loci, or "places." Agreement about common values is general, but their object is vague and ill-defined. Thus, the appeal to universal values, such as the good and the beautiful, truth and justice, reason and experience, liberty and humanity, will leave no one indifferent, but the consequences to be drawn from these notions will vary with the meaning attached to them by the different individuals. Therefore, an agreement about common values must be accompanied by an attempt to interpret and define them, so that the orator can direct the agreement to make it tally with his purposes. If the discourse is addressed to a specialized group—such as a group of philosophers or jurists or theologians—the basis of agreement will be more specific.

Types of arguments

To pass from the premises accepted by the audience to the conclusions he wishes to establish, the orator can use arguments of various types of association and dissociation. A detailed analysis of such arguments would require a whole treatise; the best known, however, are arguments by example, by analogy, by the consequences, a pari (arguing from similar propositions), ***a fortiori*** (arguing from an accepted conclusion to an even more evident one), ***a*** *contrario* (arguing from an accepted conclusion to the rejection of its contrary), and the argument of authority. The traditional figures of rhetoric are usually only abridged arguments, as, for instance, a metaphor is an abbreviated analogy.

Associative arguments transfer the adherence from the premises to the conclusion; for example, the act-person association enables one to pass from the fact that an act is courageous to the consequence that the agent is a courageous person. Argumentation leads to the dissociation of concepts if appearance is opposed to reality. Normally, reality is perceived through appearances that are taken as signs referring to it. When, however, appearances are incompatible—an oar in water looks broken but feels straight to the touch—it must be admitted, if one is to have a coherent picture of reality, that some appearances are illusory and may lead to error regarding the real. Because the status of appearance is equivocal, one is forced to distinguish between those appearances that correspond with reality and those that are only illusory. The distinction will depend on a conception of reality that can serve as a criterion for judging appearances. Whatever is conformable to this conception of the real will be given value; whatever is opposed to it will be denied value.

Every concept can be subjected to a similar dissociation of appearance and reality. Real justice, democracy, and happiness can be opposed to apparent justice, democracy, and happiness. The former, being in conformity with the criteria of what justice, democracy, and happiness really are, will keep the value normally attached to these notions. The apparent—what is taken for real by common sense or unenlightened opinion—will be depreciated because it does not correspond to what actually deserves the name of justice, democracy, or happiness. By means of this technique of dissociating concepts, philosophers can direct men's action toward what they hold to be true values and can reject those values that are only apparent. Every ontology, or theory about the nature of being, makes use of this philosophical process that gives value to certain aspects of reality and denies it to others according to dissociations that it justifies by developing a particular conception of reality.

Scope and organization of argumentation. A discourse that seeks to persuade or convince is not made up of an accumulation of disorderly arguments, indefinite in number; on the contrary, it requires an organization of selected arguments presented in the order that will give them the greatest force. After its analysis of the various types of arguments, the new rhetoric naturally deals with the study of the problems raised by the scope of the argumentation, the choice of the arguments, and their order in the discourse.

Although formal demonstrative proof is most admired when it is simple and brief, it would seem theoretically that there would be no limit to the number of arguments that could be usefully accumulated; in fact, because argumentation is concerned not with the transfer from the truth of premises to a conclusion but with the reinforcement of the adherence to a thesis, it would appear to be effective to add more and more arguments and to enlarge the audience. Because the argumentation that has persuaded some may fail to have any effect on others, it would appear to be necessary to continue the search for arguments better adapted to the enlarged audience or to the fraction of the audience that has been hitherto ignored.

Limits to argumentation

In practice, however, three different reasons point to the need to set bounds to the scope of an argumentation: First, there are limits to the capacity and the will of an audience to pay attention. It is not enough for an orator to speak or write; he must be listened to or read. Few people are prepared to listen to a 10-hour speech or read a book of 1,000 pages. Either the subject must be worth the trouble or the hearer must feel some obligation to the subject or orator. Normally, when a custom or an obligation exists, it binds not the hearer but the orator, setting limits to the space or time allotted to the presentation of a thesis. Second, it is considered impolite for an orator to draw out a speech beyond the normally allotted time. Third, by the mere fact that he occupies the platform, an orator prevents other people from expressing their point of view. Consequently, in almost all circumstances in which argumentation can be developed, there are limits that are not to be overstepped.

It thus becomes necessary to make a choice between the available arguments, taking into account the following considerations: first, arguments do not have equal strength nor do they act in the same manner on an audience. They must be considered relevant for the thesis the speaker upholds and must provide valuable support for it. It is essential that they do not—instead of reinforcing adhesion--call the thesis into question again by raising doubts that would not have occurred to the audience had they not been mentioned. Thus, proofs of the existence of God have shaken believers who would never have thought of questioning their faith had such proofs not been submitted to them. Second, there is constant interaction between the orator and his discourse; thus, the speaker's prestige intensifies the effect of his discourse, but, inversely, if his arguments are weak, the audience's opinion of his intelligence, competence, or sincerity is influenced. Therefore, it is best to avoid using weak arguments; they may induce the belief that the speaker has no better arguments to support his thesis. Third, certain arguments, especially in the case of a mixed audience whose beliefs and aspirations are greatly varied, may be persuasive for only one part of an audience. Therefore, arguments should be chosen that will not be opposed to the beliefs and aspirations of some part of the audience. Thus, by stressing the revolutionary effect of a particular measure, for example, one stiffens the opposition to that measure on the part of those who wish to prevent the revolution, but one draws to the measure the favour of those who wait for the revolution to break out. For this reason arguments that have value for all men are superior to those that have more limited appeal; they are capable of convincing all the members of what could be called the universal audience, which is composed of all normally reasonable and competent men. An argumentation that aims at convincing a universal audience is considered philosophically superior to one that aims only at persuading a particular audience without bothering about the effect it might have on another audience in some other context or circumstances.

The need for order in argumentation

Further, for a discourse to be persuasive, the arguments presented must be organized in a particular order. If they are not, they lose their effectiveness, because an argument is neither strong nor weak in an absolute sense and for every audience but only in relation to a particular audience that is prepared to accept it or not. In the first place, the orator must have a certain amount of prestige, and the problem in question must raise some interest. Should the orator be a small child, a man of ill-repute, or one supposed to be hostile to the audience or should the question be devoid of interest for the audience, there is little chance that the orator will be allowed to speak or that he will be listened to. Thus, an orator is normally introduced by someone who has the public ear, and the orator then uses the exordium, or beginning portion of his discourse, not to speak about his subject but to gain the audience's sympathy.

Effective arguments can modify the opinions or the dispositions of an audience. An argument that is weak because it is ill-adapted to the audience can become strong and effective when the audience has been modified by a previous argument. Similarly, an argument that is ineffective because it is not understood can become relevant once the audience is better informed. Research into the effectiveness of discourse can determine the order in which arguments should be presented. The best order: however, will often be whatever is expected, whether it be a chronological order, a conventional order, or the order followed by an opponent whose argumentation has to be refuted point by point.

In all these considerations—concerning the techniques of presentation and argumentation and the arrangement of a discourse—form is subordinated to content, to the action on the mind, to the effort to persuade and to convince. Consequently, the new rhetoric is not part of literature; it is concerned with the effective use of informal reasoning in all fields.

It has been seen that common principles and notions and common loci play a part in all nonspecialized discourses. When the niatter that is debated belongs to a specialized field, the discussion will normally be limited to the initiated—*i.e.*, those who, because of their more or less extensive training, have become familiar with the theses and methods that are currently accepted and regarded as valid in the field in question. In such instances, the basis of the argumentation will not be limited to common loci but to specific loci. The introduction in some field of a new thesis or new methods is always accompanied by criticism of the theses or methods that are being replaced; thus, criticism must be convincing to the specialists if the new thesis or method is to be accepted. Similarly, the rejection of a precedent in law has to be justified by argumentation giving sufficient reasons for not applying the precedent to the case in question.

SIGNIFICANCE OF THE NEW RHETORIC

The new rhetoric introduces a fundamental change in the philosophical outlook. Insofar as it aims at directing and guiding human action in all of the fields in which value judgments occur, philosophy is no longer conceived as the search for self-evident, necessary, universally and eternally valid principles but, rather, as the structuring of common principles, values, and loci, accepted by what the philosopher sees as the universal audience. The way the philosopher sees this universal audience, which is the incarnation of his idea of reason, depends on his situation in his cultural environment. The facts a philosopher recognizes, the values he accepts, and the problems he attends to are not self-evident; they cannot be determined a priori. The dialectical interaction between an orator and his audience is imposed also on the philosopher who wishes to influence his audience. Therefore, each philosophy reflects its own time and the social and cultural conditions in which it is developed. This is the fundamental truth in the thought of G.W.F. Hegel, a German Idealist: the history of philosophy is not regarded as an abstract and timeless dialectic that proceeds in a predetermined direction but as an argumentation that aims at universality at a concrete moment in history.

To the extent that the new rhetoric views all informal discourse and all philosophical discourse from the viewpoint of its action on the minds of the hearers, it integrates into the analysis of thought valuable elements from both Pragmatism and Existentialism. In stressing the effectsof discourse it allows Analytical philosophy to be given the dynamic dimension that some scholars believe that it has heretofore lacked. The new rhetoric can thus contribute to the development of a theory of knowledge and to a better understanding of the history of philosophy. (C.Pe.)

BIBLIOGRAPHY. The following works may be regarded as fundamental to the points made in the preceding article: EDWIN BLACK, *Rhetorical Criticism* (1965); WAYNE C. BOOTH, *The Rhetoric of Fiction* (1960); WILLIAM J. BRANDT, *The Rhetoric of Argumentation* (1970); KENNETH BURKE, *The Philosophy of Literary Form* (1941), *A Grammar of Motives* (1945), and *A Rhetoric of Motives* (1950); CHAIM PERELMAN and LUCIE OLBRECHTS-TYTECA, *La Nouvelle Rhetorique: traité de l'argumentation*, 2 vol. (1958; Eng. trans., *The New Rhetoric: A Treatise on Argumentation,* 1969); JOHN CROWE RANSOM, *The New Criticism* (1941); and STEPHEN E. TOULMIN, *The Uses of Argument* (1958). See also CHAIM PERELMAN, "The New Rhetoric: A Theory of Practical Reasoning," in *The Great Ideas Today* (1970).

In addition, the following is helpful in understanding the modern critique of rhetorical traditions: LLOYD F. BITZER and EDWIN BLACK (eds.), *The Prospect of Rhetoric: Report of the National Developmental Project* (1971). RAYMOND F. HOWES (ed.), *Historical Stzidies of Rhetoric artd Rhetoricians* (1961); and R.S. CRANE (ed.), *Critics and Criticism, Ancient and Modern* (1952), are particularly useful in understanding respectively the critics and rhetoricians of Cornell and Chicago, the universities at which modern rhetoric received especially strong impetus. Other works useful in a study of the history of rhetoric include WILBUR SAMUEL HOWELL, *Logic and Rhetoric in England, 1500–1700* (1956); GEORGE KENNEDY, *The Art of Persuasion in Greece* (1963); and WALTER J. ONG, *Ramus: Method, and the Decay of Dialogue* (1958). In addition to Ransom's book, I.A. RICHARDS, *The Philosophy of Rhetoric* (1936), helped illuminate the early stages of the modern relationship between rhetoric and literary criticism. A book-length treatment of non-Western rhetoric is ROBERT T. OLIVER, *Communication and Culture in Ancient India and China* (1971).

Rhine River

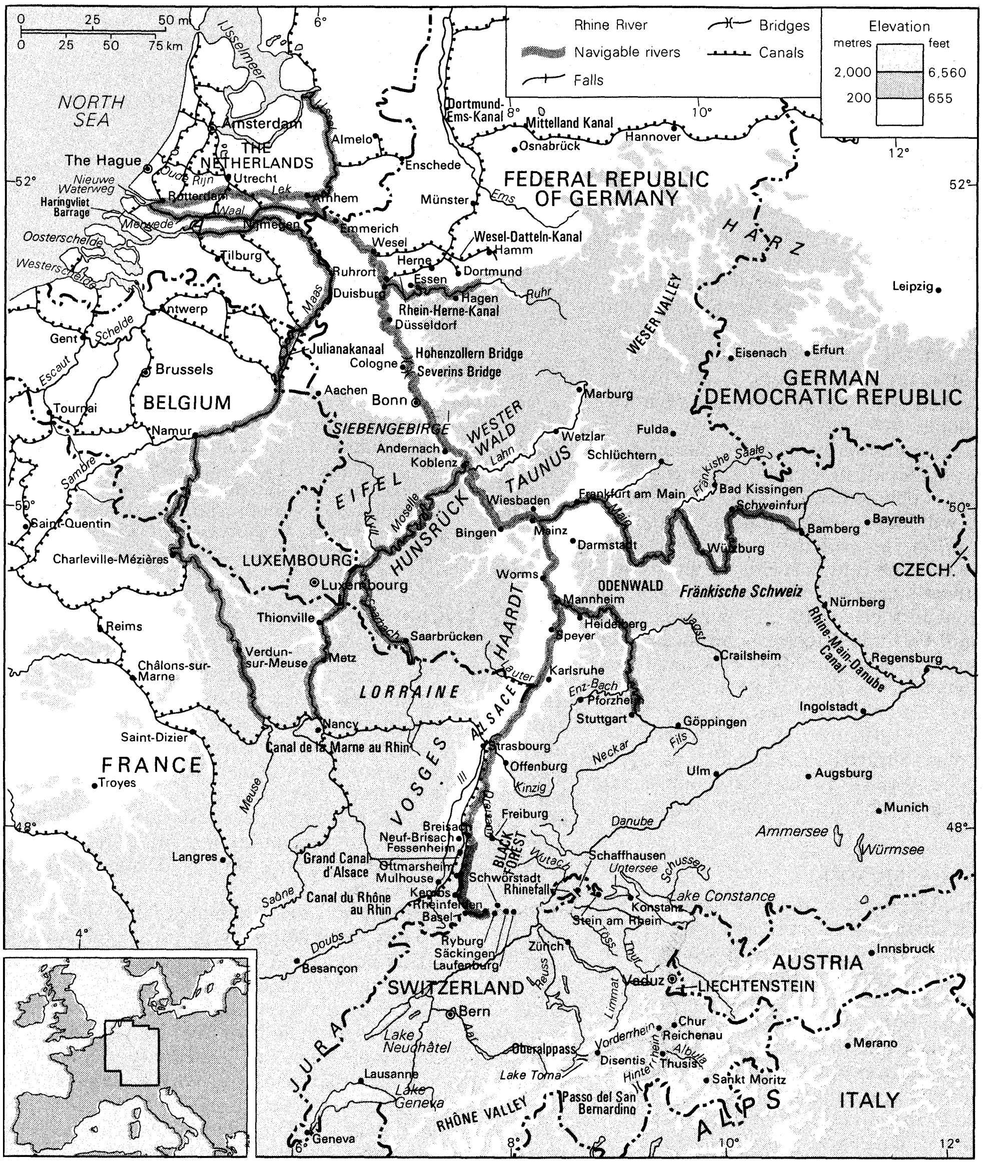
Culturally and historically one of the great rivers of Europe and the greatest European artery of waterborne traffic, the Rhine River flows 820 miles (1,320 kilometres) from east central Switzerland north and west to the North Sea, into which it drains through The Netherlands. An international waterway since the Treaty of Vienna in 1815, it is navigable overall for some 500 miles, as far as Lake Constance (Bodensee) in Switzerland. Its catchment area including the delta area exceeds 85,000 square miles (220,000 square kilometres), about twice the size of Liberia.

The character of the river

The Rhine has been a classic example of the alternating roles of great rivers as arteries of political and cultural unification and as political and cultural boundary lines. The river has also been enshrined in the literature of its lands, especially of Germany, as in the famous epic *Nibelungenlied.* In the second half of the 20th century, its importance as a trade route has increased, and political dissension about its role has given way to concern for ecological safeguards in the face of rising pollution levels.

The Alpine section of the Rhine lies in Switzerland, and, below Basel, the river forms the boundary between the German Federal Republic and France, as far downstream as the Lauter River. It then flows through German territory as far as Emmerich, below which its many-branched delta section epitomizes the landscapes characteristic of The Netherlands. The Alpine Rhine reaches its maximum flow in the spring and early summer, when its volume is swollen dramatically by snowmelt among the great peaks of the Alps. In this section, the beautiful Lake Constance acts as a filter, and the river emerges as a clear, translucent stream on its far side; the lake also helps to regulate river flow. The hydrological regime (highwater and lowwater) of the navigable Rhine is favoured by the well-distributed seasonal precipitation, with a winter maximum in the lower reaches balancing a summer maximum in the Alps. Winters are generally mild, and ice impedes navigation only in abnormally cold years. The scenic attractions of the German Rhine are marred by occasional industrial zones, with associated problems of pollution from industrial waste, but stretches of the river still present breathtaking vistas and attract tourists from near and far. For related information, see EUROPE, and also the articles on the states bordering the Rhine. See also BONN; COLOGNE.

The Alpine section of the Rhine. The Rhine rises in two headstreams high in the Swiss Alps. The Vorderrhein emerges from Lake Toma at 7,690 feet (2,344 metres), near the Oberalppass in the Central Alps, and then flows eastward past Disentis to be joined by the Hinterrhein from the south at Reichenau above Chur. (The Hinterrhein rises near the Passo del San Bernardino and



The Rhine River Basin and its drainage network.

is joined by the Albula River below Thusis.) Below Chur, the Rhine leaves the Alps to form the boundary first between Switzerland and the tiny principality of Liechtenstein and then between Switzerland and Austria, before forming a delta as the current slackens at the entrance to Lake Constance. In this flat-floored section, the Rhine has been straightened and the banks reinforced to prevent flooding. The Rhine leaves the Untersee arm of Lake Constance, and, below Stein am Rhein, the Swiss-German frontier deviates so that the Rhinefalls at Schaffhausen are entirely Swiss. Downstream, the Rhine flows swiftly between the Alpine foreland and the Black Forest region, its course interrupted by rapids, where—as at Sackingen, Laufenburg, and at Ryburg and Schworstadt—barrages (dams) have been built. In this stretch, the Rhine is joined by its Alpine tributaries, the Thur, Toss, Limmat, Reuss, and Aar (French Aare), and by the Wutach from the north. The Rhine has been made navigable between Basel and Rheinfelden since 1934 and will eventually provide a through waterway as far as Lake Constance.

The Lake Constance sector

The central course. Below Basel, the Rhine turns northward to flow across a broad, flat-floored valley, some 20 miles wide, held between, respectively, the ancient massifs of the Vosges–Black Forest and the Hardt–Odenwald. The main Alsatian tributary is the Ill, which joins the Rhine at Strasbourg, and various shorter rivers, such as the Dreisam and the Kinzig, drain from the Black Forest. Downstream, the regulated Neckar, after crossing the Odenwald in a spectacular gorge as far as Heidelberg, enters the Rhine at Mannheim; and the Main leaves the plain of lower Frankische Schweiz (Franconian Switzerland) for the Rhine opposite Mainz. Until the straightening of the Rhine in the early 19th century, the river described a series of great loops, or meanders, over its floodplain, and today their remnants, the old backwaters and cutoffs near Breisach and Karlsruhe, serve to mark the former course of the river. The important river docks were opened at Mannheim in 1840, and three years later the first steam tug, the "Matthias Stinnes," drew coal-laden barges through them. On the French side of the Rhine, a scheme (agreed upon in 1929) was evolved for the construction of the Grand Canal d'Alsace, designed to increase waterborne traffic above Strasbourg and also to generate electricity at a series of power stations located adjacent to the canal locks. The first barrage was built at Kembs, below Basel, in 1932, and, following World War 11—in which the Rhine played a major role in military strategy—installations were completed at Ottmarsheim, Fessenheim, and Neuf-Brisach. After 1956, attention was turned to the regulation of the Moselle, through a project involving agreement between France, the German Federal Republic, and Luxembourg. As a result, this formerly winding and swift-flowing river has been made navigable for vessels of 1,350 tons below Thionville in Lorraine and therefore serves both the French iron and steel region and the Ruhr–Rhine industrial area.

The great navigational improvements after World War II

The most spectacular and romantic reach of the Rhine extends between Bingen and Bonn, capital of the Federal Republic of Germany. In this 90-mile stretch the Rhine has cut a deep and winding gorge between the steep, slate-covered slopes of the Hunsruck to the west and the Taunus to the east. This is the Rhine of legend and myth, where the medieval Mouse Tower lies at water level near Bingen, and the castle of Kaub stands on an island in the river. Vineyards mantle the slopes as far as Koblenz, where the Moselle joins the Rhine at the site known to Romans as Confluentes. On the right bank the fortress of Ehrenbreitstein dominates the Rhine where the Lahn tributary enters. Downstream the hills recede, the foothills of the volcanic Eifel lying to the west and those of the Westerwald to the east. At Andernach, where the ancient Roman frontier left the Rhine, the basalt hills of the Siebengebirge rise steeply to the east of the river, where, as the English poet Lord Byron put it, "the castle crag of Drachenfels frowns o'er the wide and winding Rhine." At Bonn the modern structures of the Bundeshaus (meeting place of the federai assembly) have an impressive frontage flanking the Rhine. Below Bonn the valley opens out into a broad plain in which lignite (brown coal) is excavated for electricity generation.

The city of Cologne lies on the left bank of the Rhine. There the 1,500-foot-wide river is spanned by the modern Severin Bridge and by the rebuilt Hohenzollern railway bridge, which carries the line from Aachen to Dusseldorf and the Ruhr industrial region. Dusseldorf, on the right bank of the Rhine, is the dominant business centre of the Nordrhein-Westfalen coalfield, The twin towns of Duisburg and Ruhrort, which lie at the mouth of the Ruhr River, handle the bulk of the waterborne coal and coke from the coalfield. Following the pattern set by the construction of the Dortmund-Ems-Kana1 in 1899, the Rhine-Herne-Kanal was built in 1914, and the Wesel-Datteln-Kanal was built in 1930. Post-World War II developments have included the introduction of the sturdy vessel known as the push-pull tug, in preference to the diesel-powered barge. The heaviest traffic on the entire Rhine is, in fact, between the industrial section of the Ruhr and The Netherlands' system of inland waterways. More than half the river fleet is Dutch; a third is West German; and the rest is French, Swiss, and Belgian. Apart from the regular passenger-steamer service between Cologne and Mainz, a summer passenger service also operates between Rotterdam and Basel.

The delta region. The last section of the Rhine lies below the frontier town of Emmerich in the delta region of The Netherlands. There the Rhine breaks up into a number of wide branches, such as the Rijn, Lek, and Waal, known downstream as the Merwede. The Meuse (Maas) flows parallel to the Waal and finally forms the New Waterway on the north bank, where the port of Rotterdam lies. To the south lies the Haringvliet Barrage, part of the vast Delta Plan to reclaim and conserve the region's land.

Rhode Island

Perhaps the most remarkable feature of Rhode Island, one of the six New England states in the northeastern corner of the United States, is its size. About 48 miles (75 kilometres) long and 37 miles wide at the maximum, it is the smallest and one of the most densely populated states in the nation. The nearly 950,000 Rhode Islanders, as reported in the 1980 census, live within an area of 1,214 square miles (3,144 square kilometres), of which about 14 percent is inland water. Many of the state's ample woodlands were once farms, that were abandoned during the 19th century; during the 1800s migrations to the cities resulted in an urban population that by 1900 was 90 percent. Rhode Island has since become one of the most heavily industrialized areas in the world.

This extreme compactness of area and the proliferation of people and activity have tied Rhode Island closely to its neighbours, Connecticut on the west and Massachusetts on the north and east. The Atlantic Ocean, which lies to the south, cuts deep into the state as Narragansett Bay.

The major islands within the state are Block Island and Rhode Island. On the latter is the famous yachting and music centre, Newport. A popular resort since West Indian and Southern planters discovered the island as a summer home in the mid-18th century, Newpor! became an international symbol of wealth and elegance in the 19th century as millionaires from across the country built the many mansions that stand as memorials to a gilded past.

Historical and contemporary character

Small though it is, Rhode Island has been uncompromisingly independent throughout its history. From its founding, in 1636, it was a haven for dissenters from the religious orthodoxies imposed by most of its fellow colonies. As a result, it became something of an outcast among the 13 colonies, but it was the first to declare its independence from Great Britain. After the American Revolution, however, it was the last to join the Union, doing so only under duress, and until 1842 it continued to be governed under terms of the royal charter of 1663. As the state became one of the nation's great textile and manufacturing centres, its cities and mill villages attracted an influx of immigrants whose numbers overwhelmed the original Yankee population. Major internal issues in the 20th century included the longtime withholding of the franchise from both propertyless and foreign-born citizens and the domination of the legislature by rural and small-city interests. (For information on related topics, see the articles UNITED STATES; and UNITED STATES, HISTORY OF THE.)

THE HISTORY OF RHODE ISLAND

Colonial period. In the state's official name—The State of Rhode Island and Providence Plantations—lies a clue to its founding. The first settlement was made by the minister Roger Williams and a few followers at Providence, near the head of Narragansett Bay, in 1636. They were either under edict of banishment from Massachusetts Bay Colony—Williams for advocating freedom of conscience in religion—or were in trouble with the authorities there. In 1638 a group of prominent Bostonians, in similar difficulties, purchased the island of Aquidneck, now Rhode Island, from Indians and settled Portsmouth. Factional strife split this settlement, and William Coddington and his adherents moved to the southern end of the island, where they founded Newport, leaving Anne Hutchinson and her followers in Portsmouth. In 1643 Samuel Gorton took a dissident group south of the boundaries of Providence Plantations and settled Warwick.

Williams went to England in 1643 and returned the following year with a royal patent for the colony, but the four towns could not agree on a form of government until 1647, when a loose confederacy was established. The colony was never accepted into membership in the United Colonies of New England—comprising Plymouth, Massachusetts, Connecticut, and New Haven—and it was constantly threatened with a takeover by one or another of these governments. Coddington, by going to England and having himself made ruler for life of the island towns, split the colony between the mainland and the island towns, Williams and John Clarke, the latter representing island elements unhappy about Coddington's commission, sailed for England in 1651, succeeded in getting the com mission rescinded, and in 1654 set up a reunited government. Clarke remained in England and, in 1663, won a royal charter that was to be the basis of colonial and state government for 180 years.

Although the colony never officially joined the other New England colonies in King Philip's War (1675-76), it suffered greatly. All mainland settlements were burned, including, in the spring of 1676, many houses in Providence. Most of the mainland settlers took refuge on Rhode Island, which was not attacked. The Great Swamp Fight, the battle in which the major portion of the power of the Narragansett Indians was broken, took place in December 1675, a few miles west of the present village of Kingston.

Early commerce with the West Indies

Rhode Island almost from the beginning had commerce with the West Indies, selling horses, barrel staves, and salt fish. Eventually, some of its merchants tried the triangular trade: taking rum to the African coast, where it was traded for slaves, carrying the slaves to the West Indies, where they were traded for molasses, and carrying the molasses to Rhode Island, where it was distilled into rum. The passage of the Sugar Act by Parliament in 1764 seriously affected this trade, and the colony, never overly anxious to obey unpopular laws, began to indulge in considerable smuggling of sugar and molasses. In 1772 the British customs vessel "Gaspee," patrolling Narragansett Bay, ran aground off Namquit (now Gaspee) Point while pursuing a suspected smuggler; that night it was burned by a group of townsmen from Providence. This has been widely regarded as the first act of outright violence against the British crown in the period leading up to the American Revolution.

Traumas of revolution and independence. During the war Newport was occupied by the British. In 1778 a land force under Gen. John Sullivan and the French fleet commanded by the Comte d'Estaing cooperated in an operation designed to dislodge them. Before the French troops could be landed, however, a British fleet appeared in the bay; d'Estaing halted the landing and set out in pursuit. Two days later, before the ships had actually engaged, they were dispersed by a storm. The American ground forces, lacking French assistance, were forced to retreat from the island. At Butts Hill they fought a strong rearguard action that became known as the Battle of Rhode Island and in which a battalion of freed slaves distinguished itself. A Rhode Islander, Gen. Nathanael Greene, distinguished himself as Washington's second in command and as commander of a brilliant campaign in the South.

After the war Rhode Island was reluctant to ratify the Constitution until the Bill of Rights was proposed in the form of 10 amendments. The state's largely agricultural population was opposed to joining the Union, while the merchants of Providence and Newport worked hard for ratification. When threats of commercial isolation from the other states were raised, Rhode Island accepted the document in May 1790, but it did so by a margin of only two votes.

Newport, preeminent before the war, lost much of its economic power during the British occupation, and Providence, led by such merchants as the four Brown brothers, John, Joseph, Nicholas, and Moses, assumed the leadership.

Conflicts over suffrage and equal representation

In 1842 a movement for widening the franchise, which had been limited under the 1663 charter to freeholders and their eldest sons, resulted in a civic conflict known as Dorr's Rebellion. Led by Thomas Wilson Dorr, the son of an aristocratic family, the faction favouring universal suffrage held a convention in 1841 and adopted a constitution embodying this principle. At an election held under this constitution, Dorr was elected governor in 1842, but the election was not accepted as legal by the legislature or the state Supreme Court. When his forces were repulsed in an attempt to seize the arsenal in Providence, Dorr fled the state. Upon his return, he was tried on a charge of high treason, convicted, and sentenced to life imprisonment; he served only one year, however, and was released in 1845. By that time the state had adopted a revised constitution considerably broadening the basis of the franchise, but it was not until the mid-20th century that full rights to vote in all elections were extended to all citizens at the age of 21 (later 18).

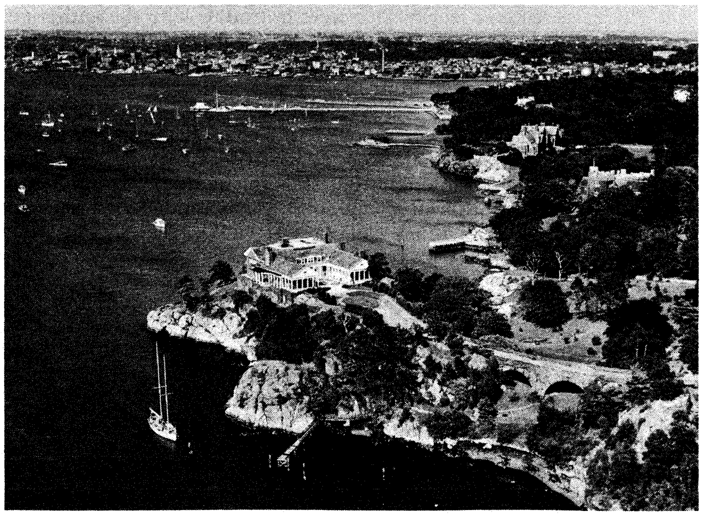
In the years after the Civil War the Republican Party, led by such political bosses as Gen. Charles R. Brayton, ruled the state completely, mainly because the cities, which were Democratic, were not represented in either chamber of the General Assembly in proportion to their population. Providence, by far the largest city, had one senator, as did a small town with only several hundred people.

Providence's representation has grown to comprise 11 senators in the state government, while often several small towns are grouped together with a single senator to represent them. Since the 1930s the Democratic Party has controlled the legislature, although Republicans have been elected governor on several occasions, and Dwight D. Eisenhower and Richard M. Nixon, among the Republican presidential candidates, were able to carry Rhode Island.

THE NATURAL AND HUMAN LANDSCAPE

Topography. Rhode Island's rocky soil is mostly glacial till deposited by the great ice sheets that covered the northern United States thousands of years ago. Glaciation also provided the material that the ocean later formed into the barrier beaches along the state's southern coast, where tidal ponds, open to the ocean through narrow

John T Hopf



Harbour and resort area of Newport, with a 19th-century summer mansion in the foreground.

breachways, stretch from the mouth of the Pawcatuck River at Westerly and Watch Hill to Point Judith. The best farmland is in Portsmouth, Middletown, and areas around the southern coast. There, potatoes and corn (maize) are the principal crops. Elsewhere the land is good only for pasture and dairy or poultry farming. Fields that have been cleared for farming are bounded by omnipresent stone walls. These old stone walls can still be found deep in the woods, evidence that the land once was under cultivation.

Although the western part of the state has hills rising as high as 800 feet (240 metres) above sea level, most of it is quite flat, and the average altitude is about 200 feet. The highest points are Jerimoth Hill, 812 feet, in the town of Foster and less than a mile from the Connecticut border; and Durfee Hill, 804 feet, in Glocester, a few miles farther north. The lowest part of the state, other than the ocean beaches, is in the vicinity of the Great Swamp in South Kingstown.

Climate. With a reasonably salubrious climate, the state is not normally subjected to great extremes of either heat or cold. The average mean temperature at Providence is 50° F (10° C), while the mean for summer is 70" F (21° C) and for winter 30° F (−1° C). Mean annual precipitation throughout the state is about 37 inches (940 millimetres).

Water-power and the mill villages

Waters of the state. Two large river systems drain Rhode Island. Most important is the Blackstone River and its tributaries. Rising near Worcester, Massachusetts, it cuts through the northeastern part of the state and was the source of waterpower for numerous textile mills that were built in the Blackstone Valley, at Woonsocket, Pawtucket, and a dozen mill villages between the two cities. The Pawcatuck River and its main branch, the Wood, provided power for numerous other small mills. Although it drains a smaller area, the Pawtuxet River was once of comparable economic importance, and its valley is crowded with mill villages.

These mill villages, which thrived in the 19th century, give rural Rhode Island its characteristic look. Small one- and two-family houses, set out in orderly rows along a single street, are not far from the mill where the residents worked. Formerly these houses were built and owned by the mill owners, but, with the demise of many of the mills or their conversion to kinds of manufacturing other than textiles, the mill village houses were sold off to the persons who lived in them.

Role of Narragansett Bay

Before the mills Narragansett Bay was the state's great asset, providing a convenient waterway running two-thirds of the length of the state and navigable as far up the Blackstone Valley as Pawtucket Falls. The small commercial trade on which the wealth of Newport, Bristol, and Providence was founded has given way to a larger ocean-borne commerce. Storage tanks for oil and gasoline dot both shores of the upper bay, and Providence has become one of the principal oil-distributing centres of the Northeast.

Narragansett Bay also has been useful in bringing U.S. Navy establishments to Rhode Island. The Naval War College has operated at Newport since the middle of the 19th century. Although before World War II the navy occupied about 500 acres (200 hectares) in Newport County, a Naval Operating Base was established and enlarged to more than 2,100 acres in 1941. The navy's presence continued to be strong through the late 1960s, when about 42,000 people were employed at Newport and other naval bases. By 1980, however, the number had been reduced to 9,500 people.

Other major waterways of the state are Mount Hope Bay, an arm of Narragansett Bay, providing navigable water to Somerset and Fall River, Massachusetts, and the Sakonnet River, a saltwater strait separating the island of Rhode Island from Little Compton and Tiverton on the east. Block Island Sound, lying between Block Island and the mainland, is highly regarded by sport fishermen seeking marlin and tuna and also yields commercial quantities of swordfish.

Patterns of settlement. Rhode Island comprises five counties, eight cities, and 31 towns. It sometimes is described as a city-state, and a large proportion of its population resides in Providence or in contiguous communities, such as Pawtucket on the north, North Providence and Johnston on the west, Cranston and Wanvick on the south, and East Providence across the river to the east. Except for Warwick, all of these communities are in Providence County, which in 1980 had a population density of 2,496 persons per square mile. Warwick and Cranston, the state's second and third largest cities, respectively, had populations in 1980 about one-half that of Providence.

THE PEOPLE OF RHODE ISLAND

Ethnic composition. Although the population of the state has undergone considerable change since World War II, with the exodus from the congested parts of such cities as Providence to the "bedroom communities" of Cranston and Warwick, much remains the same. Woonsocket still has a large population with French-Canadian ancestry whose first language is French. Pawtucket retains a large group of English whose ancestors came to work in the textile mills, and Providence has a strong Italian-American community as weil as a iarge number of Irish-Americans. In the small towns of the western and southern parts of the state, however, the typical Yankee farmers predominate, though mixed with an increasing number of people of Portuguese, Finnish, and Polish extraction and others who have fled the cities. By the 1980 census the state was 94.7 percent white. Providence had the greatest number of blacks and other nonwhites.

Although ethnic origins are a strong factor in political actions in Rhode Island, the state has returned to the principles of toleration on which the colony was founded. Despite much unwillingness to assimilate immigrant groups in the 19th century, the state has always clung to its ideals of religious freedom. In the 17th and early 18th centuries, Rhode Island was a refuge especially for Quakers and Jews, both of whom contributed substantially to the wealth and economic power of Newport. Touro Synagogue in Newport, a colonial building that has been carefully restored in decor and furnishings, is the oldest synagogue in the United States; it has been declared a national landmark.

Demography. The movement out of the urban centres caused population losses in six Rhode Island cities, according to the 1980 census. Newport lost more than one-sixth of its population and Providence nearly one-seventh, while Central Falls, Granston, Pawtucket, and Woonsocket lost smaller percentages. On the other hand, towns and cities near these centres or accessible by highways grew enormously, primarily East Greenwich, Narragansett, Portsmouth, and West Wanvick. During the 1970s Cranston replaced Pawtucket as the state's third largest city. While the state's population grew steadily until the 1970s, that of Providence reached its peak in 1925 and has decreased ever since. Like other predominantly urban states, Rhode Island has begun to feel the effect of the flight from the cities, which leaves behind more and more of the unemployed, the economically depressed, the unskilled, and those on the public welfare rolls. At the same time the cities continue to lose much of their economic and tax base.

THE STATE'S ECONOMY

Components of the economy. Rhode Island depends increasingly on brainpower and skilled labour to keep its economy afloat. Relying in its early years almost entirely on subsistence agriculture and seaborne trade, it became after the Revolution a pioneer manufacturing state, principally in the textile field. In the 20th century it has developed more diversified small industries, especially in the jewelry and allied industries, electronics, and such service fields as education and insurance.

Manufacturing employment and value

The largest group of workers is engaged in the jewelry and allied trades, whereas the once dominant textile industry has fallen to second place. The manufacture of machine tools and precision-measuring instruments is an important element in the economy; coupled with the fabrication of metal products and electrical equipment, it often employs large numbers of people, although any national retrenchment in heavy industry, such as automobile manufacturing, is quickly reflected in Rhode Island's economy. Since the jewelry industry is also remarkably sensitive to fashion trends and available money supplies, employment in this trade is frequently seasonal or otherwise erratic. One of the stablest elements of the economy is the state's educational institutions.

Rhode Island is not a rich state, and its per capita income places it in the middle ranks among the states. Jewelry and silverware manufacturing is Rhode Island's leading industry, with textiles second and metal-working machinery third.

Two Providence-based banks, the Industrial National and the Rhode Island Hospital Trust, through their branches throughout the state, are the dominant financial institutions, but there are several important banks of secondary rank.

Rhode Island has a sales tax, which exempts food and prescription drugs. In 1971, after many defeats in the General Assembly, the state adopted a personal income tax. Lotteries were widely used in colonial times and after the Revolution to raise capital for civic improvements; they later were prohibited but were reestablished in 1974. A large share of the state's income comes from its tax on pari-mutuel betting at two horse-racing tracks, Narragansett and Lincoln Downs.

Transportation. In addition to its bridges and ferries, Rhode Island has many other connections with states of the Eastern Seaboard. Providence is the centre of limited-access expressways to Boston, less than one hour away, to Cape Cod, and westward and southwestward into Connecticut. A main railroad provides the state with freight and passenger service, while interstate and intrastate bus lines run on its highways. There are several airports in Rhode Island, with most of the passenger service handled at the Theodore Francis Green State Airport, located at Hillsgrove.

ADMINISTRATION AND SOCIAL CONDITIONS

Atop the state capitol in Providence is the statue of "The Independent Man," a symbol of so much that is characteristic of Rhode Island. Roger Williams wrote that he had founded Providence as a place of refuge for "those distressed for cause of conscience," and the principle of absolute religious freedom has been an abiding article of Rhode Island's political philosophy. Because of the nature of its first settlements, which were not bound to any one religious faith, most Rhode Island towns do not have a central common, as do many New England towns, where the houses are usually clustered around a central group of churches or a single church.

Governmental traditions. Ever since its founding, the state has shown a reluctance to permit elected officials to exercise extensive powers. In the early years legislatures and elected officials served for only six months. Prior to 1854 the state had five capitals, Providence, Newport, East Greenwich, Bristol, and South Kingstown, and the General Assembly travelled from one to another. In 1900 Providence was chosen as the sole capital.

Executive, legislature, and judiciary

The governor has the power of the veto and the power to name certain department heads. Judges are elected by both houses of the General Assembly sitting as a committee of the whole, and since the 1930s they have had tenure.

Members of the General Assembly are paid by the day for 60 legislative days. A number of attempts to amend the state constitution to increase legislators' pay have been soundly beaten by the voters, who in 1968 defeated by a four-to-one margin a new constitution to replace the 126-year-old document.

In addition to the usual officers and the legislators, the state has a district court system, superior courts, a Supreme Court, which also can give advisory opinions if requested, and municipal and probate courts, the latter frequently identical with the town council in the smaller communities. There is also a Family Court, which handles both juvenile and domestic cases. In addition, a U.S. District Court sits in Providence.

Most of the cities in Rhode Island operate with a mayor and city council form of government, but some have a city manager, and the mayor is chosen from among councilmen to act as the ceremonial head of the local government. Likewise, most of the towns are governed by a town council, but in some cases operations are conducted by a town manager.

The social milieu. Early in its history, Rhode Island acted to stamp out slavery by limiting to a maximum of 10 years the period in which anyone could be held a slave. During the Revolution the General Assembly acted to raise a black regiment by decreeing that any slave who enlisted would be granted his freedom. Even in the 18th century there was a strong emancipation movement in the state, drawing much of its support from such men as Moses Brown and other prominent Quakers. In 1866 the General Assembly passed a law prohibiting the exclusion of any person from the public schools because of race or colour, thus closing separate schools maintained in Bristol, Newport, and Providence and admitting blacks to Providence High School.

Early traditions of toleration

The state maintains elaborate facilities to care for the sick and indigent, from children's centres to institutions for the elderly.

There are jails in cities and towns throughout the state, but most persons awaiting trial or sentenced to prison terms are sent to the Adult Correctional Institutions (ACI) at Howard. The ACI in recent years has adopted a work-release program to rehabilitate prisoners. Rhode Island has a force of more than 300 officers and policemen who operate out of seven barracks located throughout the state.

Education. In 1970 a Board of Regents was created and charged with responsibility over all public education, from elementary schools through the state-operated colleges and the university. A number of private preparatory schools, both sectarian and nonsectarian, send graduates to many of the major colleges and universities, especially in the East. Rhode Island is strong in its institutions of higher education. Brown University in Providence, founded in 1764 as Rhode Island College, is one of the major Eastern universities that make up the so-called Ivy League. It is noted for its library facilities, especially the John Carter Brown Library of early Americana. The Rhode Island School of Design (founded 1877) is widely known, primarily for its training in the visual and graphic arts. The University of Rhode Island, in Kingston, is a land-grant institution dating from 1892. Catholic colleges include Providence College (1917) and Salve Regina College (1947) in Newport. Rhode Island College, mainly for teacher training, dates from 1854.

Higher education

CULTURAL LIFE AND INSTITUTIONS

Cultural and historical preservation. Library facilities are plentiful throughout the state. The Redwood Library, in Newport, and the Providence Athenaeum, bbth proprietary institutions housed in architecturally important buildings, have roots going back to the mid-18th century. The public libraries of Providence and Westerly have important holdings, the former having special collections on whaling, printing, slavery, and Irish literature. The Rhode Island Historical Society, in Providence, has more than 1,000,000 manuscripts and is especially strong in its holdings of the state's newspapers. The society also operates John Brown House, a magnificent merchant's mansion in Providence; built in 1786, the house is furnished with masterpieces of the Newport school of cabinetmakers and with other 18th-century antiques.

The arts. The Museum of Art of the Rhode Island School of Design is especially strong in Greek and Roman sculpture and antiquities, Postimpressionist French paintings, American painting, and British watercolours. The School of Design also has a fine art library.

In both Providence and Newport, preservation societies have been active in restoring the surviving colonial homes. The Preservation Society of Newport County operates as museums several mansions that were formerly the summer homes of millionaires. The Newport Historical Society museum, with its fine collections; Touro Synagogue, a magnificent example of colonial architecture; Old Colony House; Redwood Library; Hunter House; the restored colonial homes of the Point section; and the National Lawn Tennis Hall of Fame and Tennis Museum in the Newport Casino building combine to give Newport an extraordinary and varied cultural heritage.

Music festivals

The Rhode Island Philharmonic Orchestra, the Rhode Island Civic Chorale and Orchestra, the Westerly Community Chorus, the Barrington Boys Choir, and numerous smaller groups and organizations are among the state's musical resources. It is visited regularly by the Boston Symphony Orchestra, and it has an annual chamber music series, as well as several series featuring renowned soloists. The State Ballet of Rhode Island performs regularly throughout the state. Many of the restored houses in Newport were the setting for the Newport Jazz Festival, a world-famous event begun with annual summertime jazz concerts in 1954 and joined in the 1960s by folk-music presentations. The festival was moved to New York City in 1971.

The Trinity Square Repertory Company, with its own home in Providence, is renowned for producing works by new piaywrights, as well as for staging novel productions of classic works. In 1968 it became the first regional theatre in the United States to be invited to perform at the Edinburgh International Festival of Music and Drama in Scotland.

Sports. Many of the recreational activities of the people of Rhode Island are centred around the state's water. For many years the waters off Newport have been the site of the yacht races for the America's Cup. An annual tuna tournament is held in Rhode Island and Block Island sounds. Newport Casino, one of the early centres of tournament tennis, has an annual grass-court tournament of national importance.

Communications. The state has several daily papers, the largest of which are *The Providence Journal* and *The Evening Bulletin.*

The state is served by three commercial television stations and by an educational station operated by the state. Boston television stations are also received in most of Rhode Island, and there are numerous radio stations.

Prospects. Rhode Island has had to live by its wits. Lacking any important natural resources except Narragansett Bay and the waterpower that could be generated on its river systems, the state prospered first by seaborne commerce and subsequently by manufacturing, especially textiles, machinery, and jewelry. The attractiveness of its colonial heritage in architecture, its assets as a summer resort, its suitability as a base in the Northeast for the navy, and its emphasis upon independence of thought and freedom of religion have given it a character unlike any other New England state.

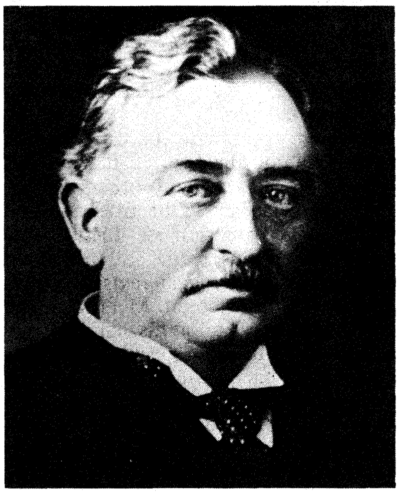
BIBLIOGRAPHY. The biennial *Rhode Island Manual* contains extensive factual data on governmental officials, committees, etc.; while the annual *Journal-Bulletin Rhode-Island Almanac* contains recent election results, economic data, and much miscellaneous information not easily obtainable elsewhere. The FEDERAL WRITERS' PROJECT, *Rhode Island* (1937, reissued 1973), is excellent for its factual material on the state's various communities. EDWARD FIELD (ed.), *State of Rhode Island and Providence Plantations at the End of the Century: A History,* 3 vol. (1902), though old, remains the most complete history for the period covered; HOWARD M. CHAPIN, *Documentary History of Rhode Island,* 2 vol. (1916), is indispensable for the earliest years of settlement; WILLIAM G. MCLOUGHLIN, *Rhode Island* (1978), is a shorter, interpretive history of the state. SAMUEL H. BROCKUNIER, *The Irrepressible Democrat, Roger Williams* (1940), is the best biography of Williams; while PERRY MILLER, *Roger Williams: His Contribution to the American Tradition* (1953), is the most important reassessment of Williams' position as a liberal thinker. JAMES B. HEDGES, *The Browns of Providence Plantations,* 2 vol. (1952–68), is a classic study of Rhode Island's most influential family. ANTOINETTE F. DOWNING and VINCENT J. SCULLY, JR., *The Architectural Heritage of Newport, Rhode Island, 1640–1915,* 2nd ed. rev. (1967), contains detailed studies of the architectural developments from colonial days to the "summer palaces" of the millionaires. Publications of the Rhode Island Historical Society, especially the quarterly *Rhode Island History.* are valuable for recent developments.

(B.F.S.)

Rhodes, Cecil

The life of Cecil John Rhodes, South African financier and statesman and one of the great empire builders, spanned the heyday of British imperialism. When he was born, central Africa was virgin territory, and it was still possible to niake a fortune and acquire power by what Rhodes called "philanrhropy plus five percent"; or to dream of "painting the map red" (to plant the British flag) from the Cape of Good Hope to Cairo. He achieved the first and made advances toward the second. By the time he died, however, the second South African (Boer) War had already exposed the weaknesses of imperialism. His notions of the superiority of the Anglo-Saxon race soon faded, and his real dreams were never fulfilled. His name survives in the Rhodes scholarships at the University of Oxford.

EB Inc



Rhodes.

Early struggles and financial successes. Rhodes was born on July 5, 1853, the son of the vicar of Bishop's Stortford in Hertfordshire. The family's roots were in the countryside, where Cecil Rhodes always felt at home: tree planting and agricultural improvement were among his lifelong passions, though his earliest ambition was to be a barrister or a clergyman. His father was prosperous enough to send one son to Eton College, another to Winchester College—both leading English private schools—and three into the army. Cecil, however, was kept at home because of a weakness of the lungs and was educated at the local grammar school. Poor health also debarred him from the professional career he planned. Instead of going to the university, he was sent to South Africa in 1870 to work on a cotton farm, where his brother Herbert was already established. Though hc was never close to his father, parting from his mother and home caused him intense sorrow.

Diamond prospecting

The cotton farm in Natal, now a province in the Republic of South Africa, was not a success. On his arrival Rhodes found that his brother had already left for the diamond fields of Griqualand West, a former division of what is now the Republic of South Africa. Although Herbert returned to the farm, and the two brothers continued stubbornly trying to grow cotton for a year, the "diamond fever" eventually overcame them. In 1871 they moved to Kimberley, the centre of mining, where life was even harder than in Natal. Herbert was restless and stayed only till 1873, but Cecil's characteristic determination kept him at Kimberley off and on for years. until at last, after a harsh beginning, his luck turned.

Rhodes was early seen as a man apart. He kept his own company and dreamed his dreams. Shy himself, at the occasional dances he sought out the plainest girls, saying that he danced only for exercise, He was addressed only as "Mr. Rhodes," and his signature on letters, even to close friends, was always "C.J. Rhodes." Unlike other adventurers seeking their fortunes, he admired the pastoral

Boers—the descendants of the Dutch settlers in South Africa—and respected their love of their land. A severe illness in 1872 led him to make a journey of convalescence to the north, from which he returned with a fresh view of the potentialities for British expansion in Africa. Another illness in 1874 isolated him still more from the rough society of Kimberley; so did his habit of intellectual study, which led him to return home in 1873 to become an undergraduate at Oxford.

For eight years, until he took a belated degree in 1881, he divided his life between Kimberley and Oxford. Both societies found him odd, though he did his best to conform outwardly to the conventions. At Oxford he read the classics desultorily, attended occasional lectures, and became attracted to the ideas of social reform of the English essayist and art critic John Ruskin. Rhodes's eccentric habits, his falsetto giggle, his rambling monologues, and his unusual background intrigued the younger men around him. So did his philosophy of an almost mystical imperialism. "To be useful to my country" summed up his creed, which somehow he identified with Aristotle's theory of "the good life."

In 1877, while still an undergraduate, he drew up the first of his famous wills, leaving the fortune that he had not yet made to the colonial secretary and others for the purpose of founding a secret society, "the true aim and object whereof shall be the extension of British rule throughout the world." In various forms, all his seven wills had some such object in view, each revision representing a new development of his thought. Meanwhile, he returned annually to Kimberley to exploit his claims.

Formation of the De Beers Mining Company

He gradually advanced from being a speculative digger to the status of a man of substance with ambitious ideas on the future of the diamond industry. His first partnerships were with young men as impoverished as himself, such as C.D. Rudd, with whom he formed the De Beers Mining Company—so called after the De Beers mining claims, many of which he had acquired. Eventually, success brought new friends and also rivals. Alfred Beit, a German who knew the diamond market intimately, was his most valued friend. The most fateful was a young doctor, Leander Starr Jameson, who became his medical adviser in 1878. Outstanding among his rivals was Barney Barnato, from the slums of London, with whom he struggled for control of the diamond fields; it was always Rhodes's way to "square^{m}—buy out—a rival if he could, rather than fight him, and finally he did so in the case of Barnato, too.

With Beit's help, Rhodes expanded his claims until all the De Beers mines were under his control. In 1887 he set about acquiring the Kimberley mine, which was mainly controlled by Barnato. A furious competition to buy up shares ended in Rhodes's favour in 1888. He finally paid over £5,000,000 ($25,000,000)—a generous settlement—for Barnato's holding and celebrated by making his rival a member of the Kimberley Club, into which Barnato had never before even been admitted. Other lesser mines fell under Rhodes's control, until by 1891 his company, De Beers Consolidated Mines, owned 90 percent of the world's production of diamonds. He also acquired a large stake in the Transvaal gold mines, which had been discovered in 1885, and formed the Gold Fields of South Africa Company in 1887. Both Rhodes's major companies had terms in their articles of association allowing them to finance schemes of northward expansion.

Political involvement in Africa. Rhodes never regarded moneymaking as an end in itself. "Painting the map red," building a railway from the Cape to Cairo, reconciling the Boers and the British under the British flag, even recovering the American colonies for the British Empire, were all part of his dream. With these ideas in view, he first went into politics in 1881, offering himself for election to the parliament of the Cape Colony in a constituency in which he had to depend on Boer support. He held it for the rest of his life. Though unimpressive as a speaker and contemptuous of parliamentary procedure, he earned respect by his original views. He made friends with many Boer politicians, particularly Jan Hofmeyr, W.P. Schreiner, and in the Afrikaner Bond, a leading Boer organization in the Cape Colony; he espoused the cause of the natives in what were then Basutoland and Bechuanaland (now Lesotho and Botswana); and always he had his eyes fixed on the north. The north, however, included the Boer republic of the Transvaal, now in the Republic of South Africa, which successfully fought a brief war of independence with Britain in 1880–81; and its president, Paul Kruger, was one obstinate rival whom Rhodes could never "square."

His first intervention in native policy came in 1882, when he was appointed to a commission to pacify Basutoland after a minor rebellion. The rebellion had been put down by the former British governor of the Egyptian Sudan, Gen. Charles Gordon, acting for the Cape government. He succeeded not by force but by organizing discussion meetings with the tribal chiefs. Rhodes was impressed by the man and his methods, though less favourably by the contempt that Gordon showed for financial reward. Gordon too was impressed—so much so that when he returned to Khartoum two years later, he invited Rhodes to accompany him. Rhodes, however, refused; although the Sudan was included in the territory he wanted eventually to paint "all red" on the map, he intended to reach it by advancing from a secure base in the south.

His determination to keep open a road to the north involved him in many disputes. Other imperial powers—the Germans, Belgians, and Portuguese—were in competition for the uncharted interior of Africa, as were the Transvaal Boers. The missionaries were, in Rhodes's view, overly solicitous of native interests; the Cape government was weak; and the British government, which he called the "imperial factor," was too distant to understand his ideas. But he assiduously cultivated the government's representatives in Cape Town—particularly the high commissioner Sir Hercules Robinson—with profitable results.

Acquisition of Bechuanaland

The crucial area was Bechuanaland, through which ran the route used by the missionaries. Rhodes intended to use it to open up the northern territories of Mashonaland and Matabeleland (both now in Rhodesia). "If we get Mashonaland," he would say, "we shall get the balance of Africa." Mineral wealth, communications, and, eventually, white settlement were his objectives. All the boundaries were unsettled, however, and many intrusions had to be frustrated first. Boers from the Transvaal, trying to annex slices of Bechuanaland, proclaimed two small independent republics in Stellaland and Goshen. In 1882 a boundary commission, to which Rhodes again secured appointment, was sent to settle the boundaries of Griqualand West. Rhodes persuaded the commission to extend its mandate to the two small republics. In 1884, when the Germans in South West Africa declared a protectorate over two territories (which, along with Stellaland and Goshen, would have sealed off the Cape Colony from the north), he persuaded the high commissioner that the Imperial government must intervene. By the London Convention of 1884, the two republics were excluded from the Transvaal, and the Cape government agreed to help finance a protectorate over Bechuanaland. During the struggle, Rhodes briefly held office in 1884 as treasurer general of the Cape Colony, but the government soon fell when an outbreak of phylloxera, a plant louse that attacked the vineyards, was blamed on the government.

His settlement of the Bechuanaland question was also soon threatened, for the deputy commissioner in the new area, John Mackenzie, a missionary whom Rhodes contemptuously labelled a "negrophilist," antagonized the Boers. Rhodes insisted on his removal and was appointed in his place. He succeeded in conciliating the Boers of Stellaland but could not prevent Kruger from declaring a protectorate over Goshen, from which he withdrew only after an expeditionary force was sent up from the Cape. A conference to settle the matter was held in February 1885 on the River Vaal, where Rhodes and Kruger met for the first time. These two stubborn men, each determined to dominate Africa, each ever ready to quote Scripture for his purpose (Kruger always from the Old Testament, Rhodes chiefly from the New), naturally failed to achieve any meeting of minds.

Struggle with Kruger

Although Kruger was forced to give up Goshen, Rhodes did not get everything his own way. It was decided that southern Bechuanaland should become a crown colony and northern Bechuanaland a protectorate. Rhodes, who wanted both annexed by the Cape Colony, resigned in protest in March 1885 and thereafter devoted strenuous efforts, both in Cape Town and London, to securing the transfer of the coiony to the Cape government.

Two men still stood in the way of Rhodes's plans for developing the north. One was Kruger, with his policy of "Africa for the Afrikaners"—the Boers. By the Franchise Law of 1890, he denied political rights to the foreigners (Uitlanders) who had come to work the gold mines in the Transvaal. He also tried to extend Boer control to Mashonaland and Matabeleland. The ruler of the Matabele was King Lobengula, Rhodes's second obstacle. Kruger had approached him for a treaty and mining concessions in 1887, and so had many others. Lobengula, however, though uneducated, knew that once he let the white men in, he would never see their backs. The only white men he trusted were missionaries; and Rhodes duly found in John Moffat, the son of a famous missionary, a man to serve his purpose.

Once Moffat, as Assistant Commissioner for the crown colony of Bechuanaland, had, in February 1888, persuaded Lobengula to sign an exclusive treaty of friendship, Rhodes sent three of his trusted agents to obtain a mining concession based on the treaty. The concession was extracted from the reluctant Lobengula in October 1888: to the last, he hoped he had only allowed the white man to dig "a big hole." In fact, however, he had virtually signed away his kingdom, and Rhodes hastened to press the Imperial government, through the high commissioner, to grant a charter to a new company, the British South Africa Company, to develop the new territory. Difficulties had still to be overcome: other concession hunters had to be bought off; Lobegula's doubts had to be overcome by sending Doctor Jameson with a gift of weapons; the Aborigines Protection Society intervened to warn Lobengula. In October 1889, however, the charter was granted, and Lobengula, captivated by Jameson's charm, allowed the digging to begin.

By then Rhodes had powerful allies: bankers, such as Lord Rothschild; influential journalists; empire builders, such as Harry Johnston and Gen. Horatio Herbert Kitchener; politicians, such as Lord Rosebery. He also attracted suspicion and hostility: Lord Salisbury and Joseph Chamberlain—both powerful politicians--disliked him, as did the future Lord Lugard, the colonial administrator, and Henry Labouchere, a radical M.P. Rhodes's habit of seeking to "square" people who might oppose his plans by offering them large shares in his companies was open to misunderstanding. So were his contributions to the Liberal Party on condition that it should not give up British control of Egypt and to the Irish Nationalists on condition that they should accept Home Rule under a federal parliament. He was useful, however, to a parsimonious government, because he undertook to develop vast territories at his own expense. Queen Victoria found his imperialism attractive, no less than his courtly rebuttal of the accusation of being a woman hater: "How could I dislike a sex to which your Majesty belongs?" The upshot of his successful propaganda was that the charter granted by the Imperial government went far beyond what Lobengula had conceded. There was no northern limit on it; and Rhodes intended to extend the chartered company's control to Northern Rhodesia (now Zambia) and Nyasaland (now Malawi), as well as to the Bechuanaland Protectorate (now in Botswana).

Founding of Salisbury

In 1890 Rhodes's Pioneers began their hazardous march into Matabeleland and thence to Mashonaland, where they established a fort in September, to be called Salisbury, after the British prime minister. The size of the expedition, clearly intended for permanent occupation, disturbed Lobengula, but Jameson was at his capital, Bulawayo, to put his mind at ease. In the following year Harry Johnston took over the administration of Nyasaland in a dual capacity, as commissioner of the Imperial government and an employee of the chartered company. Although eventually the protectorate reverted fully to the Imperial government, Rhodes's influence was felt both north and south of the River Zambezi, and soon the new territories were called by his name.

Policies as prime minister of Cape Colony. In the meantime, he had returned to office in 1890 in the only post big enough for him, as prime minister of Cape Colony. For five years he proved a successful and imaginative prime minister, though still little known to the world. He acquired a property called Groote Schuur, which he rebuilt in the Dutch colonial style and bequeathed as an official residence for future prime ministers of the Union of South Africa. There he lavishly entertained Dutch and British inhabitants of the Cape Colony and eminent visitors of all nationalities. Everything he undertook was on a massive scale. "I like the big and simple—barbaric if you like," he would say. Men found him both harsh and generous but always pertinacious and persuasive.

In parliament he cultivated the support of the Afrikaner Bond without losing the goodwill of British liberals. His agricultural policies were sensible and effective. In native policy he had to move cautiously. His Strap Bill (1891), which would have permitted the flogging of Africans in certain cases, had to be dropped. The Franchise and Ballot Act (1892) was passed, limiting the native vote by financial and educational qualifications. The Glen Grey Act (1894), assigning an area for exclusively African development, was introduced from the highest motives: "a Bill for Africa," as Rhodes proudly called it. His main aim was to prevent the Dutch and British quarrelling over such policies. To him that involved the risk of "mixing up the native question with the race question" (Rhodes used the word "race" to distinguish the Boers and the British).

Northern policy

He also sought to unite the two white races on his northern policy. The prospects were good because Kruger's obstinacy alienated the Cape Dutch. To ensure that commercial traffic did not have to reach the Transvaal through the Cape Colony, Kruger had built a railway to Delagoa Bay; then in 1894 he closed the "drifts," or fords, of the River Vaal to prevent transport of goods by wagon, besides imposing heavy duties on Cape produce. Rhodes went to the Transvaal capital to protest, but in vain. Kruger was compelled to yield only after a declaration by W.P. Schreiner, Rhodes's attorney general, that he was in breach of the London Convention, coupled with a threat by Joseph Chamberlain, who had become colonial secretary in 1895, to support a military expedition.

Rhodes's patience had begun to wear thin even earlier, partly because he knew his health was precarious, partly because he learned that the gold deposits of the Transvaal were enormous, whereas those of Mashonaland were proving poor. His northern policy was encountering unexpected frustrations. The chartered company was in financial difficulties, its resources being overstretched. Although Rhodes's agents secured some new territories for the company, including Manica (now in Mozambique [Portuguese East Africa]) and Barotseland (now in Zambia), elsewhere he was forestalled. An Anglo-German agreement of 1889 gave a strip of land to Germany, cutting off Bechuanaland from the north. The Belgian king Leopold anticipated Rhodes in laying claim to Katanga (1890), now a province in the Democratic Republic of Congo. The Anglo-Portuguese Convention of 1891 ended his hopes of eliminating Portugal from Africa. Harry Johnston proved uncooperative in administering Nyasaland. When Rhodes paid his first visit to Rhodesia in 1891, he found the pioneers in an angry mood; to pacify them, he helped them generously out of his own pocket.

Serious trouble broke out in 1893, when Lobengula tried to reassert his control over Mashonaland. Jameson, who had been appointed resident commissioner in 1891, resisted the Matabele raiders on his territory. A short, sharp war ended in the total defeat and death of Lobengula, after which Rhodes instructed Jameson to settle and administer Matabeleland. The objections of the "imperial factor" and the missionaries were gradually overcome, and in July ***1894*** the British government gave its sanction to his settlement. Rhodes was then at the pinnacle of his achievement, but still the wider union of southern Africa eluded him. He was growing petulant and impatient and was visibly aging. By ***1895*** he was determined to settle accounts with the last obstacle, President Kruger.

There was already talk of force to remedy the grievances of the Uitlanders in the Transvaal. In ***1894,*** the Cape Colony's new high commissioner, Sir Henry Loch, went up to Pretoria to reason with Kruger, who made it clear that he would never give way. The Uitlanders formed a National Union to support their cause, among its leaders being Rhodes's brother Frank. Kruger sought the support of Germany, and in ***1895*** he again closed the "drifts" across the Vaal. Again he was forced to give way, and by this time a conspiracy against him was under way. Rhodes knew about it and worked actively to foster it. The original intention was that a "spontaneous" revolt in Johannesburg should lead to a military incursion from the Bechuanaland protectorate, followed by a personal intervention by the high commissioner from Cape Town. To this end Rhodes used his influence to have Sir Hercules Robinson returned to the Cape Colony as high commissioner; and through his agents in London he secured Chamberlain's agreement to the immediate cession of a strip of the Bechuanaland protectorate, ostensibly for his railway to the north but in fact to provide a "jumping-off place" for an armed force under Jameson.

Effects of the Jameson Raid on Rhodes's career. Chamberlain was privy to the plan, but no one foresaw what actually resulted. The National Union in Johannesburg lost heart and decided not to act. Rhodes, Robinson, and Chamberlain all assumed that the plan had been called off; but Jameson recklessly decided to force the hand of the Uitlanders by invading the Transvaal on his own. He launched the famous raid on December ***29, 1895.*** It was a fiasco, his whole force being captured, apart from a few killed. Rhodes was compelled to resign all his offices, not only in the Cape government but also in the chartered company; but he refused to denounce Jameson. Official inquiries were held in Cape Town ***(1896)*** and London (1897), blaming Rhodes but tacitly acquitting Chamberlain. Rhodes protected Chamberlain by suppressing the so-called missing telegrams that had passed between them, his purpose being to put moral pressure on Chamberlain not to abrogate his company's charter.

The raid was an almost complete disaster for Rhodes. Jameson and his colleagues were sent to prison; Kruger's power was consolidated; the Dutch and British colonials were more deeply split than ever; Rhodesia and Bechuanaland were taken over by the Imperial government. Only the charter was preserved, and Rhodes spent the rest of his life promoting developments in the north. He even won public sympathy, partly because the German Kaiser had sent Kruger a foolish telegram of congratulations and partly because his own evidence to the inquiry displayed an inspiring conception of imperial destiny. He sought to embody that conception in his will, the seventh and final version of which was signed in ***1899.***

Early in ***1896,*** while Rhodes was in England, there was a serious revolt in Matableland. Rhodes returned by way of Egypt and took an active part in suppressing the revolt. He finally brought it to an end by the technique of holding a peace conference ***(indaba)*** that he had learned from Gordon. On this occasion Rhodes found the site in the Matopo Hills that he called the "View of the World" and chose it for his burial place. Knowing that his days were numbered, he compensated for political eclipse by private activities: developing a large farm at Inyanga, rebuilding Groote Schuur (which was burnt down in 1896), and sending out his young "apostles" to prospect for minerals in the north.

Not only did his old Boer allies in the Cape Colony, such as Hofmeyr and Schreiner, now distrust him but so also did the government in London and its new high commissioner in Cape Town, Sir Alfred Milner. At first Rhodes avoided Milner and resisted all pressures to reenter politics. He spent much time travelling, partly for his health, in Europe and Egypt, always promoting his plans for spanning Africa by railway and telegraph. Gradually, it became apparent that he was still indispensable in the Cape Colony. Milner began to assimilate Rhodes's views and to become even harsher in his judgment of Kruger. In ***1898*** Rhodes assumed the leadership of the Progressive Party, which had been founded to promote the British interest. Though he never held office again, he powerfully influenced successive Cape governments. As war with the Boers of the Transvaal approached, however, Rhodes kept out of the way, advising his friends to "leave it to Milner."

Boer War and Rhodes's death

He insisted that Kruger would "climb down" in the end, perhaps hoping that he was wrong. When the Boer War broke out in October ***1899,*** Rhodes spent the first few months under siege at Kimberley. After a spirited defense, during which he assumed the rank of colonel, he emerged early in ***1900*** confident that the war would soon be over. He spent five months in Rhodesia planning for the future and pressing on Milner schemes of British settlement and reconciliation with the Boers.

His last years were soured by an unfortunate relationship with an aristocratic adventuress, Princess Radziwiłł, who sought to manipulate Rhodes and Milner and even Lord Salisbury, the English prime minister, to promote her ideas of the British Empire. Rhodes was unused to scheming women, nor could the young bachelors surrounding him protect him from her. She forged letters and bills of exchange in his name and was finally sent to prison, but not before she had caused him much annoyance and scandal. In ***1901,*** while he was in Europe, he was recalled to Cape Town to give evidence at her trial. His last political act on his return was to support Milner in suspending the constitution of the colony until the war was over. He was, however, already dying of an incurable heart disease. Before either the Boer War or even Princess Radziwiłł's trial was over, he died on March ***26, 1902.*** Two weeks later he was buried in the Matopo Hills. His last journey through Africa in the funeral train was a triumphal procession.

Reputation

When Rhodes's will was read in April ***1902,*** his reputation immediately rose to new heights. The imaginative scheme of scholarships at Oxford for young men from the colonies and from the United States and Germany appealed to the public instinct for a more disinterested kind of imperialism. Most of his fortune (over £3,000,000 when the debts and legacies were paid) was devoted to this purpose. As the will forbade disqualification on grounds of race, many nonwhite students have benefitted from the scholarships, though it is doubtful if that was Rhodes's intention. He once defined his policy as "equal rights for every white man south of the Zambezi," and later, under liberal pressure, amended "white" to "civilized." But he probably regarded the possibility of native Africans becoming "civilized as so remote that the two expressions, in his mind, came to the same thing.

BIBLIOGRAPHY. J.G. LOCKHART and C.M. WOODHOUSE, ***Rhodes*** (1963), the most up-to-date biography, based on the Rhodes papers; S.G. MILLIN, ***Rhodes,*** rev, ed. (1952), a work, by a South African woman, that supersedes all earlier biographies; "VINDEX," ***Cecil Rhodes, His Political Life and Speeches,*** *1881–1900* (1900), essential to an understanding of Rhodes's style of thought and expression; J. VAN DER POEL, ***The Jameson Raid*** (1951), a definitive account of the crucial episode in Rhodes's career; BRIAN ROBERTS, ***Cecil Rhodes and the Princess*** (1969), interesting mainly for the account of the last few months of Rhodes's life.

(*C.M.*Wo.)

Rhodesia (Zimbabwe)

Rhodesia, since ***1980*** officially named Zimbabwe, is a republic in southern Africa. It achieved majority rule and internationally recognized independence in April ***1980,*** after a long armed struggle against the white minority regime that in November ***1965*** had made a unilateral and unconstitutional declaration of independence from Great Britain. Although political power passed at independence to the representatives of the country's ***7,200,000*** blacks, the economic role of its ***230,000*** whites remained dominant. The new government committed itself to the ideal of building a multiracial state. Many changes were expected in the early years of independence in the process of land resettlement and economic reconstruction after a profoundly disruptive civil war.

Zimbabwe is landlocked. It shares a 125-mile (200-kilometre) border on the south with South Africa, and is bounded on the southwest and west by Botswana, on the north by Zambia, and on the northeast and east by Mozambique. Its total area is 150,804 square miles (390,-580 square kilometres). Its capital, Salisbury, has a population of more than 700,000, swollen by the influx of wartime refugees from rural areas.

The nationalist struggle

The three-sided quarrel between the European Rhodesian leaders, successive British governments, and the African Zimbabwean nationalists has overshadowed most aspects of contemporary life in the country. While the history of this quarrel goes back to the occupation of the region in 1890 and to the rebellions of 1893–97 in both Mashonaland and Matabeleland, its immediate roots stem from the circumstances attending the dissolution of the Federation of Rhodesia and Nyasaland in 1963. Southern Rhodesia had been a self-governing colony, never directly administered by Great Britain, when it entered this federation in 1953. Its premier, Winston Field, and his successor, Ian Smith, demanded as the price of acquiescence in the dissolution of the federation by the British Conservative government that Southern Rhodesia achieve full independence (as Rhodesia) no later than Northern Rhodesia (as Zambia) or Nyasaland (as Malaŵi). The British government was not satisfied that the Rhodesian administration, with an electorate of 85,000 whites and only 12,000 blacks, was a sufficiently representative government. It countered with a statement of five principles on which an independence constitution should be based; the most important of these was "unimpeded progress to majority rule." Fruitless negotiations continued for nearly two years, until the government of Ian Smith made its unilateral declaration of independence (UDI) in 1965.

The quarrel was soon afterward enlarged to engage the United Nations. The United Kingdom, while arguing that UDI was an act of rebellion with which it alone retained authority to deal, asked UN member states not to recognize Rhodesian independence and to apply voluntary economic sanctions. It later persuaded the UN Security Council to impose first selective, and later comprehensive, mandatory sanctions.

Three separate attempts by the British government to reach a political settlement with the Smith regime on the basis of its five (later six) principles filled the first half of the period of UDI. The last attempt, in which a British commission in 1972 toured Rhodesia to judge the acceptability of its settlement proposals to the people as a whole, proved a turning point in the struggle. The overwhelming rejection of those proposals provided an impetus for a revived nationalist movement. At the same time, advances by the nationalist forces fighting against the Portuguese in Mozambique opened up terrain favourable for Zimbabwean guerrilla infiltration. Although the British government, helped actively by U.S. negotiators, continued to press political proposals, during the next seven years of UDI it was the increasing effectiveness of the guerrilla armies operating from bases in Mozambique and Zambia that drove the Smith regime to concede majority rule. This came at a cost of some 27,000 lives and more than 1,000,000 refugees. (For further coverage of historical aspects, see SOUTHERN AFRICA, HISTORY OF.)

THE LANDSCAPE

Relief. Zimbabwe lies almost entirely over 1,000 feet (300 metres) above sea level. Its principal physical feature is the broad ridge running 400 miles from southwest to northeast across the whole country, from Plumtree through Gwelo and Marandellas to Inyanga. About 50 miles wide, this ridge ranges in altitude from 4,000 to 5,000 feet, until it eventually rises to 8,503 feet at Mt. Inyangani, the highest point in Zimbabwe, in the eastern highlands. This ridge is known as the Highveld and comprises about 25 percent of the country's total area of 150,804 square miles. On each side of this central spine, sloping down northward to the Zambezi River and southward to the Limpopo River, lies the wider plateau of the Middle Veld, which, at an altitude between 3,000 and 4,000 feet, makes up about 40 percent of the area of Zimbabwe. Beyond this again, and mostly in the south, whrre the Sabi, Lundi, and Nuanetsi rivers drain from the plateau into the Limpopo, lies the Lowveld, which comprises about 23 percent of the total area. The lowest point in Zimbabwe lies at an altitude of 660 feet near Dumela, where the Limpopo Rows down toward Mozambique. There are no parts of Zimbabwe that can properly be called desert, although a sector northwest of Plumtree along the Botswana border and a lengthy belt across the Lowveld in the south are severely arid.

Geology

A characteristic of the landscape is its Precambrian rock, which is between 570,000,000 and 4,600,000,000 years old. The most ancient part of this rock formation, known as the Basement complex, covers the greater part of the country. About four-fifths of the Basement complex consists of granite; the Matopo Hills south of the city of Bulawayo are formed of a hard outcrop of granite and gneiss. These outcrops, known as balancing rocks, have been severely weathered by wind and water, leaving some blocks precariously balanced upon others. Elsewhere are found innumerable rounded hillocks known as kopjes and composed of ball granite. Belts of schist in the Basement complex contain the veins and lodes of most of the country's gold, silver, and other minerals.

The Great Dyke, which is up to eight miles wide and about 320 miles long, is another notable feature. The Alkali Ring complexes are igneous intrusions of volcanoes; they occur in the Sabi Valley and near Beitbridge. The Karroo System—a thick layer of sedimentary rocks consisting of shale, sandstone, and grit—covers the Zambezi Valley and the valleys of its tributaries from Wankie southward to Bulawayo and spreads across parts of the southern Lowveld from Tuli, near the southern border, to the Sabi River.

Drainage and soils. Major faulting from southwest to northeast formed the middle Zambezi trough, which is now partially flooded by Lake Kariba. Other faulting affected the depressions of the Sabi and Limpopo rivers. As a result of subsidiary rifting a few sizable rivers drain north and south from the Plumtree–Inyanga watershed.

Low fertility of soils

The light, sandy soils developed on granite rocks are highly weathered and leached, even in the areas of lower rainfall, and do not easily retain water. Since the bulk of the rain occurs in heavy showers during a few months of the year, problems of drainage and of retaining nutrient reserves also occur. The meagre mineral reserves in the soils imply an inherently low fertility; under cultivation, productivity drops rapidly. The difficulty of cultivating these lighter soils is greatest in the black farming areas, where population pressure no longer allows land to be temporarily abandoned after cultivation; black farmers, because of a lack of capital, are also less able than white farmers to maintain the mineral fertility with manure and chemical fertilizers. (For associated physical features, see VICTORIA FALLS; ZAMBEZI RIVER.)

Climate. Zimbabwe lies north of the Tropic of Capricorn but enjoys subtropical conditions because of its altitude. Toward the end of the hot, dry months, which last from August to October, monsoon winds that have crossed the Indian Ocean and Mozambique cause rainfall when they meet the rampart formed by the eastern highlands. The eastern districts consequently receive the heaviest rainfall and have a more prolonged rainy season (lasting from October into April) than the rest of Zimbabwe. The altitude of the broad plateau of western Zimbabwe helps to guarantee fine weather for most of the country during the cool, dry winter months of May to August.

June is generally the coolest month and October the warmest; temperature variations correspond closely to altitude. Inyanga, at about 5,500 feet in the eastern highlands, varies in temperature from a mean of 52" F (11° Cj in July to one of 65° F (18° C) in October. Salisbury, at about 4,800 feet, has temperatures varying from 57° F

(14" C) to 70° F (21° C), and Bulawayo, at 4,400 feet, has temperatures varying from 58° F (14° C) to 73° F (23° C). On a 20-year average, Salisbury and Bulawayo have had a year-round daily mean of eight hours of sunshine, and this average does not drop below six hours during the rainy season. (For rainfall patterns, see below, Traditional regions.)

Savanna country

Vegetation. Zimbabwe is predominantly savanna (tropical grassland) country, with a generous tree growth encouraged by the wet summers. The only true forests, however, are the evergreen forests of the eastern border and the savanna woodland, which includes teak, northwest of Bulawayo. Various species of Brachysregia (a hardwood tree up to 90 feet high with pale reddish-brown wood) are dominant in the Middle Veld and Highveld. Other common varieties include the mohobohobo (a medium-sized tree with large spadelike leaves) and the thorn tree. In the valleys of the Zambezi and Limpopo rivers the mopani, which resembles the mohobohobo, is common, together with baobab and the knobby thorn tree. Australasian eucalyptus trees have been widely introduced, predominantly on white-owned farms, where they are used as windbreaks and for fuel; Australian wattle has been planted in the eastern districts as a source of tannin. Pure grassland is uncommon but occurs particularly along the eastern border around Melsetter. Swamps are widespread on the Botswana border.

Wankie National Park

Animal life. Cultivation of the land has resulted in the disappearance of many forms of animal life from large areas. Wankie National Park has an area of more than 5,000 square miles and stretches from the Bulawayo–Victoria Falls railway line westward to the Botswana border. Among the flesh-eating animals found there, and occasionally elsewhere, are the lion, leopard, cheetah, serval, civet, aardvark, spotted and brown hyena, black-backed and side-striped jackal, zorilla, ratel, bat-eared fox, ant bear, and scaly anteater. Elephants are found in the northern region and giraffes in the western bushland; hippopotamuses and crocodiles live in the larger rivers. Among a great variety of hoofed and horned ruminant animals are the eland (which is immune to the deadly tsetse fly), greater kudu, blue duiker, impala, klipspringer, steenbok and grysbok, and sable and roan antelope. Snakes include mambas, boomslangs, and the black-necked cobra. Baboons, which are the bane of farmers whose crops they damage, include the Rhodesian and yellow species, as well as the chacma, the largest known baboon species. Notable among the birdlife are the martial eagle, the bateleur eagle, and the little hammerhead, which builds enormous nests and is revered as a bird of omen.

Traditional regions. Zimbabwe may be divided into six-different regions, with the amount of rainfall constituting the determining factor in land use. Of the nation's 96,500,000 acres. some 1,500,000 acres (607,000 hectares) in the eastern highlands, with more than 25 inches of rainfall annually, are suitable for diversified farming with cattle and plantation and orchard crops. A further 18.000~000acres sweeping west along the centra! spine past Salisbury and to the midlands receive 20 to 25 inchcs of rain and are used for intensive farming of corn (maize) and tobacco and the raising of livestock. An almost equal area to the southwest, enclosing Bulawayo, receives 16 to 20 inches of rain a year; it is suitable for mixed farming and for raising livestock on a semi-intensive scale. One-third of the country, lying farther outward from the spinc of Zimbabwe, mostly to the south, and receiving 14 to 18 inches of rain a year, is used for semi-extensive farming, while 25,000,000 acres in the Lowveld toward the Limpopo and Zambezi rivers, receiving less than 16 inches a year, are fit only for ranching. Finally, some 3,000,000 acres, mostly toward the Zanibezi River, are unsuitable for either agriculture or forestry.

Land ownership

Racial segregation of land ownership persisted in prac-·~k cif not in law, from the 1890s into the early years of independence. Of the 35 percent of the total land area considered suitable for intensive or semi-intensive farming. three-fifths was in the hands of white farmers and the remaining two-fifths belonged to blacks. Of the 59 percent that was fit for semi-extensive or extensive farming, each racial group had nearly a half-sharc.

The landscape under human settlement. At independence, settlement patterns in Zimbabwe reflected the segregation of land ownership first established after 1890 and formalized in the Land Apportionment Act of 1930 and the Land Tenure Act of 1969. Thc latter law apportioned the nation's lands almost equally in size between whites and blacks and set aside a national area for parks and game reserves. Of the 44,962,000 acres (18,191,000 hectares) of land assigned to the black population, 39,922,100 acres were designated as Tribal Trust Lands and 3,670,400 acres as African Purchase Areas.

The black people of Zimbabwe are still predominantly rural. In 1975, the last year before the civil war brought widespread disruption in rural areas, 83 percent lived either in their own village communities or in compounds on white-owned farms. Housing and living conditions in the Tribal Trust Lands greatly worsened during the 1970s, as the population grew to 4,500,000 on some 40,000,000 acres of such poor fertility that they could not adequately support more than 1,000,000 people. Less than 2 percent of all black rural households had electricity, and four houses out of five were still built of pole and dakha (wattle and mud) material. Access to safe water was rare because most families in the Tribal Trust Lands drew their supplies from shallow wells or unprotected surface sources. A large proportion of these families survived with the help of remittances from relatives in the agricultural cash economy or workers on white-owned farms or in towns; they could not aspire to buy land in the 66 African Purchase Areas, where hundreds of the 8,000 farms remained vacant. The purchase areas were themselves producing only about one-quarter of what was cropped from the same amount of white-owned land.

The Rhodesian Front came to power in 1962 with the promise to maintain land segregation, despite the evidence gathered in 1960 by a Rhodesian parliamentary committee that the black reserves could not support all the families with land rights under the Native Land Husbandry Act of 1951. The Front put aside the implementation of this act and attempted to establish racial division "for all time" with the Land Tenure Act of 1969. In consequence, the nationalist struggle focussed sharply upon the issue of land ownership, and a major concern for the Zimbabwe government after independence was to carry through land reform and launch large-scale settlement of black families on former white farms.

The Land Apportionment Act made no provision for blacks who chose an urban life, for towns were designated as white areas. As a result, though urban blacks now outnumber whites by four to one, blacks mostly live in rented homes in townships located some miles from city centres. The cities of Salisbury and Bulawayo therefore constitute studies in contrast, with impressive office buildings and quiet white suburbs partially ringed by crowded black townships where there is an average of two people to each room. The Land Tenure Act was amended, while the civil war was still being fought, to allow blacks to purchase white farms and urban property, and after the end of hostilities residential segregation began to be significantly breached.

PEOPLE AND POPULATION

Linguistic, ethnic, and religious groups. The majority of the population of Zimbabwe speaks Shona; these are nearly four times the number of those who speak Ndebele as their first language. Both Shona and Ndebele are Bantu languages; from the time of their great southward migration, Bantu-speaking tribes have populated what is now Zimbabwe for more than 10 centuries. Those who speak Ndebele are concentrated in a circle radiating from Bulawayo, with Shona-speaking peoples beyond them on all sides—the Kalanga to the southwest, the Karanga to the east around Fort Victoria, the Zezuru to the northeast, and the Rozwi and Tonga to the north. Generations of intermarriage have to a degree blurred the linguistic division between the Shona and Ndebele peoples.

The Shona and Ndebele

Among the 230,000 whites in Zimbabwe at independence were the descendants of the country's first European immigrants. Only about one-quarter of the adult white population, however, was born in Zimbabwe. Since World War II the white population has been trebled by heavy immigration, and more than two-thirds of the present white population have their origins in Europe, the great majority from Britain. The rest have come from South Africa.

The white population is, nevertheless, outnumbered by Zimbabwe's 7,200,000 blacks by a ratio of one white for every 31 blacks. There are nearly 11,000 Asians, forming a community that is predominantly concerned with trade. There are also 24,000 Zimbabweans of mixed race, in Zimbabwe called Coloureds, who are mainly skilled and semiskilled workers. More than 80 percent of the whites live in towns, whereas only 17 percent of the black population do so. Of the whites living in rural areas, about one-quarter are Afrikaners. English is the language of government; teaching in schools is also conducted in English, except for the instruction of the youngest children in black schools.

Traditional religion

The great majority of the black population adheres to traditional religion based on reverence for ancestors. The Shona have preserved their ancient reputation for prophecy, divination, and rainmaking; they believe in Mwari, a supreme being. The stone ruins of Great Zimbabwe are regarded as a shrine of deep religious significance, as also are parts of the Matopo Hills. In the last 50 years mission schools have exercised much influence, and most of the members of the first Cabinet of independent Zimbabwe were graduates of these schools. The strongest influence has been that of the Roman Catholic Church, with some 800 schools and more than 500,000 black members and 37,000 white members. In comparison, the Anglican Church has some 150,000 black and 80,000 white adherents. The Methodist, Presbyterian, Baptist, and Dutch Reformed churches are also represented. Because the Catholic Church supported nationalist aspirations, it held a position of influence in the post-independence period.

Demography. *Birth and mortality rates.* The annual rate of population increase among Zimbabwean blacks is one of the world's highest, at 35 persons per 1,000. The death rate of 13 per 1,000 in 1978 had declined only fractionally in a decade, while the birth rate of 48 per 1,000 remained steady. At these rates, the black population would double in 20 years. Approximately 20 percent of the black population is under five years of age, and 51 percent is under 15. The average black adult in Zimbabwe has to support more than three times as many children as his counterpart in a developed country.

Among whites, there is about one child for every two adults. The death rate among whites has been eight per 1,000, and their life expectancy is 72 years, compared with 50 years for their black compatriots. The infant mortality rate among whites is 16.8 per 1,000, compared with about 32 per 1,000 among urban blacks and about 160 per 1,000 among rural blacks.

Immigration and emigration. Migration has been the most important factor influencing the size and composition of the white population. Net migration figures have fluctuated in reaction to political events, but most striking is the extremely high turnover of the 1960s and 1970s. In the years immediately preceding the breakup of the Federation of Rhodesia and Nyasaland, there was a net emigration of 13,000 whites; this was followed during the first 10 years of UDI by a net immigration of 40,000 (with 111,270 immigrants and 71,330 emigrants). As warfare spread after 1976, the pendulum swung again from a peak white population of 260,000 to fewer than 200,000 after independence. These net figures obscure, however, the gross turnover during 1965–79 of 132,560 immigrants and 133,864 emigrants. Even when allowance is made for the subsequent return of some emigrants, it is probable that at least half of the country's adult whites were newcomers after UDI.

White migration patterns

About 300,000 blacks in Zimbabwe were born outside the country, mostly in Malaŵi and Mozambique. Men from those countries came to Rhodesia to work in the mines and on white-owned farms. Since UDI there has been a net emigration of nearly 91,000 persons categorized in official statistics as "foreign African adult males."

Distribution of population. About 20 percent of the total population lives in Zimbabwe's 14 urban centres, nearly three-fourths of them in either Salisbury or Bulawayo. This total urban population includes 80 percent of the whites, most of the Asians and Coloureds, but only 17 percent of the blacks. Of the other 83 percent of the nation's blacks, three-fourths live in the Tribal Trust Lands or African Purchase Areas and the rest on white-owned farms. The population density of the areas designated as "European" is thus only about one-fourth of what it is in the Tribal Trust Lands. Among urban blacks, there is a disproportionately high number of males of working age, leaving an excess of older people, women, and children in rural areas. At least half of the black households are partly or wholly dependent on incomes earned in the wage economy—almost always from white employers.

Official government figures of December 1979 for the population of the main urban centres apparently did not include rural refugees. These figures were: Salisbury, 641,000; Bulawayo, 375,000; Gwelo, 72,000; Umtali, 65,000; and Que Que 51,000.

Demographic trends. At the present rate of natural increase of 3.2 percent a year, the black population will have grown by another 7,000,000 to more than 14,000,000 by the year 2000. The renewal of family-planning programs in the 1980s and the raising of living standards may considerably affect the birth rate. The trend in the white population will be obscure for several years after independence; the uncertainties that independence has posed for the younger whites make any forecast particularly vulnerable to error.

Zimbabwe, Area and Population

	area		population

THE NATIONAL ECONOMY

By the index of gross national product (GNP) per capita, Zimbabwe is among the world's middle-income countries. According to the 1980 economic survey prepared by the Ministry of Finance, the GNP in 1979 was Z$2,584,000,000; this represents a GNP per capita figure of about U S. $510. The only African countries south of the Sahara with a higher or comparable per capita GNP are Gabon, South Africa, South West Africa (Namibia), the Ivory Coast, Nigeria, and Zambia. As far as Zimbabwe is concerned, however, such a comparison should be treated with caution for two reasons. First, Zimbabwe still contains what are essentially two economies—a white one and a black one—and a combined figure distorts the reality of this dualism. Second, the country's economy was under siege for 14 years of United Nations sanctions, and these siege conditions led to the creation, in turn, of a protective wall behind which import-substitution industries thrived in an abnormally favourable climate. It will be some years before it is clear whether the Zimbabwean economy will benefit from the foreign investment and access to foreign markets that came with the lifting of sanctions, or if it will suffer from greater import competition. Further uncertainties surround the patterns of employment and wages in the mining and manufacturing industries and in the farming sector, as the pressures following independence for higher minimum wages find a response, and as the government makes plain how strongly it wishes to retain skilled white labour.

Sources of national income. ***Agriculture, forestry, and fisheries.*** Agriculture contributed nearly one-fifth of Zimbabwe's national income until about 1973, when the war caused its contribution to begin a decline to about 12 percent by 1979. Even in years of drought, as in 1979–80, agriculture still provided one-third of the country's total foreign exchange and about 35 percent of total employment in the wage economy for some 344,000 workers. Neither forestry nor fisheries had become significant to the economy by 1980.

Tobacco production

Economic sanctions over the 14 years of UDI had a broad effect on patterns of commercial agriculture. Tobacco, primarily the Virginia variety that is flue-cured and grown on white-owned farms, accounted for more than half of the gross value of output in 1965 but fell below 20 percent during UDI. There were 1,750 white farmers still growing tobacco at the time of independence, however, and the flue-cured production in 1979 of 111,700 metric tons was the highest since 1965. Tobacco faced an uncertain future because of the loss of purchasers during UDI, and in 1980 sales were sought in new markets.

Livestock—mainly beef and milk production—became more valuable than tobacco, but the cattle industry was hurt in the later stages of the war. Disease spread because of breakdown in dipping services, and the national beef breeding herd was reduced by more than 30 percent. Recovery to a planned level of some 6,000,000 head was hampered by cattle rustling.

Soya bean and cotton production have increased rapidly, and cotton is likely to become a major cash crop for smallholders in the Middle Veld.

Maize (corn) production was high enough in the mid-1970s to permit export but slumped so low in the late 1970s that the country imported maize from South Africa. Although the collapse of tribal agriculture during the war, one reason for the slump, may be remedied in the early 1980s, commercial farmers found maize to be an unprofitable crop and cut their acreage. Because of this and the high rate of population increase, Zimbabwe is unlikely to be much more than self-sufficient in this staple for some time. Wheat was a minor crop in 1965, but by the late 1970s the country was able to export to neighbouring territories. Sugar output in the Lowveld toward the Limpopo was expected to increase with the lifting of sanctions and the rise in world prices. Other crops that thrived during the diversification prompted by the sanctions were coffee and various vegetables.

The biggest question for agriculture was double-barrelled: how many white farmers were likely to leave the country in the aftermath of independence, and how long would it take black farmers to recover higher production in tribal lands and to move in significant numbers into the commercial sector. The country is dependent upon a small group of white farmers. During UDI, their numbers decreased by 900, and at independence only 5,400 whites were actively farming, In comparison, there were some 700,000 black farming families.

Mining and quarrying. Although mining accounted for only 8 percent of the gross domestic product (GDP) and provided work for only 6 percent of the employed labour force in 1979, its significance in the economy was considerable as a major earner of foreign exchange. Direct mineral exports accounted in 1979 for one-third of total value. The mining sector was expected to attract large-scale foreign investment in the 1980s.

It was the prospect of great mineral wealth—comparable to the gold deposits of the Witwatersrand in neighbouring South Africa—that attracted the first permanent European settlers in the 1890s. These great expectations faded for many years after the peak of gold production was reached in 1915. By the 1950s, however, production of the chrome mines along the Great Dyke was significant, as was that of asbestos and copper. During UDI, the value of mining output increased fivefold to Z$193,000,000 in 1979. The rise in gold prices in the 1970s revived gold as the country's leading export and led to the reopening in 1979–80 of more than 100 dormant mines. Nickel mining, which began in the late 1960s, was carried out in 1980 at five mines; the Great Dyke may indeed contain more nickel than chrome ore. The more than 20 known coalfields in Zimbabwe contain proved reserves of 500,000,000 tons of salable coal.

Manufacturing. Manufacturing has been the fastest growing sector of the economy. From 1954 to 1963, Southern Rhodesia was able to rely on the resources and larger market of the Federation of Rhodesia and Nyasaland for a 150 percent increase in manufacturing output. Then, after UDI in 1965, hundreds of new manufacturing projects were begun in the effort to defeat economic sanctions by import substitution. By 1979, manufacturing contributed one-quarter of the gross national product, leaving little scope for any immediate expansion.

Energy. Electricity production contributes only about 3 percent of the gross national product. Its principal users are industries, mines, and farms. Electrification of the railways was begun in 1980, and there has also been considerable electrification of low-cost housing in urban townships. Less than half the black homes in Bulawayo and Salisbury, however, had their own electricity at the time of independence.

During the 14 years of UDI, the consumption of power trebled, and the increase was covered by drawing heavily upon the Central African Power Corporation grid (capacity: 11,500,000 kilowatt-hours per year), with its twin stations on the Zimbabwean–Zambian shores of Kariba Gorge. The manufacturing, transportation, and construction industries consumed nearly 50 percent of the power distributed in the grid, and the mining industry about 20 percent. Following independence, plans for the expansion of power resources included a two-stage Wankie thermal plant fuelled by coal, an extension of Kariba South power station, and investigation of downstream sites on the Zambezi at Mpata Gorge and Batoka Gorge.

Financial services. Banking and insurance services grew during the 1970s and by 1979 contributed 5 percent of the gross domestic product. In the later stages of the civil war, the demand for commercial bank loans fell and, after 1974, the total assets of financial institutions began to decline. This decline reflected a fall in demand for hire-purchase and lease-hire facilities and a reluctance by the general public and the business sector to commit themselves to long-term credit. The principal cause of growth in the money supply has been government borrowing for increased expenditure.

Foreign trade. Economic sanctions, which had been imposed by stages from 1966 to 1968 on both Rhodesia's imports and exports, were lifted in December 1979. They had been widely breached, particularly in mineral exports and in the supply of petroleum, but they nevertheless strongly affected certain commodities, such as tobacco exports. Although the country's trade surplus was diminished in 1979 by the rise in oil prices, the value in 1980 of exports (Z$812,200,000) still outpaced that of imports (Z$733,600,000). As a landlocked country, Zimbabwe faces heavy freight and travel costs, as well as outflows on investment account and transfers such as pensions and migrants' remittances; and these payments turn the trade surplus into a small deficit.

Private enterprise and socialism

Management of the economy. ***Private and public sectors.*** The government of independent Zimbabwe moved cautiously to alter the pattern of management that it inherited from the white minority regime. The first budget of July 1980 was described by the finance minister as "conservative [with] a mild and pragmatic application of socialism." But the whites had passed on government machinery that included many levers of economic power. While the whites by inclination were wedded to a system of private enterprise, they had evolved a system of government intervention to support infant industries and maintain agricultural prices through marketing boards. The need to cushion the blows dealt by economic sanctions during UDI brought acceptance of the imposition of exchange and import controls.

Prime Minister Robert Mugabe was swift to use this apparatus in 1980 to guarantee farmers a pre-planting price for maize more than 40 percent higher than the price of 1979–80, while subsidizing the price to consumers of this staple food in preference to continuing the import of 10,000 tons of the grain a month. The country's infrastructure of roads, power generation, transport, and communications was run down during the civil war, and heavy government expenditure in these sectors was planned. To benefit foreign investors, foreign exchange controls were gently applied in the 1980 budget, 50 percent of after-tax profits were allowed to be remitted to non-resident shareholders, and new foreign investment was to be freely repatriated after two years. The government machinery by which the Smith regime controlled the economic affairs of rural blacks was altered after independence by the establishment of district councils that took on the major task of grass roots economic development.

Taxation. The government raises nearly one-third of its revenue from personal and corporate income taxes which, since 1966, have been collected on a pay-as-you-earn system. About one-fifth of government revenue comes from customs and excise duties and sales taxes, and much of the rest from government borrowing and, since independence, international aid.

The independent Zimbabwe government removed sales taxes on the staple items of food and fuel for the poorest people and extended sales taxes to travel, hotel accommodations, taxis, telecommunications, and other services. It continued the former rates of personal income tax—under which the maximum rate of 45 cents on the dollar becomes payable only when the taxable amount exceeds Z$17,000—and corporate income tax—a rate of 45 percent—but it imposed a 10 percent surcharge on both taxes for 1980 and 1981. Married immigrants continued to receive a special tax allowance of Z$800.

Consolidation of trade unions

Trade unions and employers' associations. The evolution of the trade-union movement was some two years behind the pattern of political change by 1980. The new government dealt with immediate labour problems, such as strikes for a higher minimum wage, rather than institute a thorough revision of the basic Industrial Conciliation Act of 1959. The government seemed to favour the strengthening, by mergers or amalgamation, of small unions in the same industry; the strengthening of the whole movement by the formation of a single trade-union congress from the five or six existing confederations of unions; and an arm's-length relationship of government with such a congress. There were in 1980 some 50 recognized unions, with railway workers' and mine workers' unions prominent among them, but the largest sections of the labour force—the agricultural workers and domestic servants—remained outside the system.

Employers' groups, such as the Associated Chambers of Commerce of Zimbabwe and the Association of Rhodesian Industries, remained influential.

Economic policies. The Zimbabwe government of Prime Minister Mugabe and the Zimbabwe African National Union (ZANU), while deriving economic theory from years as a liberation movement based in the professedly Marxist state of Mozambique, was in practice making a range of compromises with the capitalist policies of the previous regime. It faced the fact that about 70 percent of the capital stock in the country is under mainly British and South African control. A further constraint is the shortage of black artisans, technicians, and engineers, which would become even more critical should there be an early exodus of the thousands of white technicians. A first initiative was the establishment of workers' committees in many industries, although with ill-defined powers. A major concern has been the creation of job opportunities for up to 100,000 workers in the first year of independence, above the 990,000 persons in formal employment in 1980. This was to be followed by the building up of industrial and commercial centres based upon the resettlement of black farmers on formerly white-owned lands.

Transportation. The main road system, which is excellent, generally follows the line of white settlement along the spine of the country, with two branches north to Victoria Falls and Kariba and a network fanning out from Fort Victoria, close to the Great Zimbabwe ruins. It consists of about 3,100 miles of paved road. Wartime operations brought an improvement in certain areas, including the construction of strategic roads in the eastern highlands and near the Zambian border. The 14,000 miles of roads in white farming areas and the 30,000 miles of gravel and earth roads in the Tribal Trust Lands received barely adequate maintenance, however.

Railways

The railway closely follows the main road network; its 1,568 miles of single track have a gauge of three feet six inches. Economic sanctions, followed by the closure of the Zambian border in 1973, drastically cut rail traffic and transit revenues from Zambia's copper exports. The southern routes, however, became the Smith regime's lifeline after the British Navy imposed an oil blockade on the Mozambique port of Beira and effectively cut the Beira–Umtali pipeline supply in 1966. Postwar reconstruction was needed on the Maputo–Malvernia line, but more important to this landlocked country was the bottleneck created at the ports of Mozambique and South Africa.

Air Zimbabwe replaced Air Rhodesia, a government-backed company that had operated only within Rhodesia and to and from South Africa. Air Zimbabwe immediately added a weekly flight to Great Britain. The international airport at Salisbury has one of the longest civil runways in the world. Five other airports—at Bulawayo, Kariba, Fort Victoria, and Victoria Falls—can accommodate medium-sized jet aircraft.

ADMINISTRATION AND SOCIAL CONDITIONS

The 1979 constitution

The constitutional framework. The independence constitution of Zimbabwe, which was written in London during September–December 1979, secured majority rule for Zimbabweans. Under the 1979 constitution, white voters, registered on a separate roll, elect 20 of the 100 members of the National Assembly. Although these members no longer can veto constitutional amendments, a unanimous vote is required during the first 10 years to alter the Declaration of Rights, which stipulates (among other matters) that, if land is acquired for settlement schemes, there must be "prompt payment of adequate compensation . . . remittable within a reasonable time to any country outside Zimbabwe." The British insisted that there be a constitutional head of state, a president elected by the National Assembly, and an executive prime minister, and that citizenship of Zimbabwe be automatically available to anyone who was (or had the qualifications to be) a citizen of Rhodesia immediately before independence.

There is a Senate of 40 members, half of whom are either nominees of the white Assembly members or of the Council of Chiefs. The Senate has the power to delay ordinary legislation for 90 days and constitutional amendments for 180 days.

Regional, state, and local governments. There are no regional or state governments in Zimbabwe. At the time of independence, whites controlled the municipal councils, but legislation was soon introduced to amalgamate each municipal council with the council of its surrounding township and, for the first time, black mayors were elected in 1981. Local government elections in rural areas replaced the old apparatus of district commissioners with a party-based council structure.

The political process. In the elections held in February 1980 under the 1979 constitution, Ian Smith's Rhodesian Front took all 20 seats on the white voters' roll. Of the nine parties that contested the 80 common roll seats, Bishop Abel Muzorewa's United African National Council (UANC) secured only three seats; Joshua Nkomo's Zimbabwe African People's Union (ZAPU) won 20 seats, representing nearly all in Matabeleland, and Mugabe's Zimbabwe African National Union (ZANU) won 57 seats, nearly all in Mashonaland. A total of 2,649,529 valid votes were cast, and the Commonwealth Observer Group drawn from 11 nations declared their satisfaction that the elections had been "free and fair."

Justice. The Ministry of Law and Order of Smith's period was renamed the Ministry of Justice by the new independent government. The government voted to extend the state of emergency, first delcared at UDI, because of unsettled conditions, mainly in rural areas.

Under the constitution of 1979, a four-member Judicial Service Commission advises the president on the appointment of judges to the High Court. High Court judges may not be removed from office except for misconduct or incapacity. The pre-independence chief justice voluntarily resigned, however, accepting that his acquiescence in the Smith regime's claim to constitutionality made his continuance in office difficult. He was succeeded by another white judge, and the first black lawyer was appointed a High Court judge later in 1980. In addition to magistrates who preside over criminal and civil litigation, other courts adjudicate on matters of African law and custom.

Integration of the armed forces

Armed forces. The integration of three rival and politicized armies—the Rhodesian Army and the armies loyal to ZAPU and ZANU—was one of the most urgent tasks facing the new government. A team of British military advisers worked in late 1980 to form nine infantry battalions, each 1,000 strong, of integrated troops after about six months of retraining. Many of the 38,000 nationalist troops who had been gathered at rural assembly points during the pre-election cease-fire period became restless with their continued confinement. How many of them eventually would be retrained for the national army or given other training was not immediately clear; it seemed likely that several thousand more than the size or economy of Zimbabwe warranted would remain in uniform, probably as reservists. The Rhodesian Air Force maintained antiquated squadrons of Hunter fighters and Canberra light bombers, having spent reequipment funds on the purchase of counter-insurgency helicopters. The paramilitary British South Africa Police had been responsible for internal security from 1890; it was renamed the Zimbabwe Republic Police and underwent retraining.

Educational services. The dismantling of Rhodesia's segregated system of schooling began less than two years before independence, and the system's effects will be long felt in Zimbabwe. The minority government had concentrated upon providing compulsory (and virtually free) education to white children between the ages of five and 15, and had left the schooling of black children in the hands of missionaries. In 1950 there were only 12 government schools for blacks, compared with 2,230 mission and independent schools. The disparities continued through the 1970s, when there were about 800,000 blacks enrolled in primary schools and less than 50,000 blacks in secondary schools. Facilities were sharply reduced after the lower primary stage, and the civil war cut opportunities for blacks even further; from 1978, at least one-quarter of all black primary schools were closed. Enrollment fell by 300 at the University of Zimbabwe, where blacks had become a majority of the 1,480-strong student body by 1979. In the 1980–81 budget, priority was given to reopening and reequipping schools and to providing new schools in the drive toward free primary education. Because of the many opportunities in higher education offered Rhodesians by Commonwealth and other countries during UDI, Zimbabwe moved to independence with one of the best educated leaderships any African country had known.

Health services and housing. Health services were biased toward curative medicine in central hospitals, two of which—Harari Hospital in Salisbury and Mpilo Hospital in Bulawayo—are known for their service to black patients. Before 1980, missionaries had the major responsibility for running rural clinics and small hospitals. In the budget of 1980–81, health allocations were increased by 55 percent. A major effort was planned to reequip rural clinics and provide free health services to the poor, concentrating on preventive care.

A severe housing shortage in the main urban centres was aggravated by the influx of rural refugees and by the trebling of the cost of building materials during UDI. The 1980–81 budget provided for the construction of 27,000 homes, and the government appealed to private contractors and individual employers to aid in the deveiopmenr of housing for lower paid workers.

Social conditions. ***Wages and the cost of living.*** Statistics are no longer broken down by racial groups in Zimbabwe, but as late as 1977 the average wage of R$590 a year for the 900,000 blacks in cash employment was less than one-tenth of the average wage paid to non-blacks. The wage average for black workers was drawn down by the low wages paid to those in agriculture and domestic service, who numbered nearly 450,000 and earned a minimum Z$30.80 a month at independence. Mine workers received a minimum Z$44.66 a month, with food and housing allowances and a pension plan. For the higher income group, the rise in the cost of living after 1964 was greatest in transport, foodstuffs, drink, and servants' wages; for the lower income group, the greatest increase was in household stores. For both groups the consumer price index rose by less than 20 percent in the first seven years of UDI and then jumped 85 to 100 percent in the second seven-year period, while average earnings doubled.

Infant mortality

Health conditions. As in other Third World countries, the burden of disease is heaviest on Zimbabwe's youngest children. The infant mortality rate for the black population in malarial parts of the Zambezi Valley has been as high as 300 per 1,000, and the rate is thought to lie between 120 and 220 per 1,000 for the black population as a whole. Measles and pneumonia are major causes of death; a tuberculosis control scheme of the mid-1970s was relatively effective. Improved nutrition is increasingly seen as the most important health need.

CULTURAL LIFE AND INSTITUTIONS

The year-round temperate climate of the Highveld has combined with the natural inclinations of the white population to produce an outdoor society. Tennis—whether on farms or at urban clubs—and bowling have many more white-clothed followers than any ballet group, while a standing joke against local artists has been that so many have drawn their inspiration solely from the mauve-flowering jacaranda and from Zimbabwe's famous balancing rocks. The civil war stimulated among whites patriotic songs and poetry of doubtful artistic quality. Happily for the cause of reconciliation, the first sport heroes after independence were the members of the all-white team that was awarded the first gold medal for women's field hockey in Olympic history at Moscow in 1980. The most famous of Rhodesian-bred writers, Doris Lessing, settled in England in 1949.

Cultural renaissance

In some contrast, the nationalist struggle prompted a renaissance of Shona culture. A forerunner of this renaissance (and a victim of the liberation struggle) was Herbert Chitepo, both as abstract painter and epic poet. Stanlake Samkange's novels reconstruct the Shona and Ndebele world of the 1890s, while those of the much younger Charles Mungoshi explore the clash of Shona and Western cultures in both the Shona and English languages.

Folk traditions have survived in dance and pottery. The revival of sculpture has drawn on tribal religion and totems to produce some remarkable works, particularly those of Takawira and the Tengenenge school of craftsmen who sculpt in hard serpentine.

Newspapers and radio, although lively at times, have not contributed much that is significant to the country's cultural life. The major newspapers, the ***Herald*** (formerly, the ***Rhodesia Herald)*** of Salisbury and the ***Chronicle*** of Bulawayo, were owned by the Johannesburg-based Argus Corporation; in 1981, the government took a controlling interest. Newspapers that appeared in the Shona and Ndebele languages were short-lived, and the most successful multilingual paper, ***Moto,*** published by the Roman Catholic Mambo Press, was banned from 1974 until 1980. Wartime censorship had a deadening effect, most noticeably upon radio and television broadcasting.

PROSPECTS FOR THE FUTURE

The potential for Zimbabwe is remarkable. Its wide range of minerals and considerable energy resources provide a solid base for economic growth and social development. Cultivable areas are large and fertile enough not only to feed the country's own rapidly increasing population but to export grain crops to neighbouring states as well. Zimbabwe has among its white population a rich store of managerial and administrative experience, peppered by pioneer inventiveness, and probably the best educated leadership of any African country at independence. If these elements can be combined productively, if a transfer of land ownership can be achieved speedily and without rancour, and if the well-noted dangers of a white exodus and tribal fighting are largely avoided, Zimbabwe can become not only a prosperous state itself but also the focal point for development in southern Africa.

Of official reports published in Salisbury, the following retain more than historical interest. ***Second Report of the Select Committee on the Resettlement of Natives*** (1960), covering the heart of the dispute over landholdings and important recommendations on land apportionment reform: ***Final Report of the 1962 Census of Africans in Southern Rhodesia*** (1964), a basic source of information on socioeconomic conditions; ***Census of Population, 1969*** (1971); ***Report of the (Phillips) Advisory Committee on the Development of the Economic Resources of Southern Rhodesia, with Particular Reference to the Role of African Agriculture*** (1962), containing details of the country's resources and potentialities. Three reports published in London cover more recent historical landmarks. ***Report of the Commission on Rhodesian Opinion*** (1972), known as the Pearce Report, a critically important state document; ***Report on the Supply of Petroleum and Petroleum Products to Rhodesia*** (1978), known as the Bingham Report, a painstaking but incomplete investigation of circumventions of sanctions by oil companies and connivance by British officials: ***Southern Rhodesian Elections*** (1980), the report of the Commonwealth Observer Group, an illuminating picture of how the main actors behaved under strain in the final scenes before independence.

(C.W.S.)

Rhône River

The RhBne is a historic river of Switzerland and France and the only significant river of Europe flowing directly to the Mediterranean Sea. It is thoroughly Alpine in character, and in this respect it differs markedly from its northern neighbour, the Rhine, which leaves all of its Alpine characteristics behind when it leaves Switzerland. The scenic and often wild course of the RhBne, the characteristics of the water flowing in it, and the way it has been used by mankind have all been shaped by the influences of the mountains, right down to the river mouth, where sediments marking the Rhône's birth in an Alpine glacier are carried into the warmer waters of the Mediterranean.

The course of the river can be divided into three sectors lying, respectively, in the Alps; between the Alps and the Jura Mountains and through the latter; and finally in the topographical furrow of Alpine origin running from the city of Lyon to the sea.

The Alpine sector

The course. The RhBne originates in the Swiss Alps, upstream from Lake Geneva (Lake Léman). It comes into being at an altitude of 6,004 feet (1,830 metres), emerging from the glacier of the same name, which descends the south flank of the Dammastock, an 11,909-foot (3,630-metre) peak. The river then traverses the Gletsch Basin (5,778 feet; 1,761 metres), from which it escapes through a gorge, and flows along the floor of the Val de Conches (Goms) at an altitude between 4,600 and 4,000 feet. It next enters another gorge before reaching the plain of the Valais, which extends between the towns of Brig and Martigny, at an altitude between 2,300 and 1,600 feet. In crossing this high and rugged mountain area, the river makes successive use of two structural troughs. The first runs between the ancient crystalline rock massifs of the Aare and of the Gothard; further downstream, the second runs between the arched rock mass of the Bernese Oberland and, on the south, the massive rock face of the Pennine Alps. From Brig onward, the landscape changes. During the last ice age, a large glacier, fed by several small ones, plowed down the valley floor of the Valais, and, except for some harder rock obstacles found near the town of Sion, succeeded in widening and deepening the narrow valley floor. As it did so, it held back both the upper RhBne and those of its tributaries that come down from the Pennine Alps. When the ice sheets retreated, both the tributaries—the Viege (Vispa), Navigenze, Borgne, and Drance—and the RhBne cut new, deep gorges to connect their lower courses to the new valley floor. These have created considerable difficulty in terms of modern transportation, necessitating a whole series of hairpin-bend road links.

After Martigny, where the valley floor is wider and liable to flooding, the youthful RhBne thrusts northward at a right angle, cutting across the Alps through a transverse valley. At first, near the town of Saint-Maurice, this is no more than a spectacular gorge, but it soon becomes wider and flatter. Here, too, the river route has been assisted by structural factors, specifically by a dip in the crystalline rock massifs running from Mont Blanc to the Aare and by the discontinuity between the limestone masses of the Dents du Midi and of the Dent de Morcles. Across the mountain barrier, the muddy waters of the RhBne enter another wide plain and then plunge into the clearer, stiller waters of Lake Geneva, forming an enlarging delta.

The second sector of the Rhône's course commences with Lake Geneva, large (224 square miles in area) and deep (1,000 feet) and lying between Switzerland and France in a basin hollowed out of the less resistant terrain by the former RhBne glacier. It is possible that the

RhBne, before the last glaciation, headed originally toward the present-day lakes of Neuchâtel or Morat, and, as the Aar does now, reached the valley of the Rhine. Upon leaving Lake Geneva, which has turned the course of the river to the southwest and decanted the sediment from its waters, the RhBne very quickly regains in full the milky colour so characteristic of Alpine rivers. Just below the city of Geneva, it receives its powerful tributary the Arve, which rushes down from the glaciers of Mont Blanc.

The middle course

From its juncture with the Arve to the city of Lyon, the Rhône has to cross a difficult obstacle, the undulating series of mountains forming the Jura Range. It does this partly by cutting through narrow cross valleys and partly by using existing structural downfolds to skirt the obstacles. It follows a complicated zigzag course. In the valleys, it surges through narrow clefts known as *cluses.* At the town of Bellegarde, the river is joined from the north by the Valserire, and, swinging south, plunges into a deep gorge now submerged in the 14-mile-long Génissiat Reservoir. In the wider sections of its course in this region, the RhBne runs through glacier-excavated basins that its own deposits have barely filled, causing intermittent swamps. It is also joined by the Ain, from the north, and, on the left bank, by the Usses, Fier, and Guiers. The river next widens, and the terrain becomes less hilly and, at Le Parc (some 95 miles above Lyon) becomes officially "navigable," although the average depth is no more than three feet.

The lower sector

The RhBne then enters its third sector, marked by the great north–south alpine furrow that is also drained by its principal tributary, the Saône. The latter lies in the basins that the Ice Age glaciers hollowed out between the Jura Range to the east and, further west, the eastern edge of the Paris Basin and the uplands of the Massif Central. It forms an important commercial link to the industrialized regions of northern France. From the city of Lyon onward, the river occupies the trough lying between the Massif Central and the Alps, a channel up which the sea of the Pliocene Epoch, 10,000,000 years ago, ascended for a great distance. Over the last 70,000,000 years, powerful deposits brought down from the Alps have hammered out a very deep channel against the Massif Central. This is, in fact, so deep that at Vienne and again at Tain the RhBne cuts right through hard crystalline outcrops. The valley consequently takes the form of a series of gorges and basins, the latter often having a series of terraces corresponding to variations in the levels of ice and of river. Although the tributaries—notably the Ardtche—rushing down into the Rhône from the Massif Central are formidable when in flood, the great Alpine rivers, the Istre, and the Durance, joining the left bank, are most important in their effect on riverbed deposits and on the volume of water. Below Mondragon the RhBne Valley becomes wider and more marshy, liable to flood if unimproved, and the river course itself becomes more braided, divided into a network of interlaced streams. The river delta extends from near Arles, about 25 miles from the sea, where the twin channels of the Grand and Petit RhBne separate the intervening wild, marshy landscape of the Camargue from the surrounding coarse pastureland known as La Crau.

Flood volumes

Hydrology. The flow regime of the RhBne owes its remarkable mean volume to the influence of the Alps. At Beaucaire the flow amounts to 64,300 cubic feet per second; at Lyon 22,600 cubic feet per second (the Saône alone contributes 14,100 cubic feet per second); the Isère adds another 12,400 cubic feet per second. The melting of the Alpine snows gives the highest mean flows in May, while the Saône attains its maximum in January. The flood volumes of spring and autumn are formidable, reaching 460,000 cubic feet per second for the RhBne at Beaucaire, 152,000 for the Saône, 102,000 for the Isbre, and even up to 124,000 for the little Ardèche, as a result of the intensity of the Mediterranean rains flung against the eastern skirt of the Massif Central. The RhBne has an abundant flow but maintains a strong gradient almost to its mouth. At Lyon, for example, its altitude is 560 feet at 205 miles from the sea; the Rhine, by way of comparison, has an altitude of 456 feet at Strasbourg, more than 360 miles from the sea. As the size of the delta region testifies, the river transports large amounts of alluvial deposits and is also powerful enough to cut through a variety of rock masses. As a result, the RhBne of today is well adapted to the production of electricity but has always been difficult to navigate.

Human geography. The utilization of the Rhône region by man has required a long historical struggle, which only entered a decisive phase in the third quarter of the 20th century. The main aspects of this struggle have been in the areas of fishing, the mastery and working of the soil, navigation, and hydroelectric power production.

Fishing is practiced in all the water courses of the basin but attains a modest local commercial importance only on the lakes fed by the RhBne, Lake Geneva and the Lac du Bourget.

Agriculture in the RhBne Valley has largely covered the low areas, plains, and islands, which the river and its tributaries threaten with periodic flooding. In the Valais Valley, in the century following 1850, the Rhône was diked and narrowed, having raised its bed and made the draining of the surrounding plain necessary. These improvements, together with the protective agricultural policies of the Swiss, have made a fine development of farms, orchards, and vineyards possible. Comparable works have been carried out in France, notably on the Isbre, at Combe de Savoie and Grésivaudan, and on the Basse Durance, where the Comtat Plain is entirely given to vegetables. The Camargue region of the delta has become a vast rice field, while the Serre-Ponçon Dam on the Durance assures reliable irrigation.

Navigation

A bad outlet to the sea, the strong gradient, and gravel shoals form obstacles to navigation. Navigation has, however, always been carried on, particularly between Lyon and the sea. At first, horses and then tugs pulled the boats upstream. In spite of the navigational improvements made to the river, steam- and, later, gas-engine navigation, subject as it is to competition from the railways, has known only small-scale success. By the 1970s, attempts were made to stimulate navigation by a complete modernization of the engineering facilities. This was to be made possible, at least on the French part of the RhBne, by hydroelectric power projects. These would enable a comprehensive solution: the elimination of shoals, which would be submerged under reservoirs or avoided through bypass canals; the replacement of the original gradient by a succession of level reaches and locks; and a series of large generating stations resulting in an immediate profitability for the project. Between 1949 and 1970 the Compagnie Nationale du RhBne had already completed an extensive series of related projects: at Génissiat (electricity only), Donzère-Mondragon, Montélimar, Baix-le-Logis Neuf, Beauchastel and Pierre-Bénite. Together these projects harnessed more than half of the entire potential hydroelectric power of the RhBne, and the work is continuing. The production of energy alone has sufficed to justify these projects. It is hoped that navigation, too, will take on new life, but this cannot be positively predicted because of the uncertain competitive role of roads and pipelines.

Even with the faults of parts of its waterway, the RhBne Basin nevertheless constitutes one of the great economic regions of Switzerland and of France, draining rich plains, as well as an important part of the Alps. Great cities attest the antiquity and the strength of man's interest in it. In addition to Lausanne and Geneva on Lake Geneva, Lyon stands at one of the great European crossways. Grenoble is an important city at the confluence of the Isère and the Drac. Avignon, Vienne, and Arles were magnificent Gallo-Roman cities, and the river was one of the spearheads for the penetration of Mediterranean cultures and peoples into northern Europe. While the rivers of the basin are not everywhere navigable, their valleys have successively accommodated paths, roads, railways, and modern highways; whatever the means of travel, the RhBne Basin has always been a noble thoroughfare.

BIBLIOGRAPHY. DANIEL FAUCHER, *L'Homme et le Rhône* (1968), is a recent, comprehensive work on the Rhône, which also contains a copious bibliography. To supplement Faucher, see the exhaustive works of MAURICE PARDE, a hydrologist of world reputation: *Le Régime du Rhône*: *Étude hydrologique*, 2 vol. (1925), and *Quelques nouveautés sur le régime du Rhône* (1942), adds some corrections and new numerical data to the *1925* work. For the RhBne Valley complex in the Valais, see PAUL and GERMAINE VEYRET, *Au coeur de l'Europe: les Alpes* (1967), useful also for all alpinistic problems of the RhBne Basin.

(P.V.)

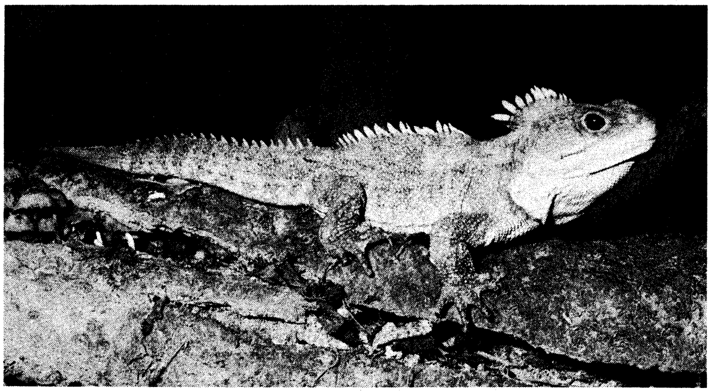
Rhynchocephalia

The Rhynchocephalia constitute one of the four orders of living reptiles; the only surviving representative of the group is the tuatara, or sphenodon (*Sphenodon punctatus*). Structurally, the tuatara is not much different from related forms, also assigned to the order Rhynchocephalia, that may have appeared as early as the Lower Triassic Period (over 200,000,000 years ago).

Distribution

Until recently the tuatara lived on the two main islands of New Zealand. Today, it is found only on certain islets in Cook Strait between the main islands and on islets between East Cape and North Cape of the North Island of New Zealand.

W.H. Dawbin



Male tuatara with white spines erected, a behaviour characteristic of the tuatara when excited or hunting.

Natural history. Male tuataras may attain a length of 60 centimetres (about 24 inches) and a weight of 1,000 grams (about 2.2 pounds). Females grow to about 50 centimetres (20 inches) and sometimes weigh as much as 500 grams (1.1 pounds). Eight to 15 eggs are laid in a nesting burrow covered by several centimetres of soil. The young emerge about 13 months later, in early summer to midsummer. Adult size is not reached for 50 to 60 years, and the animal may live to the age of 100. Sexual maturity is believed to occur after about 20 years.

During mating, the more prominent crest of the male becomes turgid and erect as he stalks the female, approaching her in a slow, jerky fashion. He then grips her over the shoulders with his forelimbs. Unlike the lizards, the tuatara does not use the jaw for grasping the female. The length of time between mating and egg laying is not known.

The mode of locomotion is primitive. The animal moves in a sprawling fashion, the belly leaving the ground only momentarily. The pattern of limb movement is unusual in that the forelimb contacts and leaves the ground before the hindlimb on the opposite side. As it moves, the body is thrown into marked lateral, or sideward, bends.

Tuataras are essentially solitary, nocturnal, burrowing animals, seldom travelling more than a few metres from their burrows during the day. Feeding takes place mainly at night. The principal diet of the young is insects; adults eat, in addition to insects, snails, lizards, young seabird chicks, and eggs. They will drink water if it is available but can survive for months on water obtained from dew and solid food.

The islands inhabited by the tuatara have large numbers of ground insects, which are an important source of food. Bird burrows often serve as ready-made homes for the tuatara, but the animal is capable, from the time it hatches, of making its own burrow if none is already available. The burrow may be shared by a bird and a tuatara, as well as by the bird's chick or egg. (Occasionally the tuatara preys on the chick or adult sharing the burrow.)

Natural enemies

The largely nocturnal habits of the animal conceal it from many potential predators, but occasionally it is preyed upon by hawks, gulls, or kingfishers. Rats, introduced by man, are serious enemies of eggs and the young. The animal may be regarded as seriously threatened with extinction on islands where rats occur.

Form and function. The tuatara has two pairs of well-developed limbs, a strong tail, and a scaly crest down the neck and back. The scales, which cover the entire animal, vary in size. The tuatara also has a bony arch, low on the skull behind the eye, that is not found in lizards. This arch is formed by the presence of two large openings (temporal fossae) in the region of the temple. It has been used as evidence that the tuatara is a survivor of the otherwise extinct order Rhynchocephalia and is not a lizard. The teeth of the tuatara are acrodont—*i.e.*, attached to the rim of the jaw rather than inserted in sockets. The tuatara is also unique among reptiles in not possessing a male copulatory organ. As in birds, sperm transfer is effected during contact between the male and female cloacae.

The heartbeat and respiratory rate of the tuatara are relatively slow; oxygen consumption, accordingly, is low. Tuataras actively forage in temperatures as low as 6° C (43" F) and can briefly tolerate temperatures above 37° C (99" F). Tests indicate that the preferred temperature is about 22° C (72" F)—rather low for a reptile. The excretion of nitrogenous wastes, a by-product of the animal's metabolism, are in the form of uric-acid masses, or concretions. About 10 to 30 percent of this waste may occur as the substance urea in the urine; the urea concentration rises as the amount of protein increases in the food consumed.

Evolution and classification. The tuatara has changed little in skeletal features since the Jurassic Period (136,000,000–190,000,000 years ago), when the closely related *Homoeosaurus* occurred in Europe. There is evidence that the line of rhynchocevhalians began as early as the Lower Triassic. Most forks of that time were of moderate size and, except for one specialized family (Rhynchosauridae), were never abundant. Fossils are unknown in any region during Tertiary times (2,500,000–65,000,000 years ago). Remains from the Pleistocene Epoch (10,000–2,500,000 years ago) in New Zealand are structurally identical with the living tuatara.

The order Rhynchocephalia belongs to the subclass Lepidosauria of the class Reptilia. Three families (Sphenodontidae, Rhynchosauridae, and Sapheosauridae) are assigned to the order; two families (Claraziidae and Pleurosauridae) are tentatively assigned.

In addition to the living species, *Sphenodon punctatus,* the family Sphenodontidae is represented by European fossils of three genera from the Upper Triassic (200,000,000 years ago); by Asian, European, and North American fossils of genera from the Upper Jurassic Period; and by a southern African fossil of a genus from the Lower Triassic.

The family Rhynchosauridae is represented by fossils of eight genera, some tentatively assigned. All are from the Triassic Period and occurred in Europe, South America, south Asia, southern Africa, and East Africa.

The family Sapheosauridae is represented by one genus from the Upper Jurassic Period in Europe.

Ricardo, David

Among the Englishmen who at the beginning of the 19th century systematized and gave classical form to the rising science of economics, the most famous and influential was David Ricardo. His theoretical work still commands the critical attention of economists.

Early life. Ricardo was born in London, Aprii 18 or 19, 1772, the third son of a Dutch Jew who had made a fortune on the London Stock Exchange. At the age of 14 he entered his father's business, for which he showed great aptitude. By the time he was 21, however, he had broken with his father over religion, become a Unitarian, and married a Quaker. This required him to set up on his own. He continued as a member of the stock exchange, where his talents and character won him the support of an eminent banking house. He did so well that in a few years he acquired a fortune and was then in a position to indulge his wide-ranging tastes in literature and science, particularly in the fields of mathematics, chemistry, and geology.

Ricardo, portrait by Thomas Phillips, 1821.
In the National Portrait Gallery, London.

Beginning of his interest in economics

His interest in economic questions arose in 1799 when he happened to read Adam Smith's *Wealth of Nations.* For ten years he studied economics, somewhat offhandedly at first and then with greater concentration. His first published work was *The High Price of Bullion, a Proof of the Depreciation of Bank Notes* (1810), an outgrowth of letters Ricardo had published in the *Morning Chronicle* the year before. His book gave a fresh stimulus to the controversy then raging over the policy of the Bank of England. The strains of the wars with France had caused the government to forbid the Bank of England to pay its notes in gold. Freed from the necessity of cash payment, both the Bank of England and the country banks had increased the amount of their note issues and the volume of their lending. The directors of the Bank of England maintained that the subsequent increase in prices and the depreciation of the pound had no relation to the increase in bank credit. Ricardo and other opponents of that view asserted that there indeed was a close connection between the volume of bank notes and the level of prices and that the level of prices in turn affected foreign exchange rates and the inflow or outflow of gold. It followed that the bank, as custodian of the central gold reserve of the country, must shape its lending policy according to general economic conditions and exercise control over the volume of money and credit. The controversy was thus of the highest importance in the development of central banking theory. A committee appointed by the House of Commons, known as the Bullion Committee, confirmed Ricardo's views and recommended the repeal of the Bank Restriction Act.

At this time Ricardo began to acquire some friends who were to have considerable influence on his further intellectual development. One of these was the philosopher and economist James Mill (father of John Stuart Mill), who became his political and editorial counsellor. Another friend was the utilitarian philosopher Jeremy Bentham. Still another was Thomas Malthus, best known for his theory that population tends to increase faster than the food supply—an idea that Ricardo accepted.

In 1815 another controversy arose over the Corn Laws, which regulated the import and export of grain. A decline in wheat prices had led Parliament to raise the tariff on imported wheat. This provoked a popular outcry and caused Ricardo to publish his *Essay on the Influence of a Low Price of Corn on the Profits of Stock* (1815), in which he argued that raising the tariff on grain imports tended to increase the rents of the country gentlemen while decreasing the profits of manufacturers.

Retirement from business. The year before his Corn Law essay, at the age of 42, he had retired from business and taken up residence in Gloucestershire, where he had extensive landholdings. In 1819 he purchased a seat in the House of Commons, as was done in those times, and entered Parliament as a member for Portarlington. He was not a frequent speaker, but so great was his reputation in economic affairs that his free-trade opinions were received with respect, although they did not yet represent the dominant thiiiking in the House.

Content of *Principles of Political Economy and Taxation*

In his *Principles of Political Economy and Taxation* (1817), Ricardo undertook to analyze the laws determining the distribution of the social product among the "three classes of the community," namely, the landlords, the workers, and the owners of capital. He applied his findings more widely, however, and elaborated various other economic principles. He found the relative domestic values of commodities to be dominated by the quantities of labour required in their production, rent being eliminated from the costs of production.

He concluded that profits vary inversely with wages, which move with the cost of necessaries, and that rent tends to increase as population grows, rising as the marginal costs of cultivation rise. He supposed that there was little tendency to unemployment; but he remained apprehensive lest population grow too rapidly, depress wages to the subsistence level, and, by extending the margin of cultivation, reduce profits and check capital formation. He also concluded that trade between countries was not dominated by relative costs of production and by differences in internal price structures that reflected the comparative advantages of the trading countries and made exchange desirable. He treated monetary questions and esyecially taxation at length. Although he built in part upon the work of Adam Smith, he defined the scope of economics more narrowly than had Smith and included little explicit social philosophy.

Illness forced Ricardo to retire from Parliament in 1823. He died that year, on September 11, at the age of 51.

Assessment. Despite his relatively short career and the fact that most of it was preoccupied with business affairs, Ricardo achieved a leading position among the economists of his time. His views won considerable support in England despite the abstract style in which he set them forth and in the face of heavy counterfire from his opponents. Although his ideas have long since been superseded or modified by other work and by new theoretical approaches, Ricardo retains his eminence as the thinker who first systematized economics. Writers of various persuasions drew heavily upon his ideas, including those who favoured laissez-faire capitalism and those, such as Karl Marx and Robert Owen, who opposed it.

BIBLIOGRAPHY. Ricardo's *Works and Correspondence,* 10 vol., were edited by PIERO SRAFFA and M.H. DOBB (1951–55). His *Principles of Political Economy and Taxation* have appeared in several editions, including Everyman's Library. A good introduction to Ricardo is J.H. HOLLANDER, *David Ricardo: A Centenary Estimate* (1910, reprinted 1960). A guide to Ricardo's opinions on economic matters is OSWALD ST. CLAIR, *A Key to Ricardo* (1957). For the serious student, two books by MARK BLAUG are to be recommended: *Ricardian Economics: A Historical Study* (1958), covering the rise and fall of Ricardian economics in the first half of the 19th century; and *Economic Theory in Retrospect,* rev. ed. (1968), which contains a treatment of Ricardo's system in modern analytical terms, as well as further bibliographical references.

Ricci, Matteo

Matteo Ricci, an Italian Jesuit missionary, introduced Christian teaching to the Chinese Empire in the 16th century. He became known in China as a man of refinement; thus he was able to direct the attention of the Chinese to Western culture, which they had largely ignored. When he arrived in China, he was called a "foreign devil"; later, his Chinese friends addressed him as the "Wise Man from the Great West." This contrast indicates the change both in his own social status and in the feeling toward him of Chinese scholars.

Early life and education

Ricci was born October 6, 1552, of a noble family in Macerata, in central Italy. His father, Giovanni Battista Ricci, a pharmacist by profession, dedicated most of his time to public affairs and for a time served as governor of the city. His mother, Giovanna Angiolelli, was a woman known for her simple piety. Matteo, their oldest child, after preliminary studies at home, entered the school that the Jesuit priests opened in 1561 in Macerata. After completing his classical studies, he set out at the age of 16 for Rome to study law. There he was attracted to the life of the Jesuits, and on August 15, 1571, he requested permission to join the order.

Approved by the Pope in 1540, the Society of Jesus (Jesuits) was already well known for its spirit of apostolic initiative. Its members were distinguishing themselves in scientific research as well as in their voyages to the new worlds. Stimulated by the examples of his seniors, Ricci dedicated himself to efforts in both fields. Shortly after beginning his study of science under the noted mathematician Christopher Clavius, he volunteered for work overseas in the Far East. In May 1577, he set off for Portugal, where he studied for a short time at the famous University of Coimbra while waiting for a ship. In the following year, on March 24, he embarked at Lisbon and arrived on September 13 at Goa, the Portuguese outpost on the central west coast of India. Ricci carried on his studies for the priesthood there but was ordained in 1580 at Cochin, on the Malabar Coast, where he had been sent for reasons of health. Returning to Goa, he was ordered, in April 1582, to proceed to China.

With its huge population, China was an area that Christian missionaries, especially the Jesuits, greatly wished to enter. St. Francis Xavier, one of the first companions of St. Ignatius of Loyola, died in 1552 on the tiny island of Shangchuan in sight of the tightly closed mainland. When Ricci arrived, China was still closed to outsiders; but the missionary strategy of the Jesuits had undergone modification. Great stress was put on the importance of learning the Chinese language and of acquiring knowledge of the culture. Previously, missionaries had attempted to impose Western customs and the use of the Latin language in religious rites. The new approach of adaptation to national customs was established by Alessandro Valignano, who had received Ricci into the Jesuits and was at this time visitor of the Jesuit missions in the Far East. (A visitor is the official responsible for making sure the religious and temporal affairs of all the houses of an institute in an area are properly followed.) First Michele Ruggieri and then Ricci were called to the Portuguese province of Macau to prepare to evangelize China; Ruggieri, however, returned to Italy in November 1588, leaving to his younger compatriot the burden and the honour of founding the church in China.

Mission to China

Ricci arrived at Macau, a small peninsula on the east coast of China, in August 1582, and began at once his study of Chinese. The following year he and Ruggieri were given permission to settle in Chao-ch'ing, then the capital of Kwangtung Province. In his *History of the Introduction of Christianity in China,* Ricci described their work as follows:

> So as not to occasion any suspicion about their work, the fathers [*i.e.*, the Jesuits] initially did not attempt to speak very clearly about our holy law. In the time that remained to them after visits, they rather tried to learn the language, literature, and etiquette of the Chinese, and to win their hearts and, by the example of their good lives, to move them in a way that they could not otherwise do because of insufficiency in speech and for lack of time.

Despite that caution, Ruggieri published the first Catholic catechism in Chinese, and Ricci produced the first edition of his remarkable map of the world, the "Great Map of Ten Thousand Countries," which showed the Chinese intelligentsia China's geographical relation to the rest of the world.

In 1589 Ricci moved from Chao-ch'ing to Shao-chou (Shiuhing), where he became a close friend of the Confucian scholar Ch'ii T'ai-su. Ricci taught him the rudiments of mathematics, receiving in return an introduction into the circles of the mandarins (high civil or military officials of the Chinese Empire) and of the Confucian scholars. Ch'ii, noting that Ricci wore the habit of a Buddhist monk (which he had adopted upon entering China), suggested that it would be better to dress as a Chinese scholar, a suggestion that Ricci followed immediately after leaving Kwangtung.

Feeling increasingly at home, Ricci decided to make an attempt to enter the imperial city of Peking. His effort in 1595, however, was not successful because a Sino-Japanese conflict in Korea had made all foreigners suspect. He had to return from Peking to stop first at Nan-ch'ang and then Nanking. During his stay at Nan-ch'ang, from 1595 to 1598, he became a friend of two princes of the royal blood. At the request of one of them, he wrote his first book in Chinese, On *Friendship.* At Nanking, where he settled in February 1599, he was engaged chiefly in astronomy and geography. In his *History,* he commented on the effects of this work:

> The fathers gave such clear and lucid explanations on all these matters which were so new to the Chinese, that many were unable to deny the truth of all that he said; and, for this reason, the information on this matter quickly spread among all the scholars of China. From this one can understand how much esteem was given to the Jesuits as well as to our land which thenceforth they did not dare to describe as barbarian, a word they were accustomed to use in describing countries other than China.

Encouraged by the reception he received at Nanking, Ricci made a second attempt to reach Peking. He entered the city in January 1601, accompanied by his Jesuit colleague, the young Spaniard Diego Pantoja. Although Ricci was not received by the Emperor, he was given permission to remain in the capital. From then on, he never left Peking, and he dedicated the rest of his life to its people, teaching them science and preaching the gospel. His efforts to attract and convert the Chinese intelligentsia brought him into contact with many outstanding personalities, among them Li Chih-tsao, Hsü Kuang-ch'i, and Yang T'ing-yiin (who became known as the "Three Pillars of the Early Catholic Church" in China and who assisted the missionaries, especially in their literary efforts) and Feng Ying-ching, a scholar and civic official who was imprisoned in Peking. During his years in Peking, Ricci wrote several books in Chinese: "The Secure Treatise on God" (1603), "The Twenty-five Words" (1605), "The First Six Books of Euclid" (1607), and "The Ten Paradoxes" (1608). He died on May 11, 1610, and was granted a place for burial by imperial order.

The secret of Ricci's success was his ability to go beyond cultural barriers and befriend men of another race and religion. His remark about his friend Feng Ying-ching brings out well the spirit of this great missionary: "He treated the affairs of our fathers as if they were his own and our fathers in turn treated his as if they were ours."

Richard I the Lion-Heart, of England

Although king of England from 1189 to 1199, Richard I, "Coeur de Lion," spent only six months of his reign in England and made little contribution to its governance. Yet his knightly manner and his prowess in the Third Crusade made him a popular king in his own time as well as the hero of countless romantic legends since. The third son of Henry II and Eleanor of Aquitaine, Richard was born on September 8, 1157. He was given the duchy of Aquitaine, his mother's inheritance, at the age of 11, and was enthroned as duke at Poitiers in 1172. Richard possessed precocious political and military ability, won fame for his knightly prowess, and quickly learned how to control the turbulent aristocracy of Poitou and Gascony. Like all Henry II's legitimate sons, he had little or no filial piety, foresight, or sense of responsibility. He joined his brothers in the great rebellion (1173–74) against their father, who invaded Aquitaine twice before Richard submitted and received pardon. Thereafter Richard was occupied with suppressing baronial revolts in his own duchy. His harshness infuriated the Gascons, who revolted in 1183 and called in the help of the "Young King" Henry and his brother Geoffrey of Brittany in an effort to drive Richard from his duchy altogether. Alarmed at the threatened disintegration of his empire, Henry II brought the feudal host of his continental lands to Richard's aid, but the younger Henry died suddenly (June 11, 1183) and the uprising collapsed.

Alliance with Philip II of France

Richard was now heir to England, and to Normandy and Anjou (which were regarded as inseparable), and his father wished him to yield Aquitaine to his youngest brother John. But Richard, a true southerner, would not surrender the duchy in which he had grown up, and even appealed, against Henry II, to his close friend, the young king of France, Philip II (Philip Augustus). In November 1188 he did homage to Philip for all the English holdings on French soil and in 1189 openly joined forces with Philip to drive Henry into abject submission. They chased him from Le Mans to Saumur, forced him to acknowledge Richard as his heir, and at last harried him to his death (July 6, 1189). Richard received Normandy on July 20 and the English throne on September 30. Richard, unlike his rival Philip of France, had only one ambition, to lead the crusade prompted by Saladin's capture of Jerusalem in 1187. He had no conception of planning for the future of the English monarchy and put up everything for sale to buy arms for the crusade. Yet he had not become king to preside over the dismemberment of the Angevin empire. He broke with Philip of France and did not neglect Angevin defenses on the Continent. Open war was averted only because Philip also took the cross. Richard dipped deep into his father's treasure, sold sheriffdoms and other offices. With all this he raised a formidable fleet and army and in 1190 departed for the Holy Land, travelling via Sicily.

Richard found the Sicilians hostile and took Messina by storm (October 4). To prevent the German emperor Henry VI from ruling their country, the Sicilians had elected the native Tancred of Lecce, who had imprisoned the late king's wife, Joan of England (Richard's sister), and denied her possession of her dower. By the Treaty of Messina Richard obtained for Joan her release and her dower, acknowledged Tancred as king of Sicily, declared Arthur of Brittany to be his own heir, and provided for Arthur to marry Tancred's daughter. This treaty infuriated the Germans, who were also taking part in the Third Crusade, and it incited Richard's brother John to treachery and rebellion. Richard joined the other crusaders at Acre on June 8, 1191, having conquered Cyprus on his way there (see CRUSADES). While at Limassol in Cyprus, Richard married (May 12) Berengaria of Navarre.

Giraudon

Results of Crusade

Acre fell in July 1191, and on September 7 Richard's brilliant victory at Arsūf put the crusaders in possession of Joppa. Twice Richard led his forces to within a few miles of Jerusalem. But the recapture of the city, which constituted the chief aim of the Third Crusade, eluded him. There were fierce quarrels among the French, German, and English contingents. Richard insulted Duke Leopold of Austria by tearing down his banner and quarrelled with Philip Augustus, who returned to France after the fall of Acre. Richard's candidate for the crown of Jerusalem was his vassal Guy de Lusignan, whom he supported against the German candidate, Conrad of Montferrat. It was rumoured, unjustly, that Richard connived at Conrad's murder. After a year's unproductive skirmishing, Richard (September 1192) made a truce for three years with Saladin that permitted the crusaders to hold Acre and a thin coastal strip and gave Christian pilgrims free access to the holy places.

Richard sailed home by way of the Adriatic, because of French hostility, and a storm drove his ship ashore near Venice. Because of the enmity of Duke Leopold of Austria he disguised himself, but was discovered at Vienna in December 1192 and imprisoned in the duke's castle at Diirrenstein on the Danube. Later, he was handed over to Henry VI, who kept him at various imperial castles. It was around Richard's captivity in a castle, whose identity was at first unknown in England, that the famous romance of Blondel was woven in the 13th century.

Under the threat of being handed over to Philip II, Richard agreed to the harsh terms imposed by Henry VI: a colossal ransom of 150,000 marks and the surrender of his kingdom to the emperor on condition that he receive it back as a fief. The raising of the ransom money was one of the most remarkable fiscal measures of the 12th century and gives striking proof of the prosperity of England. A very high proportion of the ransom was paid, and meanwhile (February 1194) Richard was released.

Return to England

He returned at once to England and was crowned for the second time on April 17, fearing that the independence of his kingship had been compromised. Within a month he went to Normandy, never to return. His last five years were spent in warfare against Philip II, interspersed with occasional truces. The king left England in the capable hands of Hubert Walter, justiciar and archbishop of Canterbury. It was Richard's impetuosity that brought him to his death at the early age of 42. The vicomte of Limoges refused to hand over a hoard of gold unearthed by a local peasant. Richard laid siege to his castle of Châlus, and in an unlucky moment was wounded. He died on April 6, 1199. He was buried in the abbey church of Fontevrault, where Henry II and Queen Eleanor are also buried, and his effigy is still preserved there.

Richard was a thoroughgoing Angevin, irresponsible and hot-tempered, possessed of tremendous energy, and capable of great cruelty. He was more accomplished than most of his family, a soldier of consummate ability, a skillful politician, and capable of inspiring loyal service. He was a lyric poet of considerable power and the hero of troubadours. In striking contrast with his father, and with King John, he was, there seems no doubt, a homosexual. He had no children by Queen Berengaria, with whom his relations seem to have been merely formal.

Richardson, Henry Hobson

One of the leading architects in the United States following the Civil War, Henry Hobson Richardson designed buildings that were influential in leading to the development of an indigenous modem American architectural style. The profuse imitation of the most obvious details of his designs led to the Romanesque revival of the 1880s and 1890s. Their more essential qualities, their generally simple horizontal silhouettes, and the external colours and textures of natural materials, however, set Richardson's buildings apart from the bulk of American architecture in the last quarter of the 19th century. His works also had a stimulating effect upon the work of the internationally influential architects Louis H. Sullivan (1856–1924) and Frank Lloyd Wright (1867–1959), the American pioneers of modern architectural design.

Richardson was born on September 29, 1838, at Priestley Plantation on the Mississippi River in St. James Parish, Louisiana. He was the great-grandson of the 18th-century political and religious dissenter and discoverer of oxygen. Joseph Priestley (1733–1804). His distinguished pedigree and his own affability made his move from the South to Harvard University in 1855 as easy as it was eventually to be rewarding. Harvard then offered more in personal contacts than in intellectual stimulation, and Richardson's later clients, such as Henry Adams (1838–1918), were largely drawn from the Porcellian Club and other social circles that he entered with ease. He never returned to the South.

Studies in Paris

Sometime during his Harvard days Richardson decided to become an architect. In Boston he was surrounded by buildings of plain granite design that affected the best of his own later work, but for formal training he had to go abroad, for there were no schools of architecture in the United States before the Civil War. Fluent in French from his Louisiana childhood, he studied at the École des Beaux-Arts in Paris from 1860 to 1862, when the military events at home cut off his income. He then worked in the office of the French architect Theodore Labrouste (1799–1885). Richardson remained with Labrouste until he returned to the United States in October 1865. In Paris he mastered the analytical architectural planning that characterizes much of his mature work and that was formulated by his friend the architect and École professor Julien Guadet (1834–1908) in his ***Éléments et théorie de l'architecture,*** published in Paris in 1902.

Richardson returned to America with every expectation of quick success, for he was among the best trained architects in the country and had many important connections. In November 1866, he was awarded his first commission, the Church of the Unity in Springfield, Massachusetts (now demolished), where one of his former classmates was an influential member of the congregation. His career launched, Richardson married Julia Gorham Hayden of Boston on January 3, 1867. They moved into a house of his own design (now altered) on Staten Island, New York, where five of his six children were born. Richardson's neighbour was Frederick Law Olmsted (1822–1903), the journalist and renowned landscape architect with whom he later frequently collaborated.

H.H. **Richardson.**

Richardson lived and worked in New York City for the next eight years, forming, in October 1867, a partnership with the architect Charles D. Gambrill (1832–80) that lasted exactly eleven years, but was never more than one of administrative convenience. From his Manhattan office and the drafting board in his Staten Island home came the drawings for the early commissions in Springfield, the State Asylum for the Insane in Buffalo, New York, and the Brattle Square and Trinity churches in Boston. Designed for the renowned preacher Phillips Brooks (1835–1893), Trinity was one of the most important Episcopal churches in America. Richardson's Romanesque revival design won him a national reputation, many imitators, and so many New England commissions that it became desirable to move to the Boston area. In 1874 he bought an early-19th-century dwelling resembling the plantation houses of the South in suburban Brookline. He added to it his office and studio. His last twelve years were spent with his family and assistants in these busy surroundings so reminiscent of his childhood environment.

The Boston years

During these last years Richardson produced the buildings upon which his reputation principally rests. He designed houses, community libraries, suburban railroad stations, educational buildings, and commercial and civic structures. Instead of the splintered massing, narrow vertical proportions, and disparate Gothic features used by his contemporaries, he favoured horizontal lines, simple silhouettes, and uniform, large-scale details of Romanesque or Byzantine inspiration. Since his best commercial structure, the Marshall Field Wholesale Store in Chicago, and most of his railroad stations in the northeastern United States were demolished long ago, the development of Richardson's work in the last years of his life can now best be studied at Sever and Austin halls at Harvard University; at the Allegheny County Buildings in Pittsburgh, Pennsylvania; at the Glessner House in Chicago; or in the series of libraries in the small towns around Boston, from Woburn and North Easton to Quincy and Malden. The Crane Memorial in Quincy, with its tripartite layering of a rough-faced granite base beneath continuous clerestory windows topped with a tiled gable roof and its cavernous entrance arch, stands with the finest and most characteristic works of his maturity.

Character and personal life

Richardson was a sociable and colourful man. A figure of immense girth, he was known for his hearty appetite for food and drink. He enjoyed entertaining his friends, such as the American sculptor Augustus Saint-Gaudens, with large quantities of champagne and gourmet cuisine. On special occasions he served such delicacies as Chesapeake Bay oysters especially shipped from Baltimore, or would have a terrapin prepared by a Philadelphia restaurant and delivered in person by its chef. Such living hastened his end, however, for he suffered throughout his career from chronic nephritis, or Bright's disease, and worked at a strenuous pace, taking just one vacation during the 1880s: a whirlwind tour of Romanesque architecture in Europe in the summer of 1882. He died four years later, bloated and fatigued, on April 27, 1886, just 48 years old, at the top of his profession and with major buildings rising in Boston; Pittsburgh, Pennsylvania; Cincinnati, Ohio; Chicago; and St. Louis, Missouri. He left it to his successors, the Boston architectural firm of Shepley, Rutan, and Coolidge, to finish these, and to the Chicago architects Sullivan and Wright to carry on in the direction he had initiated.

MAJOR WORKS

Brattle Square Church, Boston (1870–72); State Asylum for the Insane, Buffalo, N.Y. (designed 1870–72); Hampden County Courthouse, Springfield, Mass. (1871–73); North Congregational Church, Springfield, Mass. (built 1872–73); Trinity Church, Boston (designed 1872, built 1873–77); Wm. Watts Sherman House, Newport, R.I. (1874–75); New York State Capitol, Albany, completion with Eidlitz (1875); Ames Memorial Library, North Easton, Mass. (1877–79); Winn Memorial Library, Woburn, Mass. (1877–78); Sever Hall, Harvard University (1878–80); Dr. James Bryant House, Cohasset, Mass. (1880); Crane Memorial Library, Quincy, Mass. (1880–83); Ames Gate Lodge, North Easton, Mass. (1880–81); City Hall, Albany, N.Y. (1880–82); Boston & Albany Railroad Station, Auburndale, Mass. (1881); Austin Hall, Harvard University (1881–83); M.F. Stoughton House, Cambridge, Mass. (1882–83); Allegheny County Jail, Pittsburgh, Pa. (1884–86); Allegheny County Courthouse, Pittsburgh, Pa. (1884–87); Marshall Field Wholesale Store, Chicago (1885–87); Glessner House, Chicago (1885–87).

BIBLIOGRAPHY. Richardson's surviving major works are in greater Boston, North Easton, Massachusetts, Albany, Buffalo, Pittsburgh, and Chicago. Surviving sketches and drawings are mainly at Houghton Library, Harvard University and Shepley, Bulfinch, Richardson, and Abbott, Boston. M.G. VAN RENSSELAER, *Henry Hobson Richardson and His Works* (1888), is a contemporary, and a fundamental work for the study of Richardson. HENRY-RUSSELL HITCHCOCK, *The Architecture of H.H. Richardson and His Times*, rev. ed. (1961; 1966), is the standard critical study. For Richardson's influence on Sullivan and Wright, see JAMES F. O'GORMAN, "Henry Hobson Richardson and Frank Lloyd Wright," *Art Quarterly*, 32:292–315 (1969).

(J.F.O'G.)

Richardson, Samuel

Samuel Richardson's *Pamela* is often credited with being the first English novel. Although the validity of this claim depends on the definition of the term novel, it is not disputed that Richardson was innovative in his concentration on a single action, in this case a courtship. By his use of the epistolary technique—the story is told in the form of letters—he provided if not the "stream" at least the flow of consciousness of his characters, and he pioneered in showing how his characters' sense of class differences and their awareness of the conflict between sexual instincts and the moral code created dilemmas that could not always be resolved. These characteristics reappear regularly in the subsequent history of the novel.

Richardson was 50 years old when he wrote *Pamela*, but about these 50 years little is known. His ancestors were of yeoman stock. His father, also Samuel, and his mother's father, Stephen Hall, became London tradesmen; and his father, after the death of his first wife, married Stephen's daughter, Elizabeth, in 1682. A temporary move of the Richardsons to Derbyshire accounts for the fact that the novelist was born in Mackworth, near the city of Derby, on August 19, 1689. They returned to London when Richardson was 10. He had at best what he called "only Common School-Learning," but at 13 he said he had gained the reputation among the girls in his London neighbourhood of being a good story-teller and ready to write love letters for them, marked with some of the same obliquity that later led Samuel Johnson to say of Clarissa that "there is always something which she prefers to truth."

Richardson was bound apprentice to a London printer, John Wilde. Sometime after completing his apprenticeship he became associated with the Leakes, a printing family whose presses he eventually took over when he set up in business for himself in 1721 and married Martha Wilde, the daughter of his master. Elizabeth Leake, the sister of a prosperous bookseller of Bath, became his second wife in 1733, two years after Martha's death. His domestic life was marked by tragedy. Of the six children of his first marriage, four died within a year of birth, and the others at the ages of two and three. By his second wife he had four daughters who survived him, but two other children (one of them the fourth son to be named after him) died in infancy. These and other bereavements contributed to the nervous ailments of his later life.

Domestic tragedy

In his professional life, Richardson was hardworking and successful. With the growth in prominence of his press went his steady increase in prestige as a member, an officer, and later as master, of the Stationers' Company (the guild for those in the book trade). During the 1730s his press became known as one of the three best in London, and with prosperity he moved to a more spacious London house and leased the first of three country houses in which he entertained an admiring group of young girls and a circle of friends that included Dr. Johnson, the painter William Hogarth, the actors Colley Cibber and David Garrick, Edward Young (many of whose poems he printed, including the celebrated Night Thoughts), and Arthur Onslow, speaker of the House of Commons, whose influence in 1733 helped to secure for Richardson lucrative contracts for government printing that included later the journals of the House.

In this same decade he began writing in a modest way, undertaking some editing and producing what he called "a few other little things of the Pamphlet kind." More importantly he was commissioned to write a collection of letters that might serve as models for "country readers," a volume that has become known as *Familiar* Letters on *Important Occasions.* Occasionally he hit upon continuing the same subject from one letter to another, and, after a letter from "a father to a daughter in service, on hearing of her master's attempting her virtue," he supplied the daughter's answer. This was the germ of his novel *Pamela*. With a method supplied by the letter writer and a plot by a story that he remembered of an actual serving maid who preserved her virtue and was rewarded by marriage, he began writing the work in November 1739 and published it as *Pamela:* or; Virtue Rewarded, a year later.

Publication of *Pamela*

On the death of Pamela's mistress, Richardson relates, her son, Mr. B, begins a series of mild stratagems designed to end in Pamela's seduction, but, these failing, he abducts her and renews his siege in earnest. Pamela preserves her virtue, and halfway through the novel Mr. B offers marriage. In the second half Richardson shows Pamela winning over those who had disapproved of the misalliance. Though the novel was immensely popular, Richardson was adversely criticized by those who thought his heroine a calculating minx or his own morality dubious. Actually his heroine is a blend of the artful and the artless. She is a sadly perplexed girl of 15, with a divided mind, who faces a real dilemma because she wants to preserve her virtue without losing the man with whom she has fallen in love. Since Richardson wrote the novel from Pamela's point of view, it is less clear that Mr. B's problem arises from his having fallen in love with a servant, who, traditionally, would have been merely a target for seduction. The author resolved the conflicts of both characters too facilely. perhaps, because he was firmly committed to the plot of the true story he had remembered. When the instantaneous popularity of *Pamela* led to a spurious continuation of her story, he wrote his own sequel, *Panzela in her Exalted Condition* (1742), a two-volume work that did little to enhance his reputation.

His later heroine Clarissa Harlowe

By 1744 Richardson seems to have completed a first draft of his second novel, *Clarissa.* **Or,** *The History of a Young Lady,* but he spent three years trying to bring it within the compass of the seven volumes in which it was published. He presents the heroine, Clarissa Harlowe, first when she is discovering the barely masked motives of her family, who would force her into a loveless marriage to improve their fortunes. Outside the orbit of the Harlowes stands Lovelace, nephew of Lord M and a romantic who held the code of the Harlowes in contempt. In her desperate straits, Clarissa appraises too highly the qualities that set Lovelace beyond the world of her family, and, when he offers protection, she runs off with him. She is physically attracted by if not actually in love with Lovelace and is responsive to the wider horizons of his world, but she is to discover that he wants her only on his own terms. In Lovelace's letters to his friend Belford, Richardson shows that what is driving him to conquest and to rape, finally, is really her superiority. In the correspondence of Clarissa and her friend Anna Howe, Richardson shows the distance that separates her from her confidant, who thinks her quixotic in not accepting a marriage, but marriage as a way out would have been a sacrifice to that same consciousness of human dignity that had led her to defy her family. As the novel comes to its long-drawn-out close, she is removed from the world of both the Harlowes and the Lovelaces, and dies, a child of heaven. In providing confidants for his central characters and in refusing to find a place in the social structure into which to fit his sorely beset heroine, Richardson made his greatest advances over *Pamela.*

In the years after writing *Pamela,* Richardson broadened his circle of correspondents, and his third novel was his bow to the requests for the hero as a good man, a counter-attraction to the errant hero of Henry Fielding's *Tom Jones* (1749). Fielding had been among those who thought Pamela a scheming minx, as he had shown in his parody, *An Apology for the life of Mrs. Shamela Andrews* (1741) and in the opening of his *Joseph Andrews* (1742). At the time Fielding had thought Cibber to be the author of the anonymously published *Panzela,* but in spite of Fielding's critical praise of *Clarissa* and the friendship that later developed between Richardson and Fielding's sister, Sarah, Richardson never forgave the author of what he stigmatized as "that vile Pamphlet Shamela." In *The History of Sir Charles Grandison* he provides a hero who is a model of benevolence. He faces little that a good heart cannot remedy and extricates himself from the nearest thing to a dilemma that he has to encounter: a "divided love" between an English woman, Harriet Byron, and an Italian, Signora Clementina. He is saved for Harriet by the last-minute refusal of the Roman Catholic Clementina to marry a firmly committed English churchman. The uneasy minds of Clementina and Harriet are explored with some penetration, but Sir Charles faces nothing in his society or within himself that requires much of a struggle. Furthermore his dilemma is not so central to the novel as were those of Pamela and Clarissa. He is surrounded with a large cast of characters who have their parts to play in social comedy that anticipates the novel of manners of the late 18th century.

Influence and reputation

Richardson had disciples when he died, at Parson's Green, near London, on July 4, 1761. Some of them show the influence of *Clarissa,* which seems to have been most responsible for the cult of Richardson that arose on the continent. It was *Grandison,* however, that set the tone of most of Richardson's English followers and for Jane Austen, who was said to have remembered "every circumstance" in this novel, everything "that was ever said or done." By the end of the 18th century, Richardson's reputation was on the wane both in England and abroad, but the 20th century has begun to awaken to the psychological subtleties of *Pamela* and *Clarissa.*

MAJOR WORKS

NOVELS: *Pamela: or, Virtue Rewarded,* 2 vol. (1740, dated 1741); *Clarissa. Or, the History of a Young Lady,* 7 vol. (1747–48, dated 1748); *The History of Sir Charles Grandison,* 7 vol. (1753–54, dated 1754).

OTHER WORKS: *Letters Written to and for particular friends, on the Most Important Occasions: Directing Not Only the Requisite Style and Forms To Be Observed in writing 'Familiar Letters', but How to Think and Act Justly and Prudently, itt the Common Concerns of Human Life* (1741), known as *Familiar Letters on Important Occasions,* a collection of model letters; issue no. 97 (1751) of the literary periodical, *The Rambler,* its subject being advice to unmarried ladies.

BIBLIOGRAPHY. WILLIAM M. SALE, *Samuel Richardson* (1936, reprinted 1969), is an analytical bibliography with historical notes; and ALAN D. MCKILLOP, *Samuel Richardson* (1936, reprinted 1960), a reliable and thorough account of Richardson's life as a novelist, contains a good bibliography of contemporary and later criticism and foreign translations. The largest collection of manuscript correspondence is in the Victoria and Albert Museum, London. The Shakespeare Head edition of the novels (18 vol., 1929–31) is standard. A selection of the correspondence, ed. by ANNA BARBAULD (6 vol., 1804, reprinted 1966) is valuable, but not always trustworthy. JOHN CARROLL (ed.), *Selected Letters* (1964), is excellent. T.C. DUNCAN EAVES and BEN D. KIMPEL, *Samuel Richardson: A Biography* (1971), is the most comprehensive life story and will be definitive for many years. It contains an excellent census of his correspondence. WILLIAM M. SALE, *Samuel Richardson: Master Printer* (1950), is an account of Richardson's professional career with a list of books from his press. BRIAN W. DOWNS, *Richardson* (1928, reprinted 1969), provides a good critical discussion of the novels as does an essay in ALAN D. MCKILLOP, *Early Masters* of *English Fiction* (1956). IAN P. WATT, *The Rise of the Novel* (1957), contains brilliant discussions of *Pamela* and *Clarissa.* The range of modern critical essays is excellently represented in JOHN CARROLL (comp.), *Samuel Richardson* (1969).

(W.M.S.)

Richelieu, Cardinal de

Both as statesman and churchman, Armand-Jean du Plessis, Cardinal de Richelieu, is the acknowledged architect of France's greatness in the 17th century and a contributor to the secularization of international politics during the Thirty Years' War. His success in bringing political order out of chaos and in bringing about the eclipse of Spain, France's paramount rival, made him a controversial figure to his contemporaries as well as to historians.

Heritage and youth. The family of du Plessis de Richelieu was of insignificant feudal origins but by intermarriage with the legal and administrative classes had risen to some prominence and had acquired the seigneury of Richelieu in Poitou. It was perhaps here, or more likely in Paris, where his father, François du Plessis, seigneur de Richelieu, was grand provost (chief magistrate)

Giraudon

Richelieu, portrait by Philippe de Champaigne (1602–74). In the Louvre, Paris.

to Henry III, that Armand-Jean du Plessis was born on September 9, 1585. His mother, Suzanne de la Porte, was the daughter of a councillor of the Parlement of Paris (the supreme judicial assembly, second only to the king's council), and in his intelligence, administrative competence, and instinct for hard work, he resembled his middle class ancestors.

He was five years old when his father died, leaving estates that had been ruined by inflation, extravagance, and mismanagement during the Wars of Religion, (1562–98), and he was conscious from his earliest years of the threat of penury. This inspired in him the ambition to restore the honour of his house and evoked in him the sense of grandeur he was to attribute vicariously to France. His provident mother, with three boys and two girls—all under the age of 13—set about reorganizing the family's precarious resources. The principal of these was the benefice of the bishopric of Luçon near La Rochelle, which had been granted by Henry III to the Richelieu family under the Concordat of 1516 (Concordat of Bologna). Unrest of the cathedral chapter threatened a revocation of the grant, and it became necessary for a member of the family to be consecrated bishop as soon as possible. Henri, the eldest son, was heir to the seigneury of Richelieu; and Alphonse, the second son, had become a Carthusian monk; so the obligation fell on Armand-Jean, who was a student at a cadet school for nobles, destined for the army and the court.

Early career* in *the church. The prospect of a career in the church was not displeasing to the thin, pale, and at times sickly boy, for he had an inclination toward learning, a facility for debate, and a relish for the prospect of governing the lives of others. So when he entered the Collège de Calvi to study theology he prepared himself well for a future that he did not doubt would encompass more than the bishopric of Luçon. Because he was below the canonical age for consecration upon the completion of his studies, he needed a papal dispensation. To gain it he went to Rome, where Paul V fell victim to the young man's skill as a charmer. Historians have been tempted to suppose that his personal experiences with the papal chancellery bred in Richelieu a distrust of Roman politics that was to lead him into persistent opposition to the Holy See in the days of his power, but there is no evidence of this. On April 17, 1607, at the age of 22, he was ordained priest and consecrated to the see of Luçon. He found on his arrival a diocese ruined by the Wars of Religion, a hostile chapter, and a demoralized clergy, but his opponents quickly succumbed to the unaccustomed authority that radiated from the episcopal palace.

Bishop of Luçon

The enemies of Richelieu in his own lifetime and some historians, bred on the legends propagated by them, have supposed that Richelieu set out to demonstrate his administrative capacity in the only situation available to him. That he was ambitious to an extraordinary degree, and ruthless in pursuit of his ambitions, is beyond dispute, but to suggest that he was motivated, either at Luçon or later, [illegible]l by [illegible] aggrandizement is to misunderstand him and th[illegible] age. For in [illegible] li[illegible] as in hi[illegible] contemporaries, ambition and piety were compatible. A son of the Counter-Reformation, he was religious; he believed intensely in God; and his instinct for certitude and authority made him particularly susceptible to the discipline of theology. He formed an association with the leaders of the mystical movement in the church, though he was too much a rationalist to be affected by their practices. He was the first bishop in France to implement in his diocese the reforms decreed by the Council of Trent, and he was also the first theologian to write in French and to establish the conventions of vernacular theological exposition.

Religious writings

In his own time his theological writings were esteemed. There were four of them—two published when he was in disfavour and administratively inactive, in 1618 and in 1621; the other two were written when he experienced an intensification of religious conviction in the dark days of the Thirty Years' War shortly before his death and were published posthumously. They reveal a mind of apologetic rather than mystical bent, concerned with truth, and confident that doctrinal error, once exposed and recognized, would be instantly repudiated. But he was also concerned with the perfection of the soul and with cultivation of the virtues. His catechism was used throughout the 17th century and was highly influential.

At least the earlier of his writings may have been prompted by the fact that Richelieu's energy and compulsion to influence events had to find an outlet when no avenue other than writing was open to him. Intellectual though he was, the pursuit of knowledge undirected to any immediate end was insufficient to his needs. When he studied contemporary theories of government of church and state it was with a view to the refutation of ideas that he felt were subversive of that natural order that could exist only in a society in which the crown was responsible only to God.

Inactivity, anxiety, and frustrated ambition produced in Richelieu recurrent periods of ill health. For long periods, both at Luçon and at the height of his power, he was in retreat because of, or on the pretext of, ill health. Although possessed of hypnotic power to charm when disposed lo dc so, he increasingly found the emotional cost of personal confrontation too great, and he preferred to argue his case on paper, The consequent remoteness made him appear to be a sinister figure in a web of espionage and intrigue that enmeshed everyone in France—a mandarin surrounded by his 14 cats, all-knowing, all-seeing, vindictive, unscrupulous, and ruthless.

This is the picture that the gossips of his own time, mostly involved in factions that he sought to suppress, transmitted to posterity. The reality was a hard-working, conscience-stricken man, combatting powerful forces that were dedicated to divisive political and social ends—a man obsessed with order as a superior moral end.

Rise to power. The France on which the Bishop of Luçon pondered gave every indication of falling again into the disorder of the Wars of Religion. The assassination of Henry IV in 1610 released separative forces that were endemic in the administrative system. The government of the queen mother, Marie de Médicis, as regent for Louis XIII, was inefficient and corrupt, and the magnates of the realm, satraps in their own provinces, motivated by personal and regional self-interest, struggled to control or combat it. Their disobedience was always accompanied by predatory expeditions of armed men and labyrinthine negotiations with the court; and on one of these occasions the Bishop of Luçon found himself an intermediary, which led to his being elected one of the representatives of the clergy of Poitou to the States General (assembly of the representatives of the French estates) of 1614. He put all his energy into persuading the assembly of his talents and the court of his support for royal authority. In a clash between the clergy and the Third Estate (consisting of the middle classes, artisans, and peasants) on the subject of the relationship between the crown and the papacy he played a conciliatory role, and he was prominent in moves of the clergy to persuade the Third Estate that the decrees of the Council of Trent should be promulgated. The outcome was that he was chosen to present the final address of the First Estate (the clergy) at the closing session on February 23, 1615.

Election to the Estates General

Some months later he was appointed chaplain to the new queen, Anne of Austria. This was an office of no political consequence, but it held the promise of eventual entry into the royal council, which, Richelieu had argued at the States General, should accord first place to prelates of distinction. He has been charged with basely promoting his own advancement through flattery of the inconstant Queen Mother and her favourites. In his time there was nothing unusual in this, for to dissemble was both a Baroque convention and a political necessity universally practiced, although rarely with Richelieu's skill. Clever negotiations with another disobedient faction led to his appointment as a secretary of state in 1616.

Secretary of state. Up to this time Richelieu had had no insight into international relations, and the regard for Spain with which he was credited was probably genuine because he had had no occasion to question Spain's ambitions. His year of office, however, coincided with war between Spain (ruled by a Habsburg dynasty) and Venice, which invoked its alliance with France. The resultant diplomatic involvement persuaded Richelieu of three interconnected factors: the vulnerability of France to Habsburg political and economic encirclement; the domestic ramifications of various European movements in the religious controversy between Catholics and Protestants; and the dependence of the small states in France's borderlands upon an equilibrium of power between France and Spain.

Cardinalate

Richelieu's tenure of office was abruptly terminated in April 1617 when a palace revolution overthrew the regency of Marie de Médicis and brought to power a new coalition of politicians under the direct government of Louis XIII. Richelieu was first banished to Luçon and then exiled to the papal city of Avignon, where he sought distraction from his melancholy in theological writing. A new rebellion of the princes, gravitating this time to Marie de Médicis as the focus of opposition to the royal council, led in 1619 to the King recalling Richelieu to his mother's entourage on the assumption that he would exercise a moderating influence upon her. The ascendency that he gained over her, however, did not lead to her submission but the contrary. There followed four years of intricate negotiation and even overt hostilities during which the King's nomination of Richelieu for a cardinal's hat became one of the issues involved in a settlement. A revolt of the Huguenots and the death of the King's favourite brought about Marie de Médicis' recall to the council and Richelieu's promotion, although for a time the King kept him at a distance.

First minister of France. In 1624 another crisis, over the Valtellina in northern Italy, led to a ministerial reconstruction and to the Cardinal's appointment as secretary of state for commerce and marine and chief of the royal council. Four years later the title of first minister was to be created for this office. The Valtellina controversy occurred when the Protestant Swiss canton of Grisons invoked a treaty of protection with France against Spanish ambitions in the valley of that name. The struggle had ramifications both within France and throughout Europe as the Protestants made common cause with Grisons and the Catholics with the Habsburgs. Richelieu recognized that vacillation in this crisis would threaten domestic stability, and so he struck in the Valtellina, expelling the papal troops from their fortresses. It was an action that created an enormous impression in Europe and gained for Richelieu an instant reputation for decision and ruthlessness.

It also disillusioned those who had seen in him a defender of Catholic interests and of a Franco-Spanish alliance and provoked the indignation of zealous Catholics, who were horrified at this assault on the Pope's army. The fractious and the pious now coalesced in yet another of the seditious movements that had long debilitated France, and they influenced Marie de Médicis against her erstwhile client who, now that he was invested with the responsibility of government, no longer deferred to her or permitted her whims and emotions to influence him.

The Valtellina affair gave Richelieu the opportunity to demonstrate his theory that diplomacy consists in patient and protracted negotiation from positions of strength and led to his intervening, through the medium of hired pamphleteers, in a paper war on the morality of statecraft. The use of force by princes, he argued, was morally justified as an essential step in the establishment of the peace of their subjects and the security of their states. In matters in which vital national interests are involved, less strict rules of behaviour are incumbent than in other matters. "Although in the ordinary course of affairs justice requires authentic proof," he wrote, "the same is not true of those which concern the State because in such case persuasive inference must sometimes be held to be sufficient, for parties and cabals which are formed against public security ordinarily act with such cunning and secrecy that there is never any evident proof save in the event, when the matter is beyond remedy." A statesman must not have "a cringing or scrupulous conscience" but must "pursue great things with ardour commensurate with the wisdom of the judgment" which he makes.

Conspiracies against Richelieu

From his first days in office Richelieu was the object of conspiracies to remove him, by assassination if other methods failed, and this continual threat was met with the courage that "requires that man must be exempt from weakness and fear." The success of Richelieu's security organization in ferreting out the disaffected, his implacable pursuit of his foes, his suspicion of everyone, and his manipulation of state trials made him misunderstood, feared, and detested. Yet according to the standards of the age his administration of justice did not depart from the moral principles that he believed to underlie all government; and while he pursued his objective of the integrity of France with tenacity he was never unaware of the problems of conscience, which he resolved by reference to the criterion of "probabilism"—the theory that in moral questions, where certainty is impossible, any course may be followed that is seen as solidly probable —which was current in Catholic theological exposition.

Measures for internal reform. The goals that Richelieu set himself were to counter Habsburg hegemony in Europe, which threatened France's independence of action, and "to make the King absolute in his kingdom in order to establish therein order and rule, to which his conscience obliges him." This implied not only the reduction to submission of the great nobles but also the subversion of the antiquated political institutions that fragmented France and weakened its government, particularly the provincial estates and parlements. But at no time was Richelieu sufficiently powerful to achieve his domestic ends by direct and overt measures. A respecter of law and history, he accepted the necessity of working within the traditional framework of administration. His sense of the feasible and his gift for seeing both sides of a question resulted in a pragmatism in practice that often contradicted his proclaimed theories, and he confused his critics by unexpected compromise and moderation and caused them to misinterpret his empiricism as opportunism and equivocation.

The extent to which Richelieu overcame the inertia of the governmental system is questionable. His use of commissions of justice to station in the provinces officers answerable to the central government was only the revival of an older expedient spasmodically employed in the past. They'were not regularly put to use until 1635—and then only as an extraordinary war measure—and were not systematized until the last year of his life, but they did eventually lead to government by intendants (provincial administrators appointed by the crown) in the reign of Louis XIV. At no time was he able overtly to challenge a provincial government, except in the case of Languedoc in 1632, when the Duc de Montmorency, encouraged by the provincial estates over an issue of tax collection by royal instead of provincial authorities, rebelled and lost his head.

Richelieu's great intellectual capacity enabled him to penetrate to the essence of events, and his tremendous will power, overcoming illness and hostility, drove him to incessant work and relentless exercise of his power. In his theory of politics he shared the rationalism of contemporary philosophers, believing that "the light of natural reason enables everyone to know that, since man is endowed with reason, he must do nothing except by reason." While he did not doubt the capacity of the mind to know what is naturally enjoined, he participated in the prevailing pessimism about man's will to act accordingly. Hence the refractory must be ruled so that they might not act "contrary to nature, and, as a result, contrary to Him Who is its Author." This twofold view of moral causes, the natural and divine, provided a philosophical axiom for state supervision of conduct in both the secular and the spiritual spheres. Sin and civil disobedience were, to Richelieu, but two aspects of disorder.

Struggle against the Huguenots. The gravest divisive factor in French society was religion. To Richelieu, the Huguenots constituted a state within a state, entrenched in 150 strongholds, with the civil government of major cities in their hands and considerable military force at their disposal. Yet Richelieu was prepared to tolerate this religious dissent so long as it did not amount to a political challenge. In this attempt to preserve social harmony at the expense of confessional difference he failed at first, for the Huguenot community was foolishly drawn into the intrigues of the Protestant magnates, who instigated England for the most trivial of reasons to war with France. Richelieu laid siege in 1628 to La Rochelle, the Huguenot centre, but it took a year to reduce the city, during which time Spain took advantage of the distraction to extend its hegemony in northern Italy at the expense of France's allies. While promising Richelieu help to combat the Protestants, Spain in fact subsidized their leaders in order to keep the French government preoccupied, and seized the strategic fortress of Casale in northern Italy. Again Richelieu acted with surprising vigour. The moment La Rochelle fell he led the army in winter over the Alps and checked the Spanish design. This reverse was countered by the Habsburgs with the introduction of imperial garrisons into parts of the duchy of Lorraine, which were claimed as fiefs of France. There followed intricate diplomatic manoeuvres, culminating in Richelieu's dramatic refusal to ratify the peace Treaty of Regensburg in 1630, and the Habsburgs' appeal to Pope Urban VIII to excommunicate Louis XIII for this supposed breach of faith.

This was Richelieu's moment of greatest political insecurity. His relationship with the King was distant and at times tense. The Catholic zealots did not share his distrust of Spain, and, disturbed at the implications of Richelieu's foreign policy, they provoked Marie de Médicis into a state of hysteria concerning the man who she believed had ungratefully deprived her of influence. On Richelieu's return from Italy in 1630, she struck, exerting all her emotional energy to influence her son to dismiss his minister. It was called the Day of Dupes because the court believed that Richelieu, like the train of his predecessors, had fallen, but it was not so. The King perceived that the issue was his own independence or his mother's domination and that there was no one but Richelieu who could relieve him of the responsibility of decisions at a moment of bewildering complications. After a day of suspense, he supported the Cardinal and thereafter did not waver in his support, even though Richelieu was able to survive his suspicions and dislike only by consummate tact and prudence.

Day of Dupes

The Day of Dupes had vast political consequences. Marie de Médicis and the King's brother Gaston fled to the Spanish Netherlands, there to constitute a focus of sedition that Spain promoted by conspiracy and finance and that Richelieu countered by a fatal involvement with the enemies of the Habsburgs. The central objective of his foreign policy was to restore the political equilibrium in the empire that Habsburg victories had disturbed, and, to this end, fan the suspicions that the states of the German Catholic League entertained about imperial intentions so that they might make peace with the Protestants and leave the latter free to counterbalance the Emperor. Although Bavaria was disposed to seek French protection, the Emperor's military successes and the Edict of Restitution occasioned a new mutual antagonism of Catholics and Protestants, which made neutrality of the Catholic League a practical impossibility.

Franco-Habsburg War. Richelieu's German policy fell into ruins as a result of his grant of subsidies to Gustavus II Adolphus of Sweden, then engaged in the conquest of Pomerania. He intended Gustavus Adolphus to distract imperial forces away from the French borderlands while he recovered the French fiefs in Lorraine, and he believed that by making him his pensioner he could harness him to this limited design while he promoted peace in the Rhine and Danube valleys. French subsidies, however, only liberated Gustavus Adolphus from constraint, and he fell on southern Germany, became embroiled with the armies of the Catholic League, and so consolidated the imperial and Catholic cause. The war spilled over the Rhine, and France's client states were by degrees drawn into the Habsburg orbit. The seizure by Spain in 1635 of the Archbishop of Trier, who was under French protection, at length led to France's alignment with the Protestant powers in the Thirty Years' War.

Assessment of Richelieu's role in the war. This involvement on behalf of the Protestants was regarded by many Catholics in his own time and subsequently as a betrayal of the church by one of its princes, and Richelieu has been criticized for intensifying a war whose horrors have rarely been equalled, apparently unnecessarily, in view of the imminent collapse of Spain as a military power. It was, in fact, the French struggle that revealed Spain's weaknesses, so that this is a judgment of hindsight. That Richelieu was drawn unwillingly by events into the vortex is clear, just as it is clear that the cost paid in social suffering and economic decline, leading to more frequent agrarian revolts, was high. Almost as soon as war broke out with Spain in 1635, Richelieu initiated secret peace negotiations and renewed them repeatedly while he lived. That he was motivated by the idea of extending France to its natural frontiers, the Rhine and the Alps, is unsupported by the evidence, although he took advantage of the predicament of its rulers to extend French protection into Alsace.

Richelieu's justification for war was the same as that for rigorous domestic discipline: only the statesman, furnished with all available information and equipped for judicious appraisal of events, is competent to judge the justice or otherwise of policy. Hence, "the subjects must blindly obey the prince; for often necessity constrains [his ministers] to adopt policies which cannot be supported by abstract reason alone, but can be justified only in the event."

Economic policies. In economic matters Richelieu was an amateur. He committed war expenditure with little regard for the difficulties of raising revenue, and he was given to economic improvisation that was often unsound. But he eschewed doctrinaire views and retained flexibility of mind. Whereas he was early influenced by the theories of the economist Antoine de Montchrestien, who thought of specie as the finite index of national wealth and who argued for economic self-sufficiency so as to conserve it, he was later persuaded that the drain of specie could be compensated for by trade. He accordingly promoted products and industries that could give France an export advantage and discouraged, mostly ineffectively, imports of luxury goods. Glass making, tapestry and silk, sugar, and the extractive industries attracted his interest. He planned canal systems and promoted overseas trading companies, in which he was a shareholder and which began the process of French colonization in Canada and the West Indies; and he gained economic and political footholds in Morocco and Persia.

His vast horizon reflected in part his concern with the French religious missions, which spread in every direction in Africa, the Middle East, and America and which extended French influence and created a vast intelligence network that fostered his political and economic designs. He laid the foundations for the French Navy by buying ships from the Dutch; and though he failed to have much influence on seapower, he developed shipping connections with the Baltic on which the French shipbuilding programs of his successors were to be founded. The legal reforms of his period were spasmodic and often frustrated by the Parlement, and how much of their content is due to him is questionable. The Code Michaud of 1629—which regulated primary industry and trade, companies, public offices, the church, and the army and also standardized weights and measures—was promulgated under his authority, although he may not have been its architect.

Later years in the church. In his last years Richelieu found himself involved in religious conflict, in opposition to the Pope, and in a struggle with the French church over the allocation of church revenues to the financing of the war. His relationship with Urban VIII became strained over diplomatic grievances, questions of church administration, and his own ambitions to extend French political influence by acquiring benefices for himself in the Holy Roman Empire. In spite of these conflicts, Richelieu remained strictly orthodox in his views on the relationship between church and state and thus resisted the Gallican challenge to the absolutism of papal authori-

Notion of papal authority

ty. He explained his position as follows: "While religiously obeying the Pope in spiritual matters, one can justly oppose him in his temporal designs." At the same time, his theory that "the King receives his crown and his temporal power from God alone" inevitably affected his view of the boundary between spiritual and temporal matters.

The theocratic concept of the state that resulted from this notion of kingship caused Richelieu to regard heresy as political dissidence, and he harried the apparently unorthodox, such as the first Jansenists, on the ground that they disturbed at once the spiritual and secular orders, just as he harried the recalcitrant nobles and stamped out duelling. Although there were canonical irregularities in his life, notably in the matter of pluralism, (the multiplication of ecclesiastical benefices), there is no evidence of a serious departure from the principles or practices of the church, and he maintained relationships with such religious figures as St. Vincent de Paul and St. John Eudes in their charitable activities. His accumulation of wealth was excessive even by the standards of the age, but it was largely dedicated to the public service and to patronage of the arts and of the University of Paris. Richelieu himself was a playwright and musician of moderate talent, and his establishment of the French Academy is one of the achievements for which France best remembers him.

Foundation of French Academy

His last months were agitated by the most dangerous of all the conspiracies against his life, that of the youthful royal favourite Cinq-Mars, who was exposed by Richelieu's secret service and died on the block. The Cardinal's health, bad for some years, had deteriorated, and it was virtually from his deathbed that he was compelled to dictate to the King five propositions respecting royal behaviour toward ministers that he considered essential for proper government. He died in the Palais Royal, which he left in his will to the crown, on December 4, 1642, with the last rites and after nominating Cardinal Mazarin as his successor, proclaiming, so it was said, that he had never had any intention "other than the good of religion and the State" and no enemies but those of the state. He was buried in the chapel of the Sorbonne, which he had financed, and his tomb, despite desecration during the Revolution, still stands.

Assessment. While in detail he was only moderately successful, Richelieu in substance attained his goals of orderly government under the royal authority and the defeat of Habsburg hegemony. Whether the centrifugal forces in Germany that he promoted—and which the Peace of Westphalia institutionalized—were advantageous to Europe in the long run is questionable, but the political fragmentation of the empire and the military eclipse of Spain made possible the grandeur of France that Richelieu foresaw and his successors realized. This mystical aspect of his designs is difficult to articulate but is essential to his greatness. The conspiracies that erupted under Mazarin failed as much because Richelieu had wrought a fundamental psychological change in favour of the moral ascendency of the crown as because, by the destruction of castles and city walls and the centralization of military authority, he had eliminated the power base of both aristocratic and religious dissent.

Written works. Apart from the religious works referred to, Richelieu left the following manuscripts: His *Journal* of the events of the Day of Dupes; his *Mémoires*, covering from 1610 to 1638, whose authenticity is controversial; his ***Testament politique***, which purports to be a guide to statecraft directed to the King and which was published first in 1688.

BIBLIOGRAPHY

Writings: ***Mémoires***, extracts were first published by M. PETITOT, ***Collection complète des mémoires relatifs à l'histoire de France, depuis le règne de Philippe Auguste,*** 130 vol. (1819–29). The period from 1610 to 1638 is covered in the 2nd series, vol. 21–30. The Société de l'Histoire de France published the text from the original ms. in 10 vol., ed. by BARON DE COURCEL and J. LAIR (1907–31). The same period is covered in a 4-vol. folio edition (1961). ***Testament Politique d'Armand du Plessis, Cardinal duc de Richelieu,*** 3rd ed. (1688). The standard edition is the ***ddition critique publike avec une introduction et des notes par Louis Andre' et une pre'face de Le'on Noel*** (1947). ***Journal de M. le cardinal duc de Richelieu qu'il a faict durant le grand orage de la court en l'année 1630 et 1631*** (1648; republished in ***Archives curieuses de l'histoire de France,*** 2nd series, vol. 5, 1838); ***Maximes d'État et fragments politiques,*** vol. 3 of ***Les documents inédits sur l'histoire de France,*** series 1 (1880); ***Les principaux poincts de la foy de l'Église catholique defendus contre l'escrit adressé au Roy par les quatre ministres de Charenton*** (1618; reprinted 1842; Eng. trans., ***The Principall Points of the Faith of the Catholike Church: Defended Against a Writing Sent to the King by 4 Ministers of Charenton,*** 1635); ***lnsfruction du chrestien*** (1621); ***Traitté de la perfection du chrestien*** (1646); ***Traittk qui contient la me'thode la plus facile et la plus asseurée pour convertir ceux qui se sont séparez de L'Église*** (1651).

Works about Richelieu: G. HANOTAUX and LE DUC DE LA FORCE, ***Histoire du cardinal de Richelieu,*** 6 vol. (1893–1947); D.P. O'CONNELL, ***Richelieu*** (1968); C.J. BURCKHARDT, ***Richelieu,*** 4 vol. (1935–67; Eng. trans, ***Richelieu and His Age: His Rise to Power,*** 2 vol., 1940–70); H.S.J. GRIFFET, ***Histoire de règne de Louis XIII,*** 3 vol. (1758), an important work that includes material that has since disappeared; D.L.M. AVENEL, ***Lettres, instructions diplomatiques et papiers d'État du cardinal de Richelieu,*** 8 vol. (1854–77), work that contains the most important of Richelieu's correspondence; G. FAGNIEZ, ***Le Père Joseph et Richelieu, 1577–1638,*** 2 vol. (1894).

(D.P.O'C.)

Richemont, Constablede

Arthur, comte de Richemont, was the third and last of the great Breton constables who fought for the French House of Valois during the Hundred Years' War between France and England. France's implacable struggle against England for independence furnished the backdrop for Richemont's talents as diplomat, politician, and, most importantly, as a military organizer. Richemont emerged in the late 1430s and early 1440s as the only figure in the court circle around the Valois king Charles VII who was capable of reconstructing the French Army into a loyal, modern, and efficient military force. In his capacity as chief of military operations, Richemont was responsible for the final French victories of 1449–53, which cleared his country of the English armies and were a direct preliminary to the emergence of France as the most powerful military and political force in late-15th-century Europe.

Early career and capture by English

Born in 1393 as a younger son of John IV, duke of Brittany, Arthur was given the English title of earl of Richmond (in French, comte de Richemont) by his older brother, Duke John V, in 1399. The marriage of their mother, Joanna, to Henry IV of England after her first husband's death, had re-established Brittany's connection with the English crown, but Richemont's primary interests remained in French affairs. In the bitter and divisive feud between the houses of Orléans and Burgundy—branches of the Valois dynasty—Richemont fought on the side of the former faction, shortly to be renamed Armagnac. During this same period, Arthur also became the intimate friend and partisan of the dauphin Louis, son of the French king Charles VI.

Richemont fought at Agincourt in 1415, where he was wounded and captured by the English victors, who, allied with the Burgundians, sought to unite France and England under the English crown. Richemont remained a prisoner in England until 1420, when he was released on parole and threw his support to the English side. He was now influential in persuading his brother, John, the duke of Brittany, to support the Treaty of Troyes under which Henry V of England became "Heir of France." Henry rewarded Richemont with the French county of Ivry. Richemont's connection with the Anglo-Burgundian faction was further sealed in 1423 by his marriage to Margaret of Burgundy, widow of the dauphin Louis, who had died young. This match made Richemont the brother-in-law of Philip, the duke of Burgundy, and John, the duke of Bedford, the English regent of France. Richemont was well on his way toward a high position in the ruling circles around Bedford and Burgundy when an unexplained quarrel broke out between him and the English regent. Richemont now deserted the English cause and

Return to French allegiance

returned to his initial French allegiance. Appointed constable of France by Charles VII in March 1425, he attempted to assume control of France's battered and unreliable military forces. He now totally supported the French cause, persuading his brother, John V of Brittany, to sign the Treaty of Saumur with France in October 1425.

The new constable quickly made himself unpopuiar by his rough manners and his grim insistence upon a vigorous prosecution of the war. His political power was therefore overshadowed by that of Charles VII's incompetent favourites, especially Georges de La Trtmoille. Richemont's influence at court was further weakened by Brittany's retum to the English cause. A treaty between John V and the regent Bedford in September 1427 caused the expulsion of the Constable from the French court. Richemont joined Joan of Arc at Orleans in 1429, fighting under her banner in several victorious engagements against the English until the influence of La Trtmoille forced him out of the army once again. Despite the favourite's power, Richemont was able to bring Brittany and Charles VII together once again in the Treaty of Rennes, but it was not until La Trémoille's final overthrow in 1432 that the Constable was able to retum to court.

Using his Burgundian connections, Richemont was able to arrange the Treaty of Arras (September 21, 1435), which ended the long quarrel between Duke Philip of Burgundy and the French king. Arras was the political and diplomatic turning point of the Hundred Years' War, as well as an important milestone in Richemont's own career.

But the military task of winning the war still remained. In April 1436 Richemont marched into Paris as the city rose against the English garrison, but the poorly organized French armies were unable to make much headway in the years that followed. Richemont now determined upon a total reform of the French Army, along with a reorganization of the financial structure of the French state in order to provide the revenues necessary for its support. Strongly supported by Charles VII and given a steady source of revenue by the taxes upon hearths and salt, Richemont now reorganized the French cavalry into the regular and highly professional ***gens d'armes d'ordonnance.*** These regular companies enabled Richemont to renew the war with overwhelming success after a brief truce had been concluded in 1444. In this final act of the long struggle, the Constable de Richemont played an active role, driving the English from the Cotentin Peninsula in September and October of 1449 and taking a decisive part in the climactic Battle of Formigny in April 1450. The conquest of Normandy followed in short order and that of Guyenne in the succeeding two years.

Reform of army and expulsion of English

France had finally won the Hundred Years' War, and Richemont's active career now drew to a close. Succeeding his nephew Peter II, he became duke of Brittany in September 1457. He died on December 26, 1458, leaving no legitimate children.

BIBLIOGRAPHY. The main, eyewitness source for Richemont's life is that written by his friend and companion, GUILLAUME GRUEL, *Chronique d'Arthur **de Richemont*** (1890). ***See*** also EUGENE COSNEAU's somewhat dated biography, ***Le Connétable de Richemont*** (1886); G. DU FRESNE DE BEAUCOURT's old but reliable ***Histoire de Charles VIZ, 6*** vol. (1881–91); and E. PERROY, ***La Guerre de cent ans*** (1945; Eng. trans., ***The Hundred Years War,*** 1951). No definitive modern work on Richemont presently exists.

(R.Br.)

Riding and Horsemanship

Before the advent of mechanized vehicles, riding on horseback was one of the chief means of transportation. As the horse never chose to be ridden, man of necessity evolved horsemanship, which is the art of riding with maximum discernment and a minimum of interference with the horse. Until recent years riding was a monopoly of the cavalry, cowboys, and others whose work required riding on horseback and of the wealthy, who rode for sport. A rapid change has taken place, however. Although hunting and polo tend to remain the sport of the wealthy and the role of the horse in battle has ended, especial value is now placed on horse shows of a high standard, in which the most popular event is undoubtedly show jumping. The finer aspects of horsemanship have remained a valued social asset and symbol of prestige, but the opening of many new riding clubs and stables has made riding and horsemanship accessible to a much larger segment of the population.

This article will treat the history of riding from the earliest known times to the development of horsemanship as an organized sport. The main emphasis here will be on modern equestrian competition, including the main events of both dressage and jumping, and on the art of horsemanship.

HISTORY

Origins **and** early history. From the 2nd millennium BC, and probably even earlier, the horse was employed as a riding animal by fierce nomadic peoples of central Asia. One of these peoples, the Scythians, were accomplished horsemen and used saddles. It is also likely that they realized the importance of a firm seat and were the first to devise a form of stirrup. A saddled horse with straps hanging at the side and looped at the lower end is portrayed on a vase of the 4th century BC found at Chertomlyk in the Soviet Union. This contrivance may have been used for mounting only, however, because of the danger of being unable to free the foot quickly in dismounting. The Greek historian Strabo says that the indocility of the Scythians' wild horses made gelding necessary, a practice until then unknown in the ancient world. The Sarmatians, superb horsemen who superseded the Scythians, rode bareback, controlling their horses with knee pressure and distribution of the rider's weight.

Among the earliest peoples to fight and hunt on horseback were the Hittites, the Assyrians, and the Babylonians; at the same time (about 1500 BC) the Hyksos, or Shepherd Kings, introduced horses into Egypt and rode them in all their wars. In the 8th and 7th centuries BC, the Scythians brought horses to Greece where the art of riding developed rapidly, at first only for pleasure. A frieze from the Parthenon in Athens shows Greeks riding bareback. Philip II of Macedon had a body of cavalry in his army, and his son Alexander's army had separate, organized horse units. In the 4th century BC another Greek historian, Xenophon, wrote his treatise ***Hippikē*** giving excellent advice on horsemanship. Many of his principles are still perfectly valid. He advocated the use of the mildest possible bits and disapproved of the use of force in training and in riding. The Roman mounted troops were normally barbarian archers who rode without stirrups and apparently without reins, leaving the hands free to use the bow and arrow.

Classical horsemanship

Early riding equipment. As a general rule almost every item of riding equipment originated among the horsemen of the Eurasian steppes and was adopted by the people of the lands they overran to the east, the south, and later the west.

Horseshoes of various types were used by migratory Eurasian tribes about the 2nd century BC, but the nailed iron horsehoe as used today first appeared in Europe about the 5th century AD, introduced by invaders from the East. One such, complete with nails, was found in the tomb of the Frankish king Childeric I (died 481/482) at Tournai, Belgium.

Attila is said to have brought the stirrup to Europe. Round or triangular iron stirrups were used by the Avars in the 6th century AD, and metal stirrups were used by the Byzantine cavalry. They were in use in China and Japan about 600 AD.

The principle of controlling a horse by exerting pressure on its mouth through a bit and reins was practiced from the earliest times, and bits made of bone and antlers have been found dating from before 1000 BC. The flexible mouthpiece with two links and its variations have been in use down the centuries, leading directly to the jointed snaffle bit of the present day.

Early, stumpy prickspurs have been found in Bohemia on 4th-century BC Celtic sites.

Military horsemanship. The importance of cavalry increased in the early Middle Ages, and in the 1,000 years that followed, mounted warriors became predominant in battle. Armour steadily became bulkier and heavier, forcing the breeding of more and more massive horses, until the combination rendered manoeuvrability nearly impossible.

Efforts to overcome this were made at a Naples riding academy in the early 16th century, when Federico Grisone and Giovanni Battista Pignatelli tried to combine classical Greek principles with the requirements of medieval mounted combat. After Xenophon, except for a 14th century treatise by Ibn Hudhayl, an Arab of Granada, Spain, apparently no literature on riding was produced until Grisone published his ***Gli Ordini di Cavalcare*** in 1550.

The development of firearms led to the shedding of armour, making it possible for some further modifications in methods and training under followers of the school of Pignatelli and Grisone, such as William Cavendish, Duke of Newcastle. In 1733 François Robichon de la Guérinière published ***Ecole de Cavalerie*** in which he explained how a horse can be trained without being forced into submission, the fundamental precept of modern dressage. Dressage, the French word for schooling, is the methodical training of a horse for any of a wide range of purposes, excluding only racing and cross-country riding.

Growth of modern technique

Meanwhile, the Imperial Spanish Riding School of Vienna and the French cavalry centre at Saumur aimed at perfecting the combined performance of horse and rider. Their technique and academic seat, a formal riding position or style in which the rider sits deep in the middle of the saddle holding his body erect, exerted considerable influence in Europe and America during the 18th and 19th centuries and are still used in modern dressage. The head riding master at Saumur, Comte Antoine d'Aure, however, promoted a bold, relaxed, and more natural, if less "correct," style of riding across country, in disagreement with his 19th-century contemporary, François Baucher, a horseman of great ability with formal *haute école* ("high school") ideas. Classical exercises in the manège, or school for riding, had to make way for simplified and more rational riding in war and the hunt. During this period hunters jumped obstacles with their feet forward, their torso back on the horse's haunches, and its head held up. The horse often leaped in terror.

At the turn of the 20th century, Captain Federico Caprilli, an Italian cavalry instructor, made a thorough study of the psychology and mechanics of lowmotion of the horse. He completely revolutionized the established system by innovating the forward seat, a position and style of riding in which the rider's weight is centred forward in the saddle, over the horse's withers. About the same time the American flat-racing jockey Tod Sloan had astounding success with his "monkey seat," an extreme forward riding position and the racing seat of today. Caprilli wrote very little, but his pupil, Piero Santini, popularized his master's fundamental principles. Except in dressage and showing, the forward seat is the one now most frequently used, especially for jumping.

THE ART OF HORSEMANSHIP

The basic principle of horsemanship is to obtain results in a humane way by a combination of balance, seat, hands, and legs.

Fundamentals. The horse's natural centre of gravity shifts with its every movement and change of gait. Considering that a mounted horse also carries a comparatively unstable burden approximately one-fifth of its own weight, it is up to the rider to conform with the movements of the horse as much as possible.

Before mounting, the horseman sees that the saddle fits him and the horse. In the saddle his position is such that he can stay on the horse and control it. The seat he adopts depends on the particular task at hand. A secure seat is essential, giving the rider complete independence and freedom to apply effectively the aids at his disposal. He does not overrule the horse, but, firmly and without inflicting pain, he persuades it to submit to his wishes.

The horse's movements. The natural gaits of the horse are the walk, the trot, the canter or slow gallop, and the gallop, although in dressage the canter and gallop are not usually differentiated. A riding horse is trained in each gait and in the change from one to another.

During the walk and the gallop the horse's head moves down and forward, then up and back (only at the trot is it still), and the rider follows these movements with his hands.

Walk. The walk is a slow, four-beat, rhythmical pace of distinct successive hoof beats in an order such as near (left) hind, near fore, off (right) hind, off fore. Alternately two or three feet may be touching the ground simultaneously. It may be a free, or ordinary, walk in which relaxed extended action allows the horse freedom of its head and neck, but contact with the mouth is maintained; or it may be a collected walk, a short-striding gait full of impulsion, or vigour; or it may be an extended walk of long, unhurried strides.

Trot. The trot is a two-beat gait, light and balanced, the fore and hind diagonal pairs of legs following each other almost simultaneously—near fore, off hind, off fore, and near hind. The rider can either sit in the saddle and be bumped as the horse springs from one diagonal to the other or he can rise to the trot, also termed posting, rising out of the saddle slightly and allowing more of his weight to bear on the stirrups when one or the other of the diagonal pairs of legs leaves the ground. Posting reduces the impact of the trot on both horse and rider.

Canter. As the horse moves faster, its gait changes into the canter, or ordinary gallop, in which the rider does not rise or bump. It is a three-beat gait, graceful and elegant, characterized by one or the other of the forelegs and both hindlegs leading—near hind, off hind, and near fore practically together, then off fore, followed briefly by complete suspension. Cantering can be on the near lead or the off, depending on which is the last foot to leave the ground. The rider's body is more forward than at the trot, his weight taken by the stirrups.

Gallop. An accelerated canter becomes the gallop, in which the rider's weight is brought sharply forward as the horse reaches speeds up to 30 miles (48 kilometres) an hour. The horse's movements are the same as in the canter.

Other gaits. There are a number of disconnected and intermediate gaits, some of which are done only by horses bred especially to perform them. One is the rack, a four-beat gait, with each beat evenly spaced in perfect cadence and rapid succession. The legs on either side move together, with the hindleg striking the ground slightly before the foreleg. The single foot is similar to the rack but slower. In the pace, the legs on either side move and strike the ground together, resulting in a two-beat gait. The fox trot and the amble are both four-beat gaits, the latter smoother and gliding.

The rack gait

Training. Depending on the abilities and inclinations of horse and trainer, training may include such elements as collection (controlled, precise, elevated style of movement) and extension (smooth, swift, reaching movement —the opposite of collection) at all paces; turns on the forehand (that part of the horse that is in front of the rider) and hindquarters; changing lead leg at the canter; change of speed; reining back, or moving backwards; lateral movements; and finally the refinements of dressage, jumping, and cross-country riding.

Communication with the horse is rendered possible by the use of the bit and the aids. The rider signals his intentions to the horse by a combination of recognized movements of his hands and legs, using several articles of equipment. By repetition the horse remembers this language, understands what is required, and obeys.

Bits. There are several types of bits, the most commonly used being the snaffle, the double bridle, and, to a lesser extent, the Pelham.

The simplest is the snaffle, also called the bridoon. It consists of a single straight or jointed mouthpiece with a ring at each end for the reins. The snaffle is used for racing and frequently for riding across country. It is appropriate for preliminary schooling, and, until the horse has accepted it and is thoroughly confident, a double bridle should not be used.

The double bridle

The double bridle is used for advanced schooling. It consists of a jointed snaffle and a straight bit placed together in the mouth, first the snaffle, then the bit, both functioning independently and attached to separate reins. The mouthpiece of the bit can have a port or indentation in its centre to give more control. The slightest pull on the bit rein exerts pressure on the mouth.

The Pelham is a snaffle with a straight mouthpiece; cheekpieces with rings at the lower ends for curb action; and a curb chain, with which pressure may be applied to the lower outside of the horse's mouth. The Pelham gives ample control with only slight discomfort and is popular for polo.

Aids. The principal features of a horse's mentality are acute powers of observation, innate timidity, and a good memory. To a certain extent it can also understand. Schooling is based on these faculties, and the rider's aids are applied accordingly. The natural aids are the voice, the hands through the reins and the bit, the legs and heels, and movement of the rider's weight. The whip, the spur, and devices such as martingales, special nosebands, and reins are artificial aids, so termed in theory, as the horse does not discriminate between natural and artificial.

Horses are easily startled. A good horseman will approach them quietly, speaking to them and patting them to give them confidence. Silence on the part of the rider can even cause disquiet to some horses, but they should not be shouted at. The rider's voice and its tone make a useful aid in teaching a horse in its early schooling to walk, trot, canter, and halt.

To keep the horse alert at all times, the rider's hands keep a light, continual contact with its mouth, even at the halt. The hands are employed together with the legs to maintain contact, to urge the horse forward, to turn, to rein back, and generally to control the forehand. The horse is said to be collected and light in hand when the action of the bit can cause it to flex, or relax, its jaw with its head bent at the poll, or top.

When pressed simultaneously against the flanks, immediately after the hands ease the reins, the legs induce the forward movement of the horse. They are of the greatest importance in creating and maintaining impulsion, in controlling the hindquarters, and for lateral movement.

The rider achieves unity of balance by means of the weight aid, that is, by moving his body in harmony with the movements of the horse, forward, backward, or to a side. Thus, in cantering to the left, he leans to the left; or when about to descend a steep slope, he stays erect while the horse is feeling for the edge with its forefeet, but as soon as the descent starts he leans forward, leaving the hindquarters free to act as a brake and to prevent scraping the back of the horse's rear legs on rough ground. Meanwhile the hands keep the horse headed straight to maintain its balance.

The use of the whip

The whip is used chiefly to reinforce the leg aid for control, to command attention, and to demand obedience, but it can be used as a punishment in cases of deliberate rebellion. A horse may show resistance by gnashing its teeth and swishing its tail. Striking should always be on the quarters, behind the saddle girth, and must be immediate since a horse can associate only nearly simultaneous events. This applies equally to rewards. A friendly tone of voice or a pat on the neck are types of reward.

Although normally the leg or the heel, or both, should be sufficient, spurs, which should always be blunt, assist the legs in directing the precision movements of advanced schooling. Their use must be correctly timed.

Martingales are straps used to control a horse's head carriage and are usually one of three types: running, standing, or Irish.

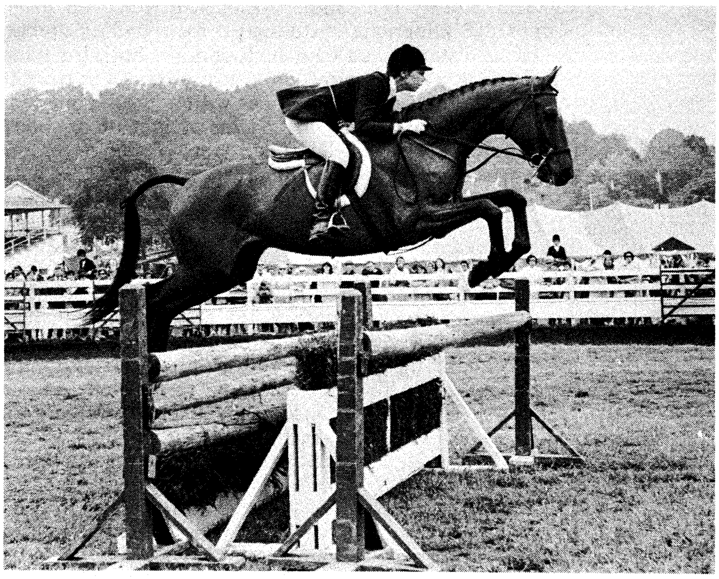
The running and standing martingales are attached to the saddle straps at one end and the bit reins or bridle at the other. The Irish martingale, a short strap below the horse's chin through which the reins pass, is used for racing and stops the horse from jerking the reins over its head. As the horse cannot see below a line from the eye to the nostril, it should not be allowed to toss its head back, particularly on approaching an obstacle, as it is liable to leap blindly. A martingale should not be necessary with a well-schooled horse, however.

The noseband, a strap of the bridle that encircles the horse's nose, may be either a cavesson, with a headpiece and rings for attaching a long training rein, or a noseband with a headstrap, only necessary if a standing martingale is used. A variety of other nosebands are intended for horses that pull, or bear, on the reins unnecessarily.

Seats. The saddle, the length of the stirrup, and the rider's seat, or style of riding, should suit the purpose for which the horse is ridden. The first use of the stirrup is to enable the rider to get on the horse, normally from the near (left) side. With his raised foot in the stirrup the rider should avoid digging the horse in the flank on springing up and should gradually slide into position without landing on the horse's kidneys with a bump. With an excitable horse, the rider may wait, resting on knees and stirrups, until the horse moves forward.

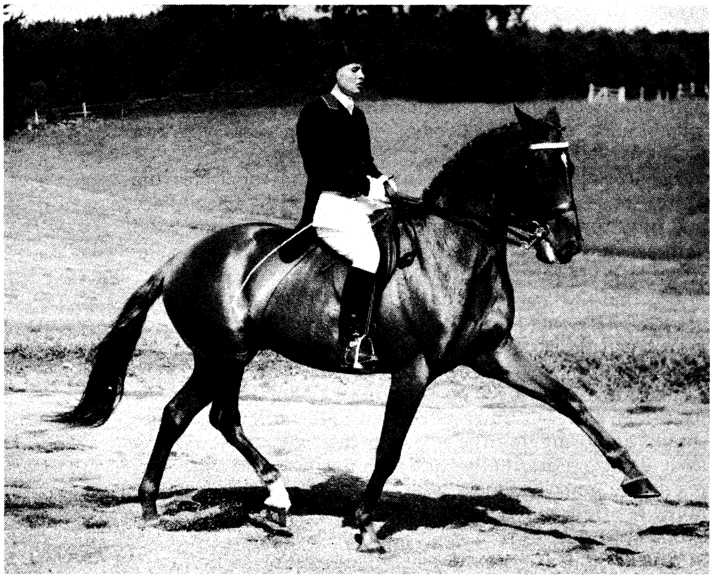
Forward. The forward seat, favoured for show jumping, hunting, and cross-country riding, is generally considered to conform with the natural action of the horse. The rider sits near the middle of the saddle, his torso a trifle forward, even at the halt. The saddle is shaped with the flaps forward, sometimes with knee rolls for added support in jumping. The length of the stirrup leather is such that, with continual lower thigh and knee grip, the arch of the foot can press on the tread of the iron with the heel well down. A wide and heavy stirrup iron allows easy release of the foot in case of accidents. The line along the forearm from the elbow to the hands and along the reins to the bit is held straight. As the horse moves forward, so does the rider with his hands, to suit the horse's comfort in all its movements.

Freudy Photos. N.Y.



Forward seat in jumping.

Dressage. In the show and dressage seat the rider sinks deep into the saddle, in a supple, relaxed but erect position above it. The saddle flaps are practically straight so as to show as much expanse of the horse's front as possible. The stirrup leather is of sufficient length for the rider's knee to bend at an angle of about 140 degrees and for the calf of his leg to make light contact with the horse's flank, the heel well down, and the toes or the ball of the foot resting on the tread of the stirrup iron. The rider keeps continual, light contact with the horse's mouth; and the intention is to convey an impression of graceful, collected action. In the past this type of saddle with its straight cut flaps was used for hunting and polo, for which the forward seat recently has become more popular.



Dressage seat—in the extended trot.
Freudy Photos, N.Y.

Stock saddle. The stock saddle seat is appropriate for ranchers but is also used at rodeos and by many pleasure and trail riders. The saddle, which can weigh up to 40 pounds (18 kilograms), is designed for rounding up cattle and is distinguished by a high pommel horn for tying a lariat. The rider employs long stirrups and a severe bit that he seldom uses since he rides with a loose rein, guiding his horse chiefly by shifting the weight of his body in the saddle. The gaucho roughriders of the Argentine Pampa have adopted a similar seat, using a saddle with a high pommel and cantle. Australian stockmen have used a saddle with a short flap, equipped with knee and thigh rolls, or props, which give an extremely secure seat.

Fiat racing. The flat-racing seat is a positively forward seat, with the jockey's knees on the withers and with very short stirrups. The rider stays on mainly by balancing himself above the point where the horse can carry the most weight, the flattened position of his body at the gallop offering less resistance to the air. The steeplechase seat is similar to the flat-racing seat, with slightly longer stirrups, and many riders now adopt a forward seat at the jumps.

Side saddle. Though now not so fashionable, the elegant and classical side-saddle seat is still favoured and considered correct by many horsewomen. On the near side the saddle has an upright pommel on which the rider's right leg rests. There is a lower, or leaping, pommel, against which the left leg can push upward when grip is required, and a single stirrup. Although the rider sits with both legs on one side of the saddle, forward action to suit the movement of the horse is feasible across country.

Bareback. Bareback means riding without saddle or blanket, the rider sitting in the hollow of the horse's back and staying there chiefly by balance. It is an uncomfortable seat but less so at the walk and the slow canter. When suffering from saddle galls horses are sometimes ridden bareback for exercise.

Dressage. Originally intended for military use, dressage training was begun early in the 16th century. Until recently manuals on the subject were written chiefly by cavalrymen.

The international rules for dressage are based on the traditions and practice of the best riding schools in the world. The following is an extract from these rules of the Fédération Équestre Internationale:

Object and general principles.

> The object of dressage is the harmonious development of the physique and ability of the horse. As a result, it makes the horse calm, supple and keen, thus achieving perfect understanding with its rider. These qualities are revealed by the freedom and regularity of the paces; the harmony, lightness, and ease of the movements; the lightening of the forehand, and the engagement of the hindquarters; the horse remaining absolutely straight in any movement along a straight line, and bending accordingly when moving on curved lines.
>
> The horse thus gives the impression of doing of his own account what is required of him. Confident and attentive, he submits generously to the control of his rider (Used with permission of the publisher).

Campagne is the term used for elementary but thorough training, including work on the longeing rein. This long rein, also used for training young or difficult horses, is attached to a headpiece with a noseband called a cavesson. The horse is bitted and saddled and is schooled in circles to left and right at the end of the rein. It is an accessory to training from the saddle, which is always best. Basic to *campagne* is collection, teaching the horse to arch its neck, shift its weight backward onto its hindquarters, and move in a showy, animated manner. Other important elements include riding in a straight line, turns, and lateral movements.

Haute école dressage

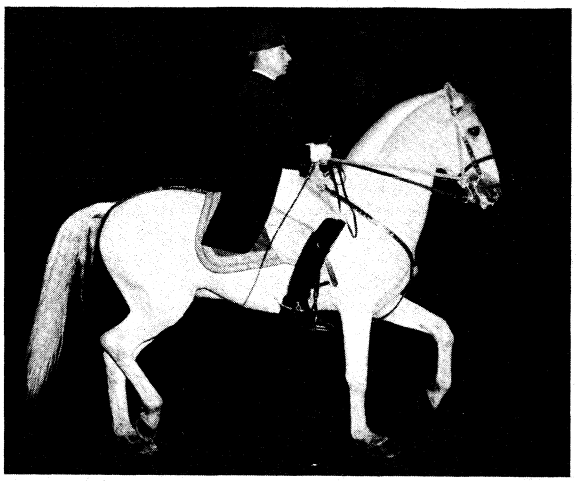
Haute école is the most elaborate and specialized form of dressage, reaching its ultimate development at the Vienna school in its traditional white Lippizaner horses. Some characteristic ***haute école*** airs, or movements, are the pirouettes, which are turns on the haunches at the walk and the canter; the piaffe, in which the horse trots without moving forward, backward, or sideways, the impulse being upward; the passage, high-stepping trot in which the impulse is more upward than forward; the levade, in which the horse stands balanced on its hindlegs, its forelegs drawn in; the courvet, which is a jump forward in the levade position; and the croupade, ballotade, and capriole, a variety of spectacular airs in which the horse jumps and lands again in the same spot.

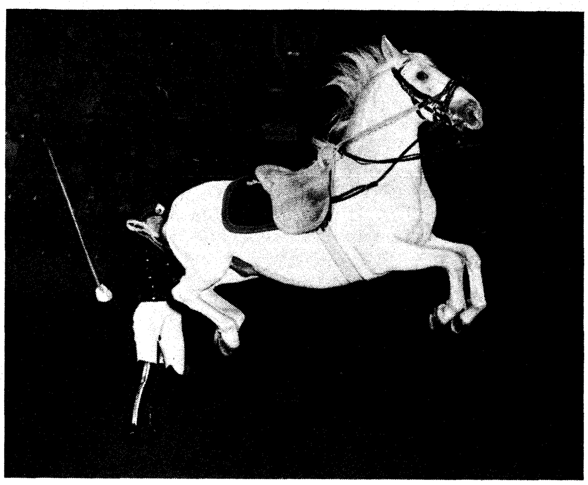
All of these movements are based, perhaps remotely in some instances, on those that the horse performs naturally.

Jumping. The most sensitive parts of the horse when ridden are the mouth and the loins, particularly in jumping. The rider's hands control the forehand while his legs act on the hindquarters. As speed is increased the seat is raised slightly from the saddle, with the back straight and the trunk and hands forward, the lower thighs and the knees taking the weight of the body and gripping the saddle, leaving the legs from the knees down free for impulsion. Contact with the mouth is maintained evenly and continually, the rider conforming with every movement of his mount as the horse's head goes forward after takeoff and as it is retracted on landing, the hands always moving in line with the horse's shoulder. In order to give complete freedom to the hindquarters and to the hocks, the rider does not sit back in the saddle until at least two strides after landing.

The horse is a natural jumper, but if ridden, schooling becomes necessary. Training is started in an enclosed level area by walking the horse, preferably in a snaffle, over a number of wooden bars or poles laid fiat on the ground. When the horse has become accustomed to this, its speed is increased. As the horse progresses, the series of obstacles is systematically raised, varied, and spaced irregularly. The object is to teach the horse: (1) to keep its head down; (2) to approach an obstacle at a quiet, collected, yet energetic pace; (3) to decide how and where to take off; and (4) after landing to proceed quietly to the next obstacle. The horse should be thoroughly confident over every jump before it is raised and should be familiarized with a variety of obstacles.

Only thoroughly trained riders and horses compete. Very strenuous effort is required of the horse, as well as of the rider, who does not by any of his actions give his mount the impression that something out of the ordinary is impending. If possible the horse is warmed up by at least a half-hour's walking and trotting before entering the ring. The horse is guided toward the exact centre of every obstacle, the rider looking straight ahead and not looking around after takeoff for any reason, as that might unbalance the horse. The broader the obstacle, the greater the speed of approach. Although a few experienced riders can adjust the horse's stride for a correct takeoff, this should not be necessary with a well-schooled horse.





Haute école figures: Lippizaner horses in (left) piaffe and (right) ballotade.
Freudy Photos

The rider is always made to conform with every action of the horse, the only assistance necessary being that of direction and increasing or decreasing speed according to the obstacle.

RIDING AND SHOWS

Racing on horseback probably originated soon after man first mastered the horse. By the 7th century BC organized mounted games were held at Olympia. The Romans held race meetings, and in medieval Europe tournaments, jousting, and horse fairs were frequent and popular events. Played in Persia for centuries, polo was brought to England from India about 1870. In North America, Western ranch riding produced the rodeo.

Associa-
tions
and clubs

Horse associations and pony clubs are today the mainstay of equine sport. They have improved the standards of riding instruction and the competitive activities of dressage, hunter trials, and show jumping. The latter has become an important event since 1869, when what was probably the first "competition for leaping horses" was included in the program of an Agricultural Hall Society horse show in London. National organizations such as the British Horse Society, the American Horse Shows Association (AHSA), the Federazione Italiana Sports Equestri, the National Equestrian Federation of Ireland, the Fédération Française des Sports Équestres, and similar groups from about 50 other nations are affiliated with the Fédération Équestre Internationale (FEI), founded in 1921 with headquarters at Brussels, the official international governing body and the authority on the requirements of equitation.

Horse shows. Horse shows are a popular institution that evolved from the horse sections of agricultural fairs. Originally they were informal displays intended to attract buyers and encourage the improvement of every type of horse. Now they are organized and conducted by committees of experts and by associations that enforce uniform rules, appoint judges, settle disputes, maintain records, and disseminate information. Riding contests included in the program, in which highly trained riders and horses compete in a number of events and classes, have become increasingly important.

Under the auspices of the Royal Dublin Society, an international horse show was first held at Dublin in 1864. It is an annual exhibition of every type of saddle horse, as well as broodmares and ponies. International jumping contests similar to Olympic competition, events for children, and auction sales are held during this five-day show.

The National Horse Show at New York, first held in 1883, is another great yearly event. Held at Madison Square Garden, it lasts several days and includes about 10 different events. Among the most important are the international jumping under FEI rules and the open jumping under AHSA rules. Other shows are held in many sections of the United States.

Horse and pony shows are held regularly in the United Kingdom, the most important being the Richmond Royal Horse Show, the Horse of the Year Show, and the Royal International Horse Show. The latter, an annual event first held in 1907, has flourished under royal patronage and includes international jumping, special items such as the visit of the Spanish Riding School with its Lippizaners in 1953, and a Supreme Riding Horse competition.

In Canada, the Royal Agricultural Winter Fair at Toronto, opened in 1922 and known in Canada as the "Royal," is a major event, and in Australia the Royal Agricultural Society organizes horse shows annually in every state. Further examples are the shows at Verona and at the Piazza di Siena in Rome; frequent horse shows in Belgium, France, Germany, and The Netherlands; the winter show in July in Buenos Aires; and the Exhibition of Economic Achievement in Moscow.

Olympic equestrian competition. The FEI organizes and controls the equestrian events at the Olympic Games. Included in each Olympics since the Games at Stockholm in 1912 (equestrian events were also held in 1900), these events are the occasion for keen rivalry and evoke high standards of horsemanship. They comprise a dressage grand prix, a three-day event, and a jumping grand prix, all open to team and individual competition.

The Grand Prix de Dressage involves performance of the walk, trot, canter, and collected paces and several conventional dressage figures and movements, as well as the correct rider's position. Scoring on each item is from a maximum of 10 for excellent down to 1 for very bad. A score of 0 means the rider has performed nothing that was required.

The Three-Day Event consists of tests in dressage, endurance or cross-country riding, and show jumping. Dressage is on the first day. On the second day there is an endurance test over a course 25 to 35 kilometres (16 to 22 miles) in length, covering swamp roads, tracks, steeplechase obstacles, and across country. Jumping tests, less strenuous than the Prix des Nations jumping event, are held on the third day.

The Prix des Nations jumping event is a competition involving 13 or 14 obstacles, heights varying between 1.30 and 1.60 metres (51 and 63 inches), and a water jump 4 metres (13 feet) across, over a course with 60 metres (200 feet) between obstacles. Penalties are scored for disobedience, knocking down or touching an obstacle, and for a fall. The rider with the lowest penalty score wins.

In addition to these competitions there is a riding section of the modem pentathlon, also conducted under FEI rules. Competitors must clear, riding a strange horse chosen by lot, 20 obstacles over a course of 1,000 metres (3,000 feet) (for lists of Olympic Games equestrian champions see ATHLETIC GAMES AND CONTESTS: The *Olympic* record).

Riemann, Bernhard

Georg Friedrich Bernhard Riemann was one of the most creative mathematicians of the 19th century. His relatively few published papers widely influenced geometry and analysis. Moreover, his bold ideas concerning the geometry of space had a profound effect on the development of modern theoretical physics. To a large extent, they provided the foundation for the concepts and methods used by Albert Einstein to develop his theory of relativity in the 20th century.

Born on September 17, 1826, in the village of Breselenz in Hannover, Germany, Riemann was the second of six children of a Lutheran pastor, who gave him his first instruction. He obtained a good education'with the encouragement of a happy and devout family. At the local Gymnasium (high school), he quickly progressed in mathematics beyond the guidance of his teachers, mastering calculus and the *Théorie des nombres* ("Theory of Numbers") of Adrien-Marie Legendre. In 1846–51 he studied at the universities of Gottingen and Berlin, where he was interested in problems concerning the theory of prime numbers, elliptic functions, and geometry. Following studies in experimental physics and Naturphilosophie, which sought to derive universal principles from all natural phenomena, he concluded that mathematical theory could secure a connection between magnetism, light, gravitation, and electricity; Riemann then suggested field theories, in which the space surrounding electrical charges may be mathematically described. Thus, during his student days he had already begun to develop some of the original ideas that later were to become important to modern mathematical physics.

Riernann, lithograph after a portrait by an unknown artist, 1863.

Development of function theory

In 1851 he obtained the doctorate at Gottingen with a dissertation on the "Grundlagen fur eine allgemeine Theorie der Functionen einer veranderlichen complexen Grosse" ("Foundations for a General Theory of Functions of a Complex Variable"). Function theory, which treats the relations between varying complex numbers, is one of the major achievements of 19th-century mathematics. Riemann based his treatment on geometrical ideas rather than algebraic calculation alone. His work, which earned the rare praise of the renowned mathematician Carl Friedrich Gauss, led to the idea of the Reimann surface—a multilayered surface—on which a multivalued function of a complex variable can be interpreted as a single-valued function. This idea, in turn, contributed to methods in topology, which deals with position and place instead of measure and quantity. His probationary essay (Habilitationsschrift) for admission to the faculty in 1853 was "On the Represention of a Function by Means of a Tngonometrical Series."

Riemann's non-Euclidean geometry

While continuing to develop unifying mathematical themes in the laws of physics, Riemann also prepared in 1854 for his inaugural lecture at Gottingen, required for admission to the faculty as a *Privatdozent*, an unpaid lecturer dependent entirely on student fees. He listed three topics, from which Gauss, representing the faculty, chose "Über die Hypothesen, welche der Geometrie zu Grunde liegen" ("On the Hypotheses Which Form the Foundations of Geometry"). Gauss himself had devoted long, profound speculations to this difficult subject. In this lecture, one of the most celebrated in the history of mathematics, Riemann developed a comprehensive view of geometry. With a thorough understanding of the limitations of ordinary, Euclidean geometry, which is based on the postulate of parallels, he independently formulated a non-Euclidean geometry. In so doing, he was apparently unaware that Nikolay Lobachevsky and János Bolyai had already shown the possibility of devising a consistent geometry without this postulate. Riemann's non-Euclidean geometry was an alternative to theirs and to that formulated by Gauss. He postulated that, through a point outside a line, there are no parallels to that line, a physical example of which can be seen in the fact that two ships on a meridian must meet at a pole. He correctly perceived that his ideas would benefit physics, as indeed they did when Einstein later drew upon them to build his model of space–time in relativity theory (see PHYSICAL THEORIES, MATHEMATICAL ASPECTS OF: Relativity theory).

Beginning in 1855, Riemann received a small stipend that represented unusual academic progress at the time and removed him from the ranks of the hardship cases. In 1857 he became professor extraordinarius (associate professor) and in 1859 professor, succeeding the mathematician Peter Gustav Lejeune Dirichlet, who had succeeded Gauss four years earlier. Riemann was beset by overwork, deaths in his family, and his own faltering health. He continued, however, to produce original papers, which, though few in number—some were published posthumously—contained many rich ideas, such as his work on partial differential equations. A measure of his influence is the extensive list of methods, theorems, and concepts that bear his name: the Riemann approach to function theory, the Riemann–Roch theorem on algebraic functions, Riemann surfaces, the Riemann mapping theorem, the Riemann integral, the Riemann–Lebesgue lemma on trigonometrical integrals, the Riemann method in the theory of trigonometrical series, Riemannian geometry, Riemann curvature, Riemann matrices in the theory of Abelian functions, the Riemann zeta functions, the Riemann hypothesis, the Riemann method of solving hyperbolic partial differential equations, and Riemann–Liouville integrals of fractional order. In 1859 he wrote the paper "Über die Anzahle der Primzahlen unter einer gegebenen Grosse" ("On the Number of Primes in a Given Magnitude"), in which he partially described the asymptotic frequency of primes (positive integral numbers that have no other factors except one and themselves, as 2, 3, 5, . . .).

Riemann's growing reputation finally earned him a permanent post in 1859 at Gottingen as the second successor to Gauss. In 1862 he married Elise Koch, and, for a time, the conditions of his life improved. Then he fell ill with pleurisy, which was complicated by tuberculosis. His strength gradually ebbed, despite several visits to Italy for recuperation. He died, in the Lutheran faith of his childhood, on July 20, 1866, at Selasca, in northern Italy.

BIBLIOGRAPHY. Riemann's collected works (all in German), ed. by HEINRICH WEBER and RICHARD DEDEKIND, were published in one volume in 1876, including an extensive biography by Dedekind. A second edition was published in 1892, and a supplement, containing a large amount of previously unpublished material, appeared in 1902. A French translation of selections from the collected works appeared in 1898; although Dedekind's biography was among the items omitted, this volume did contain a French translation of a long address by FELIX KLEIN given in Vienna in 1894 on Riemann's influence on modern mathematics. The collected works were published in the United States in 1953; in addition to the 1892 German edition and the 1902 supplement, it contained an excellent article by HANS LEVY.

Rift Valleys

A rift valley is formed by subsidence between parallel, opposing scarps or cliffs produced by faulting (displacement of the Earth's crust). A rift valley, or simply rift, is therefore a tectonic feature, attributable to Earth movements, in contrast with river or glacier valleys, which are produced by erosional processes. The floors of rift valleys were initially contiguous with their bordering plateau highlands prior to faulting, although large-scale crustal separation, volcanism, and valley filling by sedimentation can complicate this simple picture.

The neologism the Great Rift Valley was applied in 1893 to the extensive system of tectonic valleys that traverses eastern Africa and the Middle East. The unity of this system, between Mozambique and the Dead Sea, had been recognized since the exploration of the chain of lakes between latitudes 15" S and 8° N in Africa in the late 1800s. The similarity of the valleys of eastern Africa to the Rhine Graben in Germany, which had been intensively studied, was particularly noted. The German term graben (trench or ditch) thus came to be synonymous with rift valley, though there is now a growing tendency to use "rift valley" for the gross structure and graben for smaller, faulted valleys that may occur within or diverge from the main rift valleys.

Continental and oceanic rifts

Rift valleys are sparsely and irregularly distributed in the continents of the world. The African–Middle East rifts are unique in magnitude and extent, but similar structures form the Rhine rift valleys (with possible extensions into France and Scandinavia), the Baikal Rift Valley of central Siberia, and the Imperial Valley of Southern California.

The post-World War II discovery of a very extensive system of faulted valleys on the ocean floors, in particular along the crests of large ridges running the length of the Atlantic and Indian oceans, has given rise to the term oceanic (or midoceanic) rifts. Though morphologically similar to continental rift valleys, oceanic rifts are formed by different processes: crustal separation and upwelling of molten material from beneath the Earth's crust, followed by a poorly understood process of faulting and uplift of the rift margins.

Oceanic rifts are a fundamental feature of global tectonics (Earth deformation). They marked the precise boundaries between pairs of crustal plates that are drifting apart in response to sea-floor spreading. As the plates move apart, the suture along the rift floor is healed with an upwelling of basaltic magma, which solidifies and accretes on the trailing edges of the separating plates. The results of this phenomenon can be closely observed in Iceland, where the Mid-Atlantic Rift is exposed above sea level. The direct connection of the oceanic rift system with the continental rift system of Africa, through the northwestern Indian Ocean and Gulf of Aden, suggests that the continental system is similar but complicated by the presence of thick continental crust that overlies the active zones of the upper mantle. This similarity has not yet been clearly established to the satisfaction of all.

Influence of the African system on man

The nature of the East African Rift System, with which this article is primarily concerned, has had far-reaching effects on man and his society, Volcanic eruptions and lake deposits, associated with development of the African rifts, have buried and preserved evidence of mankind's origins and earliest evolution. From those earliest times, man has found the climatic, pastoral, and agricultural conditions of the high plateaus of eastern Africa congenial to his needs. In Ethiopia, perhaps more than anywhere else in the world, it is possible to identify a nation's consciousness, historical development, and actual survival with intimate physiographic and geological determinants. It has been said that the rift valley lies like a natural moat in front of Abyssinia, which it has helped to render one of the most independent of African countries.

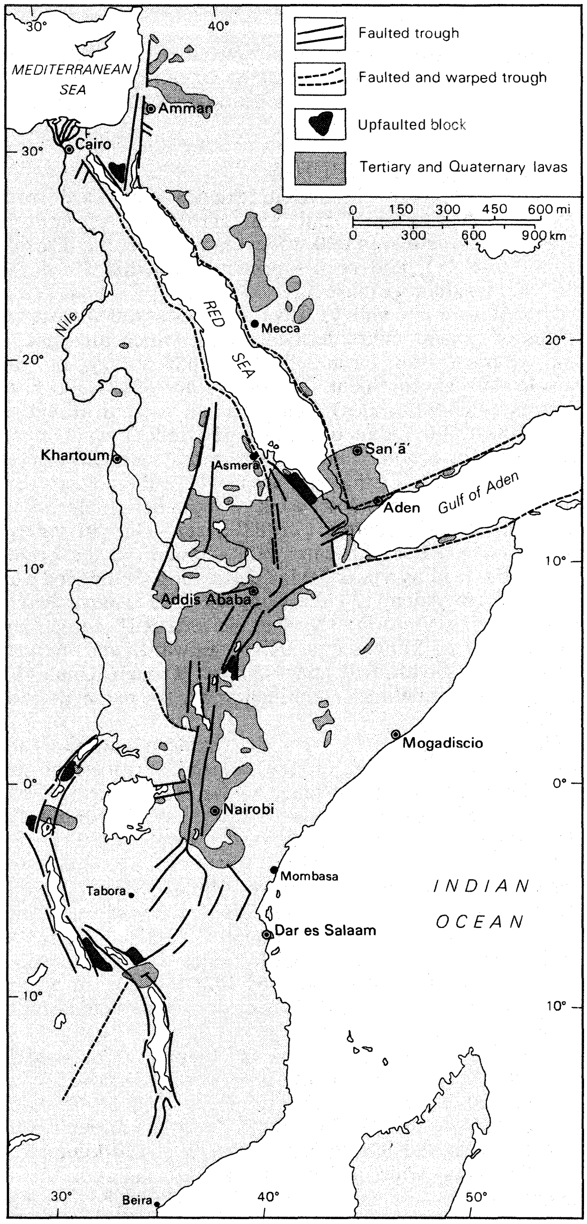

Figure 1: The Afro-Arabian rift system (see text).

This article treats the morphology, structure, geological history, and origin of rift valleys, principally by use of the most prominent terrestrial example, the East African Rift System. The nature and origin of rift systems is intimately associated with Earth history in general, and

GEOMORPHIC CHARACTERISTICS

The Afro-Arabian rift system extends northward from Mozambique to the Dead Sea, across 50° of latitude (6,000 kilometres [4,000 miles], or 1/7 of the Earth's circumference), and occurs principally within 5° of the 35° E meridian (Figure 1).

The African rift valleys traverse broad, oval-shaped regions of crustal uplift, termed swells, which are part of the characteristic basin-and-swell morphology of the whole African continent. The swells are 600–1,500 kilometres (400–900 miles) long in a north–south direction and 300–1,000 kilometres (200–600 miles) wide in an east–west direction. The largest, most mountainous of these swells is the Ethiopian area, where the plateau surface that was once below sea level now lies at elevations as high as 3,300 metres (11,000 feet). The rift valleys that bisect the East African swells include (1) the Ethiopian rifts, leading via the Afar depression to the Red Sea and Gulf of Aden; (2) the Gregory Rift (Kenya Rift), east of Lake Victoria; (3) the Western Rift, containing lakes Rukwa, Tanganyika, Kivu, Edward, and Albert; and (4) the Nyasa Rift and Luangwa Trough. Units (1) and (2) are sometimes combined under the name Eastern Rift.

The swells associated with the Western and Gregory rifts are superimposed on the respective fringes of the broader East African plateau, whose shallow central sag is occupied by Lake Victoria (1,130 metres [3,706 feet]). The flat surfaces of the high swells have been dissected by erosion to form steep-sided canyons such as the 1,500 metre-deep (5,000-foot) Abay (Blue Nile) Canyon. They also have provided the base for several superimposed volcanic cones—Kilimanjaro (5,895 metres or 19,340 feet), Mt. Kenya (5,200 metres or 17,060 feet), and Ras Dejen (4,540 metres or 14,890 feet), for example. The rift valleys and their boundary scarps cut abruptly across this uplifted terrain.

Dimensions of the rifts

In Africa the width between the boundary fractures is remarkably constant: for the most part, it is 40–55 kilometres (25–34 miles) and within limits of 30–75 kilometres (19–47 miles). Similar widths occur in other continental rifts: the Rhine Rift Valley is 30-40 kilometres (19–25 miles) wide, and the Baikal Rift Valley is 55–70 kilometres (34–44 miles) wide. This similarity is quite meaningful, because structural studies show that rift dimensions partly reflect the thickness of the fractured crust. The Mid-Atlantic Rift, by way of contrast, is only 10–20 kilometres (6–12 miles) wide, and this reflects the fact that the Earth's crust thins markedly in oceanic areas.

The depths of rift valley floors below their uplifted margins are more variable than widths. Values vary from only a few hundred metres through 1,000 metres (3,300 feet) in the central sectors of the Ethiopian, Gregory, and Western rifts to 2,500 metres (8,200 feet) in the deep troughs occupied by Lake Nyasa and Lake Tanganyika. The floor of the Baikal Rift is as much as 3,000 metres (9,800 feet) below the bordering plateau surface. These large elevation differences are entirely attributable to depression of the rift floor, and not to any exceptional uplift of bordering plateaus.

Along the Eastern Rift of Africa, the elevations of the rift floor and the plateau margins vary in unison and increase from the fringes to the centre of each swell. Thus, the rift floor rises from 400 metres to 2,000 metres (1,300 to 6,600 feet) in central Kenya and from 500 metres to 1,700 metres (1,600 to 5,600 feet) in central Ethiopia. In these regions, however, there is a very thick infilling of the rift valleys with volcanic sediments that masks the presence of a basement floor as deep as that under Lake Tanganyika and Lake Baikal.

Rift valleys tend to be linear over distances of as much as several hundred kilometres, and any lateral displacements are usually accomplished in an *en echelon* pattern (parallel offsets, such as roofing shingles). Nevertheless, some strikingly arcuate trends mark the Western Rift and also the Baikal Rift. The Western Rift is an arc of about 900-kilometre (560-mile) radius, with a hypothetical focus near Kilimanjaro. Arcuate rift valleys appear to be unique to continents; oceanic rifts are characteristically linear.

Drainage and sedimentation

The plateaus bordering rift valleys are notably upwarped to produce "rift shoulders." This is clearly shown by the resulting drainage pattern; the rift valleys are left as narrow, isolated basins of internal drainage, without possible outflow.

Quaternary (occurring within the last 2,500,000 years) upwarping of the rift shoulders has visibly affected previously established drainage patterns. The classic example is the ponding of Lake Kyoga in northern Uganda from the upwarping of the eastern shoulder of the Western Rift at Lake Albert. The Victoria Nile is forced to flow up an old tributary valley, and thence circuitously into the northern end of Lake Albert, instead of following its old course directly westward into the southern end of that same lake.

Recent and continuing uplift of the East African swells has led to rapid downcutting by rivers and the formation of deep canyons. This dissection raises considerable problems for communications, especially in Ethiopia, where the relief is most violent and where, when convenient, the main roads tend to follow the watershed along the rift shoulders.

The floors of rift valleys are typically divided into a number of internal drainage basins, separated by broad transverse arches. In the Eastern Rift this results in a chain of relatively small lakes that, because of the dry climatic regime and very high insolation, (incoming solar radiation), are natural evaporating pans for the alkaline emanations of rift valley volcanoes. Lake Natron, in the Gregory Rift, takes its name from the salt that saturates its waters, natron (a hydrated sodium carbonate), which also occurs in abundance in Lake Shala, Ethiopia.

The small volume of drainage entering the rift valley lakes produces a relatively slow infilling by sediments, despite the violent erosion of rift escarpments by thunderstorm flash floods. The rate of sedimentary infilling may not keep pace with the rate of subsidence unless it is complemented by volcanism. The rate of rift-floor subsidence relative to elevation of the plateaus is geodetically measured to be a few millimetres per year in the Icelandic and Dead Sea rifts, and geological evidence indicates that a similar average rate has prevailed in the African rift valleys during the last 20,000,000 years.

Effectsof climate on configuration

The climate of eastern Africa has had an important effect on the morphology of the rift system. Neglecting the wetter glacial periods of the Pleistocene Epoch (10,000 to 2,500,000 years ago), the climate of the plateaus is essentially a long dry season terminated by a rainy season of a few months duration. The range of temperature rarely exceeds limits of 5° and 30° C (41" and 86" F). The rift valleys themselves are drier and hotter than the plateaus, and erosion is not of great significance within them. On the plateaus, however, geological durations of fluvial erosion have resulted in the formation of relatively flat erosion surfaces, with remnants of older surfaces preserved at successively higher levels (except where faulting has caused them to be moved down into the rift valley). Such surfaces have been subjected to uplift and warping at several times during their history. There have been several alternations of uplift and fluvial erosion since the Paleozoic Era (which ended 225,000,000 years ago) in Africa, and dating of the various surfaces by means of sediments and their contained fossils (or by radiometric dates, where available) provides a clear insight into the evolution of the swells and the subsiding rift valleys. (See further LANDFORM EVOLUTION for a discussion of erosion surfaces and the relation of climate and morphology.)

GEOLOGICAL HISTORY AND STRUCTURE

History of the East African Rift System. The East African Rift System traverses continental crust until it meets with oceanic crust at its junction with the Red Sea and Gulf of Aden. The foundation of the African continent is the Precambrian basement (older than 570,000,000 years), which consists of nuclei of rocks older than 2,000,000,000 years surrounded by interweaving and intersecting orogenic belts (zones of mountain building) of younger Precambrian age. The last episode of basement tectonism (Earth movements and deformation) affected primarily the border regions of the present African continent, during the 450,000,000–700,000,000-year period. Rocks of this age form the Mozambique Belt, which occupies the eastern fringe of Africa from Mozambique to Egypt. The structural trend of the belt is meridional, though some large departures do occur. The Mozambique Belt consists, at least in part, of older rocks that were altered under conditions of high temperature and pressure—*i.e.*, metamorphosed. The intensity of metamorphism and related deformation increases eastward, from the eastern edge of the ancient Precambrian nucleus of the Congo. Numerous plutons (deep-seated bodies of crystalline rock), dominantly granodiorite, were emplaced during and immediately after this orogenic episode.

The East African Rift System is situated almost entirely within the Mozambique Belt. The close relationship of rift valleys to the younger elements of basement structure, with a frequent parallelism of rift faults and basement foliation (grain of the rocks), has led to suggestions of a long-standing common cause. But several instances of regional nonparallelism occur, particularly in Ethiopia, and a genetic relationship between such differing structural features is most unlikely. The rift valley faults merely take advantage of the basement "grain" where the trend is suitable; they follow a path of least resistance. This is true also of the Baikal Rift.

The splitting up of Gondwanaland, the ancient continent of the Southern Hemisphere, in the Early Mesozoic Era (from 65,000,000 to 225,000,000 years ago), following a long period of erosion throughout the Paleozoic Era (from 225,000,000 to 570,000,000 years ago), led to marine invasion and sedimentation over eastern Africa. Fossiliferous limestones and sandstones of Jurassic–Cretaceous age (65,000,000 to 190,000,000 years old) were formed; today these rocks crop out on the high plateaus east and west of the Ethiopian Rift, bearing witness to the subsequent uplift phases of Tertiary (2,500,000 to 65,000,000 years ago) and Quaternary times.

Tertiary and Quaternary events

In the Early Tertiary, the present line of rift valleys was marked by an intermittent chain of troughs that became accentuated by uplift of the bordering plateaus (this uplift occurred in stages throughout the Tertiary and Quaternary). As the troughs deepened, they were partly filled by thick sedimentary deposits; in the Red Sea, these sediments were dominantly halite (sodium chloride, or common salt). In Ethiopia and Kenya, the fill was largely volcanic, with colossal outpourings of extruded lavas—fissure basalts and fissure phonolites (rocks rich in feldspar and feldspathoid minerals), respectively. Volcanism and sedimentation has continued through the Quaternary, especially in the northern half of the East African Rift System. During Pliocene–Pleistocene time (about 3,000,000 years ago), the most marked phase of plateau uplift occurred, and the rift troughs were finally faulted to their present form.

The surface rocks of the rift-valley floors are dominantly of Quaternary age. This has caused recent questioning of the concept of rift valleys as subsided blocks covered by younger sediments; some authorities have asked whether continental rifts may be somewhat like oceanic rifts, zones of crustal separation without a basement of ancient rocks. This will be discussed later, in the section treating theories of origin.

Surface structures. Rift valleys are zones of normal faulting—one block being dropped down relative to the other. Transcurrent faulting, involving primarily lateral movement, is important in the narrow Dead Sea Rift and possibly in the Baikal Rift, but in Africa the dominating movements at the surface have been vertical.

Kinds of tectonic features

The typical rift valley is formed by two parallel fault zones, of complementary direction and magnitude of vertical displacement, about 50 kilometres (30 miles) apart. Although faulting sometimes takes the form of a single, huge scarp (for example, the Nguruman Escarpment west of Lake Magadi and the Guraghe Escarpment south of Addis Ababa), several closely spaced, steplike faults are more commonly developed. The total displacement is typically in excess of 1,000 metres (3,300 feet), but accurate estimates are difficult to obtain where the thick fill of young rocks in the rift prevents the matching of displaced, older strata.

The classical, ditchlike rift valley, exemplified in western Uganda, central Kenya, and southern Ethiopia, is not developed everywhere along the East African Rift System. Almost equally common are asymmetric rifts, where one margin is typically faulted, but the opposing margin is a downwarp cut by small antithetic faults (which dip in the opposite direction); examples are the rifts at Lakes Natron, Magadi, Rukwa, Tanganyika, and Rudolf. In the downwarped margins of asymmetric rifts, the strata and erosion surfaces may incline as steeply as 30" into the rift. Another tectonic style is the occurrence of tilted blocks, without the occurrence of faulted or warped grabens. This type of structure occurs at the southern ends of the Gregory and Western rifts and in the western United States in the Basin and Range Province.

Crustal blocks that are uplifted between parallel faults are termed horsts. Large horsts composed of Precambrian rocks form the Mbeya, Kungwe, Ruwenzori, and Amaro mountains, and in some of these cases the horsts rise from the rift floor to higher elevations than the hordering plateaus. In the culminating example of Mt.

Ruwenzori (5,109 metres [16,758 feet]), upwarping has accompanied the raising of the horst, particularly on the eastern flank. They tend to be situated in the fork of rift-valley bifurcations.

Rift valleys and their boundary faults may be arcuate on a small scale (southern Gregory Rift) or on a large scale (Western Rift). Sometimes an abrupt change of trend results in a transition zone of intersecting faults, as at the northern end of the Aberdare Range, central Kenya. Very commonly, rift-valley faulting is transposed in an *en echelon* pattern; such a pattern is strongly developed at the northern end of the Ethiopian Rift. Thus, although east of Addis Ababa the rift faulting retains its north-northeastern trend, *en echelon* displacements of these faults to the right have resulted in a northeastern topographic trend to the rift valley itself.

The floors of the rift valleys are usually fairly flat. This is due to lacustrine sedimentation and volcanic deposition rather than a reflection of any underlying sunken plateau surface. The planar rift floors have been intensely fractured by a narrow belt of very recent faulting (with associated volcanic fissures and cones) that is generally median to the boundary faults of the rift. The median belt is five to ten kilometres (three to six miles) wide, and its closely spaced faults, termed grid faults, have produced numerous small horsts and grabens. Such fine fracturing of the rift floor is suggestive of strong crustal distension and thinning.

Association with alkaline lavas

Volcanism. Rift valleys are intimately associated with volcanism. Compared with the lavas of oceanic ridge rifts or of island arcs, rift-valley lavas and tuffs are enriched in sodium and potassium and depleted in silica and alumina. The extreme case is revealed in the carbonatite (carbonate rocks derived from the Earth's mantle) volcanoes and plutons of East and Central Africa, where the magma was extraordinarily enriched in carbonates at the expense of silicates. The active volcano Oldoinyo Lengai, at the southern end of the Gregory Rift, erupts ashes and lavas in which the chief constituent is sodium carbonate.

More abundant, however, are lavas ranging in composition from alkali olivine basalt, alkali trachyte to peralkaline rhyolite (comendite and pantellerite). Parallel to this series of rocks is a second series, poorer in silica, with feldspar minerals replaced by feldspathoids: this is the melaneyhelinite-nevhelinite-uhonoliteseries.

Volcanism shows an unmistakable yet capricious relationship to rift valleys in space and time. In Ethiopia, volcanism has been intense and is still continuing. Voluminous flood basalts commencing in the early Eocene (38,000,000 to 54,000,000 years ago) were followed by the building up of Hawaiian-like shield volcanoes (layered forms with a central vent) in the Miocene, but after that the volcanism abruptly became more silicic, with extensive ignimbrites (pyroclastic rocks deposited from hot volcanic clouds of debris) during the Pliocene (2,500,000 to 7,000,000 years ago). Quaternary volcanism has been restricted largely to the rift floor, and in particular to the median fault belt. Volcanoes are situated at *en echelon* displacements along the fault belt, and some of the faults have provided escape for fissure basalts.

In Kenya, the volcanism has been less voluminous, and commenced only in Miocene time (7,000,000 to 26,000,000 years ago). Its alkaline character is even more pronounced, however, and the extensive fissure phonolites of the Gregory Rift have no parallel in any other rift valley. The great volcanoes of Elgon, Kenya, Meru, and Kilimanjaro are all situated about 100 kilometres (60 miles) into the plateaus from the rift margins, but otherwise it is the rift floor that has been the main site for volcanism in the Pliocene to Quaternary time interval, and a chain of dormant trachyte calderas occurs along the median fault belt as in Ethiopia.

Volcanism in the Western Rift and Nyasa Rift has been sparse and is comparable to that in the Rhine and Baikal rifts. The volcanics of the Western Rift are in some cases strongly enriched in potassium, as compared with the soda-enriched volcanics of the Eastern Rift.

Geophysical data. Continental rifts, like oceanic rifts, are zones of shallow-focus earthquakes. The greatest recorded depth is about 60 kilometres (35 miles), but an average depth is about 20 kilometres (12 miles). Theoretical calculations indicate both vertical and occasionally lateral movements at the focuses. The largest recorded magnitude for an African rift earthquake is 6.75 on the Richter earthquake-intensity scale; by comparison, some of the largest earthquakes that have been recorded anywhere (*e.g.*, the Alaskan event of 1964) have a magnitude of about 8.5.

Earthquake, heat-flow, and gravity observations

The dispersion of earthquake epicentres outside the rifts in Africa is much greater than for the oceanic rifts. Regions of high seismicity occur at the northern end of Lake Tanganyika, the Ruwenzori–Lake Albert region. the southern end of the Gregory Rift, and the western margin of the Afar depression. By contrast, the northern part of the Gregory Rift is virtually aseismic, despite fresh faulting and active volcanism. These patterns of high and low seismicity appear to change over periods of a century or more, however.

Heat-flow measurements have so far been made only in the Nyasa Rift. There the values range from 0.5 to 0.7 microcalorie per square centimetre of surface per second (μ cal/cm^{2}sec) at the northern and southern ends of the lake to 2.3 μ cal/cm^{2}sec in the central region, and this abrupt change suggests a local heat source within a few tens of kilometres of the surface. Heat flow in the Eastern Rift is suspected to be much higher than this because abundant fumaroles, volcanic vents that emit steam and other gases, and hot springs occur; and in the Red Sea and Gulf of Aden rifts, values of 5 μ cal/cm^{2}sec or more compare with an average of 1.3 μ cal/cm^{2}sec for the Indian Ocean basins.

Gravity data confirm the attenuation of the crust under the rift valleys compared with the plateaus and also indicate the presence of lighter, modified mantle material beneath the swells. The latter represents a shallowing of the low-velocity layer of the upper mantle, and this conforms with the active magmatism of the rift zones and the failure of near-surface shear waves to be transmitted under these zones. Negative Bouguer gravity anomalies (indicating mass deficiencies relative to the expected mass of the Earth's crust) for the Gregory, Western, and Nyasa rifts are not attributable entirely to the presence of a light sedimentary infilling, and they indicate the accretion of unspecified light material, possibly syenite, at the base of the crust.

The median fault belt of the rift valleys is marked by a positive gravity anomaly in Kenya and Ethiopia. This suggests basaltic injection to shallow levels in a strongly distended crust. Where such injection reaches the surface, as in the Red Sea and the oceanic rifts along lines of sea-floor spreading, strong positive Bouguer anomalies occur.

ORIGIN OF RIFT VALLEYS

The "dropped keystone" theory

Early theories. In the early part of the 19th century, the Rhine Graben was first envisaged as a collapsed strip between the Vosges and Schwarzwald plateaus. Subsequently, the sinking of the graben was connected with an uparching of the adjacent plateaus, giving rise to the "dropped keystone of the arch" theory, a theory that was extended to include the East African Rift System in 1898.

The early explorers of eastern Africa realized that the long lake-filled valleys could not have been eroded by rivers. By the end of the 19th century it was clear that the rift valleys were of tectonic origin and that the nature of the faulting, especially the step faulting of the rift margins, signified tensional forces pulling at right angles to a massive line of weakness in the Earth's crust. The origin of the East African Rift System was related to the foundering and splitting of Gondwanaland, and the "dropped keystone" theory was widely accepted. The possible importance of crustal separation in rift genesis was also mooted in the 19th century, but this idea remained unpopular until the recent revival of the continental-drift hypothesis.

One of the fundamental problems in theories of rift genesis is to explain the uplift of the rift shoulders, and indeed the swell as a whole. Simple crustal tension could not explain this uplift, and in the early 1900s a compressional origin was suggested for rift valleys. The absence of exposed surfaces of thrusting along the rift margins, which would he expected if compression was involved, was explained in terms of subsequent downward sliding and faulting of the thrusted margins, which masked these supposed fundamental structures. Compression was held to account for the uplift of the swells, the upwarping of the rift shoulders, the exceptional depth of the rift in Lake Tanganyika (excessive for a dropped keystone), and the absence of volcanism from the deepest rifts. The deeper the rift, the stronger the presumed compression, and thus the more effective the bottling down of volcanic magmas; however, it is now suspected that, allowing for volcanic infill, the Eastern Rift is even deeper than Lake Tanganyika.

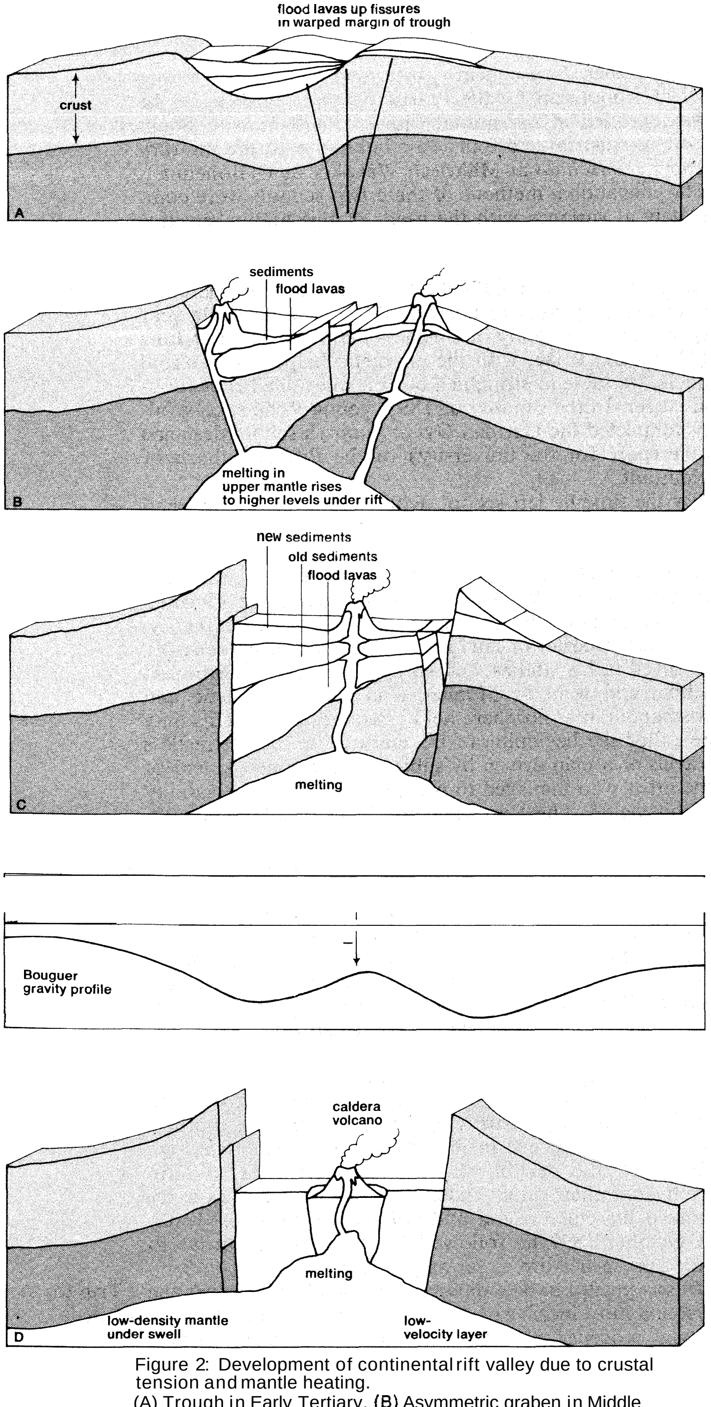

Figure 2: Development of continental rift valley due to crustal tension and mantle heating.
(A) Trough in Early Tertiary, (B) Asymmetric graben in Middle Tertiary, (C) Simple rift valley in Late Tertiary, (D) Graben-in-graben form (Quaternary) with corresponding Bouguer gravity profile.

The discovery in the 1930s that the East African rift valleys had strongly negative Bouguer gravity anomalies gave apparent confirmation to the compressional theory, the supposed thrust faults preventing the light rift block from rising to an equilibrium position. The anomalies are now explained as due to the infill of light sediments, however, and the accretion of silicic igneous rocks at the base of the crust under the rift. The absence of compressional folding, the confirmation that the main rift faults are, without exception, normal faults even in regions of bifurcation, and the focal mechanism of rift earthquakes all indicate tension as the basic process operating at rift valleys.

Sea-floor spreading and the tensional model

Modern theories. Since the early 1960s, the origin of rift valleys has been related to sea-floor-spreading processes, though the complicating presence of thick continental crust, compared to the thin crust of the oceans, has yet to be evaluated. The uplift of the swells, like the midoceanic ridges, is ultimately the result of high heat flow from an underlying hot zone in the mantle beneath the crust, which results in the transformation and expansion of rock mineral assemblages into lower pressure, lighter density forms. This thermal regime is also favourable for the generation of magmas of the alkaline type that are observed in rift valleys.

A model of the tensional processes thought to produce rift valleys demonstrates that a rigid crustal layer overlying a relatively mobile subcrust will fracture to produce a sunken graben block. The fracture planes are inclined at 60°–65° to the horizontal, and the graben width approximates the thickness of the fractured crust. Asymmetric graben can be produced if the graben block is free to sink into the mobile subcrust, a fractured margin being opposed by a warped margin. This simple tensional model accounts for some features of the African rift valleys, but not all.

As mentioned previously, the great depth of rift valleys, allowing for infilling in places, is incompatible with a "dropped keystone" model, and some absolute separation is also required, especially in the central regions of the swells. The grid faulting and caldera (*i.e.*, a greatly enlarged crater resulting from explosive activity and ultimate collapse) volcanism of the Eastern Rift floor suggests a thinning of the rift "block." And the gravity data show a concentration of low-density material under the rifts and adjacent plateau regions. These factors are compatible with crustal separation allied to high heat flow.

Oceanic rifts are entirely the result of crustal separation, the fissuring of the rift crust being healed by injection of basalt magma. This process is exposed in Iceland, where *gja* fissures—through which magma has failed to rise to the surface—flood basalts, and normal faults are intimately associated. *Gja* fissures recently have been identified in the Ethiopian Rift Valley. There are some major differences between the oceanic and African rifts, however. In the oceans, the ridge crust was generated at the rift and has since been transported outward and upward in the sea-floor-spreading process. The African plateaus are continental crust and have not been generated in the rift zone. Furthermore, continental rocks are present and exposed in some sectors of the East African Rift System; for example, at the southern end of the Ethiopian Rift.

A suggested sequence of events in the evolution of the African rift valleys is presented in Figure 2. This sequence shows that the rift valleys have been depressed regions from the beginning; that to the concept of a dropped keystone must be added downwarping of sufficient magnitude to produce the observed depths of rift valleys; and finally, that crustal separation has only begun to operate in recent geological times.

Plate tectonics and the Afar junction

The remarkable success of plate theory (the concept that the Earth's continents and ocean basins consist of six or more great plates that move about relative to each other) in unifying tectonics on a global scale has invited its application to such a major feature as the East African

Rift System. Plate geometry has been applied to the Afar triple junction, where the Ethiopian Rift meets with the proven sea-floor-spreading zones of the Red Sea and Gulf of Aden. The rates of spreading in these two zones have been calculated from a knowledge of magnetic lineations and fault orientations, as in the oceans; and these rates, together with their directions, uniquely determine the third conjoining spreading zone: the East African Rift System. This geometric computation is dependent on an absence of deformation outside the three spreading zones, which seismic and geological evidence indicates to be not altogether true.

The geometric result is that the East African Rift System has opened by 1.9" about a rotation pole located at 8.5" S, 31.0" E. This result fits the geological observations fairly well, especially when it is considered that this is the first application to a continental rift system. But many difficulties remain. The African rift valleys extend south beyond the rotation pole; they lack the linear offset pattern characteristic of the oceanic rifts and instead are arcuate and frequently bifurcate; and an opening of 1.9" is incompatible with the amount of continental crust exposed in some sectors of the rift valleys.

The model has been modified subsequently to better accord with observation, such that the indicated spreading rate in the African rift valleys is now estimated to be one millimetre per year or less, averaged over the last 20,000,000 years. This rate may well have accelerated in more recent times, but it fits with estimates for the Rhine and Baikal rift valleys, neither of which have yet been fitted into the global tectonic pattern. It seems certain that the presence of thick, light continental crust is modifying the spreading phenomenon observed in the oceans and that continental rifts are not necessarily potential oceanic basins.

BIBLIOGRAPHY. The following references are listed chronologically to better accord with the historical development of knowledge on rift valleys: E. SUESS, "Die Briiche des ostlichen Afrika," *Denkschr. Akad. Wiss., Wien,* 58:555–584 (1891), the first clear insight into East African tectonics; J.W. GREGORY, *The Great Rift Valley* (1896), the classic account of the East African rift valley; *Rift Valleys and Geology of East Africa* (1921), Gregory's final synthesis on the African rift valleys, of astonishingly wide compass; B. WILLIS, *East African Plateaus and Rift Valleys* (1936), a good historical review of ideas on rift valleys to date of publication; F. DIXEY, *The East African Rift System* (1956), a terse and thorough review of rift-valley geology, with emphasis on geomorphology rather than geophysics; A. HOLMES, "Plateaus and Rift Valleys," in *Principles of Physical Geology,* 2nd ed., ch. 29 (1965), a lucid summary of rift-valley structure and volcanism; B.H. BAKER, P.A. MOHR, and L.A.J. WILLIAMS, *Geology of the Eastern Rift System of Africa* (1971), a review of rift valleys in terms of geology, geophysics, volcanic petrogenesis, and plate tectonics.

(P.A.M.)

Rilke, Rainer Maria

Rainer (René) Maria Rilke was a major Austro-German poet whose contribution to 20th-century German literature has won worldwide recognition. Together with writers such as James Joyce, Marcel Proust, T.S. Eliot, and Franz Kafka, he stands as one of the founders and giants of modern literature.

Early life. Rilke was born on December 4, 1875, in Prague (then the capital of the Kingdom of Bohemia, one of the original members of the Austro-Hungarian monarchy), the only son of a not too happy marriage. His father, Josef, a minor civil servant, was a man frustrated in his professional career; his mother, the daughter of an upper middle class merchant and imperial councillor, was a difficult and pretentious woman, though not devoid of some talent, who felt that she had married beneath her station. She had a penchant for the nobility and high society and liked to dress in sombre black in the manner of aristocratic dowagers. She left her husband in 1884 and moved to Vienna so as to be close to the imperial court.

Education

The education afforded the young Rilke was ill planned and fragmentary. It had been decided that Rainer was to become an officer to assure him the social standing barred to his father. Consequently, after some years at a rather select school run by the Piarist brothers of Prague, he was enrolled in the military lower *Realschule* of Sankt Pölten (Austria) and four years later entered the military upper *Realschule* at Mahrisch-Weisskirchen (Bohemia). The educational methods of these two schools were completely at variance with the needs of this highly sensitive boy, and he finally was forced to leave the school prematurely because of poor health. In later life he called these years of his "misused" childhood a time of merciless affliction, a "primer of horror." After another futile year spent at the Academy of Business Administration at Linz (1891–92), Rilke, with the energetic help of a paternal uncle, was able to straighten out his misguided educational career. In the summer of 1895, young RenC successfully completed the German *Gymnasium* (a school designed to prepare for the university) of the Prague suburb of Neustadt.

Rilke, 1925.

By the time he left school, Rilke had already published his first volume of poetry (1894), and there was little doubt in his mind that he would pursue a literary career. Matriculating at Prague's Charles University in the fall of 1895, he enrolled in courses in German literature and art history and also, to appease his family, read one semester of law. But he could not become really involved in his studies, and so in September 1896 he left school and went to Munich, a city whose artistic and cosmopolitan atmosphere held a strong appeal. This may be called the beginning of his mature life, of the restless travels of a man driven by subjective inner needs, and of the artist who managed to persuade others of the validity of his vision. The European continent in all its breadth and variety—Russia, France, Spain, Austria, Switzerland, and Italy, always Italy—was to be the physical setting of that life.

Mature life and works. In May 1897 Rilke met Lou Andreas-Salomé, who within a few weeks of their meeting became his mistress. Lou, then 36 years of age, was a native of St. Petersburg, the daughter of a Russian general of Huguenot descent and a German mother. In her youth she had been wooed by—and had turned down—the great philosopher Friedrich Nietzsche; 10 years before her meeting with Rilke she had married a German professor. Rilke's affair with Lou was a turning point in his life. More than mistress, she was surrogate mother, the leading influence in his *éducation sentimentale* and, above all, the person who introduced Russia to him. Even after their affair ended some years later, Lou remained his close friend and confidante until his death. In October 1897 he followed her to Berlin in order to take part in her life as far as possible.

Trip to Russia

Russia proved to be a milestone in Rilke's life. It was the first and most incisive of a series of "elective homelands," leaving a deeper mark than any of his subsequent discoveries, with the possible exception of Paris. He and Lou visited Russia twice at the turn of the century, first in the spring of 1899 and then in the summer of 1900. There he found an external reality that he saw as the ideal objective correlative, or symbol, of his feelings, his inner reality. Russia for him was imbued with an amorphous, elemental, almost religiously moving quality—a harmonious, powerful constellation of "God," "human community," and "nature"—the distillation (one is almost tempted to say) of the "cosmic" spirit of being.

Russia evoked in him a poetic response that he later said marked the true beginning of his serious work: a long three-part cycle of poems written between 1899 and 1903 and published in 1905 under the title ***Dns Studen-Buch,*** which is dedicated to Lou. Here the poetic "I" presents itself to the reader in the guise of a young monk who circles his god with swarms of prayers, a god conceived not as an extraterrestrial or superterrestrial "Thou" but as the incarnation of "life," as the numinous quality of the innerworldly diversity of "things." The language and motifs of the work are largely those of Europe of the 1890s. Art Nouveau, moods inspired by the dramas of Henrik Ibsen and Maurice Maeterlinck, the enthusiasm for art of John Ruskin and Walter Pater, and, above all, the emphasis on "life" of Nietzsche's philosophy—all of these appear in the ***Stunden-Buch.*** And yet, the self-celebratory fervour of these devotional exercises, with their rhythmic, suggestive power and flowing musicality, contained a completely new element. In them, a poet of unique stature had found his voice.

Soon after returning from his second trip to Russia, Rilke accepted an invitation to join the artists' colony of Worpswede, near Bremen, where he hoped to settle down in the attractive countryside among congenial artists experimenting with developing a new life-style. In April 1901 he married Clara Westhoff, a young sculptor from Bremen who had studied with Auguste Rodin. The couple set up housekeeping in a farm cottage in nearby Westerwede. There Rilke worked on the second part of the ***Stunden-Buch*** and also wrote a book about the Worpswede colony, which appeared in 1903. In December 1901 Clara gave birth to a daughter, and soon afterward the two decided on a friendly separation so as to be free to pursue their separate careers.

Move to Paris

Rilke, having been commissioned by a German publisher to write a book about Rodin, left for Paris (where the sculptor lived) in August 1902. For the next 12 years, until the outbreak of World War I, Paris was to be the geographic centre of Rilke's life. During those years he frequently left the city for short or lengthy visits to other cities and countries, beginning in the spring of 1903 when, to recover from what seemed to him the indifferent and cruel life of Paris, he went to Viareggio, Italy. There he wrote the third part of the ***Stunden-Buch.*** For a time he also lived and worked in Rome (1903–04), in Sweden (1904), and repeatedly in Capri (1906–08); he also made voyages of discovery to the south of France, to Spain, Tunisia, and Egypt and frequent visits to his friends in Germany and Austria. Yet Paris was his second elective home, no less important than Russia, both for its historic, human, "scenic" qualities and its intellectual challenge.

Rilke's Paris was not the ***belle époque*** capital steeped in luxury and eroticism; it was a city of abysmal, dehumanizing misery, of the faceless and the dispossessed, and of the aged, sick, and dying. It was the capital of fear, poverty, and death. This preoccupation with these phenomena combined with a second one: his growing awareness of new approaches to art and creativity, an awareness gained through his association with Rodin. Their friendship lasted about four years, until the spring of 1906. Rodin taught him his personal art ethic of *toujours travailler*, or unremitting work, which stood in sharp contrast to the traditional idea of artistic inspiration. Rodin's method was one of fanatical dedication to detail and nuance and of unswerving search for "form" in the sense of concentration and objectivization. Rodin also gave Rilke new insight into the treasures of the Louvre, the Cathedral of Chartres, and the forms and shapes of Paris. Of the literary models France had to offer, the poet Charles Baudelaire impressed and influenced him the most.

During those Paris years Rilke developed a new style of lyrical poetry, the so-called ***Ding-Gedicht*** ("object poem"), which attempts to capture the plastic essence of a physical object in language. Some of the most successful of these poems are imaginative verbal translations of certain works of the visual arts. Other poems deal with such subjects as landscapes, portraits, and biblical and mythological themes as a painter would depict them. These ***Neue Gedichte*** (1907–08) represented a departure from traditional German lyric poetry. Here Rilke forced his language to such extremes of subtlety and refinement that one is tempted to characterize it as a distinct art among other arts and a language distinct from existing languages. The worldly elegance of these poems cannot obscure their inherent emotional and moral engagement. When Rilke, in the letters about Paul Cézanne written in the autumn of 1907, defines the painter's method as a "using up of love in anonymous labour," he doubtless was also speaking of himself. In a letter to Lou Salomé written in July 1903, he had defined his method with this significant formulation: "making objects out of fear."

Die Aufzeichnungen ***des*** *Malte Laurids Brigge* (***The Notebook of Malte Laurids*** *Brigge*, 1930), on which he began work in Rome in 1904 and which was published in 1910, is a prose counterpart to the ***Neue Gedichte.*** The two works complement one another. That which hovered in the background in the poems, behind the perfection of style, is in the foreground of the prose work; the subjective, personal problems of the lonely occupant of a Paris hotel room, the "fear" that is the inspiration for the creation of "the objects." And if the poems seem like a glorious affirmation of the Symbolists' idea of "pure poetry," the ***Aufzeichnungen*** read like a brilliant early example of Existentialist writing. They are an artfully assembled suite of descriptive, reminiscent, and meditative parts, supposedly written by Malte, a young Danish expatriate in Paris (a member of the sophisticated, world-weary, and despairing generation of fin ***de siècle*** European decadents) who refuses to abide by the traditional chronology of narrative exposition but, instead, presents his themes as "simultaneous" occurrences set against a background of an all-encompassing "spatial time." Here are found all of Rilke's major themes: love, death, the fears of childhood, the idolization of woman, and, finally, the matter of "God," which is treated simply as a "tendency of the heart." The work in its entirety must be seen as the description of the disintegration of a soul—but a disintegration not devoid of a dialectic mental reservation: "Only a step," writes the narrator (Malte), "and my deepest misery could turn into bliss."

Themes of the *Aufzeichnungen*

The price Rilke had to pay for these two masterpieces was a writing block and depression so severe that it led him to toy with the idea of giving up writing altogether. Aside from a short and not first-rate poetry cycle, ***Das Marienleben,*** which appeared in 1913, he did not publish anything for 13 years. The first works in which he transcended even his ***Neue Gedichte*** were written in the early part of 1912—two long poems in the style of elegies. He did not undertake their immediate publication, however, because they promised to become part of a new cycle. He wrote these two poems while staying at Duino Castle, near Trieste, as the guest of Princess Marie von Thurn und Taxis, whom he had met and befriended in 1909.

The outbreak of World War I found him in Munich, and there for the time being he decided to remain. He spent most of the war years there. In December 1915 he was called up for military service with the Austrian army at Vienna, but by June 1916, he had returned to civilian life. The social climate of these years was inimical to his way of life and to his poetry, and by the time the war ended he felt almost completely paralyzed. He had only one relatively productive phase: the late fall of 1915, when, in addition to a series of superb new poems, he wrote the "Fourth Duino Elegy."

Late life and works. Rilke spent most of the remaining seven years of his life in Switzerland, the last of his series of elective homes. There he once more came into full command of his creative gifts. In the summer of 1921 he took up residence at the Château de Muzot, a small, old castle in the Rhône Valley, as the guest of a wealthy Swiss patron. In February 1922, within the space of a few days of obsessive productivity, he completed the Duino cycle begun years earlier. And unexpectedly and almost effortlessly, another superb cycle of 55 poems, in mood and theme closely related to the *Elegies*, came into being—his *Sonette an Orpheus* (*Sonnets to Orpheus*).

The myth-like character of the *Duino Elegies*

The *Duineser Elegien (Duinn Elegies)* are the culmination of the development of Rilke's poetry. That which in the *Stunden-Buch* had begun as a naïvely uncertain celebration of "life," as a devotional exercise of mystical worship of God, and which in *Malte* led him to assert that "this life suspended over an abyss is in fact impossible" in the *Elegies* sounds an affirmative note, in panegyric justification of life as an entity: "The affirmation of life and death prove to be identical in the *Elegies*," wrote Rilke in a letter (1925) in which he sought to define the meaning of his "expression of being." These poems can be seen as a new myth that reflects the condition of "modern" man, the condition of an emancipated, "disinherited" consciousness maintaining itself as a counterpart to the traditional cosmic image of Christianity. Like Nietzsche, Rilke opposes the Christian dualism of immanence and transcendence. Instead, he speaks out for an emphatic monism of the "cosmic inner space," gathering life and death, earth and space, and all dimensions of time into one undifferentiated, all-encompassing unity. This Rilkean myth is articulated in an image-laden cosmology that, analogous to medieval models, sees all of reality—from animal to "angel"—as a hierarchical order. This cosmology in turn results in a systematic, consistent doctrine of life and being in which man is assigned the task of transforming everything that is visible into the invisible through the power of his sensory perceptions: "We are the bees of the invisible." And this ultimate fate of man is concretized in the activity that alternately is called "saying," "singing," "extolling," or "praising." Thus it comes about that the poet is turned into the protagonist of humanity, its representative "before the Angel" (the pseudonym of God), as in the "Ninth Elegy," and even more strikingly in the *Sonnets* to *Orpheus*. This message of the late Rilke has been celebrated by some as a new religion of "life" and rejected by others as the expression of an unbridled aestheticism and an attempt on the part of the poet at "self-redemption" by virtue of his personal gift. It might be best to refrain from an overproblemizing of his message and instead look at the poetry that celebrates itself as a plea to value poetry "as poetry"—as a free play of the imagination, which, by the very act of raising problems of meaning, disposes of them.

Other late poems

The triumphant breakthrough of February 1922 was Rilke's last major contribution, yet both thematically and stylistically some of his late poems go beyond even the *Elegies* and the *Sonnets* in their experimentation with forms that no longer seem at all related to the nature of the poetic language of the 1920s. In addition to these late works he also wrote a number of simple, almost songlike poems, some short cycles, and four collections in French, in which he pays homage to the landscape of Valais, tendering his thanks.

Muzot remained his home until his death, but still he continued his travels, mostly within Switzerland, devoting himself to his friends and his vast, superbly articulate correspondence. In the early part of 1925 he once more went to Paris, with whose literary life he had remained in close touch. He was royally received by such old friends as André Gide and Paul Valéry as well as by new admirers; for the first and only time in his life he found himself at the centre of a literary season in a European metropolis. But the strain of this visit proved too much for his frail health. On August 18, abruptly and unannounced, he slipped out of Paris. He had been in ill health since the end of 1923, with frequent visits to sanatoriums and health resorts. The cause of his debility, a rare form of incurable leukemia, was not diagnosed until a few weeks before his death. He died on December 29, 1926, at Valmont, a sanatorium above Territet, on Lake Geneva. In accordance with his wishes, he was buried in the cemetery adjoining the church at Raron, a half-hour drive from Muzot upstream along the Rhône.

MAJOR WORKS

VERSE: *Leben und Lieder. Bilder und Tagebuchblatter* (1894); *Wegwarten* (1896); *Larenopfer* (1896); *Im Friihfrost* (1897); *Traumgekrönt* (1897); *Advent* (1898); *Mir zur Feier* (1899; republished with alterations as *Die friihen Gedichte*, 1909); *Das Buch der Bilder* (1902; 2nd ed., with 37 additional poems, 1906); *Das Stunden-Buch* (1905), consisting of *Das Buch vom monchischen Leben*, *Das Buch von der Pilgerschaft*, and *Das Buch von der Armut und vom Tode* (*The Rook of Hours*, trans. by A.L. Peck, 1961); *Neue Gedichte*, 2 vol. (1907–08; *New Poems*, trans. by J.B. Leishman, 1964); *Requiem* (1909; *Requiem and Other Poems*, trans. by J.B. Leishman, 2nd ed., 1949); *Das Marienleben* (1913; *The Life of the Virgin Mary*, trans. by Stephen Spender, 1951); *Duineser Elegien* (1923; *Duino Elegies*, trans. by J.B. Leishman and Stephen Spender, 4th ed., 1963); *Die Sonette an Orpheus* (1923; *Sonnets to Orpheus*, trans. by J.B. Leishman, 2nd ed., 1946); *Späte Gedlichte* (1934; *Later Poems*, trans. by *J.B.* Leishman, 1938); *Poèmes français* (1935); *Aus dem Nachlass des Grafen C.W.* (1950; *From the Remains of Count C.W.*, trans. by J.B. Leishman, 1952). Other translations by J.B. Leishman include: *Selected Works*, vol. 2, *Poetry* (1954–60); and *Poems* 1906–26, 2nd ed. (1959).

PROSE: *Vom lieben Gott und Anderes* (1900; *Stories of God*, 1932); *Worpswede* (1903); *Auguste Rodin* (1903; Eng. trans., 1919); *Die Weise von Liebe und Tod des Cornets Christoph Rilke* (1906; *The Tale of the Love and Death of Cornet Christopher Rilke*, trans. by *M.D.* Herter Norton, 1932); *Die Aufzeichnungen des Malte Laurids Brigge* (1910; *The Notebook of Malte Laurids Brigge*, trans. by John Linton, 1930); *Aus der Friihzeit Rainer Maria Rilkes. Vers. Prosa. Drame. 1894–1899* (1921); *Ewald Tragy* (1927–28); *Erzählungen und Skizzen aus der Friihzeit* (1928). Other translations of Rilke's prose are in *Selected Works*, vol. 1, *Prose*, by G. Craig Houston (1954–60).

BIBLIOGRAPHY

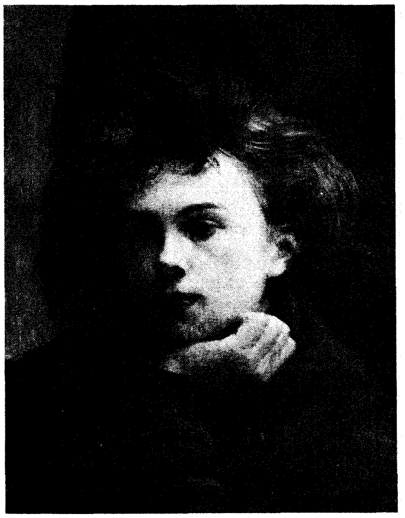
Editions and correspondence: Gesammelte Werke, 6 vol. (1927); *Sämtliche Werke*, 6 vol. (1955–66); *Werke*, 3 vol. (1966); *Gedichte in franzosischer Sprache* (1949); *Gesammelte Briefe*, 6 vol. (1936–39); *Briefe*, 2 vol. (1950); *Tagebücher aus der Friihzeit* (1942); *Briefe an einen jungen Dichter* (1929; Eng. trans., *Letters to a Young Poet*, rev. ed., 1954); *Briefe an eine junge Frau* (1931; Eng. trans., *Letters to a Young Woman*, 1945).

Biography and criticism: Because there is not yet a comprehensive, scholarly Rilke biography, the following may be recommended as sources of information: HANS E. HOLTHUSEN, *Rainer Maria Rilke in Selbstzeugnissen und Bilddokurnenten* (1967; Eng. trans., *Portrait of Rilke*, 1971), an illustrated biographical-critical essay; INGEBORG SCHNACK (ed.), *Rilkes Leben und Werk im Bild* (1956), a biographical survey in photographic documents; and JEAN R. DE SALIS, *Rainer Maria Rilkes Schweizer Jahre* (1952; Eng. trans., *Rainer Maria Rilke: The Years in Switzerland*, 1964), which treats only the last part of Rilke's life in detail. Memoirs that can be designated as classic are MARIE VON THURN UND TAXIS, *Erinnerungen an Rainer Maria Rilke* (1933); and the brilliant essays of RUDOLF KASSNER in *Buch der Erinnerung* (1938), *Umgang der Jahre* (1949), and *Geistige Welten* (1958). Two earlier monographs by friends of the poet are LOU ANDREAS-SALOME, *Rainer Maria Rilke* (1928); and NORA WYDENBRUCK, *Rilke, Man and Poet* (1949). Among the critical works on Rilke in English, the following are prominent: ELIZA M. BUTLER, *Rainer Maria Rilke*, 2nd ed. (1945); E.C. MASON, *Rilke, Europe, and the English-Speaking World* (1961) and *Rilke* (1963); also, H.W. BELMORE, *Rilke's Craftsmanship* (1954), a special investigation interested in formal questions. A comprehensive presentation from the psychoanalytic point of view is ERICH SIMENAUER, *Rainer Maria Rilke: Legende* und *Mythos* (1953). So far as the extensive German Rilke literature is concerned, after the enthusiasm of the 1930s and 1940s, it passed through a phase of disillusionment, indeed even of devaluation. At the end of the 1960s, however, in books such as JACOB STEINER, *Rilkes Duineser Elegien*, 2nd ed. (1969); and KAETEHAMBURGER (ed.), *Rilke in neuer Sicht* (1971), a younger generation of scholars came forth with new arguments on the classical merit of Rilke.

(H.E.H.)

Rimbaud, Arthur

Arthur Rimbaud was a French poet and adventurer, who, although his creative life lasted only from his 15th to his 20th year, became, unbeknown to himself, a revered model for the Symbolist movement, whose devotees sought in their poems to combine a technical perfection of language with subtly mysterious imagery.



Rimbaud, detail of an oil painting by Henri Fantin-Latour, 1872. In the Louvre, Paris.
Giraudon

Few poets have been the object of more passionate study or have exercised greater influence on modern poetry. It is in the prose poems *Illuminations* that he reached the highest peak of his originality, and this is the form best suited to his elliptical and esoteric style. He stripped the prose poem of all the anecdotal, narrative, and even descriptive content of his predecessors and, by divesting words of their dictionary meaning or logical content, endowed the poem with a quasi-magical power intended to evoke a state of mind—"&tat*d'âme*," the Symbolists were to say. He also showed how much rich material for poetry exists in the subconscious mind and in the half-remembered sensations of childhood. His writings are still capable of expressing intensely modern revolt and recoil from the very essence of life in a so-called civilized society.

Childhood. Rimbaud was born at Charlesville in the Ardennes, in northeastern France, on October 20, 1854, the second son of an army captain and a local farmer's daughter: his brother was a year older, and there were two younger sisters. In 1860 Captain Rimbaud and his wife separated, and the children were brought up by their mother, who hoped to keep her sons from following the example of her two wastrel brothers. Arthur, who early displayed unusual intellectual ability, showed a gift for writing at the age of eight. Later, he was the most brilliant pupil at the Collège de Charleville. He had a particular talent for Latin verse and in August 1870 won the first prize for a Latin poem at the Concours Acadtmique. His first published poem had appeared in January 1870 in La *Revue pour Tous*, and in May he had submitted to the distinguished poet Théodore de Banville, one of the selection committee for *Le Parnasse Contemporain,* a number of poems including one entitled "Credo in Unam," which, although derivative, showed signs of an original genius.

Early escapades

The outbreak of the Franco-Prussian War (July 1870) ended his formal education. In August he ran away to Paris but was arrested for travelling without a ticket and spent some days in prison. His friend and schoolmaster Georges Izambard paid his fine and had him sent to Douai, where he spent three weeks at the house of Izambard's aunts and where he joined the national guard. Izambard then took him home, but in October he disappeared again, wandering through northern France and Belgium in the wake of the invading armies. Again, he arrived at Douai, where he made fair copies of the poems composed during his two weeks of freedom, hunger, and rough living. These express an innocent joy in life and liberty and are his first wholly original works. His mother had him brought back by the police, but in February 1871 he sold his watch and again went to Paris, where for a fortnight he lived in great poverty.

Revolt and poetic vision. In early March he returned home on foot, a completely changed character, perhaps as a result of some shattering, yet enlightening, experience. He repudiated his early verses as false and wrote some of his most violent and blasphemous poems, expressing a disgust with life, a desire to escape into a world of innocence, and a sense of struggle between good and evil. His behaviour matched his poetic mood—he refused to work and spent his days drinking in cafés, in conscious revolt against religion, morality, and every kind of discipline. At the same time, he read books on occult philosophy, Kabbalism, magic, and alchemy and formulated his new aesthetic doctrine, expressed in two letters (May 13 and 15, 1871), later called "Lettres du voyant." This title is based on the belief that the poet must become a seer, a *"voyant,"* who can penetrate infinity and who, by breaking down the restraints and controls that make up the conventional conception of individual personality, must become the instrument for the voice of the eternal. But, because the new visions cannot be rendered in contemporary forms, a new language must be invented, a language accessible to all the senses—this is the ideal of "total art" first formulated by Charles Baudelaire and adopted by the Symbolists.

At the end of August 1871, on the advice of a literary friend in Charleville, Rimbaud sent to the poet Paul Verlaine specimens of his new poetry, among them the sonnet "Voyelles" in which he attributes to each vowel a different colour—"A noir, E blanc, I rouge, U vert, O bleu." The poem has been variously interpreted, but its true beauty lies in the originality of its images. Verlaine, impressed by the brilliance of the poems, summoned Rimbaud to Paris and sent the money for his fare. In a burst of self-confidence, Rimbaud composed "Le Bateau ivre." Although traditional in versification, it is a poem of astonishing verbal virtuosity and of daring choice of images and metaphors, inspired by a deep emotional and spiritual experience. In this masterpiece, Rimbaud reached one of the highest peaks of his art.

Meeting with Verlaine

Arriving in Paris in September 1871, he stayed for three months with the Verlaines, who were living with Mathilde Verlaine's parents, and met most of the well-known poets of the day but antagonized them all—except Verlaine himself—by his arrogance, boorishness, and obscenity. Requested to leave, he lived for some weeks in destitution and then in an attic in the house where Banville was living. Again his behaviour caused complaints, and in January 1872 he moved to a room where he lived, on money subscribed by Verlaine and his friends, a life of drink and debauch and was involved in a homosexual relationship with the older poet that gave rise to scandal. In March he returned to Charleville so that Verlaine could attempt a reconciliation with his wife but was recalled in May by his friend, who vowed that he could not live without him.

During this period (September 1871–July 1872), Rimbaud composed the last of his poems in verse, which show an advance in technical freedom and originality on those written earlier. This freedom is daring for that period then at its height, during which prevailed the strictly impersonal themes and descriptive imagery of the Parnassian poets, so-called because of the anthology, Le *Parnasse Contemporain*, to which they contributed. At this time he also composed the work that Verlaine called his masterpiece, "La Chasse spirituelle," the manuscript of which disappeared when Verlaine and Rimbaud went to England. Some critics also assign to this creative period the transcendental prose poems *Illuminations,* not one of which was dated by Rimbaud himself.

In July 1872 Verlaine abandoned his wife and fled with Rimbaud via Belgium to London, where they lived in Soho. Rimbaud may there have composed some of his *Illuminations.* He returned home for Christmas but was recalled (January 1873) by Verlaine, who dramatized an illness to play on his sympathy. In April Rimbaud went to the farm at Roche, near Charleville, where his mother and sisters were staying, and began to write what he called his "Livre païen, ou Livre nègre," which eventually became *Une Saison en enfer.* Verlaine was meanwhile

Quarrel with Verlaine

staying at Jehonville, near Roche, and in May he persuaded Rimbaud to accompany him to London. Rimbaud's sense of guilt at yielding to an influence from which he had wished to escape caused him to treat Verlaine with sadistic cruelty, varied by remorseful kindness. Finally, at the beginning of July, after one of their frequent quarrels, Verlaine abandoned Rimbaud and went to Belgium. Failing, however, to effect a reconciliation with his wife, he sent for Rimbaud and begged him to return with him to London. When Rimbaud tried to leave, Verlaine shot at him, wounding him in the wrist, and threatened to do so again. Rimbaud, terrified, asked a policeman for protection; Verlaine was arrested, jailed, and later sentenced to two years' imprisonment. After a week in the hospital, Rimbaud returned to Roche. There, he finished *Une Saison en enfer*, an account of his spiritual descent into hell and of his failure in art and love, which acquired some of its tragic character from the events in Brussels. It was printed in Belgium, and, in October 1873, he went to Brussels to collect the copies and then to Paris to arrange for its publicity. Discouraged by its reception there and unable to pay the printers, he abandoned the whole edition and, returning on foot to Charleville, he is said to have burned his manuscripts and papers. The bales of the book remained in the attics of the printers, where they were discovered in 1901 by the Belgian bibliophile Léon Losseau. Out of consideration for his fellow bibliophiles, who possessed the only copies known to exist, Losseau did not make his discovery public until 1915.

In February 1874 Rimbaud returned to London with Germain Nouveau, a wild bohemian poet. There they earned a precarious living in menial employment: Rimbaud may also have been composing some of the *Illuminations*. Nouveau returned to Paris in June; and Rimbaud seems to have fallen ill or to have suffered acutely from poverty, for his mother and elder sister went over to help him find a job. At the end of July he took up a post at a coaching establishment at Reading, Berkshire, but went home for Christmas, never to return.

In January 1875, he went to Stuttgart to learn German, for his interest then was in languages. There, he was visited by Verlaine, but this, their last meeting, ended in a violent quarrel. It was probably then that Rimbaud gave Verlaine the manuscript of *Illuminations*.

Traveller and trader. In May Rimbaud left for Italy, crossing the Alps on foot but, taken ill with sunstroke, was repatriated by the French consul at Leghorn. He spent the winter at home, learning Arabic, Hindustani, and Russian, and, in April 1876, set out for Russia. After being robbed of money and luggage in Vienna, he was arrested as a beggar and again sent home. In May he went to Holland, where he enlisted in the Dutch colonial army. He arrived at Batavia (now Djakarta, Indonesia) on July 23 but deserted on August 15 and eventually reached home at the end of December. In the spring of 1877, he went to Hamburg, and, failing to find work on a ship sailing east, he is said to have joined a circus going to Scandinavia, though he returned to France in the summer. In the autumn he set out for Alexandria but, taken ill on board ship, was landed in Italy and again returned home. There, he remained, enfeebled by illness, until October 1878, when he again set off for Egypt. He took a boat from Genoa to Alexandria and then went to Cyprus, where he worked as a labourer; but in June 1879 he fell ill with typhoid fever and returned home to recover.

Life in Ethiopia

It was during this winter of illness that he apparently decided to abandon his life of wandering and to plan for the future. Returning to Cyprus in the spring, he found work as a builder's foreman; in August, however, he quarrelled with his employers and again set out in search of work. A coffee exporter at Aden, Pierre Bardey, sent him to open a trading post at Harer (Harar), in the interior, at that time occupied by the Egyptians, but, after the Mahdist uprising in the Sudan and the consequent Egyptian evacuation of Harer, the trading post was closed, and Rimbaud went back to Aden. From Harer, however, he had been sent by Bardey on a journey of exploration into Ogaden, the region south of Harer, where no white man had ever penetrated. His report of this journey, in the proceedings of the Société de Géographie (February 1884), aroused some interest.

After the Egyptian withdrawal from Ethiopia the contest for power between the emperor, Yohannes IV, and Menelik II, king of Shewa (Shoa), gave rise to an arms race. Rimbaud, deciding to risk his savings on an expedition to sell arms to Menelik, resigned his position with Bardey (October 1885) and, in October 1886, after a series of frustrating delays, set out for the interior. He reached the capital of Shewa in February 1887, but unforeseen circumstances and the rapacity and double-dealing of Menelik robbed him of his expected profits; and he returned to Aden no better off than when he had left it. Exhausted and embittered, he had no prospect of employment. He spent the summer in Cairo, where an account of his journey was published in *Le Bosplzove Égyptien* (August 1887), and then returned to Aden, where he looked in vain for work. In May 1888 he returned to Harer as manager of a trading station for a firm called Tian, which, as well as exporting coffee, gum, ivory, and hides, engaged in the profitable traffic in arms and ammunition. At first, Rimbaud's chief business was supplying Menelik with arms, but he may also have been in some way associated with the slave trade. After Yohannes IV was killed (1889), however, and Menelik became emperor, the profits from gunrunning declined. In addition, although Harer was the chief trading centre of the empire and the more settled conditions encouraged commerce, Rimbaud lacked the hardheaded business sense needed for success. He lived as simply as the poorest native, spending as little as possible in order to save money so that he could one day retire and live at leisure. His meanness to himself was matched by unobtrusive generosity to others, and the little house where he lived with a native woman became the meeting place of the Europeans in Ethiopia.

His gift for languages and his humane treatment of the Ethiopians made him popular with them, and by his honesty and sincerity he even managed to win the confidence of the chiefs and of Menelik's nephew, the Governor of Harer, who became his close friend. He began to wish to do "something good, something useful," and his letters to his mother reveal a desire for affection and intellectual companionship. The marriage of his servant and only close companion, Djami, made him long for a family of his own, and he planned to go home for a holiday in order to look for a wife, in the spring of 1891.

Growing reputation in France

While Rimbaud was in Ethiopia, he had become known as a poet in France. Verlaine had written about him in *Les Poètes maudits* (1884) and had published a selection of his poems. These had been enthusiastically received, and in 1886, unable to discover where Rimbaud was or to get an answer from him, Verlaine published the prose poems, under the title *Illuminations*, and further verse poems, in the Symbolist periodical *La Vogue*, as the work of "the late Arthur Rimbaud." It is not known whether Rimbaud ever saw these publications. But he certainly knew of his rising fame after the appearance of *Les Poètes maudits*, for, in August 1885, he had received a letter from an old schoolmate, Paul Bourde, who told him of the vogue, of his poems—especially the sonnet "Voyelles"—among avant-garde poets. Also, he did preserve, for it was found among his papers, a letter received in July 1890 from a review inviting him to return to France and put himself at the head of the new literary movement, but he does not seem to have answered it. In February 1891 he developed a tumour on his right knee, and, when he left Harer on April 7, he had to be carried by stretcher for the week's journey to the coast. At Aden, the treatment tried had no result, and he was sent back to France. He landed at Marseilles in May and was taken to the Hospital of the Immaculate Conception, where his right leg was amputated. His mother had gone to Marseilles to be with him, but, despite the growing warmth of their letters toward the end of his time at Harer, she remained unable to show her affection for him, to his great disappointment. In letters to his sister Isabelle, he poured out his sense of frustration and despair, and, when, in July, he returned to Roche, a helpless cripple, it was she who looked after him.

He still hoped to marry and return to Ethiopia, but his health grew steadily worse. At last, made wretched by his helplessness and by the gloom of a bad northern summer, in August 1891 he set out on a nightmare journey to Marseilles. His disease was diagnosed as cancer, and Isabelle, who had accompanied him, was told that his case was hopeless Rimbaud himself, however, still believed that he might be cured and endured agonizing treatment. Shortly before he died, Isabelle persuaded him to make his confession to a priest. This conversion seemed to bring him new peace and to reawaken the poetic imagination of his early youth so that he became once more a *voyant,* seeing visions that, according to his sister, surpassed in depth and beauty those that had inspired the ***Illuminations.*** For this account, however, one has only the word of Isabelle, who in other respects (notably in her "emendations" of some of Rimbaud's letters from Ethiopia) has been proved a false witness. The conversion in *extremis,* accompanied by a reawakening of visionary power, belongs to the realm of uncertainty and legend. Rimbaud died in Marseilles on November 10, 1891, at the age of 37.

MAJOR **WORKS**

"Le Bateau ivre" (written 1871, first published in complete collection, 1898; ***The Drunken Boat; 36 Poems,*** trans. by B. Hill, 1952); "La Chasse spirituelle" considered by Verlaine his masterpiece—the manuscript written 1871–72 disappeared; ***Une Saison en enfer*** (1873; ***A Season in Hell,*** trans. and introd. by G.F. Lees, 1932; trans. by L. Varèse, 1945; and by N. Cameron, 1949); ***lllurninations*** (1886; ***Illuminations, and Other Prose Poems,*** trans. by H. Rootham, 1932; and by L. Varèse, 1957; also ***Rimbaud's Illuminations: A Study in Angelism,*** trans. by Wallace Fowlie, 1953, reprinted 1971); see also the ***Oeuvres complètes*** (1948); ***Selected Verse Poems of Arthur Rimbaud,*** trans. by N. Cameron (1942); ***Rimbaud,*** introd. and ed. by O. Bernard, with plain prose translation of each poem (1962); and ***Rimbaud: Complete Works, Selected Letters,*** trans. and introd. by Wallace Fowlie (1966).

BIBLIOGRAPHY

Editions and correspondence: The first collected edition of Rimbaud's writings was that of PATERNE BERRICHON and ERNEST DELAHAYE (1898). The principal editions of the ***Oeuvres complètes*** are'those of the "Pléiade," the first edited by ROLLAND DE RENEVILLE and JULES MOUQUET (1946; rev. eds., 1954, 1960, and 1965), and the new edition by ANTOINE ADAM (1972). The best annotated edition is that of SUZANNE BERNARD (1960; 2nd ed., 1962). HENRY DE BOUILLANE DE LACOSTE'S critical editions of ***Poésies*** (1939); ***Une Saison en enfer*** (1941); ***lllumінations*** (1949), have been followed by ALBERT PY'S annotated edition, with commentaries, of ***Illuminations*** (1967). Rimbaud's correspondence from the East was edited by PATERNE BERRICHON in ***Letfres de Jean-Arthur Rimbaud. Égypte, Arabie, Bthiopie*** (1899). Earlier letters were edited by J.-M. CARRE as ***Lettres de la vie litte'raire d'Arthur Rimbaud, 1870–1875,*** 5th ed. (1931). Important, recently discovered letters have been published in ***Arthur Rimbaud, Correspondance, 1888–1891,*** with preface and notes by JEAN VOELLMY (1965).

Biography: The indispensable biography for English readers is ENID STARKIE, ***Arthur Rimbaud,*** 3rd ed. (1961). It may be supplemented by HENRI MATARASSO and PIERRE PETITFILS, ***Vie d'Arthur Rimbaud*** (1962). Of the earlier notices one cannot ignore the authentic insights of PAUL VERLAINE in ***Les Poètes maudits*** (1884); but the first complete biography, albeit of dubious frankness, is that of PATERNE BERRICHON, ***La Vie de Jean-Arthur Rimbaud*** (1897).

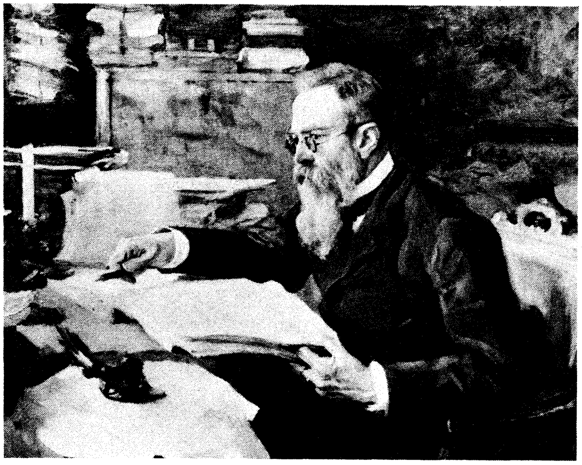
Criticism: In the vast corpus of literary criticism the reader may first consult EDGELL RICKWORD, ***Rimbaud, the Boy and the Poet,*** new ed. (1963); and the authoritative work by ROLLAND DE RENEVILLE, ***Rimbaud le voyant,*** rev. ed. (1947). The legend of Rimbaud is magisterially surveyed by the eminent critic RENE ETIEMBLE in ***Le Mythe de Rimbaud,*** 2 vol. (1952–54; new ed., 1961–68), to which his ***Rimbaud,*** new ed. (1950), in collaboration with YASSU GAUCLERE, may be considered as a preliminary. Subsequent studies include HENRY DE BOUILLANE DE LACOSTE, ***Rimbaud et le problème des "lllurninations"*** (1949); JACQUES GENGOUX, ***La Pensée poe'tique de Rimbaud*** (1950); CHARLES CHADWICK, ***Btudes sur Rimbaud*** (1960); W.M. FROHOCK, ***Rimbaud's Poetic Practice: Image and Theme in the Major Poems*** (1963); J.P. HOUSTON, ***The Design of Rimbaud's Poetry*** (1963); C.A. HACKETT, ***Autour de Rimbaud*** (1967); JACQUES PLESSEN, ***Promenade et Poésie, l'expe'rience de la marche et du mouvement dans I'oeuvre de Rimbaud*** (1967); and MARCEL RUFF, ***Rimbaud*** (1968), in French.

(En.S.)

Rimsky-Korsakov, Nikolay

A celebrated Russian composer and educator, Nikolay Andreyevich Rimsky-Korsakov is historically significant as a founder of what has become known as the Russian school of composition. He contributed to Russian musical culture by his teaching, conducting, and editing of works by Russian composers, including those of his own students. He composed in all genres, excelling particularly in scenes of fantasy and magic, which he depicted in his operas and symphonic works in luxuriant colours often imbued with Oriental inflections. In this respect he followed the traditions of Mikhail Glinka, who is often called the father of Russian music. In his last works, Rimsky-Korsakov approached the frontiers of Modernism in ultrachromatic and strikingly dissonant harmonies.

H. Roger-Viollet



Rimsky-Korsakov, portrait by V.A. Serov (18651911). In the Tretyakov Museum, Moscow.

Early life and naval career

Rimsky-Korsakov was born at Tikhvin, near Novgorod, on March 18 (March 6, old style), 1844. His father was a government official of liberal views; his mother was well educated and could play the piano. His uncle was an admiral in the Russian Navy and his elder brother a marine officer; from them Rimsky-Korsakov acquired his abiding love for the sea. When he was 12 the family moved to St. Petersburg (now Leningrad), where he entered the naval academy. At the age of 15 he began taking piano lessons with Theodore Canillé, a professional pianist, who also taught him the rudiments of composition. In 1861 he met the composer, Mily Balakirev, a man of great musical culture, and under the older man's guidance he began to compose a symphony. In 1862 he graduated from the naval academy. Soon afterward he sailed on the clipper ship "Almaz" on a long voyage, the vessel anchoring in New York, Baltimore, and Washington, D.C., at the height of the U.S. Civil War. The Russian sailors were cordially welcomed there, since Russia was politically sympathetic toward the North. Subsequent ports of call were Brazil (where Rimsky-Korsakov was promoted to the rank of midshipman), Spain, Italy, France, England, and Norway. The ship returned to its Russian home port in Kronstadt in May 1865. For young Rimsky-Korsakov the voyage confirmed a fascination with the sea. Aquatic scenes abound in his operas and symphonic works: the ocean in ***Scheherazade, Sadko,*** and ***The Tale of the Tsar Saltan,*** the lake in ***The Legend of the Invisible City of Kitezh and the Maiden Fevronia.***

On his return to St. Petersburg, he completed the symphony begun before his voyage, and it was performed with gratifying success in St. Petersburg on December 31, 1865, when the composer was only 21 years old. It was an auspicious beginning to his career; it was also the first performance of a full-fledged symphony by a Russian. His next important work was ***Fantasy on Serbian Themes*** for orchestra, first performed at a concert of Slavonic music conducted by Balakirev in St. Petersburg, on May *24, 1867.* The occasion was of historic significance, for, in reviewing the concert, the critic Vladimir Stasov proudly proclaimed that henceforth Russia, too, had its own "mighty little heap" (*moguchaya kuchka)* of native composers. The title caught on quickly and found its way into music history books, with specific reference to Rimsky-Korsakov, Balakirev, Aleksandr Borodin, César Cui, and Modest Mussorgsky, who became known collectively as "The Five," and whose purpose was to assert the musical independence of Russia from the West. Of these Rimsky-Korsakov was the most learned and the most productive; his works embrace all genres, but he excelled mostly in the field of opera.

Teacher and conductor

So high was Rimsky-Korsakov's reputation that in *1871,* still as a very young man, he was engaged to teach composition at the St. Petersburg Conservatory. In his autobiographical *My Musical Life,* he frankly admitted his lack of qualifications for this important position; he himself had never taken a systematic academic course in musical theory, even though he had profited from Balakirev's desultory instruction and by Tchaikovsky's professional advice. Eager to complete his own musical education, he undertook in *1873* an ambitious program of study, concentrating mainly on counterpoint and the fugue. He ended his studies in *1875* by sending *10* fugues to Tchaikovsky, who found them impeccable.

In *1873* Rimsky-Korsakov left the Russian naval service and assumed charge of military bands as inspector and conductor. Although he lacked brilliance as an orchestral leader, he attained excellent results in the training of inexperienced instrumentalists. His first professional appearance on the podium took place in St. Petersburg on March *2, 1874,* when he conducted the first performance of his *Third Symphony.* In the same year he was appointed to be director of the Free Music School in St. Petersburg, a post that he held until *1881.* He served as conductor of concerts at the court chapel from *1883* to *1894.* Between *1886* and *1900* he was chief conductor of the Russian symphony concerts. In *1889* he led concerts of Russian music at the Paris World Exposition; in the spring of *1907* he conducted in Paris two Russian historic concerts in connection with Sergey Diaghilev's Ballets Russes.

Music editor

Rimsky-Korsakov rendered an inestimable service to Russian music as the de facto editor and head of a unique publishing enterprise financed by the Russian industrialist Belayev and dedicated exclusively to the publication of music by Russian composers. After Mussorgsky's death, Rimsky-Korsakov edited his colleague's scores for publication, making radical changes in what he considered to be awkward melodic and harmonic progressions, and he practically rewrote Mussorgsky's opera *Khovanshchina.* His edited and altered version of *Boris Godunov* evoked sharp criticism as a pedantically professorial arrangement of a great, innovative masterpiece; but his masterly handling of the materials cannot be denied. Mussorgsky's score was later published in *1928* and had several performances in Russia and abroad, but ultimately the more effective Rimsky-Korsakov version prevailed in opera houses. Rimsky-Korsakov also edited (with the composer Glazunov) the posthumous works of Borodin.

A strict disciplinarian in artistic matters, he was also a severe critic of his own music. He made constant revisions of his early compositions, in which he found technical imperfections. As a result, double dates, indicating early and revised versions, frequently appear in his catalog of works. He was at his best and most typical in descriptive orchestration, in suggesting a place or an ambience. With but two exceptions *(Servilia* and *Mozart and Salieri),* the subjects of Rimsky-Korsakov's operas are taken from Russian or other Slavonic fairy tales, literature, and history. The most important among them are *Snow Maiden, Sadko, The Tsar's Bride, Tale of the Tsar Saltan, The Legend of the Invisible City of Kitezh and the Maiden Fevronia,* and *Le Coq d'or (The Golden Cockerel).* Although these operas are part of the regular repertory in Russian opera houses, they are rarely heard abroad; only *Le Coq d'or* enjoys occasional production in western Europe and America.

Of the composer's orchestral works, the best known are *Capriccio espagnol (1887;* Russian *Zspanskoye Kaprichchio),* the symphonic suite *Scheherazade* (1888), and *Russian Easter Festival* overture *(1888).* "The Flight of the Bumble Bee" from *The Tale of the Tsar Saltan* and the "Song of India" from *Sadko* are perennial favourites in a variety of arrangements. Rimsky-Korsakov's songs are distinguished by simple elegance and fine Russian prosody; his chamber music is of less importance. He also wrote a piano concerto.

As professor of composition and orchestration at the St. Petersburg Conservatory from *1871* until the end of his life (with the exception of a brief period during *1905* when he was dismissed by the reactionary directorate because of his defense of students on strike), Rimsky-Korsakov taught two generations of Russian composers, and his influence, therefore, was pervasive. Igor Stravinsky studied with him privately for several years. His *Practical Manual of Harmony (1884)* and *Fundamentals of Orchestration* (posthumous, *1913)* are still used as basic musical textbooks in the Soviet Union. Rimsky-Korsakov died at his estate in Lyubensk, on June *21* (June *8,* old style), *1908.*

MAJOR WORKS

Operas

Sixteen, including *Pskovityanka* (first performed *1873; The Maid of Pskov*); *Mayskaya noch (1880; May Night,* performed in French as *La Nuit de Mai); Snegurochka (1882; The Snow Maiden); Sadko (1898); Motsart i Salyeri (1898; Mozart and Salieri); Tsarskaya nevesta (1899; The Tsar's Bride); Skazka o tsare Saltane (1900; The Tale of the Tsar Saltan*), *Servilia (1902); Kashchey Bessmertny (1902; Kashchey the Immortal); Skazaniye o nevidimom grade Kitezhe i deve Fevroniy (1907; The Legend of the Invisible City of Kitezh and the Maiden Fevronia); Zolotoy petushok (1909;* performed in French as *Le Coq d'or* and in English as *The Golden Cockerel).*

Choral Works

Song of Oleg the Wise, after Pushkin, for tenor, bass, male chorus, and orchestra (composed *1899);* various settings of folk songs.

Orchestral

SYMPHONIES: *No.* I *in E Flat Minor (1861–65,* rev. *1884); No.* 2, *Antar (1868,* rev. *1876); No.* **3** *in C Major (1874,* rev. *1886).*

OTHER ORCHESTRAL MUSIC: *Overture on Russian Themes (1866); Piano Concerto in C Sharp Minor (1882–83); Fantasy on Russian Themes* for violin and orchestra *(1886); Fantasy on Serbian Themes (1867); Capriccio espagnol (1887);* symphonic suite *Sheherazade (1888);* overture *Russian Easter Festival (1888).*

Chamber Music

String Quartet in F Major (1875); String Sextet in A Major (1876): Quintet for Piano and Winds in B Flat Major (1876); String Quartet in G Major (1897).

Songs

More than *80* songs, mostly written in sets of four.

Римский-Корсаков, жизнь и творчество,* 5 fasc. *(1933–46).* A useful compendium is A. SOLOVTZOV, *Жизнь и творчество Н.А. Римского-Корсакова (1964).* See also GERALD ABRAHAM, *Rimsky-Korsakov: A Short Biography (1948).*

(N.Sl.)

Rio de Janeiro (State)

Rio de Janeiro is one of the states (*estados*) of the republic of Brazil. Located in the southeastern region of the country, it is bounded by the states of Espirito Santo and Minas Gerais (to the north) and São Paulo (to the west); to the south lies the Atlantic Ocean. The state's name is derived from the city of Rio de Janeiro, which exerted a strong influence on its formation. The state has an area of *17,092* square miles *(44,268* square kilometres), of which *300* square miles consist of coastal lagoons and other internal waters. At the time of the *1980* census it had a population of almost *11,500,000* and a population density of more than *675* persons per square mile *(260* persons per square kilometre). The capital is the city of Rio de Janeiro, which had a population in 1980 of about 5,100,000.

History. The history of the state is enmeshed with that of the city of Rio de Janeiro, its chief economic and political centre from the early 16th century until 1834, when the city first became a separate entity. In 1835 Niteroi became the capital of the province of Rio de Janeiro. In 1889, when the Brazilian republic was proclaimed, the province became a state, and in 1890 Teresopolis became the capital; in 1902, however, the seat of government returned to Niteroi. When the capital of Brazil was moved to the newly established city of Brasilia in 1960, the territory that formerly had been the Federal District became the new Guanabara state, which existed as an enclave within Rio de Janeiro state. In 1975 the two states were merged into the reorganized State of Rio De Janeiro. The city of Rio de Janeiro was then made the capital once again.

From the time of its temtorial formation, the province depended on sugar production as the basis of its economy. By the end of the 18th century it had about 168,000 inhabitants, almost half of whom were slaves who were working. either in agriculture or in one of 600 sugar mills in the province. During the 19th century coffee replaced sugar as the most commercially significant crop, enriching the landowners of the Paraiba Valley, who constituted the ruling group of the Brazilian Empire until the abolition of slavery in 1888 and the proclamation of the republic in 1889.

The three regions

Relief and environment. The state's relief has three distinct features: the plain, or coastal lowland; the mountainous highland; and the plateau of the interior. The coastal lowland—broken by occasional massifs or rocks that sometimes extend far into the sea, as happens at Cabo Frio and Saquarema and along the stretch of coast opposite the offshore island of Ilha Grande—is narrower to the west, where the mountains of the Serra do Mar compress it against the sea. The prevailing climate is hot and humid and is characterized by summer showers. In winter the climate is modified by cold air masses from the south. The average temperature is generally above 72" F (22" C).

The mountainous highland comprises part of the Serra do Mar and, farther inland, part of the Serra da Mantiqueira, both of which run parallel to the coast in a roughly southwest-to-northeast direction. Some important tourist and holiday resorts—Petropolis, Teresopolis, and Nova Friburgo—are located in this region, which is characterized by mild temperatures that average below 68° F (20° C) because of the high altitude. The highest summits are found in a range called the Serra dos Orgãos and in the Massif of Itatiaia, where the Pico das Agulhas Negras reaches a height of 9,134 feet (2,784 metres).

The most important area in the landscape of the plateau is the Rio Paraiba do Sul. In its valleys coffee plantations were first developed in the 19th century. The temperature remains mild at the highest altitudes but grows progressively hotter toward the bed of the Rio Paraiba do Sul, which flows northeastward before turning eastward to drain into the Atlantic in the northeastern part of the state. At the level of the river itself the climate is tropical, and the temperatures are high.

Destruction of the humid tropical forest that originally covered the territory of the present state of Rio de Janeiro began in the 16th century with the introduction of the *queimadas* (slash-and-burn) technique, used by Indians and European settlers alike to clear tracts of land for temporary cultivation. The clearing of the forest cover continued with the cultivation of sugarcane on plantations, was intensified with the expansion of coffee growing, and was completed with the progress of urbanization. In the mid-20th century the Brazilian government undertook reforestation of large areas on the hillsides and massifs, granting the areas protection as national parks and thus helping to preserve remains of the original forest. Part of the area, commonly known as the Forest of Tijuca (8,200 acres [3,300 hectares]), was established by the federal government as a nature reserve in 1961 to help preserve both vegetation and animal life. About 74,000 acres of the Serra dos Órgãos have been made a national park, and Itatiaia National Park was created on the Itatiaia massif in the Mantiqueira chain. Trees represented in the parks include jequitibas, perobas, and imbuias, as well as ferns and palm trees.

Apart from these public parks some patches of forest vegetation still survive on a few hillsides near the city of Rio de Janeiro, but these are disappearing as the urbanized area is gradually enlarged. On the Santa Cruz, Campo Grande, and Jacarepagua plains, grassland prevails, whereas on the muddy coastland red, yellow, and white mangroves grow.

Animals continue to inhabit the forests, but man's predatory activities in earlier periods and the continuing extension of the urban perimeter have forced the animals to flee to the thickest parts of the forest reserves or to a few natural shelters. Still found in these areas are the black-tailed, soft-furred nail monkey, or mico; a type of squirrel called *caxinguelê*; a bird called *macuco*; and the *jaguatirica*, as well as more common animals as parrots, anteaters, armadillos, raccoons, bush dogs, opossums, and snakes.

Government and political institutions. The State of Rio de Janeiro, according to the terms of its 1967 constitution, is an "integrated and inseparable part of the Brazilian Republic" and is entitled, in its territory, to all the power not bestowed on the union (federal government) by the Brazilian constitution. On March 15, 1975, the former State of Guanabara was merged with the surrounding State of Rio de Janeiro, and the new state was named Rio de Janeiro. It has its own symbols, as well as a flag, a hymn, and a coat of arms.

The government of the state consists of legislative, executive, and judiciary powers, the first being held by the state Legislative Assembly, the second by the state governor and his secretaries, and the third by the law courts and judges. The Legislative Assembly is composed of at least 55 deputies of Brazilian nationality and of legal age, who are elected by direct and secret ballot for a four-year mandate. The number of deputies increases as the population grows, at a ratio of one deputy per 100,000 inhabitants or a fraction greater than 50,000. The assembly meets at the city of Rio de Janeiro during the period from March 1 to November 30 each year, with a break in July. Since 1980 the state governor has been elected by direct popular vote. The governor's term also lasts four years. He must be Brazilian by birth and must meet certain other requirements.

The judiciary

The state judiciary power is exercised by a series of institutions—the Tribunal de Justiça (lawcourts); the Tribunal de Alçada (jurisdiction courts); the Conselho da Magistratura (Council of Magistrates); the Corregedoria da Justiça (Magistracy of Justice), as well as judges and appeal courts, and such courts as may be created by law. There is also a Tribunal do Juri (jury court), and tribunals of military justice.

According to the constitution, 22 percent of the total expenditure of the state budget, ratified in the previous session, must be reserved for educational and cultural activities. Teaching of all types and the granting of degrees are the responsibility of the state school system. Private institutions, however, also have freedom to teach. The state university of Rio de Janeiro, which is organized as a foundation, is responsible for education at the undergraduate level and for the promotion of artistic culture. It is autonomous and receives an annual grant of not less than 15 percent of the state's total expenditure on education and culture.

As stipulated by the Brazilian constitution, the state promotes the development of industries, especially of those enterprises in which the greater part of the capital is invested by Brazilian nationals. Factories operating in the urban zone or in other Brazilian states benefit if they transfer to areas zoned for industry in the rural and suburban areas of the state.

Population and administration. The state has one of the highest urbanization rates in Brazil, with more than 80 percent of the population living in the city of Rio de

Janeiro and other urban centres. About 90 percent of the state's inhabitants are Roman Catholic, about 5 percent Protestant, and almost 3 percent Spiritists (believers in spiritualism).

The State of Rio de Janeiro is subdivided into 5 major regions and 14 minor regions with 64 municipalities. In 1980 more than four-fifths of the population of the state lived in the 12 municipalities that had more than 100,000 inhabitants.

Health and Education

Social conditions. Medical facilities in the late 1970s were provided by almost 550 hospitals, which together had about 70,600 beds; there were more than 13,100 doctors. The educational system included some 6,075 primary schools, 1,390 secondary schools, and nine universities; there also were about 100 independent schools that provided higher education.

The economy. About 5 percent of the working population of the state is engaged in agriculture, 25 percent in manufacturing, and 55 percent in service industries. Agriculture, however, accounts for only about 16 percent of the state's income, whereas manufacturing produces about 33 percent, and service industries a little more than 50 percent. The principal industries are metallurgy, printing, shipbuilding, and oil refining, and manufactured products include textiles, foodstuffs, and chemicals. Cement manufacturing, sugar refining, and automobile production are other important economic activities. Agricultural products include sugarcane, oranges, and bananas.

Transportation. More than 12,700 miles of roads, of which about 1,860 miles are paved, cross the state. The Central do Brasil and the Leopoldina railroads link the state with Brazil's national rail network. The Rio–Niteroi Bridge, which is about 9 miles long, connects the city of Rio de Janeiro with Niteroi, located on the east side of the bay. Ferry and hydrofoil service also link the two cities. The state has two airports: Santos Dumont, on Guanabara Bay within the city of Rio; and Galeão, on Governador Island in the bay, which was opened in January 1977 to accommodate international as well as domestic fights.

Cultural life. In the early 1980s the State of Rio de Janeiro had more than 60 museums, almost 300 cinemas and theatres, and some 30 broadcasting stations. There were more than 60 newspapers published in the state, of which 17 were dailies.

BIBLIOGRAPHY. JOSÉ DE SOUSA AZEVEDO PIZARRO E ARAUJO, *Memórias Histdricas do Rio de Janeiro,* 7 vol. (1948); and ALBERTO RIBEIRO LAMEGO, *O Homem e o Brejo* (1945), are two sources for the study of the historical development of the State of Rio de Janeiro. SYLVIO FROES ABREU, *O Distrito Federal e Seus Recursos Naturais* (1957); and ANTONIO TEIXEIRA GUERRA, "Paisagens físicas da Guanabara," *Revista Brasileira de Geografia,* 27:539–568 (1965), describe the state's environment, natural resources, and landscape. The INSTITUTO BRASILEIRO DE GEOGRAFIA E ESTATISTICA, *Enciclopédia dos Municípios Brasileiros,* vol. 22–23 (1959–60), gives a comprehensive account of the development of the State of Rio de Janeiro up to the 1960s.

(A.P.G.)

Rio de Janeiro (City)

Rio de Janeiro, a major port city of Brazil and capital of the State of Rio de Janeiro, is located on the Atlantic Ocean, in the southeastern part of the tropical zone in South America. The name was given to the city's original site by Portuguese navigators who arrived at the port on January 1, 1502, and mistook the entrance of the bay for the mouth of a river (***rio*** is the Portuguese word for river and ***janeiro,*** the word for January). When the foundations of the future town were laid in 1565, it was named Cidade de São Sebastião do Rio de Janeiro (City of Saint Sebastian of Rio de Janeiro), for both St. Sebastian and Dom Sebastian, king of Portugal. It is officially and commonly called Rio de Janeiro, but is often referred to, in a shortened form, as Rio.

When the capital of the Brazilian republic was transferred to Brasilia in 1960, the territory belonging to the former Federal District was converted into Guanabara state, which formed an enclave in Rio de Janeiro state. In March 1975 the two states were fused as the State of Rio de Janeiro; Guanabara and the city of Rio de Janeiro (former Guanabara state) became one of the 14 ***municípios*** (municipal districts) of the Metropolitan Region of Rio de Janeiro, or Greater Rio. The city of Rio de Janeiro became the capital of the reorganized State of Rio de Janeiro.

The city of Rio de Janeiro occupies an area of 452 square miles (1,171 square kilometres). It lies on an inlet of the Atlantic, the Baia de Guanabara (Bay of Guanabara), the entrance to which is marked by a point of land called Pão de Açúcar (Sugar Loaf). The core of the city lies on the western shore of the Baia de Guanabara on a plain, composed of marine and continental sediments, that is interrupted by several rocky mountains. At the time of the 1980 census the population of the city of Rio de Janeiro was about 5,100,000.

HISTORY

The city of Rio de Janeiro, surrounded by the sea and the mountains, is an urban agglomeration with exceptional features. The site was won from nature in a long succession of battles, which resulted in the transformation of inhospitable areas into a remarkable landscape, slowly and progressively adapted to the demands of human occupation.

Early settlement

Several years after the Portuguese first explored Brazil, French traders in search of ***pau-brasil*** (a type of brazilwood) explored the rich area extending from the Cabo Frio (Cold Cape) coast to the beaches and islands of the Baia de Guanabara—the economic and, above all, strategic importance of which was already well known. On one of these islands, which now bears his name, a French Huguenot, Nicolas Durand de Villegaignon, founded a colony that was called La France Antarctique (Antarctic France).

The Portuguese wanted to expel the French from Brazil; and the task was given to Estacio de Sa, the nephew of Governor Mem de Sa of Brazil, who in 1565 occupied the plain between the Morro Cara de Cão (Dog Face Hill), and the Sugar Loaf and Urca mounts, thus laying the foundations of the future town of Rio de Janeiro. After two years (1565–67) of bloody battles, in which Estacio de Sá was killed, Mem de Sa chose a new site for the town, further inland on the coast of the bay, at the top of the Morro do Descanso (Hill of Rest), or São Januario (St. Januarius Hill), later called the Morro do Castelo (Castle Hill). In 1568 the settlement was laid out in the form of a medieval citadel, protected by a bulwark and cannons.

As the settlement slowly developed, spreading around the feet of the hills and along the beach, the local marsh did not hinder expansion. The surrounding fertile land, allotted to Portuguese settlers by the Portuguese king in enormous plots called ***sesmarias,*** was planted with sugarcane, which was to provide the colony with its main source of income.

In 1660 the community became the seat of the government of the southern captaincies (Portuguese administrative units, each governed by a captain) of Brazil. In the second half of the 17th century, the captaincy population grew from 7,000 to 8,000 inhabitants, two-thirds of whom were probably Indian or Negro slaves.

At the beginning of the 18th century, Brazil began to engage in mining, which brought about remarkable changes in the colony's economic life. Only three decades after the discovery of gold, diamonds were discovered, resulting in a great migration, both from Brazil itself and from abroad, to the colony's hinterland. As a result the former village became a town and increased its population from 12,000 in 1740 to 24,000 in 1749.

Because of its rapid expansion, quick solutions had to be found for its pressing new problems. The construction of the Carioca aqueduct solved the most important problem—the water supply; this monumental aqueduct brought water from the Rio Carioca to a public fountain in the town. When the colonial capital was transferred from Bahia to Rio de Janeiro in 1763, the resulting demographic growth made the town expand further, far beyond its walls.

Kurt Scholz—Shostal Assoc

At the end of the 18th century, the town's economy, as well as that of the colony as a whole, was in a crisis because of the decline of the mines, as a result of which thousands of gold seekers became vagrants. In 1796 the value of exports from Rio's port was less than half of what it had been in 1760.

Colonial improvements

When the Portuguese royal family resettled in Brazil in 1808, the colony prospered again. By 1815, when Brazil became a kingdom, Rio de Janeiro was large enough to accommodate a foreign population. At about this time the city's initial features were being transformed; from 1808 to 1818, 600 houses and 100 country houses were built, and many older buildings were restored. Many streets were lighted and paved, more land was reclaimed, new roads opened, and new public fountains installed. Among new institutions established were the Royal Press, the Royal Library, the Theatre of Saint John, the Academy of Fine Arts, the Botanical Gardens, and the Bank of Brazil. When King John VI returned to Portugal in 1821, Rio had almost 113,000 inhabitants and 13,500 buildings, and the town had extended both northward and southward.

After Brazil won its independence in 1822, the expansion of coffee plantations in the State of Rio de Janeiro gave a new impulse to the city's development. Nobles and rich bourgeois moved their residences north to the São Cristóvão district. Merchants and English bankers chose to live around the Outeiro da Gloria (Gloria Hill) and Praia do Flamengo (Flamengo Beach) areas in the east, or they established their residences in the nearby Botafogo and Laranjeiras districts. The French, on the other hand, lived in country houses scattered in the Tijuca area farther westward.

In this era the city changed its appearance, and the traces of its colonial past were effaced. In 1829 oxcart traffic was banned from the Rua do Ouvidor, then the city's most elegant highway. In 1838 the first public transportation—horse-drawn buses—began to run to the districts of São Cristóvão, Engenho Velho, and Botafogo. In 1868 the first tramcars, also drawn by animals, were introduced. A steamboat service to Niteroi, on the eastern shore of Baia de Guanabara, began to operate in 1835. The first railroad was built in 1852 to Petropolis to the northeast, and a line reached Queimados to the northwest in 1858. In 1854 gas replaced oil for street-lighting, and wireless telegraphy was inaugurated. Sewerage was installed in 1864, and telephone service began in 1877.

When Rio de Janeiro, which had formerly been the capital of the empire, became capital of the republic of Brazil in 1889, it was already a considerable community. At the time of the 1890 census, it had more than 520,000 inhabitants. In both its population and its urban area (61 square miles), the city of Rio de Janeiro ranked as the largest city in Brazil and as one of the large cities in the world. The 1891 constitution gave it the status and name of the Federal District.

During the federal administration of President Francisco de Paula Rodrigues Alves, from 1902 to 1906, the Federal District was transformed into a modern city. As a result of the work of a team of administrators and technicians, endemic yellow fever and smallpox were subdued, the death rate decreased, health conditions were improved, huge swamps were drained, slums were cleared, and more streets were paved and widened. Important changes were also made in the city's plan: the central avenue (called Avenida Rio Branco from 1912), running northeast to southwest, was opened during this period; Avenida Beira-Mar, running parallel to part of the south shore, was built; and several other important avenues were opened.

Changes in the early 20th century

During the first three or four decades of the 20th century the city underwent no striking changes. The population of the Federal District exceeded 1,000,000 by 1920 and increased to 1,750,000 inhabitants by 1940. The proportion of foreigners decreased from 30 percent in 1890 to 13 percent in 1940. Migration continued to be the main factor in demographic growth, supplying the city with a ceaseless influx of people born in other parts of Brazil. The death rates were lower than the birth rates, and they continued to decline. Industry also developed during this period, industrial establishments in the Federal District increasing from about 1,500 in 1920 to more than 4,000 in 1940.

NATURAL SETTING

Rio de Janeiro lies on a strip of Brazil's coast and faces south. The greater portion of the city—embracing the centre and the North Zone—lies on the western shore of Guanabara Bay and is cut off from the South Zone by coastal mountains. The peaks, ridges, and hills of Rio are offshoots of the Serra do Mar, an ancient gneiss-granite mountain chain.

Although the region's climate is generally tropical, hot, and humid, the climate of Greater Rio is strongly affected by its topography and its proximity to the ocean. Along the coast, the breeze, blowing alternately onshore and offshore, modifies the temperature. Because of its geographic situation, the city is reached by south and the southeast winds, blowing from the Antarctic, which carry large amounts of moisture and cause frequent weather changes. During certain periods of the year these changes are accompanied by strong showers that sometimes provoke catastrophic floods and landslides. The hilly areas register greater rainfall since they constitute a barrier to the humid wind that comes from the Atlantic. The highest rainfall rates are found in the urban districts of Jardim Botânico (more than 63 inches [1,600 millimetres]), Urca, Deodoro, Paqueta, Bangu, and Santa Cruz (more than 47 inches).

The temperature varies according to the altitude, the distance from the coast, the type of vegetation, and the season. Winter (from June 21 to September 23) is particularly pleasant, both because of its mild temperature and because it is, in general, less rainy than the summer (December 21 to March 21), which is both hotter and wetter. The average temperature at Rio is about 73° F (23° C).

THE CONTEMPORARY CITY

Greater Rio. The demographic and economic expansion that took place in Rio during the decades of the mid-20th century transformed the city into the country's second regional metropolis, the first being São Paulo. Many neighbouring settlements have become integrated into its area of influence, since they depend economically and socially on the central nucleus. These local communities, most of which became part of Rio's conurbation after World War II, have changed from commuter areas to suburbs that are firmly integrated in the industrial, commercial, and cultural activities of the metropolis.

Fourteen *municípios* comprise Greater Rio. Five of these municipios—Nova Iguaçu, São Gonçalo, Duque de Caxias, Niteroi, and São João de Meriti—are themselves large urban agglomerations. Petropolis, situated in the Serra do Mar at an altitude of 2,900 feet, is an important tourist resort. The remaining *municípios*—Itaboraí, Itaguai, Mage, Mangaratiba, Maricá, Nilópolis, and Paracambi—are smaller localities scattered in the urban periphery. Together with the municipio of Rio de Janeiro, they form the area that is called Greater Rio. In the 1980 census the total metropolitan population of Greater Rio was almost 9,100,000 people.

Demography. The municipio of Rio de Janeiro, or the city of Rio, had 5,100,000 inhabitants by 1980. It is entirely urbanized and is divided into 24 administrative regions: Portuaria, Centro, Rio Comprido, Botafogo, Copacabana, Lagoa, São Cristóvão, Tijuca, Vila Isabel, Ramos, Penha, Meier, Engenho Novo, Iraja, Madureira, Jacarepagua, Bangu, Campo Grande, Santa Cruz, Ilha do Governador, Ilha de Paquetá, Anchieta, Santa Teresa, and Barra da Tijuca.

Between 1940 and 1960 the city's population expanded at a rate of more than 3 percent a year. After 1960, when the capital of Brazil was transferred to Brasilia, development stabilized in the city of Rio de Janeiro, and the population growth rate fell to 2.3 percent annually. The population density in 1980 reached 11,268 persons per square mile (4,349 persons per square kilometre), with a maximum of 88,126 inhabitants per square mile in the crowded administrative region of Copacabana. At the other extreme, in the scantily populated administrative region of Santa Cruz, a former rural zone, the density was 2,097 per square mile.

The city of Rio de Janeiro

The following were the 12 most populated administrative regions at the time of the 1980 census: Bangu (530,378 inhabitants); Méier (411,343); Anchieta (337,873); Campo Grande (333,941); Jacarepagua (326,855); Penha (315,-837); Madureira (277,537); Iraja (273,281); Botafogo (268,047); Ramos (254,952); Copacabana (228,703); and Lagoa (218,002). The administrative regions of the North Zone are more heavily populated than those of the South Zone.

The population of Rio de Janeiro has always grown primarily as a result of migration, which in some years has accounted for two-thirds of its increase. When the flow of immigrants from abroad began to decline (between the years 1890 and 1960 the proportion of foreigners in the former Federal District decreased from 30 percent to 7 percent), the number of migrants coming from other parts of Brazil increased. Nearly 45 percent of the population of Rio de Janeiro in the late 1970s were migrants from other places in the country. Most migrants were born in the states of Rio de Janeiro, Minas Gerais, or Espirito Santo. Among the foreign-born in Greater Rio in the early 1980s, the largest groups were Portuguese, Italians, and Spaniards.

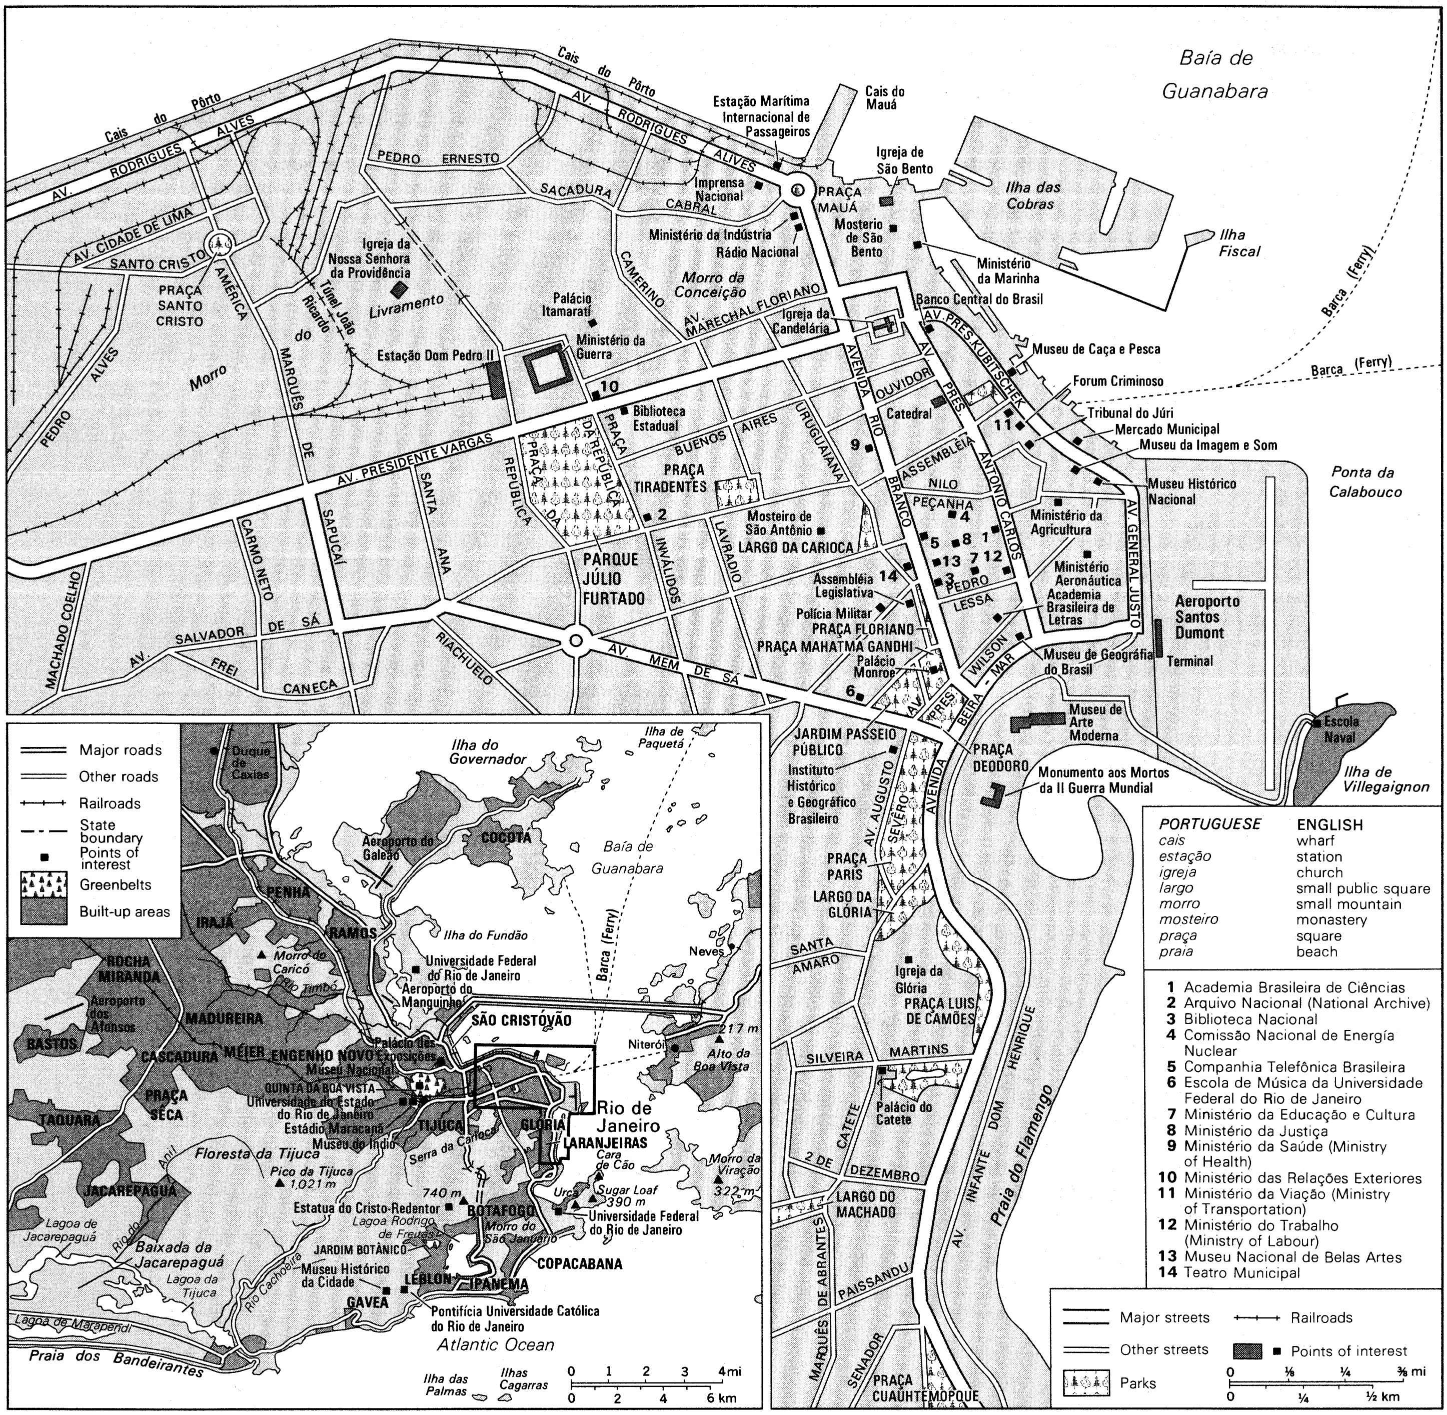
As in other Brazilian urban centres, the inhabitants of the city of Rio de Janeiro are mainly Christian, with about 89 percent Roman Catholic and 4 percent Protestant; Spiritists represent 4 percent and Jews about 1 percent of the population. Most of the people of Rio de Janeiro are white (70 percent), although the proportion of blacks (11 percent) and mestizos (18 percent) is also significant.

Town planning. A great effort of urban renewal in Rio de Janeiro, beginning about 1920, has had encouraging results. Rio is no longer the "soaked sponge," as it was called by a historian referring to the great number of existing lagoons and swamps that characterized it in its earlier periods. After the first decades of the 20th century it became a comfortable and pleasant city and was able to renew, in a short period of time, not only its natural landscape but also the main part of its architectural heritage.

In less than 40 years the urban centre of Rio de Janeiro and some South Zone districts were almost entirely demolished and reconstructed; in some areas older two- or three-storied houses were replaced by skyscrapers that ranged from 10 to 30 floors. Some of these buildings are the product of remarkable architectural concepts and have made the names of such architects as Affonso Eduardo Reidy, Lúcio Costa, and Oscar Niemeyer internationally known.

Urban growth

The accelerating urban development of the city of Rio de Janeiro has attracted many low-income groups from the other parts of the country and especially from rural areas. This is the origin of the rapid growth in the number of barracos ("huts"), or hovels, which are frequently clustered together in agglomerations. Some estimates have put the number of favelas ("shantytowns") at more than 200 and have estimated their total population at about



Central Rio de Janeiro and (inset) its metropolitan area

1,000,000 people. Census data, however, indicate somewhat lower figures—between 1950 and 1960 the census reported that the number of *favelas* increased from 58 to 147, rising to 165 by 1970; their population was reported to have grown from 165,000 in 1950 to 337,000 in 1960 and to 565,000 in 1970.

In the late 1960s, agencies jointly administered by the federal and the state governments began to encourage the purchase of houses and flats that were built for sale in long-term installments to poor families living in the *favela* ~This policy led to the disappearance of some of these agglomerations of substandard dwellings, but it did not prevent the emergence of similar nuclei of huts that, sooner or later, threatened to develop into new shantytowns. At the time of the 1980 census it was reported that there were 192 *favelas* in Greater Rio, with a total population of 628,000.

Economic life. Nearly 75 percent of the internal income of Greater Rio is produced by the service sector of the economy. The contribution of industry amounts to approximately 25 percent.

In 1977 there were almost 10,300 industrial establishments employing some 467,800 people. The most important classes of industry are metallurgy (53,500 employed), machinery (41,000), wearing apparel and footwear (41,700), textiles (35,200), and nonmetallic mineral products (32,100).

The state government and the financial institutions under its control developed, in the early 1970s, a plan to finance and to stimulate industrial growth; the federal government also provided incentives. In accordance with this policy of industrialization, the Metropolitan Region was divided into five industrial sectors (Fazenda Botafogo, Palmares, Paciência, Santa Cruz, and Campo Grande), which together account for about 20,000,000 acres (8,094,000 hectares) for sale to industrial enterprises.

As an important port and trading centre, Rio de Janeiro each year receives and distributes considerable amounts of foreign and national products throughout its zone of economic influence, which includes large regions in southern, northeastern, and southeastern Brazil. Its imports come from other parts of the Americas, from Europe, and from other continents. By value, exports in 1979 totalled U.S. $2,536,000,000, and imports totalled U.S. $1,363,000,000; exports normally greatly exceed imports. From Rio's port almost 5,000,000 tons of commodities are distributed each year to various points in Brazil; this is in addition to a great volume of internal trade by railway and road.

Banks and financial institutions

As one of the most important financial centres of Brazil, the Metropolitan Region of Rio de Janeiro has more than 850 bank branches, 80 percent of which are private. A significant number of banks have their headquarters in the city of Rio de Janeiro. Its stock market is one of the most important in the country. The securities market, which expanded rapidly during the 1970s and early 1980s, is supported by powerful financial corporations that have their headquarters in Rio.

In Greater Rio, which has one of the highest per capita incomes in Brazil, the retail trade is substantial. Although many of the most important establishments are located on the main streets of the city centre, others are scattered throughout the commercial areas of the northern and southern districts, where branches of shops, department stores, warehouses, supermarkets, and other retail businesses have been established.

The building industry is most active and performs an important role in the economy of Rio de Janeiro; it is a major consumer of manufactured products, as well as being a source of employment for large contingents of unskilled labor.

Government and political institutions. The *município* of Rio de Janeiro is governed by a ***prefeito*** (mayor) with the assistance of seven administrative departments (administration, social development, education and culture, financial, public works, planning, and health). The mayor is appointed by the governor of the State of Rio de Janeiro. Municipal legislative power is held by the members of the Municipal Chamber. The assembly meets in the city from March to November each year, with a break in July.

Transportation. Greater Rio is crossed by 700 miles of paved roads, through which it is linked with major cities in Brazil, as well as cities in other countries throughout South America. Nearly 200 road transport enterprises, with equipment totalling more than 6,000 buses and 2,000 trucks, carry some 900,000,000 passengers and 3,000,000 tons of goods a year. The traditional railroads, the Central do Brasil and the Leopoldina railways, both of which are part of the federal rail system, provide daily passenger train service, carrying some 118,000,000 passengers annually between the city centre and the main suburban and rural centres.

Rio has facilities for water traffic along the shores of the Baia de Guanabara, such as at Niteroi, as well as on the islands in the interior of the bay, such as at Paqueta; service is provided by ferry boats, motorboats, and hydrofoils. The construction of a subway was begun in 1972, and the first station was opened in 1979. Traffic on the subway has grown as each new station was opened, and by the early 1980s the subway transported some 250,000 passengers per day. Surface urban traffic is becoming more dense and more complex. Congestion in the city and its environs is increasing as the number of automobiles grows. By the early 1980s there were more than 900,000 automobiles in Greater Rio.

Two modern airports—Galeão for domestic and international services and Santos Dumont for domestic lines only—make Rio the primary centre for air services in Brazil.

The port of Rio de Janeiro is one of the largest in the country, and it is the first in the amount of freight carried (almost 30,000,000 tons in 1980). The port has 24,250 feet of quay.

Municipal services. ***The water and sewer systems.*** As frequently happens in rapidly developing metropolitan areas, the city of Rio de Janeiro throughout its history has confronted serious difficulties in providing urban services and facilities.

Since 1723, when Aires Saldanha, governor of Rio, built the Carioca aqueduct, Rio's water supply has continuously expanded. The historical aqueduct has now become a viaduct, crossed by old and picturesque streetcars. Rio de Janeiro now has a modern water supply furnished by the Companhia Estadual de Águas e Esgotos, a state company. By the late 1970s an average of 500,000,000 gallons of water per day was being supplied, and new reservoirs had been constructed to supply the area's needs. Proposals include the construction of additional reservoirs and the modernization of the entire water supply system.

Rio's first sewer system was constructed in 1864. The present system, like the water supply system, is operated by the Companhia Estadual de Águas e Esgotos. The sewer network is 4,287 miles long, and the number of the buildings served is estimated to be more than 200,000. A sewage disposal facility has been constructed in deep water several miles from the coast in order to avoid pollution of the beaches in the area.

Electricity. The capacity of Rio de Janeiro state's thermoelectric power installations is 662 megawatts, but the supply system is interlinked with a system of power stations among which Light—Serviços de Eletricidade S.A., a state enterprise, is predominant. The total installed power in the Rio area is 1,750 megawatts, of which 1,088 megawatts come from hydroelectric power stations. The consumption of electric power in the area is growing at a rate of more than 10 percent per year. By 1979 it had reached 16,500,000 megawatt-hours, of which 33 percent went to industry, 25 percent to residential uses, and 17 percent to commerce. The remaining 25 percent was allocated to public lighting, electrified transportation, and other purposes.

Health and security. Health services are provided by almost 200 hospitals. About two-thirds are private, and the remainder are run by the state. They provide about 40,000 beds. The staffs of the hospitals are composed of about 15,000 medical doctors and other licensed personnel.

Military agencies

A great variety of civilian and military agencies are responsible for internal security. The city of Rio de Janeiro is the seat of the 1st Military Region, which comprises the army elite forces; of the 1st Naval District, as well as of naval technical, industrial, and training organizations; and of the Third Zone Air Command and other Brazilian air force organizations. The fire brigade of the city has modern equipment and has a tradition of great efficiency. The civilian and the military police forces consist of more than 20,000 men. A total of more than 90,000 people in Rio are engaged in work concerned with the public security and national defense.

Educational and cultural life. The city of Rio de Janeiro has one of the highest literacy and education rates in Brazil. The literate population comprises approximately 90 percent of those age 10 or older. The national average was around 80 percent in 1978. In the late 1970s education at the primary level was provided by almost 1,800 school units, with a staff of almost 36,100 teachers and with 887,000 students. Education at the secondary level in 1978 consisted of 340 school units, almost 13,100 teachers, and 201,300 students.

The three most important universities in Rio de Janeiro are the Universidade Federal do Rio de Janeiro, the Universidade do Estado do Rio de Janeiro, and the Pontifícia Universidade Catolica do Rio de Janeiro. In addition, there are some 50 other university establishments. Some of these are grouped in a federation and offer a great variety of courses.

Museums

As the country's cultural capital, Rio de Janeiro has many prestigious artistic, literary, and scientific institutions. These include the Academia Brasileira de Letras (Brazilian Academy of Letters), the Instituto Histórico e Geografico Brasileiro, and the Academia Brasileira de Ciências (Brazilian Academy of Sciences), as well as 28 museums. Of the museums, the National Museum of Fine Arts, founded in 1818, is the oldest. It is located in the former Imperial Palace of the Quinta da Boa Vista. The Museum of the Republic and the Literary Museum are established in the older Catete Palace, where the presidency of the republic was installed during the period when Rio was the Federal District. Other museums of interest include those devoted to special interests such as the historical city, modern art, image and sound, and the Brazilian Indian people.

Greater Rio has some 100 cinemas and some 50 theatres. There are about 45 libraries, with estimated holdings of 5,000,000 volumes. The city of Rio de Janeiro has a municipal library and 14 regional libraries, all of which are maintained by the city government; their services include mobile libraries and a braille section. The most important library in the city, however, is the National Library; it was founded in 1810 with the remains of the Royal Library of Ajuda, which were brought to Brazil from Portugal after being saved from the fire that followed the 1755 earthquake in Lisbon. The National Library has its own building, in which are kept a total of some 3,500,000 volumes, 600,000 manuscripts, and 250,000 maps and prints.

There are more than 20 radio broadcasting stations and six television stations located in Rio de Janeiro. Many periodicals are published there, including some 14 daily newspapers.

Tourism

The majority of tourists (60 percent) who travel to Brazil visit the city of Rio de Janeiro. Among the picturesque places frequently toured are the Morro do Corcovado (Mount Corcovado), 2,310 feet (704 metres) high, on top of which is found the monument to Christ the Redeemer (Cristo-Redentor); Pão de Açúcar, 1,296 feet (395 metres) high, which affords a spectacular view of the South Zone of the city and which is reached by a funicular railway; the Quinta da Boa Vista, a park in which the National Museum and the Zoological Garden are located; and the Botanical Gardens (Jardim Botânico), which dates from 1808 and displays more than 60,000 species. The Tijuca National Park, located in the Forest of Tijuca, is crossed by a road that reaches several places of touristic interest; the road also links the South and the North zones of the city.

The city of Rio de Janeiro has a number of excellent first-class hotels. The chief hotels are located in the area along the beaches. Rio's well-known carnival, which lasts for four days each year, is a traditional festival in which the people of the city actively participate. The most popular sport in Rio de Janeiro, as in Brazil as a whole, is association football (soccer); the most important matches take place in the Municipal Stadium (Estadio Municipal do Maracanã). A monumental athletic ground that was inaugurated in 1950, the stadium can seat 200,000 spectators.

(A.P.G.)

Rio Grande

The fifth longest river of North America, the Rio Grande forms the entire border between the U.S. state of Texas and Mexico, in which country it is known as the Rio Bravo del Norte. The river's basin drains an area of about 172,000 square miles (445,000 square kilometres) and has a population of about 5,000,000 persons. The Rio Grande rises as a clear, snow-fed stream more than 12,000 feet (3,700 metres) high in the Rocky Mountains of Colorado and descends across steppes and deserts, watering rich agricultural regions on its way to the Gulf of Mexico.

Exploration and early use. Probably the first Europeans to see any part of the Rio Grande were those of an expedition sent out in 1519 to survey the coast of the Gulf of Mexico. The maps that illustrated this voyage, however, show only nameless indentations on a smooth coast for the mouths of rivers. The name Rio Bravo shows up for the first time on a map of 1536 compiled by a royal Spanish cartographer. In about 1536, the Spanish explorer Álvar Núñez Cabeza de Vaca and three companions crossed the Rio Grande in their travels, and Núñez later described their river crossings in his narrative *Naufragios* (1542). The expedition led by Francisco Vázquez de Coronado in 1540 to locate rumoured rich cities to the north of Mexico resulted in encounters with various Pueblo Indian communities and explorations in the Middle Rio Grande and upper Pecos areas.

The first thorough exploration of the basin of the Rio Grande, however, was made preliminary to the mining and agricultural settlements that were founded sporadically from the latter part of the 16th century into the 18th century. The earliest settlements were mining communities in the upper Conchos drainage in 1563; intermediate was the colonization of the Upper Rio Grande area in New Mexico in 1598; and the last colonization was begun in 1749 along the Lower Rio Grande. With the Mexican explorations of Gov. Juan Bautista de Anza in the San Luis Valley of modern Colorado in 1779, the exploration of the entire Rio Grande Basin was completed. Because most of the entire narratives of exploration and the corresponding maps remained unpublished in the various archives of the Spanish government, however, historians in the United States and Europe have tended to stress later but unpublished non-Spanish explorations such as those led by Zebulon M. Pike in 1807 and by John C. Frémont in 1848–49 in the Upper Rio Grande Area.

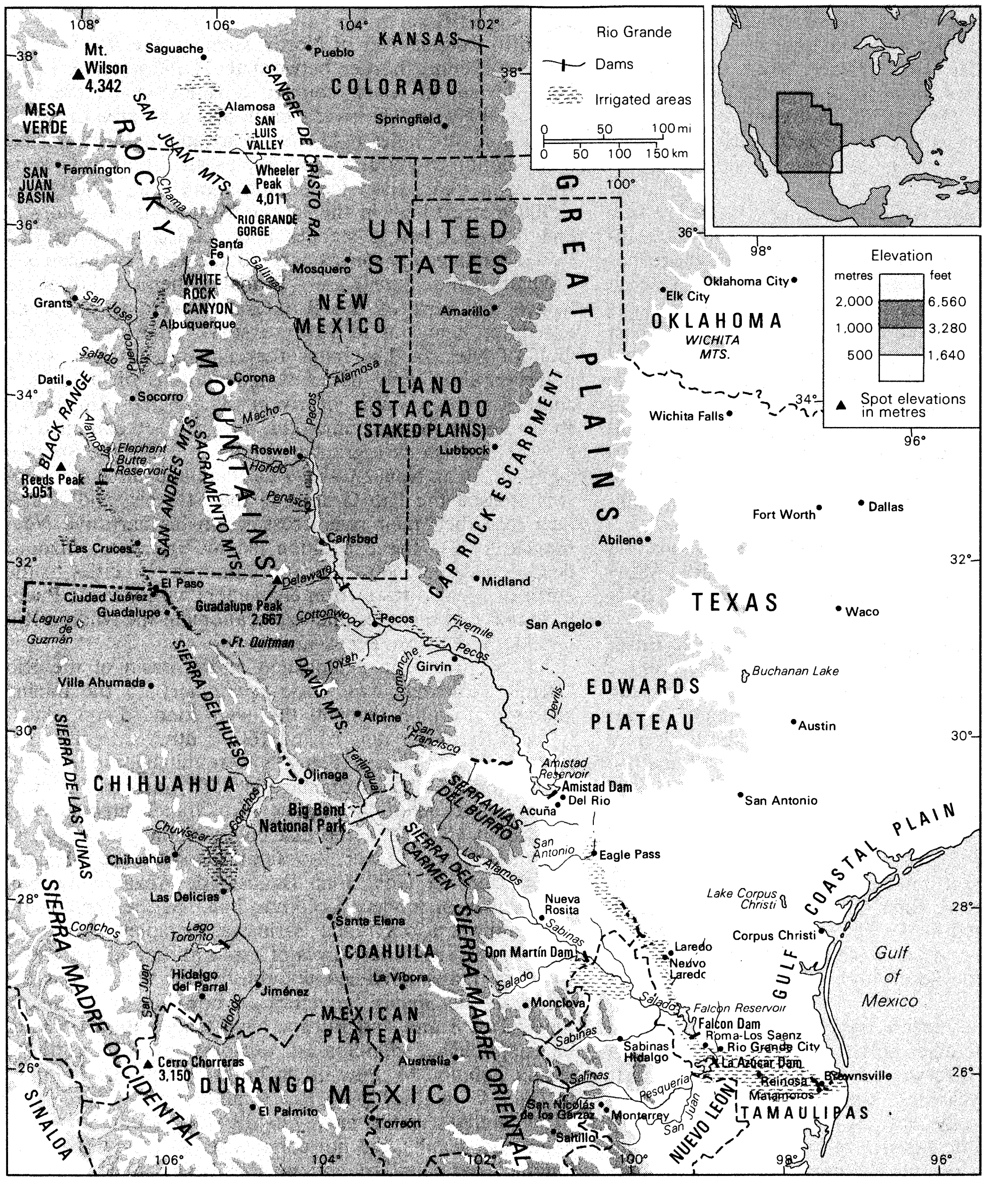
The careful scientific survey of the river, accompanied by good cartography, did not commence until the first of the international boundary commissions began its fieldwork in 1853, directed by a Mexican commissioner and surveyor and their counterparts from the United States. Small steamboats were used on the Lower Rio Grande up to Rio Grande City, and even to Roma when the river was high, from the 1850s until the great hurricane of 1874 swept the river clean of all man-made structures. Since then, accelerated erosion, silting, and sandbar formation have precluded navigation on the Rio Grande and have forced the United States and Mexico to spend much money and time in adjusting the boundary to the numerous changes in the river channel. On October 28, 1967, the United States formally returned to Mexico the Chamizal area, between El Paso and Ciudad Juarez, which a shift of the river in 1864 transferred to the left bank.

Erosion, silting, and changes in course

The river course. From its sources in the San Juan Mountains of southwestern Colorado, the Rio Grande flows southeast and south 175 miles (282 kilometres) in Colorado, southerly about 470 miles across New Mexico, and southeasterly between Texas and the Mexican states of Chihuahua, Coahuila, Nuevo Leon, and Tamaulipas for about 1,240 miles to the Gulf of Mexico. The total length of the river is approximately 1,885 miles.

Diversity of landscapes and environments

Its early course follows a canyon through forests of spruce, fir, and aspen into the broad San Luis Valley in Colorado, after which it cuts the Rio Grande Gorge and White Rock Canyon of northern New Mexico and enters the open terrain of the basin and range and the Mexican Highland physiographic provinces. There, declining elevation, decreasing latitude, and increasing aridity and temperature produce a transition from a cold steppe cli-



The Rio Grande Basin and its drainage network.

mate with a vegetation of piiion, juniper, and sagebrush to a hot steppe and desert climate characterized by mesquite, creosote bush, cactus, yucca, and other desert plants. Shortly before entering the Gulf Coastal Plain, the Rio Grande cuts three canyons between 1,500 and 1,700 feet in depth across the faulted area occupied by the "big bend," where the Texas side of the river comprises the Big Bend National Park. Along the remainder of its course the river wanders sluggishly across the Coastal Plain to end in a true delta in the Gulf of Mexico.

The principal tributaries of the Rio Grande are the Pecos, Devils, Chama, and Puerco rivers in the United States and the Conchos, Salado, and San Juan in Mexico. The peak of flow may occur in any month from April to October. In the upper reaches it usually is in May or June because of melting snow and occasional thunderstorms, whereas the lower portion commonly has its highest water in June or September because of summer rainstorms. It has been estimated that the Rio Grande has an average annual yield of more than 9,000,000 acre-feet (1,000,000 hectare metres), of which about one-third reached the Gulf before the building of the Falcon Dam, upstream from Rio Grande City, in 1953.

Human exploitation. Irrigation has been practiced in the Rio Grande Basin since prehistoric times, notably, among the ancestors of the Pueblo Indians of New Mexico. Increases in population and in the use of water made necessary the 1905–07 and 1944–45 water treaties between the United States and Mexico, as well as the Rio Grande Compact (1939) among Colorado, New Mexico, and Texas, concerning shared use of the waters of the Upper Rio Grande sub-basin (above the site of former Ft. Quitman, Texas), and the Pecos River Compact (1948) between New Mexico and Texas concerning the Pecos above Girvin, Texas. Essentially all of the average annual production of more than 3,000,000 acre-feet in the Upper Rio Grande (including the 60,000 acre-feet allotted to Mexico by treaty) is consumed within this sub-basin. Not only below Ft. Quitman but also in many stretches of the river from the New Mexico–Colorado border to below Brownsville, there has been no surface flow at various times. In some places the depth has varied from nearly 60 feet to a bare trickle or nothing. Below Ft. Quitman the Rio Grande is renewed by the Conchos and other Mexican rivers, which produce about two-thirds of the available water. A number of large springs in the area between Hot Springs in the Big Bend National Park and the town of Del Rio, Texas, including many in the bed of the river, are important and dependable producers of water.

Reservoirs and dams

The total storage capacity of the reservoirs in the basin is nearly 19,000,000 acre-feet, with a normal storage of more than 5,000,000 acre-feet, chiefly in the Falcon Reservoir on the Lower Rio Grande, Lago Toronto (La Boquilla Dam) on the Conchos, Elephant Butte on the Rio Grande in New Mexico, Marte Gómez (La Azúcar Dam) reservoir on the San Juan, and Venustiano Carranza (Don Martin Dam) on the Salado. The international Amistad Dam, below the confluence of Devils River, designed for a capacity of some 5,325,000 acre-feet, was completed in 1969 under terms of a U.S.–Mexico treaty. Considerable amounts of hydroelectricity are produced within the basin. More than 3,000,000 acres (1.200.000 hectares) are irrigated within the basin (about two-thirds of these in the United States). The leading crops raised by irrigation vary from potatoes and alfalfa in Colorado to cotton, citrus fruits, and vegetables in the valley of the deltaic Lower Rio Grande in Texas and Tamaulipas.

After agriculture and animal husbandry, the leading industries of the Rio Grande area are mining (petroleum, natural gas, coal, uranium ore. silver, lead, gold, potash, and gypsum), and recreation (national and state parks and monuments, dude ranches, fishing and hunting, summer and winter resorts). Urban communities include Monterrey, Ciudad Juárez, Chihuahua, Saltillo, Matamoros, Guadalupe, Nuevo Laredo, Reinosa, and San Nicolás de los Garzas in Mexico; Albuquerque, New Mexico; and El Paso, Laredo, and Brownsville, Texas.

(1960), the best historical treatment available of the main river and the U.S. basin—Mexican portions are treated less adequately; LAURA GILPIN, *The Rio Grande, River of Destiny: An Interpretation of the River, the Land, and the People* (1949), a satisfying book of photographs and sketch maps, with a useful text; *Report of the President's Water Resources Policy Commission: Ten Rivers in America's Future*, vol. 2, pp. 285–351 (1950), a good physical description of the basin and a good map; NORRIS HUNDLEY, JR., *Dividing the Waters: A Century of Controversy Between the United States and Mexico* (1966), a detailed discussion of the Rio Grande to 1963, featuring political aspects.

(D.D.Br.)

Rio Grande do Norte

Rio Grande do Norte, a primarily agricultural and salt-producing state in northeastern Brazil and one of the smallest of all Brazilian states, is bounded by the Atlantic Ocean on the north and east, by the State of Ceará on the west, and by the State of Paraiba on the south. Its area is 20,469 square miles (53,015 square kilometres), and its population in 1970 was 1,611,606. The state capital is Natal, so named for the date of its official founding, Christmas Day (Natal), 1599.

In this northeastern region Brazil projects farthest eastward into the Atlantic, and largely for this reason an air base at Natal became an important stop on the Allied air route to and from Africa during World War II. The airport at Parnamirim, near Natal, is still important in serving airlines in the transatlantic trade.

Physical features

The coastal strip around Natal and southward is forested, and the salt marshes in this area are economically important (the saltworks produce about 95 percent of Brazil's salt). The northern seaboard, north of Natal, is low and sandy, with dunes and coconut palms; here the deep-sea fishermen common to the Northeast—the *jangadeiros*—ride the waves in rafts formed of lightweight tree trunks and powered by small triangular sails. From this narrow coastland in the north the land rises gradually to some low mesas (*taboleiros*). Inland from Natal and the south, the land rises abruptly to the northern edge of a hilly upland known as the Planalto da Borborema, which stretches southward into the States of Paraiba and Pernambuco. In the western interior of the state are several mountain ranges.

Except for the coastland from Natal southward, where the prevailing winds from the Atlantic bring abundant rainfall to support a forest, the state is semi-arid. The rainfall is usually so slight that the few rivers—mainly the Açu (Piranhas), the Apodi, and the Potengi—flow only intermittently. Average temperatures in Natal vary from 77" to 86° F (25" to 30° C), but higher elevations are cooler.

Much of the forests that formerly existed were sacrificed to sugarcane production, but there are vast areas of carnauba trees in the lowlands and coconut palms on the coast, as well as a scattering of various other tropical trees and flora. Animal life is scarce, because hunters have reduced or wiped out most of the native species. There are, however, some armadillos, deer, rhea birds, cariama birds, raccoon, skunks, foxes, and wildcats; in the ponds and lagoons are teal, ducks, jacanas, finfoots, bitterns, and herons, as well as alligators and numerous kinds of fish.

The territory was first settled by the Portuguese in the late 16th century. As early as 1534 the Portuguese crown had considered establishing fiefdoms, or captaincies, in the region, but not until 1598, after successfully repelling local French pirates, did the Portuguese succeed in establishing the Fort of the Three Wise Kings on the future site of Natal and laying the foundation of a government. From then until 1822, when Brazil proclaimed independence, the captaincy was ruled by a succession of Portuguese commanders and governors and, for a while (1633–54), by Dutch invaders. From 1822 to 1889, as part of the Brazilian Empire, the province of Rio Grande do Norte was governed by presidents; ever since, as a state in the republic, there have been a ruling governor and legislature.

Socio-economic conditions

In the colonial period the economy centred chiefly on sugar plantations, ruled by a few wealthy families and manned largely by slaves. Cotton, introduced in the 18th century, became, and remains today, the leading crop in an economy that is basically agricultural; sugarcane, though, is still grown. Other crops include corn, rice, manioc, millet, red beans, potatoes, coconut, and cassava. Cattle and horses are also raised. In addition to the saltworks, there is some mining in the Serra de Borborema, the tungsten mines being the most important in Brazil and constituting an important export. Other mineral products include gypsum, limestone, marble, monazite, gold, and beryl. Outside of Natal and such towns as Mossoró and Caicó, socio-economic conditions are very poor, the rural working families being mostly illiterate and living in hovels on very low incomes. In the towns a measure of industrialization has improved conditions somewhat; there are now factories producing textiles, clothes, oils, leather, furniture, food, tools, plastics, ceramics, paper, and cement. Schools, hospitals, housing, and other welfare items are being expanded. There are two universities, one at Natal and one at Mossoró.

There are three railroads—from the harbour in Areia Branca to the city of Sousa, Paraiba, from the capital to São Rafael, and from Natal to Recife, the capital of Pernambuco. There are several highways—from Natal to the south of the country, cutting through various states; from the north of the country to Ceará; and from the coast to the western interior.

BIBLIOGRAPHY. Few works are devoted strictly to Rio Grande do Norte, but a considerable number deal with the northeastern region of Brazil of which it forms part. Titles particularly recommended include LUIS DA CAMARA CASCUDO, *Histdria do Rio Grande do Norte* (1955), a detailed and well-documented study by an historian native to the area; GILBERTO FREYRE, *Casa-grande y Senzala*, 5th ed., 2 vol. (1943; Eng. trans., *The Masters and the Slaves*, 2nd ed., 1956), a classic work by an internationally esteemed scholar in the field of anthropology that describes a Brazilian family of the northeast as it existed in colonial times; and *Sobrados e Mucambos*, 2nd ed., 3 vol. (1951), a continuation of the preceding study, describing the transformation of rural patriarchal society as a result of growing urbanization; SERGIO BUARQUE DE HOLANDA, *História Geral da Civilização Brasileira*, vol. 1, *A Epoca Colonial* (1960), traces in detail the colonization and subsequent development of the northeast (as well as other areas) during the colonial period, written in a popular style; and ANTONIO DA SILVA MELLO, *Nordeste Brasileiro*, 2nd ed. (1964), a panoramic view of the complexities of the area, written by an outstanding scholar.

(J.E.F.P.)

Rio Grande do Sul

The southernmost state *(estado)* of Brazil, Rio Grande do Sul is bordered by the State of Santa Catarina on the north, Argentina on the west, Uruguay on the south, and the Atlantic Ocean on the east. It covers about 108,951 square miles (282,184 square kilometres), or 3 percent of the nation's total area. The population early in the 1970s was over 6,750,000. The capital of PBrto Alegre is the state's main industrial area and port. The state is a major agricultural and livestock region. Poor in mineral resources it also has little industrial development. (For a related article see BRAZIL.)

History. The state was originally thinly inhabited by Tupi-Guarani, Ge, and Guaicurú Indians. It was first explored and colonized by the Portuguese during the late 17th century. Long disputed between Spain and Portugal, the region was the site of intermittent warfare between 1754 and 1870. The state was also wracked by wars of secession during the 19th century. (For further discussion of the state's history see BRAZIL, HISTORY OF.)

Relief features

The environment. The north occupies part of the Paraná Plateau, which is composed of outpourings of basaltic lava solidified into sheets of rock known as diabase. The plateau stands between 2,000 and 3,000 feet (600 and 900 metres) above sea level. It has been dissected into rolling hills by streams, but its margins are marked by steep cliffs. Cliffs also cap the Serra Geral, the southern extremity of the Serra do Mar—the eastern edge of the Brazilian Highlands—along the Atlantic coast. North of PBrto Alegre, the cliffs turn westward and descend southward along the Rio Jacui Valley.

In the south, the Rio Jacui and its tributary, the Taquari, drain a lowland along the base of the plateau. South of the river, gently rolling hills stand between 1,000 and 1,500 feet in elevation. West of Livramento are tabular landforms of diabase; the Uruguay River cuts through the diabase and is broken by rapids. The coast is lined with sandbars and lagoons including the Lagoa dos Patos and Lagoa Mirim.

The climate is generaliy mild. In winter, cold air masses from the south bring heavy rains and occasional snow to the higher elevations. In summer the prevailing northeast winds bring less precipitation and hot weather, especially inland. Temperatures range from a minimum of 18° F (−8° C) to a maximum of 109" F (43" C), with an annual average of 68° F (20" C). Precipitation measures about 52 inches (1,300 millimetres) annually.

Most of the state is tall-grass prairie, with pine and tropical forests in the higher altitudes and deeper river valleys. Animal life includes deer, rodents, otters, armadillos, monkeys, and porcupines, but there are no large wild mammals. Of the abundant birdlife, the Brazilian lapwing is common. There are about 40 species of snakes, five of which are poisonous. Coastal and inland waters abound with fish (anchovies, dolphins, king fish, flat fish, mullet) and shrimp.

The population. The state's 6,755,000 inhabitants include descendants of the Portuguese in the Jacui Valley, Germans on the lower slopes of the Paraná Plateau and above the Jacui, and Italians on the plateau. There are also descendants of Polish and other European immigrants. About 6 percent of the population is composed of blacks and mulattos (persons of mixed white and black ancestry), and there is a small number of Indians in the northwest and Asians.

The main language is Portuguese. About 80 percent of the people are adherents of Roman Catholicism; other Christian denominations are also represented.

Administration and social conditions. As a federated state of Brazil, Rio Grande do Sul is governed by its own constitution, based on that of the federal government. Governmental powers are divided among the executive, legislative, and judicial branches. Local government is carried out through more than 230 municipalities.

Educational services include primary, secondary, and technical schools and several universities such as the Universidade Federal do Rio Grande do Sul (founded in 1934) and the Universidade Católica de Pelotas (1960). About 27 percent of the population is illiterate.

Role as the "Granary of Brazil"

The economy. The region was long known as the "Granary of Brazil." About 25 percent of Brazil's rice is raised on the floodplain of the Jacui and Taquari rivers. Wheat and maize (corn) are grown on the Paraná Plateau and the terraces above the Jacui. Other crops include grapes and tobacco. The southern plains serve as vast pastures for the state's livestock industry. Herds of cattle and sheep are tended by the gauchos, the herdsmen of the Llanos, whose animals feed across the vast unimproved pasturelands of the plains and produce mainly a lean, tough meat. Pigs are also raised.

Industrialization did not reach the south until the 1930s, and the state contributes only a small portion of the national industrial output. Industries are concentrated at PBrto Alegre, Rio Grande, and Pelotas. Coal is mined at São Jerônimo on the Rio Jacui and shipped downstream to PBrto Alegre; it is used to generate electricity and manufacture gas.

Transportation. The state is served by about 106,000 miles (171,000 kilometres) of roads. There are 2,500 miles (4,000 kilometres) of railways. The main line runs west from PBrto Alegre through Santa Maria and Alegrete to the Argentine border at Uruguaiana. Branch lines run north to São Paulo state, south to the Uruguay border, and southeast to the port of Rio Grande.

There are about 800 miles of inland waterways on the Jacui and Taquari rivers and the Lagoa dos Patos. There is also shipping along the state's 390-mile ocean coastline. The busy network of airports serves more than 30 cities.

Cultural life. Folkloric tradition centres upon the near-legendary courage, generosity, and romantic chivalry of the gaucho and his life under the wide skies of the plains. The Museu "Julio de Castilhos" in PBrto Alegre contains exhibits of national history and Indian artefacts, and the Museu Oceanogrbfico is located in Rio Grande. There are public libraries in Pelotas, PBrto Alegre, and Rio Grande.

Ritschl, Albrecht

A German Lutheran theologian, Albrecht Ritschl initiated and, with his followers, led one of the most significant Christian movements in the years between 1875 and 1918, first in Germany and subsequently in the Anglo-Saxon world. Ritschl's interpretation of Christianity was influential because he was able to synthesize the teaching of the Scriptures and of the Protestant Reformation with some aspects of modern knowledge so as to show both the religious and ethical relevance of the Christian faith.

Early life and career

Ritschl was born in Berlin on March 25, 1822. His father and grandfather were Lutheran clergymen, and his lifelong interest in the Protestant Reformation was due, in part, to his family background. He completed both his secondary schooling and university theological studies with distinction. Ritschl was apparently well suited for his vocation intellectually, temperamentally, and by virtue of his education. In addition, his father had inculcated in him a strong sense of duty, the fear of 'God, and humility.

Ritschl was trained in theology and philosophy at the universities of Bonn (1839–41) and Halle (1841–43). He moved gradually from a more conservative, traditional theological position to a more liberal one. This shift was precipitated, in part, by the influence of the philosophy of G.W.F. Hegel upon most of Ritschl's generation. While a student Ritschl studied the classical theological disciplines and also developed a special interest in the doctrine of the redemptive work of Jesus Christ and, more specifically, the doctrine of the Atonement—that Christ died for man's sins. Other German philosophers, in addition to Hegel, influenced Ritschl: Immanuel Kant (1724–1804) and Friedrich Schleiermacher (1768–1834), the father of liberal Protestantism. After receiving his doctorate in 1843, Ritschl joined the ranks of the Tübin-

Ritschl.

gen school, a dominant theological movement involved in reconstructing the origins of Christianity and the early history of the church and its theology.

Works and significance

Ritschl taught at the University of Bonn (1846–64) and at Gottingen from 1864 until his death on March 20, 1889. His first significant publication, ***Die Entstehung der altkatholischen Kirche*** ("The Origin of the Old Catholic Church"; 1850, 2nd ed. 1857), revealed both his initial indebtedness to and gradual breach with the Tübingen school, which, in their analysis of the early history of Christianity, he found too indebted to Hegelian presuppositions.

In his interpretation of Christianity, Ritschl interacted with the Scriptures, the whole history of the church and its theology, and, especially, with the theology of Martin Luther and the confessions of the Reformation, as well as with the philosophical methodology and ethics of Kant and the theology of Schleiermacher. Virtually all of his research came to fulfillment in his major work, ***Die christliche Lehre von der Rechtfertigung und Versohnung (The Christian Doctrine of Justification and Reconciliation),*** published in three volumes (1870–74); it deals, respectively, with the historical and biblical materials (vols. 1–2) and with Ritschl's own reconstruction (vol. 3). Ritschl depicted Christianity as an ellipse with two focuses; namely, (1) the reconciliation established between God and man through the divine love manifested in the life and death of Jesus and (2) the Kingdom of God as the goal toward which all of God's activities are directed. Ritschl stressed the significance of the Kingdom of God in the teaching of Jesus and was critical of Protestantism's neglect of the Kingdom.

Over against Protestant Pietism, which emphasized the spiritual piety of the individual from a rather antiworldly perspective, Ritschl argued persuasively for the ethical development of man in his individual and corporate life. If man's forgiveness (justification) represents the religious pole of Christianity, reconciliation—which has to do with the practical consequences of justification—represents the ethical pole. Forgiveness of sin should give rise to a new life-style marked by doing God's will in both the personal and social spheres, thereby advancing the growth of the Kingdom of God (the brotherhood of all men united by the love of God) in society.

Ritschl was both esteemed and vilified by critics both during and after his lifetime. The dominant 20th-century Protestant movement known as Neo-orthodoxy, which restated Reformation principles such as justification and grace, attacked Ritschl as an advocate of cultural Christianity—the identification of Christianity with prevailing cultural norms. Contemporary reassessments of 19th-century theology are, however, more appreciative of Ritschl's interpretation of Christianity and the Kingdom of God and of their relevance to man's personal and corporate existence.

BIBLIOGRAPHY. OTTO RITSCHL, ***Albrecht Ritschls Leben,*** 2 vol. (1892–96), is the definitive biography by Ritschl's son; contains a complete bibliography of Albrecht Ritschl's writings from 1842–89. English translations of these writings include: ***A Critical History of the Christian Doctrine of Justification and Reconciliation,*** trans. *by* JOHN S. BLACK (1872); ***The Christian Doctrine of Justification and Reconciliation: The Positive Development of the Doctrine,*** 2nd ed., trans. by H.R. MAC [illegible] A.B. MACAULAY 19[illegible] reprinted 1966) and 'Instruction in th[illegible] Christi[illegible] [illegible]eli[illegible] trans. by ALICE MEAD SWING, in ALBERT T. SWING, ***The Theology of Albrecht Ritschl*** (1901). Works discussing his theology are: ALFRED E. GARVIE, ***The Ritschlian Theology,*** 2nd ed. (1902), a standard treatment; PHILIP HEFNER, ***Faith and the Vitalities of History*** (1966), an analysis of aspects of Ritschl's theology and Hefner's suggestions concerning a viable theological method (bibliography included); GOSTA HOK, ***Die elliptische Theologie Albrecht Ritschls*** (1942), the best treatment of Ritschl's theological method; includes an extensive bibliography of secondary sources; DAVID L. MUELLER, ***An Introduction to the Theology of Albrecht Ritschl*** (1969), an assessment of the major lines of Ritschl's theology including a statement concerning his relevance today; and ROLF SCHAFER, ***Ritschl*** (1968), a new analysis including current bibliography.

(D.L.M.)

Ritual

Exhibited by all known societies, ritual is a specific, observable kind of behaviour based upon established or traditional rules. It is thus possible to view ritual as a way of defining or describing man.

Parallel between man's ritual and verbal behaviour

Nature and significance. Man is sometimes described or defined as a basically rational, economic, political, or playing species. Man may, however, also be viewed as a ritual being, who exhibits a striking parallel between his ritual and verbal behaviour. Ritual, a pervasive kind of behaviour, can be seen as basic to the understanding of man. Just as language is a symbolic system based upon arbitrary rules, ritual may be viewed as a symbolic system of acts based upon arbitrary rules.

The intricate, yet complex, relation between ritual and language can be seen in the history of various attempts to explain ritual behaviour. In most explanations, language becomes a necessary factor in the theory concerning the nature of ritual, and the specific form of language that is tied to explanations of ritual is the language of myth. Both myth and ritual remain fundamental to any analysis of religions.

Three general approaches to a theory about the nature and origin of ritual prevail.

The origin approach. The earliest approach was an attempt to explain ritual, as well as religion, by means of a theory concerned with historical origin. In most cases, this theory also assumed an evolutionary hypothesis that would explain the development of ritual behaviour through history. The basic premise, or law, for this approach is that ontogeny (development of an individual organism) recapitulates phylogeny (evolution of a related group of organisms), just as the human embryo recapitulates one stage of human evolutionary history in the womb; *e.g.*, the gill stage. The solution to explaining the apparently universal scope of ritual depended upon the success in locating the oldest cultures and cults. Scholars believed that if they could discover this origin, they would be able to explain the contemporary rituals of man.

Early emphasis on sacrifice

There are almost as many solutions as authors in this approach. In the search for an origin of ritual, research turned from the well-known literate cultures to those that appeared to be less complex and preliterate. The use of the terms primitive religion and primitive cultures comes from this approach in seeking an answer to the meaning of ritual, myth, and religion. Various cultures and rituals were singled out, sacrifice of either men or animals becoming one of the main topics for speculation, though the exact motivation or cause of sacrificial ritual was disputed among the leading authors of the theory. For W. Robertson Smith, a British biblical scholar who first published his theory in the ninth edition of *Encyclopædia*

Britannica (1875–89), sacrifice was motivated by the desire for communion between members of a primitive group and their god. The origin of ritual, therefore, was believed to be found in totemic (animal symbolic clan) cults; and totemism, for many authors, was thus believed to be the earliest stage of religion and ritual. The various stages of ritual development and evolution, however, were never agreed upon. Given this origin hypothesis, rituals of purification, gift giving, piacular (expiatory) rites, and worship were viewed as developments, or secondary stages, of the original sacrificial ritual. The Christian Eucharist (Holy Communion), along with contemporary banquets and table etiquette, were explained as late developments or traits that had their origin and meaning in the totemic sacrifice.

The influence of Robertson Smith's theory on the origin of ritual can be seen in the works of the English anthropologist Sir James Frazer, the French sociologist Émile Durkheim, and Sigmund Freud, the father of psychoanalysis. Though they were not in complete agreement with Smith, sacrifice and totemism remained a primary concern in their search for the origin of religion. For Frazer, the search led to magic, a stage preceding religion. Both Smith and Frazer led Durkheim to seek the origin of ritual and religion in totemism as exemplified in Australia. Durkheim believed that in totemism scholars would find the original form of ritual and the division of experience into the sacred and the profane. Ritual behaviour, they held, entails an attitude concerned with the sacred; and sacred acts and things, therefore, are nothing more than symbolic representations of society. In his last published work, *Moses and Monotheism,* Freud also remained convinced that the origin of religion and ritual is to be found in sacrifice.

The functional approach. The second approach to explaining ritual behaviour is certainly indebted to the work of such men as Smith, Freud, and Durkheim. Yet very few, if any, of the leading contemporary scholars working on the problems of religion, ritual, and myth begin with a quest for origins. The origin-evolutionary hypothesis of ritual behaviour has been rejected as quite inadequate for explaining human behaviour because no one can verify any of these bold ideas; they remain creative speculations that cannot be confirmed or denied.

Turning from origin hypotheses, scholars next emphasized empirical data gathered by actual observation. Contemporary literature is rich in descriptions of rituals observed throughout the world. If the term origin can be used as central to the first approach, the term function can be used as indicative of the primary focus of the second approach. The nature of ritual, in other words, is to be defined in terms of its function in a society.

Individual needs and social equilibrium

The aim of functionalism is to explain ritual behaviour in terms of individual needs and social equilibrium. Ritual is thus viewed as an adaptive and adjustive response to the social and physical environment. Many leading authorities on religion and ritual have taken this approach as the most adequate way to explain rituals. Bronisław Malinowski, A.R. Radcliffe-Brown, E.E. Evans-Pritchard, Clyde Kluckhohn, Talcott Parsons, and Edmund Leach, all English or American anthropologists, have adopted a functional approach to explain ritual, religion, and myth.

Most functional explanations of ritual attempt to explain this behaviour in relation to the needs and maintenance of a society. The strengths of this approach are dependent upon a claim that it is both logical and empirical. It is a claim, however, that is open to serious criticism. If the aim of functionalism is to explain why rituals are present in a society, it will be necessary to clarify such terms as need, maintenance, and a society functioning adequately, and this becomes crucial if they are to be taken as empirical terms. From a logical point of view, functionalism remains a heuristic device, or indicator, for describing the role of ritual in society. If it is asserted that a society functions adequately only if necessary needs are satisfied; and if it is further asserted that ritual does satisfy that need, scholars cannot conclude that, therefore, ritual is present in that society without committing the logical fallacy of affirming the consequent. To assert that the need is satisfied "if and only if" ritual is present is a tautology and a reversal of the claim to be empirical.

The history of religions approach. A third approach to the study of ritual is centred on the studies of historians of religion. The distinction between this approach and the first two is that though many historians of religions agree with functionalists that the origin-evolutionary theories are useless as hypotheses, they also reject functionalism as an adequate explanation of ritual. Most historians of religions, such as Gerardus van der Leeuw in The Netherlands, Rudolf Otto in Germany, Joachim Wach and Mircea Eliade in the United States, and E.O. James in England, have held the view that ritual behaviour signifies or expresses the sacred (the realm of transcendent or ultimate reality). This approach, however, has never been represented as an explanation of ritual. The basic problem with it remains that it cannot be confirmed unless scholars agree beforehand that such a transcendent reality exists (see also RELIGION, STUDY OF).

Functions of ritual. Ritual behaviour, established or fixed by traditional rules, has been observed the world over and throughout history. In the study of this behaviour, the terms sacred (the transcendent realm) and profane (the realm of time, space, and cause and effect) have remained useful in distinguishing ritual behaviour from other types of action.

The sacred and the profane

Although there is no consensus on a definition of the sacred and the profane, there is common agreement on the characteristics of these two realms by those who use the terms to describe religions, myth, and ritual. For Durkheim and others who use these terms, ritual is a determined mode of action. According to Durkheim, the reference, or object, of ritual is the belief system of a society, which is constituted by a classification of everything into the two realms of the sacred and the profane. This classification is taken as a universal feature of religion. Belief systems, myths, and the like, are viewed as expressions of the nature of the sacred realm in which ritual becomes the determined conduct of the individual in a society expressing a relation to the sacred and the profane. The sacred is that aspect of a community's beliefs, myths, and sacred objects that is set apart and forbidden. The function of ritual in the community is that of providing the proper rules for action in the realm of the sacred as well as supplying a bridge for passing into the realm of the profane.

Although the distinction between the sacred and profane is taken as absolute and universal, there is an almost infinite variation on how this dichotomy is represented—not only between cultures but also within a culture. What is profane for one culture may be sacred to another. This may also be true, however, within a culture. The relative nature of things sacred and the proper ritual conducted in relation to the sacred as well as the profane varies according to the status of the participants. What is set apart, or holy, for a sacred king, priest, or shaman (a religious personage having healing and psychic transformation powers), for example, will differ from the proper ritual of others in the community who are related to them, even though they share the same belief systems. The crucial feature that both sustains these relations and sets their limits is the ritual of initiation.

Three further characteristics are generally used to specify ritual action beyond that of the dichotomy of sacred and profane thought and action. The first characteristic is a feeling or emotion of respect, awe, fascination, or dread in relation to the sacred. The second characteristic of ritual involves its dependence upon a belief system that is usually expressed in the language of myth. The third characteristic of ritual action is that it is symbolic in relation to its reference. Agreement on these characteristics can be found in most descriptions of the functions of ritual.

The scholarly disputes that have arisen over the functions of ritual centre around the exact relation between ritual and belief or the reference of ritual action. There is little agreement, for example, on the priority of ritual or myth. In some cases, the distinction between ritual, myth, and belief systems is so blurred that ritual is taken to include myth or belief (see also SACRED OR HOLY; MYTH AND MYTHOLOGY).

The variety of ritual references

The function of ritual depends upon its reference. Once again, although there is common agreement about the symbolic nature of ritual, there is little agreement with respect to the reference of ritual as symbolic. Ritual is often described as a symbolic expression of actual social relations, status, or the role of individuals in a society. Ritual is also described as referring to a transcendent, numinous (spiritual) reality and to the ultimate values of a community.

Whatever the referent, ritual as symbolic behaviour presupposes that the action is nonrational. That is to say, the means–end relation of ritual to its referent is not intrinsic or necessary. Such terms as latent, unintended, or symbolic are often used to specify the nonrational function of ritual. The fundamental problem in all of this is that ritual is described from an observer's point of view. Whether ritual man is basically nonrational or rational, as far as his behaviour and his belief system are concerned, is largely dependent upon whether he also understands both his behaviour and belief to be symbolic of social, psychological, or numinous realities. It is difficult to imagine a Buddhist, a Christian, or an Australian aborigine agreeing that his ritual action and beliefs are nothing but symbols for social, psychological, or ultimate realities. The notion of the sacred as a transcendent reality may, however, come closest to the participant's own experience. The universal nature of the sacred-profane dichotomy, however, remains a disputed issue.

What is needed is a new theory that will overcome the basic weaknesses of functional descriptions of ritual and belief. Until such a time, ritual will remain a mystery. The progress made in the study of language may be of help in devising a more adequate explanation of nonverbal behaviour in general and of ritual in particular.

Types of ritual. Because of the complexities inherent in any discussion of ritual, it is often useful to make distinctions by means of typology. Although typologies do not explain anything, they do help to identify rituals that resemble each other within and across cultures.

Imitative. All rituals are dependent upon some belief system for their complete meaning. A great many rituals are patterned after myths. Such rituals can be typed as imitative rituals in that the ritual repeats the myth or an aspect of the myth. Some of the best examples of this type of ritual include rituals of the New Year, which very often repeat the story of creation. In a passage from an Indian *Brāhmaṇa* (a Hindu scripture) the answer to the question of why the ritual is performed is that the gods did it this way "in the beginning." Rituals of this imitative type can be seen as a repetition of the creative act of the gods, a return to the beginning.

The "myth-ritual" school

This type of myth has led to a theory that all rituals repeat myths or basic motifs in myths. A version of this line of thought, often called "the myth-ritual" school, is that myth is the thing said over ritual. In other words, myths are the librettos for ritual. The works of such scholars as Jane Harrison and S.H. Hooke are examples of this theory. Although it cannot be denied that some rituals explicitly imitate or repeat a myth (*e.g.*, a myth of creation), it cannot be maintained that all rituals do so. The ritual pattern of the ancient Near East, which Hooke considers basic to the festival celebrating the creation, is itself a typological construction. In any case, al-, though there is a combat and killing narrated in the festival myth, no known evidence exists of ritual killing or of king-sacrifice in the ancient Near East. Nevertheless, some rituals do repeat the story of a myth and represent an important type of ritual behaviour, even though the type cannot be universalized as a description of all ritual action.

Positive and negative. Rituals may also be classified as positive or negative. Most positive rituals are concerned with consecrating or renewing an object or an individual, and negative rituals are always in relation to positive ritual behaviour. Avoidance is a term that better describes the negative ritual; the Polynesian word *tabu* (English, taboo) also has become popular as a descriptive term for this kind of ritual. The word taboo has been applied to those rituals that concern something to be avoided or forbidden. Thus, negative rituals focus on rules of prohibition, which cover an almost infinite variety of rites and behaviour. The one characteristic they all share, however, is that breaking the ritual rule results in a dramatic change in ritual man, usually bringing him some misfortune.

Variation in this type of ritual can be seen from within a culture as well as cross-culturally. What is prohibited for a subject, for example, may not be prohibited for a king, chief, or shaman. Rituals of avoidance also depend upon the belief system of a community and the ritual status of the individuals in their relation to each other. Contact with the forbidden or transgression of the ritual rules is often offset by rituals of purification.

Negative ritual, as noted above, is always in polarity with positive ritual. The birth of a child, the consecration of a king, a marriage, or a death are ritualized both positively and negatively. The ritual of birth or death involves the child or corpse in a ritual that, in turn, places the child or the corpse in a prohibitive status and thus to be avoided by others. The ritual itself, therefore, determines the positive or negative characteristic of ritual behaviour.

Sacrificial. Another type of ritual is classified as sacrificial. Its importance can be seen in the assessment of sacrificial ritual as the earliest or elementary form of religion (see also SACRIFICE).

Differentiation between sacrifice and other ritual acts

The significance of sacrifice in the history of religions is well documented. One of the best descriptions of the nature and structure of sacrifice is to be found in *Essai sur la nature et le fonction du sacrifice,* by the French sociologists Henri Hubert and Marcel Mauss, who differentiated between sacrifice and rituals of oblation, offering, and consecration. This does not mean that sacrificial rituals do not at times have elements of consecration, offering, or oblation but these are not the distinctive characteristics of sacrificial ritual. Its distinctive feature is to be found in the destruction, either partly or totally, of the victim. The victim need not be human or animal; vegetables, cakes, milk, and the like are also "victims" in this type of ritual. The total or partial destruction of the victim may take place through burning, dismembering or cutting into pieces, eating, or burying.

Hubert and Mauss have provided a very useful structure for dividing this type of ritual into subtypes. Though sacrificial rituals are very complex and diverse throughout the world, nevertheless, they can be divided into two classes: those in which the participant or participants receive the benefit of the sacrificial act and those in which an object is the direct recipient of the action. This division highlights the fact that it is not just individuals who are affected by sacrificial ritual but in many instances objects such as a house, a particular place, a thing, an action (such as a hunt or war), a family or community, or spirits or gods that become the intended recipients of the sacrifice. The variety of such rituals is very extensive, but the unity in this type of ritual is maintained in the "victim" that is sacrificed.

Life crisis. Any typology of rituals would not be complete without including a number of very important rites that can be found in practically all religious traditions and mark the passage from one domain, stage of life, or vocation into another. Such rituals have often been classified as rites of passage, and the French anthropologist Arnold van Gennep's study of these rituals remains the classic book on the subject.

The basic characteristic of the life-crisis ritual is the transition from one mode of life to another. Rites of passage have often been described as rituals that mark a crisis in individual or communal life. These rituals often define the life of an individual. They include rituals of birth, puberty (entrance into the full social life of a community), marriage, conception, and death. Many of these rituals mark a separation from an old situation or mode of life, a transition rite celebrating the new situation, and a ritual of incorporation. Rituals of passage do not always manifest these three divisions; many such rites stress only one or two of these characteristics.

Rituals of initiation

Rituals of initiation into a secret society or a religious vocation (viz., priesthood, ascetic life, medicine man) are often included among rites of passage as characteristic rituals of transition. The great New Year's rituals known throughout the world also represent the characteristic passage from old to new on a larger scale, that includes the whole society or community.

One of the dominant motifs of the life-crisis ritual is the emphasis on separation, as either a death or a return to infancy or the womb. In India, a striking example is the Hindu rite of being "twice born." The young boy who receives the sacred thread in the *upanayana* ritual, a ceremony of initiation, goes through an elaborate ritual that is viewed as a second birth. Rituals such as Baptism in early Christianity, Yoga in India, and the complex puberty rituals among North American Indian cultures exemplify this motif of death and rebirth in rites of passage.

Rituals of crisis and passage are often classified as types of initiation. An excellent description of such rites is found in *Birth and Rebirth* by Mircea Eliade. From Eliade's point of view, rituals, especially initiation rituals, are to be interpreted both historically and existentially. They are related to the history and structure of a particular society and to an experience of the sacred that is both transhistorical and transcendent of a particular social or cultural context. Culture, from this perspective, can be viewed as a series of cults, or rituals, that transform natural experiences into cultural modes of life. This transformation involves both the transmission of social structures and the disclosure of the sacred and spiritual life of man.

Initiation rituals can be classified in many ways. The patterns emphasized by Eliade all include a separation or symbolic death, followed by a rebirth. They include rites all the way from separation from the mother to the more complex and dramatic rituals of circumcision, ordeals of suffering, or a descent into hell, all of which are symbolic of a death followed by a rebirth. Rites of withdrawal and quest, as well as rituals characteristic of shamans and religious specialists, are typically initiatory in theme and structure. Some of the most dramatic rituals of this type express a death and return to a new period of gestation and birth and often in terms that are specifically embryological or gynecological. Finally, there are the actual rituals of physical death itself, a rite of passage and transition into a spiritual or immortal existence.

The various typologies of ritual that can be found in texts on religion and culture often overlap or reveal a common agreement in the way in which ritual behaviour can be classified. There is a striking contrast in the use of these typologies to interpret the meaning of ritual. In general, this contrast can be described in terms of two positions: the first emphasizes the sociopsychological function of ritual; the second, although not denying the first, asserts the religious value of ritual as a specific expression of a transcendental reality.

Nonverbal communication and meaning

Conclusion. Ritual behaviour is obviously a means of nonverbal communication and meaning. This aspect of ritual is often overlooked in the stress on the relation of ritual to myth. Thus, the meaning of ritual is often looked for in the verbal, spoken, or belief system that is taken as its semantic correlate. The spoken elements in a ritual setting do often reveal the meaning of a ritual by reference to a belief system or mythology, but not always. Such a connection has led to an overemphasis on the importance of the belief system or myth over ritual. To assert that myths disclose more than ritual ever can is an oversimplification of the complex correlation of these two important aspects of religion. A partial explanation of this emphasis is undoubtedly the fact that a vast amount of data, both primary and secondary, is literary in form. Theories about ritual are either deduced from the primary literature of a religious tradition or are translated into written language as a result of observation.

Ritual can be studied as nonverbal communication disclosing its own structure and semantics. Scholars have only recently turned to a systematic analysis of this important aspect of human behaviour; and progress in kinesics, the study of nonverbal communication, may provide new approaches to the analysis of ritual. This development may well parallel the progress in linguistics and the analysis of myth as an aspect of language.

A complete analysis of ritual would also include its relation to art, architecture, and the specific objects used in ritual such as specific forms of ritual dress. All of these components are found in ritual contexts, and all of them are nonverbal in structure and meaning.

Significance of "sacred time" and "sacred space"

Most rituals mark off a particular time of the day, month, year, stage in life, or commencement of a new event or vocation. This temporal characteristic of ritual is often called "sacred time." What must not be forgotten in the study of ritual is a special aspect of ritual that is often described as "sacred space." Time and place are essential features of ritual action, and both mark a specific orientation or setting for ritual. Time and space, whether a plot of ground or a magnificent temple, are ritually created and become, in turn, the context for other rituals. Examples of ritual time and ritual space orientation can be found in the rituals for building the sacrifice in Brahmanic Indian ritual texts; for the building of a Hindu temple or a Christian cathedral; and for consecrating those structures that symbolize a definite space-time orientation in which rituals are enacted. The shape, spatial orientation, and location of the ritual setting are essential features of the semantics of ritual action.

When particular ritual objects, dances, gestures, music, and dress are included in the study of ritual, the total structure and meaning of ritual behaviour far exceed any one description or explanation of ritual man. Most descriptions are selective and are dependent upon the theory and intent with which rituals are to be studied.

In recent years there has been little consensus among scholars on an adequate theory, or framework, for explaining or describing ritual. Though the term has often been used to describe the determined, or fixed, behaviour of both animals and men, the future study of ritual may disclose that this behaviour, found throughout history and cultures, is as unique to man as his capacity for speaking a language and that change in ritual behaviour is parallel to, or correlated with, change in language. Although great progress has been made in the analysis of man as the species who speaks, the syntax and semantics of ritual man are yet to be discovered.

BIBLIOGRAPHY. WILLIAM LESSA and EVON Z. VOGT, *Reader in Comparative Religion,* 3rd ed. (1971), is the best general anthology on classical and modern positions on religion, ritual, and myth (mainly concerned with nonliterate cultures). The *Reader* also includes an excellent bibliography. *Gods and Rituals,* ed. by JOHN MIDDLETON (1967), contains a good collection of essays on ritual practices in nonliterate cultures, with a fine bibliography for further study. Among the classic texts dealing with the origin of ritual and religion, there are three authors who remain important because of their enduring influence: W. ROBERTSON SMITH, *Lectures on the Religion of the Semites* (1889); EMILE DURKHEIM, *Les Formes élémentaires de la vie religieuse* (1912; Eng. trans., *The Elementary Forms of the Religious Life,* 1915); and SIGMUND FREUD, *Totem und Tabu* (1913; Eng. trans., *Totem and Taboo,* 1918). Among the classic positions on a functional approach to ritual are those of BRONISLAW MALINOWSKI, in his *Coral Gardens and Their Magic, 2* vol. (1935); and A.R. RADCLIFFE-BROWN, *The Andaman Islanders* (1922). Among more recent anthropological texts, E.E. EVANS-PRITCHARD, *Nuer Religion* (1956); and EDMUND LEACH, *Political Systems of Highland Burma* (1954), are very good examples of the continued development of the functional approach. MELFORD E. SPIRO, *Burmese Supernaturalism* (1967), is one of the best critical texts using data from Burmese Buddhism as support for a revised approach. VICTOR W. TURNER, *The Forest of Symbols* (1967), represents a novel analysis of dominant symbols in belief and ritual. Among valuable approaches by theologians and historians of religion are RUDOLF OTTO, *Das Heilige* (1917; Eng. trans., *The Idea of the Holy,* 1923); and JOACHIM WACH, *The Comparative Study of Religions* (1958). JANE E. HARRISON, *Themis,* 2nd ed. rev. (1927); and S.H. HOOKE (ed.), *Myth, Ritual and Kingship* (1958), are the best examples of the myth-ritual school. An excellent critique of this school may be found in JOSEPH E. FONTENROSE, *The Ritual Theory of Myth* (1966). HENRI HUBERT and MARCEL MAUSS, *Essai sur la nature et le fonction du sacrifice*

(1899; Eng. trans., ***Sacrifice: Its Nature and Function*** (1964), remains the standard analysis of sacrifice as ritual; and ARNOLD VAN GENNEP, ***Les Rites du passage*** (Eng. trans. 1960), although written in 1909, continues to remain an important work on ritual as passage. MIRCEA ELIADE, ***Birth and Rebirth*** (1958), is an excellent study of ritual as initiation from a history of religions viewpoint; has a good bibliography.

(Ha.P.)

River Deltas

Deltas are low-lying plains composed of stream-borne sediments deposited by a river at its mouth as it enters the sea. Some 2,500 years ago, Herodotus recognized that the land bound by the seaward-diverging distributary branches of the Nile and the sea was deltoid in shape; and so used the Greek letter Δ (delta) to describe it. Although many of the world's great deltas are deltoid or triangular in shape, notable exceptions occur; often the delta shape is controlled by the outline of the water body being filled. For this reason, the term delta is now normally applied, without reference to shape, to the exposed and submerged plain formed by a river at its mouth.

Deltas are widely distributed; they form along the coasts of virtually every landmass on the globe and occur in all climatic regions, from harsh arctic and desert climates to humid tropical and temperate zones (Table). Of the larger deltas in the world, 11 are located in the U.S.S.R., 7 are in Southeast Asia, 6 are in South America, and 4 each are in Africa and North America.

Deltas display enormous variety in size, shape, structure, composition, and genesis. These differences result from the same event taking place in a wide range of settings. Numerous factors influence the character of a delta; the more important are: (1) geologic setting and sediment sources in the drainage basin, (2) climatic conditions, (3) tectonic stability (magnitude and frequency of uplift), (4) river slope and flooding characteristics, (5) intensities of depasitional and erosional processes, and (6) tidal range and offshore energy conditions. Combinations of these factors and time result in the wide variety of modern deltas and their changing configurations.

Deltas have been important to mankind since prehistoric times. The abundant wildlife and edible plants in deltaic areas attracted early man. Mazes of interconnecting waterways provided natural avenues for communication and trade. Sands, silts, and clays deposited by floodwaters were extremely productive; and, as man's agricultural technology increased, huge civilizations flourished in the deltaic plains of the Nile and Tigris-Euphrates. Excavations by archaeologists have revealed the grandeur of those civilizations.

River mouths give seagoing ships access to interior ports, and many of the world's great harbours are located in delta plains. Alexandria on the Nile and New Orleans on the Mississippi, both flourishing seaports, owe their success to their location along rivers.

In recent years geologists have discovered that much of the world's petroleum resource is found in ancient deltaic rocks. Thus understanding of deltas is important to petroleum exploration.

Man has failed to exploit the potential of the majority of the deltas. Even though the Irrawaddy, Ganges-Brahmaputra, and Mekong deltas are the rice bowls of Asia, present agricultural practices do not allow maximum utilization of the fertile lands found there. Improved farming techniques, especially those developed by the United Nations-sponsored Economic Commission for Asia and the Far East (ECAFE), will undoubtedly increase future yields in these areas. Other large tropical deltas, such as the ·Niger, Amazon, Orinoco, and Magdalena, have been virtually untouched, and only a thorough knowledge of deltaic processes will lead to development of these areas.

This article treats the processes that are involved in river delta formation, the morphology, stratigraphy, and structure of deltas, and deltaic changes that occur through time by reason of changes in the supply and removal of sediment. A concluding section on experimental studies treats computer-simulation models of the growth of deltas. For additional detail on those aspects of flowing water and current systems that are relevant to delta formation, growth, and maintenance, see RIVERS AND RIVER SYSTEMS; FLUVIAL PROCESSES; DENSITY CURRENTS; and WATER WAVES. The ultimate source of deltaic sediments is covered in SEDIMENT YIELD OF DRAINAGE SYSTEMS, and the general distribution of sediment along coastal areas is treated in the articles BEACHES; COASTAL FEATURES; and CONTINENTAL SHELF AND SLOPE. Lacustrine sedimentation is dealt with in LAKES AND LAKE SYSTEMS and the terrestrial analogues of deltas are separately discussed in ALLUVIAL FANS. For information on sea level changes that have affected the world's deltas in the geological past, see PLEISTOCENE EPOCH and HOLOCENE EPOCH. Finally, the interested reader should consult the articles COMPUTER and MATHEMATICS AS A CALCULATOR-SCIENCE for further insight to computer modelling generally.

PROCESSES RESPONSIBLE FOR DELTA FORMATION AND OCCURRENCE

The presence of a delta represents the continuing ability of rivers and river systems (*q.v.*) to supply and deposit stream-borne sediments more rapidly than they can be removed by water waves and ocean currents (*qq.v.*). Because delta building is a contest between the river and the sea, it presents one of the most dynamic situations in nature. Many factors, some resulting from fluvial processes (*q.v.*) and others from marine processes, affect the riverine-marine balance. Conditions existing in the drainage basin or source area of a river exert considerable influence on the formation of the delta. The size, shape, relief, soil development, and geologic type of rocks in the basin control, to a large degree, the type and amount of sediment available for transport to the sea.

Runoff and sediment transport

One of the most important factors is the type of climate that exists in the drainage area. In tropical climates, rainfall is distributed abundantly over the basin throughout the year; maximum downpours occur during a few months of the year. Water and sediment discharge are therefore continuous all year, but maximums coincide with periods of heaviest rainfall. In arid climates rainfall is not continuous throughout the year; rather, it occurs sporadically, causing rapid and catastrophic runoff. Rivers draining this type of basin have erratic floodwater and sediment discharges. Arctic climates result in similar runoff characteristics, except that throughout most of the year the water available for runoff is frozen and cannot serve as a transport agent until the period of thaw. In the three cases cited the total yearly rainfall could be identical in the basins, but because the frequency of occurrence and the availability of the rivers to serve as transport agents differ, the sediment supply and water reaching the delta cause quite different morphological features to develop. In the case of a rather constant supply of sediment and water all year, channel systems in the delta can adjust quite easily to handling the volume of water and sediment, and as a consequence, channels are quite stable and do not tend to migrate rapidly. Erratic flood conditions, such as exist under arid and Arctic climates, supply large quantities of sediment and water to the delta during a short period of time. Distributary channels therefore never completely adjust to the large, rapid influx of sediments and water. New channels form rapidly during flood, function for a short period of time, and then are abandoned and filled as floodwaters recede. Channels are unstable and therefore tend to migrate considerably. Other climatic conditions, not quite so harsh as those described, impose similar control on delta morphology. Thus climatic factors in the basin determine the quantity of both water and sediment supplied to the delta and also control the frequency of the input to the delta.

Sediment transport within the delta proper is in the form of bed load and suspended load. Bed load consists of coarser particles that travel close to the bed of the channel; in contrast, the suspended load consists of finer particles that travel primarily above the bed. Channels carrying large volumes of bed load will normally be wide and shallow and will tend to rapid lateral migration. A high percentage of suspended load results in deep, narrow

channels that are relatively stable. Large sediment concentrations transported in a delta also increase the density of river water. The greater the contrast in density between river water and seawater, however, the more compressed the sediment plume will be as it moves offshore from a river mouth. Thus, to some degree the amount of sediment load controls lateral spreading of stream-borne material along the coast at a river mouth (see also DENSITY CURRENTS).

Marine processes and tectonic effects

Marine processes also play a key role in molding the landforms in the delta. Wave-energy levels, wind intensity and direction, coastal currents, tidal action, and offshore slope are the major factors involved. High-energy levels along the front of a delta rapidly rework the stream-borne sediment introduced to the sea and tend to spread sediments laterally, clogging channels. Thus high-energy conditions favour the formation of fewer channel outlets and of sandy beach deposits between channel outlets. Sediment spreading at river mouths is also enhanced by offshore currents and tidal action. Low-energy conditions, weak currents, and small tidal range result in less lateral spreading of sediment and in a highly indented delta coastline with many river mouths. See further WATER WAVES; COASTAL FEATURES; BEACHES.

Many of the world's large and important deltas occur in subsiding basins and are controlled by regional tectonics or local fault systems. There is still controversy as to whether it is the subsiding basin that attracts the river system or whether it is the load of the sediment deposited by the river that causes the earth's crust to buckle and subside. In addition to regional subsidence, local compaction caused by differential sediment loading is an important process in delta building. Although compaction is operative in nearly all deltas, it is much more prevalent in deltas that transport large fine-grained sediment loads. In such cases, heavier sandy deposits form at the river mouths, sink into the underlying soft muds, forcing large masses of clay to rise toward the surface. In some deltas these clay deposits will reach the surface and form mud islands around the river mouths. Such a condition exists in the Mississippi River Delta, where the islands, referred to as mud lumps, offer serious obstructions to ships navigating the river mouths.

MORPHOLOGY OF DELTAS

In plan or map view, deltas appear to be hoeplessly complex mazes of channels, lakes, and marshes. There is, however, an orderly arrangement of component parts, three of which are found in most deltas. The most landward section is called the upper delta plain, the middle one the lower delta plain, and the third the subaqueous delta, which lies seaward of the shoreline and forms below sea level. Variations in the proportions of each of these components give rise to the differing sizes and shapes of the world's deltas (Figure 1).

Delta plains

That part of the river confined by valley walls, so that the river commonly is restricted from spreading out, is called the alluvial plain. It may be thought of as a conduit through which sediment and water derived from the drainage basin are brought to the sea. At some point downstream the plain broadens out, and most river channels break up into more than one course. This is the apex of the delta and the beginning of the upper delta plain. This part of the delta possesses many morphologic surfaces and processes that are similar to those of the alluvial plain. All of this land lies at an elevation above the effective intrusion of tidal water and is formed entirely by riverine processes. Areas between channels usually support broad freshwater marshes, swamps, or shallow lakes. The lower delta plain is periodically inundated by tidal waters, and landforms result from the interaction of both riverine and marine processes. Areas between the channels show a variety of landforms, ranging from brackish water bays, marshes, and mangrove swamps to

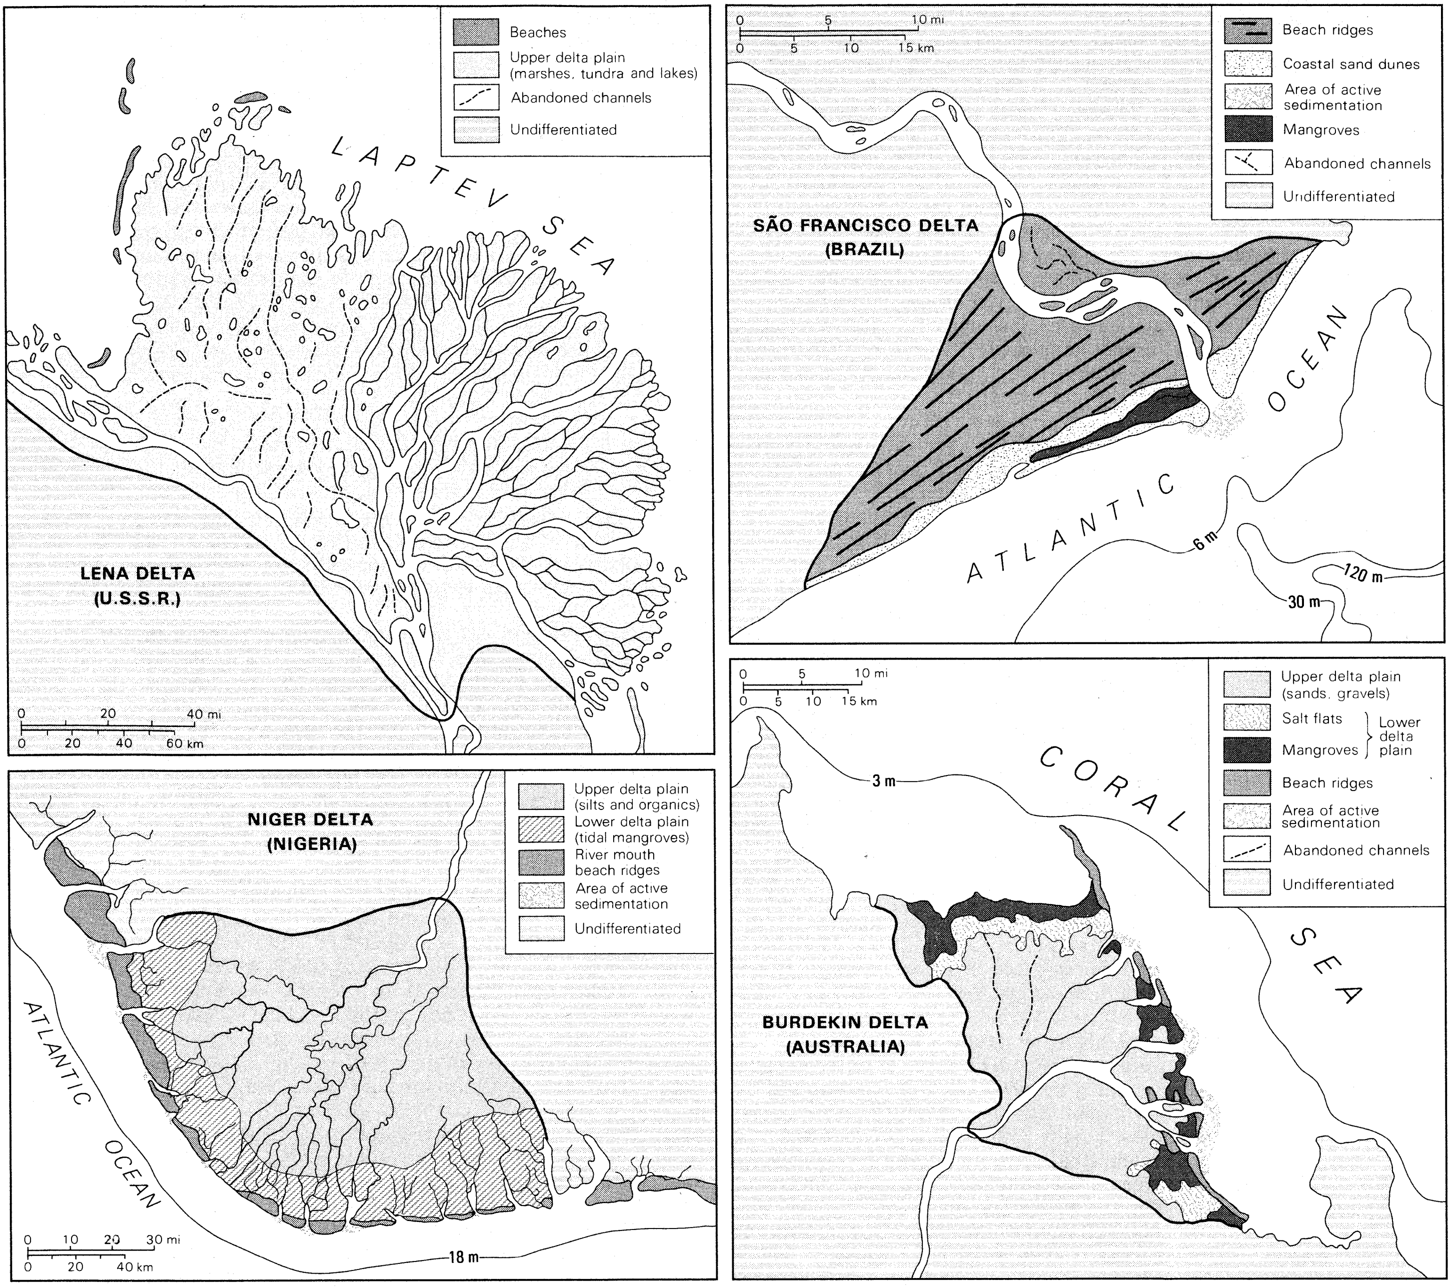

Figure 1: The component parts of four representative river deltas.

hypersaline tidal flats and beach ridges. The subaqueous delta forms entirely below the level of the sea and commonly constitutes the obvious bulge on the continental shelf seen seaward of many deltas. Marine processes are dominant, riverine factors playing a secondary role. The importance of this component, however, should not be underrated, because it is the foundation for construction of the exposed portion of the delta.

One of the largest delta plains, the Ganges-Brahmaputra in Bangladesh, encompasses some 60,000 square kilometres (23,166 square miles), over half of which is inundated by tidal waters (lower delta plain), forming vast mangrove swamps locally referred to as the sunderbands. Deltas such as the Ganges-Brahmaputra and Niger (Figure 1), in which high tidal ranges occur, normally display broad lower delta plains at the expense of upper delta plains. Other deltas, such as the Lena (U.S.S.R.; Figure 1), Nile (Egypt), and Volga (U.S.S.R.), in which tidal range is small, have poorly developed lower delta plains but large, well-developed upper delta plains. Formation of a large subaqueous delta plain appears to be controlled by offshore slope and sediment load. Low, sloping continental shelfs such as exist off the deltas of the Amazon (Brazil), Orinoco (Venezuela), and Huang Ho (China) favour development of broad, widespread, subaqueous delta plains.

Channels and levees

Channel patterns within most delta plains can be grouped into three general patterns: single or simple, long, straight channels; complex, multiple-braided channels; and continuous seaward-bifurcating or seaward-branching channels. The first type most commonly develops in deltas that carry a fine-grained sediment load and that have nonerratic flood discharges and high wave energy offshore (Mekong, Congo, San Francisco del Norte). The second type is characterized by complex anastomosing patterns within the lower delta plain; it results from high wave energy offshore, large tidal ranges, somewhat erratic flooding, and large sediment (bedload) volumes. The Niger (Figure 1) and Zambezi provide excellent examples of this type. Weak wave energy, fine-grained sediments, and a low tidal range tend to form seaward-bifurcating channel patterns; for example, such as those that exist in the Mississippi River and Volga River deltas.

Bordering the channels in most deltas are slightly higher areas called natural levees. These form as a result of the deposition of sediment during river floods. As floodwaters top the channel banks, velocity is reduced, causing deposition of the coarser suspended sediment near the channel margins. Natural levees are best developed in rivers that flood and reach bankfull stage each year and that carry a heavy suspended sediment load. The Mississippi, Mekong, Volga, and Nile have well-developed natural levees, whereas the Lena, Mackenzie, and San Francisco have poorly developed levees. Between the channels within a delta are usually found low-lying interlevee basins or interfluves. These areas vary considerably from one delta region to another. Climatic factors, offshore energy conditions, and tidal range exert the major controlling factors. Thus in regions of low energy, small tidal range, and tropical and temperate climate, interlevee basins will commonly show broad, flat, marsh plains, open-water bays, or broad freshwater swamps. In regions having high tidal ranges and tropical climates, vast mangrove swamps and numerous tidal channels are most common. In high-tide arid deltas, broad salt flats and occasional areas of wind-blown dune fields are encountered. Extreme wave action, when combined with a heavy sediment load, will result in a considerable number of beach ridges in the interdistributary area.

Delta front and river mouth

The subaqueous delta plain, or delta front, forms the submarine platform across which the exposed delta will eventually build. Broad subaqueous delta plains are normally associated with shallow, sloping continental shelves, whereas little or no development is associated with steeply sloping continental shelves or with areas where large submarine canyons originate near river mouths. For example, the Congo River carries an extremely heavy load of sediment, yet has a poorly developed subaqueous delta. A large submarine canyon exists immediately off the river mouth, and all sediments delivered to the sea by the river are funnelled down this canyon for deposition beyond the edge of the continental shelf. In deltas where the continental shelf has a low slope, the sediment leaves the seaward termination of the distributary channels and is deposited on the continental shelf, thereby forming a bulge in the offshore contours (see also CANYONS, SUBMARINE; CONTINENTAL SHELF AND SLOPE).

River mouths are highly variable. Some display broad, bell-shaped patterns, and others protrude as narrow bands into the sea, resembling the artificial jetties constructed by man at many river mouths. The reason for these variations in river-mouth patterns is poorly understood, but most scientists agree that offshore energy levels, density differences between river water and seawater, and tidal range are important processes in producing the differences that exist in many world deltas. Seaward of the river mouths are shoal areas referred to as river-mouth bars. As the river water leaves the confines of its channel banks, current velocities are reduced, and the coarser sediment is deposited as a shoal in front of the river mouth. Here it is reworked and redistributed by waves and tidal currents. The finer grained suspended sediments do not drop out immediately, but rather spread out and are deposited seaward of the bar, forming the resulting delta front.

DELTAIC STRATIGRAPHY AND STRUCTURE

Sediment distribution and aggradation

The presence of a delta along a coast represents the ability of the river to bring sediments to a coast and deposit them faster than marine currents and waves can remove them. Essentially a dispersal mechanism, delta building consists of distributing and sorting the sediments derived from the drainage basin and brought to the coast by the river. The sediment is dispersed in two distinct ways during a single year or during a flood cycle. During low river stage or times of normal discharge, transported sediment essentially remains within the channels throughout its travel through the delta and does not begin to be dispersed laterally until it reaches the river mouth. During this time river-current velocities are generally low near the river mouths, and marine currents and waves can easily rework and distribute the sediment laterally along the front of the delta. The coarser grained sediments are concentrated by waves near the river mouth, whereas the finer grained sediments are moved laterally along the delta coastline or offshore. When flood period ensues, however, transported sediment and water are no longer confined to the channels within the delta but spread over the river banks into the adjacent interdistributary areas. Silts and clays are therefore introduced rapidly into areas that normally have very low rates of sediment accumulation. This process is the major factor in building up or aggrading the subaerial delta plain. At the river mouth, river-current velocities are appreciably higher than those which prevail during low river stage and tend to overpower marine currents and wave action. Sediments are dispersed much farther seaward during flood season than during low stage when they are distributed laterally along the coast. Silts, and occasionally sands, are transported across the river-mouth shoal and are deposited along the delta front or steeper sloping portion of the subaqueous delta. This seaward spreading of sediments is the mechanism by which the delta grows seaward. The seaward movement of the delta is known as prograding.

The depositional sequence

The dispersal patterns and sorting of sediment result in a well-drained, well-developed depositional sequence both horizontally and vertically. In the subaerial delta plain, fine-grained silts and clays are deposited by the river along with the organic material that accumulates *in situ* in the interdistributary areas. Immediately in front of the delta mouths, sands and silts are accumulating and are constantly being reworked and sorted by marine processes. These deposits are building seaward and thus have a fairly steep seaward slope. Farther offshore, the fine-grained sediments, predominantly clays, are accumulating beyond the delta front. Thus, the horizontal sequence of deltaic sediments is a gradation from silts, clays, and organic material in a landward position, through coarser sands and silts near the delta mouths, to finer grained marine clays offshore. Vertically, this same sequence also can be found: the clays and organic sediments are found at the highest levels, sands and silts at the intermediate level (shallow nearshore water depths), and marine clays at the lowest level 30.5- to 71-metre (100- to 200-foot) water depths. This horizontal and vertical sequence has long been recognized, and in 1890 G.K. Gilbert, the American geologist, used the terms topset, foreset, and bottomset deposits to denote the three units. The topset deposits correspond to the subaerial delta sediments, the foreset deposits to the coarse sands and silts laid down along the delta front, and the bottomset deposits to the marine clays accumulating beyond the delta front. These relationships are shown clearly in the cross section of a typical delta (Figure 2). Gilbert used these terms to describe the sediments composing small lake deltas in the Pleistocene glacial Lake Bonneville. In large, complex deltas where many processes are interacting, with differing intensities, and where compaction of sediments is an active process, it is more difficult to recognize these simple depositional components. As more details of different types of deltas become better known, the concept still appears valid, but sediments composing each of these components become increasingly more complex and highly variable.

The subaerial delta, or topset component, consists primarily of channel sands, natural levee silts and clays, and interdistributary peats and clays (Figure 2). Channel deposits commonly consist of poorly sorted sands that contain a high percentage of included clays, wood and clay fragments, heavy minerals, and a normally high mica content. In some cases, channel deposits are composed of interbedded silts, clays, and transported organic sediments instead of sands. In these cases, the process of channel abandonment was quite slow, and only fine-grained material was available for filling the channel. Regardless of composition, channel deposits are normally lenticular (lens shaped) in cross-sectional shape and elongate in nature. Thickness is dependent on channel scour depth as well as intensity of compaction. Natural-levee sediments overlie channel deposits and are much finer grained. They are composed of suspended sediments, interbedded silts and clays being predominant. Because they are exposed to air

a large part of the time, oxidation and a constantly fluctuating water table are common. These processes impart a red coloration to the sediment and result in inclusions of calcium carbonate. Encasing the channel and natural levee deposits are interdistributary sediments. These deposits are highly variable from one delta to another, but most commonly they include finely laminated clays containing zones of lenticular silt and peat layers. In some cases, burrowing organisms rework the clays as they accumulate, and mottled deposits result. In many deltas these deposits form the highest percentage of the topset stratum.

The delta front or foreset deposits are laid down in subaqueous environments immediately seaward of the delta coastline. Nearest the river mouths and in shallow water, coarse-grained sands accumulate as river-mouth bars (Figure 2). Normally, they are the coarsest material found in delta deposits, are relatively clean, and contain occasional thin stringers of clay and transported (rafted) organics. In a seaward direction and radiating away from the river mouth, the sands grade laterally into silts that are deposited in somewhat deeper water. Such deposits commonly consist of interbedded silt, silty clay, and clay layers; the coarser material is deposited farther offshore during flood stage. Quite often subaqueous mass movement will result in distortion of these sediments. In deeper water and still farther offshore, only the finest of the stream-borne material slowly settles to the bottom. These deposits are referred to as prodelta clays, they commonly consist of fine-grained clays containing an abundant marine faunal assemblage.

Thus, delta deposits grade from coarse to fine in an offshore direction and from fine to coarse in an upward direction in a vertical section.

DELTAIC CHANGES THROUGH TIME

The discussion of the processes controlling delta formation thus far has largely ignored the element of time, yet geologic time and the numerous combinations of processes result in dynamically changing conditions within deltas. Because the mechanisms of supply and removal of sediment cannot remain constant throughout time, one of the major characteristics of deltas is that in time they tend to shift position. As a delta progrades or builds farther and farther into the sea, the gradient and sediment-carrying capacity of the river gradually decreases, and shorter, more efficient routes to the sea can be found in adjacent areas. Eventually the river will seek the shorter route, and active deltaic sedimentation will be initiated in a new site. The new delta will then begin to prograde seaward rapidly. This phase is referred to as the constructional phase of delta building. The abandoned or inactive delta, however, will be rapidly attacked by the sea because it will no longer be fed sediment by the river; the balance between sea and river forces will then favour erosion, and the delta shoreline will retreat. This phase of delta evolution has been termed the destructional phase. The distinction between these two phases is normally clear in most deltas, but in others it is less apparent. The major reason for this difference is that not all deltas switch their courses in the same manner. Three major types of deltaic change can be recognized: (1) lobe switching, (2) channel switching, and (3) alternate channel extension. These three types are illustrated diagrammatically in Figure 3.

Lobe switching

In type 1, the delta builds a complex of distributaries that prograde simultaneously seaward, producing a lobe of sediment that protrudes seaward from the coastline. Adjacent areas are deprived of sediment; and, because of rapid subsidence or heavy wave attack, these areas open up and form open-water areas adjacent to the active delta. At some point, generally upstream from the delta apex, the river will eventually break out of its levees and seek a shorter route to the sea, which will normally correspond to the adjacent indented coastline. The new channels will rapidly prograde, forming another site of active deposition. The abandoned delta will then be attached by the sea, and sandy islands commonly will form offshore. Thus, in this type of switching, the delta plain will be composed of alternate and overlapping lobes of deltaic distributaries that are active at different periods through geologic time. The condition is shown by the upper three diagrams in Figure 3. The Mississippi and Rurdekin deltas are examples of this type.

Channel switching

Type 2, channel switching (Figure 3), is characterized by the Niger, Lena, and Ganges-Brahmaputra. At any one time, a series of distributary channels is active at different sites within the delta plain. Development of an excessive number of bars within a channel, closure of the river mouth by heavy wave action or migrating coastal sand spits, decrease of channel gradient by excessive seaward buildout, as well as several other factors, will result in the abandonment of the channel and formation of a new one, generally in an area of more favourable gradient. Thus, the delta is constantly being prograded seaward in different parts of the delta plain simultaneously. In this case all parts of the plain are likewise active, and switching is dependent on changes in individual channels rather than in the location of the delta lobe, as in type 1.

Alternate channel extension (type 3) is commonly found

Alternate channel extension

in deltas where stable basement conditions are encountered, such as in the Danube River Delta. In this type (Figure 3), distributary channels will remain in constant positions through relatively long periods of time and, instead of switching to different sites within the delta plain, tend to extend themselves seaward at alternate times. Those channels receiving the higher percentage of water and sediment discharge will prograde seaward; riverine processes will overpower marine destructive processes. On the other hand, channels receiving smaller volumes of water and sediment will be acted on by marine processes, normally resulting in the formation of river-mouth beach ridges. With time, however, the prograding channels will extend their mouths seaward to a point at which channel gradients become so low that dominant discharge will switch to one of the former partially inactive channels. This channel will then begin to prograde seaward, stranding the beach ridges that were developed at that river mouth. This process is illustrated diagrammatically in the lower three diagrams of Figure 3. Sites of active deposition therefore occur at different time periods within the delta plain, but in more or less specified sites.

These three types of deltaic evolution result in dynamically changing delta configuration and shoreline. The extent of changes in deltas is drastic; for example, within the past 2,000 years the Huang Ho (Yellow) River of China has shifted its delta some six times, the maximum distance between sites being in excess of 200 miles (321 kilometres). Other deltas, especially the lobe switching type, display similar changes through time. Even during periods of relative stability the shoreline is constantly changing; many deltas prograde their shorelines seaward at a rate of several hundred feet a year. Delta switching also controls rates of sedimentation within the delta plain. In various areas of active delta growth, especially in the vicinity of the river mouths, sedimentation rates are regarded as quite high, whereas in the abandoned or inactive parts of a delta accumulation rates are quite low, and in many cases erosion is active.

Deltas in the geological past

Modern deltas of various sizes and shapes are being constructed along the margins of oceans, seas, and lakes, and similar deltas were formed throughout geologic time. A lack of knowledge of the three-dimensional configuration of various types of modern deltas has hampered interpretations of ancient deltaic sequences. In spite of this shortcoming, however, deltaic sequences have been recognized in rocks of essentially all geologic ages and in many parts of the world. Among the ancient rock deltas that have been described in the geologic literature are the Blount Delta (Ordovician) in Tennessee, Queenstone Delta (Ordovician) of New York and Pennsylvania, Catskill Delta (Devonian) of Pennsylvania and New York, Old

Red Sandstone (Devonian) of Great Britain, Red Bedford Delta (Mississippian) of Ohio, Pennsylvania Coal Bearing Cycles of Kentucky, Pennsylvania, and Ohio; Rawlins Delta (Cretaceous) of Wyoming; Mesa Verde Delta (Cretaceous) of Colorado; and the Miocene (Tertiary) subsurface deltas of the Gulf Coast. Many of these deltas, especially the Tertiary deltas of the Gulf Coast, contain vast reserves of petroleum, and therefore a thorough understanding of deltaic processes and deposits is critical for future exploration. (For further information on the structures and sediments of ancient deltaic deposits see SEDIMENTARY ROCKS; and SANDSTONES.) (J.M.C.)

EXPERIMENTAL STUDY OF DELTAS

River deltas are difficult to study experimentally because of their size. In most cases it is totally impractical, and even impossible, to alter parameters such as sediment supply, sea level, or tidal patterns to observe the resulting responses. Furthermore, even if such changes could be made, it would usually take much too long to complete a meaningful experiment, perhaps several months to several years, even for quite small river deltas.

Naturally investigators have turned to model studies, which provide a cheap and fast way of doing experiments. Results obtained from models of any sort have to be treated carefully, of course, because the models may not behave exactly like their prototypes. Physical scale models, such as sedimentation tanks and flumes, have been widely used to build small-scale deltas. In only a few cases, however, has this work led to a systematic quantitative investigation, probably because of difficulties encountered in correctly scaling down the physical properties of the models.

With the development of high-speed computers, some attempts have recently been made to perform delta experiments using simulation models. Although computer-simulation models are at present limited, due to lack of knowledge of the mathematics of the processes involved in deltaic sedimentation, potentially they are enormously useful experimental devices capable of reproducing hundreds of years of deltaic sedimentation in a few seconds of computer time.

Instead of building a delta in a tank, a series of "deposits" representing the delta is formed as output from a computer program. The model can provide for inputs such as river flow, sediment supply, depth of water in the basin, and so forth. Within the program deltaic processes are represented by sequences of logical and mathematical statements that manipulate the values specified for the inputs. Finally the model prints out and automatically plots tables, graphs and other diagrams to show the form and composition of the hypothetical delta that has been produced.

A *computer* model. The first step in developing a computer model is to draw up a flow chart showing the parameters and processes to be included in the model. A computer model that deals with a part of such a flow chart, but in great detail, has been programmed for a digital computer. The model is concerned with the phase of sediment transport and deposition at the mouth of a single delta distributary. The model ignores compaction, tectonic subsidence, and changes in sea level and assumes that the depositional basin is free from all of the energy sources that originate offshore, sources such as tides, currents, and winds.

The aim of the model is to determine the rate at which sediment with different particle sizes accumulates at various positions in front of a river mouth. Specifically, what shape will the sedimentary deposit have in plan view, what will be the "foreset" slope, and how will these factors respond to changes in hydraulic and grain-size parameters? Do mouth bars and subaqueous levees form, and if so where are they to be expected?

The basic form of the model is illustrated in Figure 4. The river channel is subdivided into a number of stream segments, each containing water and sediment particles. The average sediment load in a particular stream tube is represented by a statistical particle travelling at the centre of the tube. It is assumed that in the river, statistical particles travel with the flow parallel to the bottom, but once the river mouth is reached they begin to settle downward. An accounting grid in front of the river mouth "catches" the sediment as it settles to the floor and keeps track of the rate of sediment accumulation.

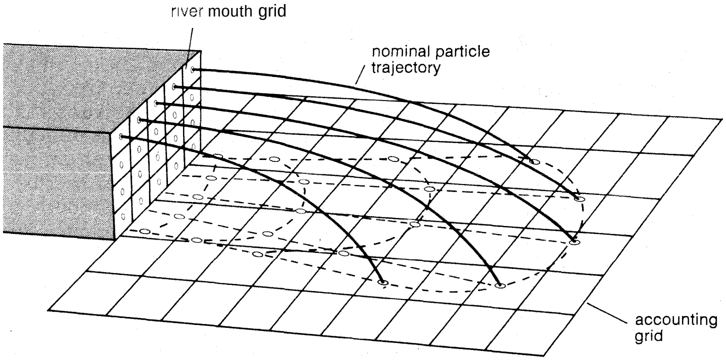

Figure 4: Structure of delta simulation model, showing vertical river grid and horizontal accounting grid. Statistical particles issuing from the centre of each river grid cell (section through a stream tube) are traced along settling trajectories until they land in accounting grid cells (see text).

From G.F. Bonham-Carter and A.J. Sutherland, "Mathematical Model and Fortran IV Program for Computer Simulation of Deltaic Sedimentation," *Computer Contribution* PC (1968); Kansas Geological Survey

The space and time variables are represented in discrete form because the model is programmed for a digital (as opposed to an analogue) computer. Thus the spatial variables are subdivided by grids that consist of a meshwork of rectangular cells. The first part of the model is static, in that only a single time step is considered. The second, or dynamic part of the model, assumes that time is represented by a series of discrete steps.

The key factor in the static model is the calculation of the settling trajectories of statistical particles. The problem is treated ballistically, each trajectory being described by the resultant of settling velocity and forward velocity. This requires knowledge of a three-dimensional velocity field. The model assumes that the flow is like a series of thin two-dimensional horizontal jets placed one on top of the other, with the initial velocity in each being given by the velocity at that elevation in the river channel. It is further assumed that the fresh river water flows out over, and floats on top of, the salty seawater, and that the two do not mix because of different densities.

With these and other assumptions, a series of experiments has been carried out with the static model to determine the effects of changing hydraulic and grain size parameters. The computer output shows that the area of sediment deposition, depicted by the positions of statistical particles in the accounting grid, is rather narrow and cigar shaped. With an arithmetic decrease in grain size, the depositional area increases geometrically, reflecting the relationship between grain size and settling velocity. More interesting is the elevation view, not shown here, in which the "foreset" slope of the deposits is about half of a degree, decreasing slightly with decrease in grain size. Considering the gross assumptions, this figure compares favourably with values for foreset slopes reported for the Grand Rhône distributary (2°), the Mississippi (1°), and the Orinoco (¼°).

Changes in the hydraulic parameters (river width, depth, and slope) produce only small differences in the same basic pattern. The mole typical fanlike shape of delta deposits is not developed. There are a number of possible reasons. First, the jet model is probably not fully appropriate for the velocity field, except possibly during periods of high river discharge when water is literally jetted out of the mouth. During periods of low discharge, the flow in real deltas appears to spread laterally more rapidly than predicted by the jet model. Second, offshore energy factors, which not considered in the model, modify the flow considerably. Third, the presence of river-mouth bars and subaqueous levees tend to disrupt the ideal flow pattern used in the model.

The model in the form described thus far sheds no light on the processes responsible for formation of levees and mouth bars. The theoretical deposits contain no irregularities suggesting the presence of these subaqueous forms. Furthermore the rate of accumulation remains constant with time in each cell of the accounting grid, a situation that rapidly leads to blockage of the river mouth. A dynamic version of the model overcomes this difficulty by cutting off sediment accumulation in any cell already filled to a specified "limiting depth." In other words, a delta platform is allowed to build out from the mouth, on which sediment can no longer settle. The computer program for the dynamic model prevents the particle trajectories from bending downward until the edge of the platform has been crossed.

Several experiments have been carried out using the dynamic model, one of which is illustrated in Figure 5. In this experiment a grain size of 0.3 millimetres (0.01 inch) diameter was employed. Figure 5A shows plots of the particle maps at the end of 2, 4, *6*, 8, and 10 time increments. The delta platform (in black) is shown to build out and gradually force the statistical particles farther from the mouth. However, the velocity field is assumed to be unchanged, and in time the particle trajectories become very steep so that at the distal end of the deposit sediment is being deposited very rapidly. This situation is shown in Figure 5A at time increments 8 and 10, where an increased density of particles can clearly be seen round the terminus of the deposit. In a vertical section parallel to the main axis (Figure 5B), successive sedimentary layers are shown, separated by time lines that simply record the sequence of sediment-water surfaces, one for each time step. The first bar produced is simply the outcome of assuming the form of the limiting depth surface. The second, or distal, bar corresponds to the high density of particles seen in Figure 5A. In further experiments in which the cells were made much smaller in relation to the channel width, thereby giving a higher resolution, deposits were formed marginal to the flow, possibly analogous to subaqueous levees.

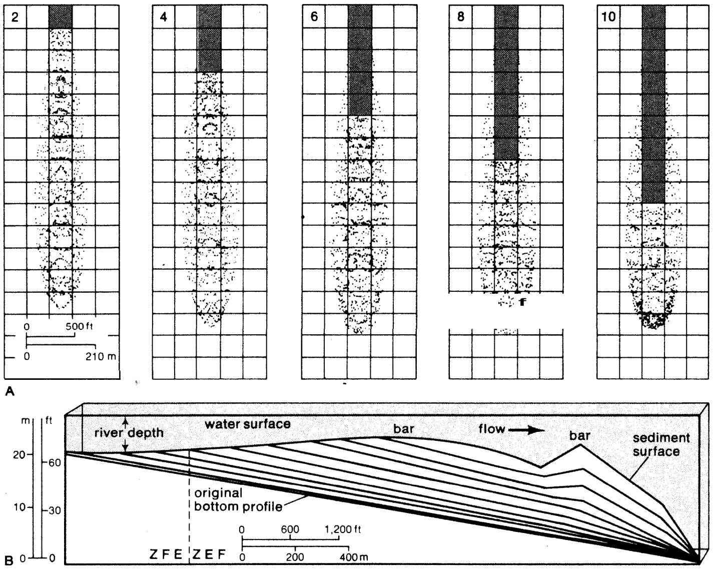

Figure 5: Computer-drawn output of results obtained from dynamic model (see text).
(A) Plan view showing build out of delta platform (solid black) during time increments 2, **4,** 6, **8,** and 10. Note the increased density of points around the distal end in increments 8 and 10.
(B) Vertical section along the centre of the delta showing the buildup of successive sediment layers. The bar on the right corresponds to the increased density of points shown in the plan view for increment 10. Note the grossly exaggerated vertical scale. ZFE and ZEF refer to flow regions in the jet model.

Value of experi-mental studies

The restrictive assumptions of this delta model make it difficult to compare in detail the theoretically produced deposits with actual deltas. Nevertheless, reasonable predictions are made for foreset slopes, and the experiments suggest that the basic shape of river-mouth deposits in plan view is not very sensitive to changes in river flow or grain-size parameters. Even though the existing dynamic model is crude in many respects, it indicates that the sediment-water surface may develop in a complex fashion when a feedback relationship between depth of water near the mouth and sediment deposition is taken into consideration.

The process of developing a simulation model forces the model builder to think very clearly about how a delta works. In order to reach the stage of writing a useful computer program, a great deal of time must first be spent in drawing together a number of theoretical and empirical relationships into a general synthesis. This focusses attention on areas in which knowledge is lacking, suggests areas for new research, and provides a framework to which new data may be related. Although very little work has yet been done on computer models of river deltas, as indicated by the sparse bibliography, it seems likely that simulation will become an increasingly important tool in delta studies. Indeed, it has become important in the geological sciences and hydrological sciences (*qq.v.*) in general. (G.B-C.)

Rivers and River Systems

By original usage, a river is flowing water in a channel with defined banks (ultimately from Latin *ripa*, "bank"). Modern usage includes rivers that are multichannelled, intermittent, or ephemeral in flow and channels that are practically bankless. The concept of channelled surface flow, however, remains central. The word stream (ultimately from the Indo-European root ***srou-)*** emphasizes the fact of flow; as a noun it is synonymous with river and is often preferred in technical writing. Small natural watercourses are sometimes called rivulets, but branch, brook, burn, and creek are more common, occurring regionally to nationaliy in piace-names. Arroyo and (dry) wash connote ephemeral streams or their resultant channels. Tiny streams or channels are known as rills or runnels.

Rivers are nourished by precipitation, by direct overland runoff, through springs and seepages, or from meltwater at the edges of snowfields and glaciers. The contribution of direct precipitation on the water surface is usually minute, except where much of a catchment area is occupied by lakes. River water losses result from seepage and percolation into shallow or deep aquifers (water-bearing layers), and particularly from evaporation. The difference between the water input and loss sustains surface discharge or streamflow. The amount of water in river systems at any time is but a tiny fraction of the earth's total water; 97 percent of all water is contained in the oceans and about three-quarters of fresh water is stored as land ice; nearly all the remainder occurs as groundwater. Lakes hold less than 0.5 percent of all fresh water, soil moisture accounts for about 0.05 percent, and water in river channels for about half as much, 0.025 percent, which is one four-thousandth of the earth's total fresh water.

Water is constantly cycled through the systems of land ice, soil, lakes, groundwater (in part), and river channels, however. The discharge of rivers to the oceans delivers to these systems the equivalent of the water vapour that is blown overland and then consequently precipitated as rain or snow, that is, some 7 percent of mean annual precipitation on the globe, and 30 percent of precipitation on land areas.

Prehistoric importance of rivers

The inner valleys of some great alluvial rivers contain the sites of ancestral permanent settlements, including pioneer cities. Sedentary settlement in Hither Asia began about 10,000 BP (years before present) at the site of Arīhā (ancient Jericho). Similar settlement in the Tigris-Euphrates and Nile valleys dates back to at least 6000 BP. The first settlers are thought to have practiced a hunting economy, supplemented by harvesting of wild grain. Conversion to the management of domesticated animals and the cultivation of food crops provided the surpluses that made possible the rise of towns, with parts of their populations freed from direct dependence on food getting. Civilization in the Indus Valley, prominently represented at Mohenjo-daro, dates from about 4500 BP, civilization in the Ganges Valley from about 3000 BP. Permanent settlement in the valley of the Huang Ho (Yellow River) has a history 4,000 years long, and the first large irrigation system in the Yangtze catchment dates back to roughly the same time. Greek invaders of the Syrdarya, Amu Darya, and other valleys draining to the Aral Sea, east of the Caspian, encountered irrigating communities that had developed from about 2300 BP onward.

The influence of climatic shifts on these prehistoric communities has yet to be worked out. In wide areas, these shifts included episodic desiccation from 12,000 or 10,000 BP onward; in what are now desert environments, increased dependence on the rivers may have proved as much a matter of necessity as of choice. All of the rivers concerned have broad floodplains subject to annual inundation by rivers carrying heavy sediment loads. Prehistoric works of flood defense and irrigation demanded firm community structures and required the development of engineering practice. Highly elaborate irrigation works are known from Mohenjo-daro; the ziggurats (temple mounds) of the Euphrates Valley may well have originated in ancient Egypt in response to the complete annual inundation of the Nile floodplain, where holdings had to be redefined after each flood subsided. It is not surprising that the communities named have been styled hydraulic civilizations. But it would be oversimplistic to claim that riparian sites held the monopoly of the developments described: elaborate urban systems arising in Mexico, Peru, and the eastern Mediterranean from about 4000 BP onward were not immediately dependent on the resources of livers.

Where riverine cities did arise, they commanded ready means of communication; the Two Lands of Upper and Lower Egypt, for instance, were unified by the Nile. At the same time, it can be argued that eariy riverine and river-dependent civilizations bore the seeds of their own destruction, independent of climatic shifts and natural evolutionary changes in the river systems. High-consuming cities downstream inevitably exploited the upstream catchments, especially for timber. Deforestation there may possibly have led to ruinous silting in downstream reaches, although the contribution of this to the eventual decline of civilization on the Euphrates and the Indus remains largely a matter of guesswork. An alternative or conjoint possibility is that continued irrigation promoted progressive salinization of the soils of irrigated lands, eventually preventing effective cropping. Salinization is known to have damaged the irrigated lands of Ur, progressively from about 4400 to 4000 BP, and may have ruined the Sumerian Empire of the time; but the relative importance of environmental and social deterioration in prehistoric hydraulic civilizations remains a matter of debate. Furthermore, defective design and maintenance of irrigation works promote the spread of malarial mosquitoes, which certainly afflicted the prehistoric hydraulic communities of the lower Tigris-Euphrates Valley; these same communities may also have been affected by bilharziasis (blood fluke disease), which requires a species of freshwater snail for propagation and which even today follows many extensions of irrigation into arid lands.

Historical and present importance

In various intervals of history, rivers have provided the easiest, and in many areas the only, means of entry and circulation for explorers, traders, conquerors, and settlers. They assumed high importance in Europe after the fall of the Roman Empire and the dismemberment of its roads; regardless of political structures, control of crossing points was expressed in strongholds· and the rise of bridge-towns. Rivers in medieval Europe dominantly supplied the water that could sustain cities and the sewers that could carry away city waste and were widely used, either directly or with offtakes, as power sources. Western European history records the rise of 13 national capitals on sizable rivers, exclusive of seawater inlets; three (Vienna, Budapest, and Belgrade) lie on the Danube, with two others, Sofia and Bucharest, on feeder streams above stem floodplain level. The location of provincial and corresponding capitals is even more strongly specialized on riparian sites, as is readily illustrated from the United Kingdom, France, and Germany. In modern history, both in North America and northern Asia, natural waterways directed the lines of exploration, conquest, and settlement: in both areas, passage from system to system was facilitated by portage along lines defined by temporary ice-marginal or ice-diverted channels. Many pioneer settlers of the North American interior entered by means of natural waterways, especially in Ohio.

The historical record includes marked shifts in the appreciation of rivers, numerous conflicts in use demand, and an intensification of use that has rapidly accelerated in the present century. External freight trade concentrated in estuarine ports rather than inland ports when ocean craft increased in size; even the port of London, though constrained by high capital investment, has displaced itself toward its estuary. The Amazon remains naturally navigable by ocean ships for 3,700 kilometres (2,300 miles), the Yangtze for 1,000 kilometres (625 miles), and the partly artificial St. Lawrence Seaway for 2,100 kilometres (1,300 miles). Internal freight traffic on the Rhine system and its associated canals amounts to one-quarter or more of total traffic in the basin, and to more than half in some parts. Waterborne freight movement currently is recovering much of the ground lost to railways in the later 19th and the first half of the present century, notably in interior America and the northern plainlands of the U.S.S.R. Extensive commercial navigation, however, usually implies much artificial improvement of natural channels, allied to efforts to bring variations of regime under some control. The nearly 145,000 kilometres of navigable natural waterway in the U.S.S.R., for example, are mainly subject to summer floods.

Use for irrigation and hydroelectric power

Demand on open-channel water incteases as population and per capita water use increase and as underground water supplies fall short. Domestic per capita use, foı example, already has reached about 200 gallons per day in the U.S. and 100 gallons per day in the U.K. Irrigation use undoubtedly constitutes the bulk of total irrigation supply. With a history of at least 5,000 years, controlled irrigation now affects nearly 750,000 square miles of land (1,940,000 square kilometres), three-quarters of it in East and South Asia and two-fifths in mainland China alone. Most of this involves natural floodwater, although reliance on artificially impounded storage is fast increasing; irrigation in the 1,300-kilometre (700-mile) length of the Indus Valley, for instance, depends almost exclusively on barrages (*i.e.*, distributor canals) running down alluvial fans and along floodplains. Rice is the great crop of seasonally irrigated land; perennial irrigation inserts additional crops into the rotation or makes possible highly specialized commercial cropping, as in Australia, which, with about one-fourth of an acre of irrigated land per capita, leads the world in this respect among developed and intensively irrigated countries. Modern demands on rivers as power sources range from the floating of timber, through the use of water for cooling, to hydroelectric generation. Logging in forests relies primarily on flotation during the season of meltwater high flow. Large thermal generating stations are typically sited on rivers, which supply the huge quantities of water needed for cooling; the demand is as great as 1,000 tons of water for every ton of coal burned. Some other types of industrial installation make corresponding demands ranging from 250 to 600 tons of water per ton of steel, wood pulp, or woollen cloth. Hydroelectric power generation has a history about a century long, but the bulk of the existing installations have been built since 1950. All great industrial countries, regardless of their other power supplies, have developed their hydropower—in Europe, to about 30 percent of potential, and in North America, to about 20 percent. Norway and Switzerland are among countries depending almost solely on hydropower for internally generated energy. Capacity of major plants now existing is 6,000,000 kilowatts and the level is still rising. Potential supplies are greatest in Africa and South America (combined, about half the world potential and 1 percent of world developed hydropower). Use demand of more immediate kinds relate to freshwater fisheries (including fish farming) and to dwelling in houseboats. Reliable data for these kinds of dependence on rivers do not exist; published estimates that freshwater and migratory fish provide up to some 15 percent of world catch could be too low. In parts of tropical Asia, the yield of freshwater fish runs up to 1,000 pounds per acre (1,120 kilograms per hectare) and 75 percent of national take, whereas Denmark produces about half the world's trout by pisciculture. Certainly, millions of people are concerned with freshwater fishery and houseboat living, principally in the deltaic areas of eastern Asia, where dwelling, marketing, and travel can be located almost exclusively on the water.

Political observers have recorded the difficulties entailed in using rivers as boundaries or drainage basins as areal entities. Multipurpose works and the reconciliation of conflicting use demands cause difficulties even within a single political unit, as is illustrated by the controversy attending the Tennessee Valley project in the U.S. and the continued rarity of interbasin transfer of water in that country today. Very large scale integrated projects frequently involve more than one country, as with the Columbia River scheme and the St. Lawrence Seaway project. The general tendency seems to be toward international cooperation in water use, even between politically inimical countries. The present extreme of technical possibility is illustrated by the Kariba and Aswan High dams, each of which impounds enough water to cover 200,000 square miles (518,000 square kilometres) a foot deep, permits a carryover of storage, and allows considerable control over discharge regime. Projections of water demand, however, indicate that by the year 2000 the U.S. will expend 75 percent of supply on irrigation, southeast England will expend 50 percent on industrial use, and comparable percentages will be required in Asiatic U.S.S.R. These figures suggest that regional projects of river management that at present seem grandiose will in another generation or so become both necessary and ordinary.

Geological significance

Rivers are 100 times more effective than coastal erosion in delivering rock waste to the sea. Their rate of sediment delivery is equivalent to an average lowering of the lands by one foot in 9,000 years, a rate that is sufficient to remove all the existing continental relief in 25,000,000 years.

Rock waste enters fluvial systems either as fragments eroded from rocky channels or in dissolved form. During transit downstream, the solid particles undergo systematic changes in size and shape, travelling as bed load or suspension load. Except in high latitudes and on steep coasts generally, little or no coarse bed load reaches the sea. Downvalley movement of the solid load is irregular, both because streamflow is irregular and because the material is liable to enter temporary storage, forming distinctive river-built features that range through riffles, midstream bars, point bars, floodplains, levees, alluvial fans, and river terraces. In one sense, such features belong to the same series as deltas, estuary fills, and the terrestrial sediments of many inland basins.

Rates of erosion and transportation, and comparative amounts of solid and dissolved load, vary widely from river to river. Least is known about dissolved load, which at coastal outlets is added to oceanic salt. Its concentration in tropical rivers is not necessarily high, although very high discharges can move large amounts; the dissolved load of the lowermost Amazon averages about 40 parts per million, whereas the Elbe and the Rio Grande average more than 800 parts per million. Suspended load for the world in general perhaps equals two and one-half times dissolved load; well over half of it is deposited at river mouths as deltaic and estuarine sediment. About one-quarter of all suspended load is estimated to come down the Ganges–Brahmaputra and the Huang Ho, which together deliver some 4,500,000,000 tons a year; the Yangtze, Indus, Amazon, and Mississippi deliver quantities ranging from about 500,000,000 to about 350,000,000 tons a year. Suspended sediment transport on the Huang Ho equals a denudation rate of about 3,090 tons per square kilometre (8,000 tons per square mile) per year; the corresponding rate for the Ganges–Brahmaputra is almost half as great. Extraordinarily high rates are recorded for some lesser rivers: for instance, 1,060 tons per square kilometre (2,750 tons per square mile) per year on the Ching and 1,080 tons per square kilometre (2,800 tons per square mile) per year on the Lo, loess-plateau tributaries of the Huang Ho.

This article treats the distribution, patterns, and geometry of steamflow in nature, as well as floods, fluvial landforms, and life in river systems. For further details of relevance on the action of flowing water on the Earth's surface, see FLUVIAL PROCESSES; SEDIMENT YIELD OF DRAINAGE SYSTEMS; and LANDFORM EVOLUTION. See also RIVER DELTAS and ALLUVIAL FANS, sedimentary deposits that occur wherever the competence of fluvial transport diminishes; CANYONS, SUBMARINE, analogues of terrestrial canyons that are cut in the world's continental shelves and slopes by sediment-laden density currents (*q.v.*); and WATERFALLS, which occur at breaks in the longitudinal profile of a given river. Certain aspects of the changes in river systems through time are treated in the articles PLEISTOCENE EPOCH; HOLOCENE EPOCH; and CLIMATIC CHANGE; and the general interrelationship of rivers with other parts of the Earth's hydrosphere is covered in HYDROLOGIC CYCLE.

DISTRIBUTION OF RIVERS IN NATURE

World's largest rivers. Obvious bases by which to compare the world's great rivers include the size of the drainage area, the length of the main stem, and the mean discharge; but reliable comparative data, even for the

world's greatest rivers, do not exist. Some of the values listed in the Table are approximate. The Nile, the world's longest river, is about 130 miles longer than the Amazon, according to latest revised figures. It is possible that well over 100 of the greatest rivers may exceed a 1,600-kilometre (1,000-mile) length on their main stems.

Drainage area, length, and discharge

Area–length–discharge combinations vary considerably, although length tends to increase with area and area and discharge to increase through their individual ranking series. On all counts except length, the Amazon is the world's principal river; the Congo and the La Plata–Parana are among the first five by area and discharge, but the Mississippi, third in length and fifth in area, is only seventh in discharge. The Ganges–Brahmaputra, third in discharge, is 13th (or lower) in area and well down the list of length for its two main stems taken separately.

Ranking in the Table is by drainage area. In combination, the rivers listed drain some 44,000,000 square kilometres (17,000,000 square miles), 30 percent of the world's land area. If volume of discharge is taken to be the basis of comparison, then certain other rivers not tabulated above must also be mentioned. The most important of these is the Orinoco, mean discharge 19,800 cubic metres (700,000 cubic feet) per second and a basin of 948,000 square kilometres (360,000 square miles). Others are the Irrawaddy, discharge 13,000 cubic metres (460,000 cubic feet) per second, basin 411,000 square kilometres (159,500 square miles); the Mekong, 11,000 cubic metres (390,000 cubic feet) per second, basin 795,000 square kilometres (306,000 square miles); the St. Lawrence, 10,200 cubic metres (360,000 cubic feet) per second, 1,463,000 square kilometres (565,000 square miles); and the Niger, 6,100 cubic metres (215,000 cubic feet) per second, 1,890,000 square kilometres (730,000 square miles). The 20 greatest of these rivers, draining about 30 percent of the world's land area, discharge nearly 40 percent of total runoff, reckoned from a mean equivalent of 29.2 centimetres (11.5 inches) of precipitation. They deliver to the sea about 92 cubic kilometres (22 cubic miles) of water per day, about 33,325 cubic kilometres (8,000 cubic miles) a year. The Amazon, the La Plata–Parana, the Congo, and the Ganges–Brahmaputra, combined, discharge more than 54 cubic kilometres (13 cubic miles) a day and nearly 20,800 cubic kilometres (5,000 cubic miles) a year, one-third of the world's total runoff to the oceans, the Amazon alone accounting for almost one-fifth.

World average external runoff is about 0.01 cubic metre per second per square kilometre (0.6 cubic foot per second per square mile). Great rivers with notably higher discharges are fed either by the convectional rains of Equatorial regions or by monsoon rains that are usually increased by altitudinal effects. The Huang Ho averages 0.046 cubic metre per second per square kilometre (4.25 cubic feet per second per square mile), the Irrawaddy 0.032 cubic metre per second per square kilometre (2.90 cubic feet per second per square mile), the Magdalena and the Amazon 0.026 cubic metre per second per square kilometre (2.40 cubic feet per second per square mile), the Orinoco 0.21 cubic metre per second per square kilometre (1.91 cubic feet per second per square mile), and the Ganges–Brahmaputra, whose mean discharge is above 0.023 cubic metre per second per square kilometre (2.10 cubic feet per second per square mile). Very high mean discharges per unit area are also recorded for lesser basins in mountainous coastlands exposed to the zonal westerlies of midlatitudes. Among great rivers with mean discharges near or not far below world averages per unit area are those of Siberia, the Mackenzie, and the Yukon (828,000 square kilometres, 5,900 cubic metres per second), all affected by low precipitation for which low evaporation rates barely compensate. The basins of the Mississippi, Niger, and Zambezi include some areas of dry climate. The Nelson illustrates the extreme effects of low precipitation in a cool climate, while the Nile, Murray–Darling, and Shatt al-Arab (Tigris–Euphrates) experience low precipitation combined with high evaporation losses.

The lower end of the Table lists comparative data for selected rivers in highly inhabited or otherwise hydrographically interesting valleys. The Rhine, Rhône, and Danube record regimes that vary along the length of their courses, in response to glacier melt in the headwaters and the entry of contrasting tributaries downstream. The Columbia is noteworthy as incorporated in an international project of regulation and power generation; the Rio Grande, like the Orange and the Colorado, suffers progressive downstream losses, both natural and irrigational. The Thames is special, as it experiences a very high tidal range in its estuary; this results in a number of benefits to navigation but also considerable handicaps in flood control.

Principles **governing** distribution and **flow.** Moisture supply sufficient to sustain channelled surface flow is governed primarily by climate, which regulates precipitation, temperature, and evapotranspiration water loss caused by vegetation. In rainy tropical and exposed midlatitude areas, runoff commonly equals 38 centimetres (15 inches) or more of rain a year, rising to more than 102 centimetres (40 inches). Negligible external runoff occurs in subtropical and rain-shadow deserts; perennial, intermittent, and ephemeral lakes, expanding in response to local runoff, prevent the drainage of desert basins from finding escape routes.

Variation of stream regime

Seasonal variation in discharge defines river regime. Three broad classes of regime can be distinguished for perennial streams. In the megathermal class, related to hot equatorial and tropical climates, two main variants occur; discharge is powerfully sustained throughout the year, usually with a double maximum (two peak values), but in some areas with a strong single maximum. In the mesothermal class, some regimes resemble those of tropical and equatorial areas, with single or double summer maxima corresponding to heavy seasonal rainfall, while others include sustained flow with slight warm-season minima. Where midlatitude climates include dry summers, streamflow decreases markedly and may cease altogether in the warm half of the year. In areas affected by release of meltwater, winter minima and spring maxima of discharge are characteristic. Microthermal regimes, influenced by snow cover, include winter minima and summer maxima resulting from snowmelt and convectional rain; alternatively, spring meltwater maxima are accompanied by secondary fall maxima associated with late-season thunder rain, or spring snowmelt maxima can be followed by a summer glacier-melt maximum, as on the Amu Darya. Megathermal regimes, controlled by systematic fluctuations in seasonal rain, and microthermal regimes, controlled by seasonal release of meltwater, may be more reliable than mesothermal regimes.

The regime can vary considerably along the length of a single river in timing and in seasonal characteristics. Spring maxima in the Volga headwaters are not followed by peak flows in the delta until two months later. The October seasonal peak on the upper Niger becomes a December peak on the middle river; the swing from tropical-rainy through steppe climate reduces volume by 25 percent through a 483-kilometre (300-mile) stretch. The seasonal headwater flood wave travels at 0.09 metre (0.3 foot) per second, taking some four months over 2,011 kilometres (1,250 miles), but earlier seasonal peaks are re-established on the lower river by tributaries fed by hot-season rains. The great Siberian rivers, flowing northward into regions of increasingly deferred thaw, habitually cause extensive flooding in their lower leaches, which remain ice-covered when upstream reaches have already thawed and are receiving the meltwaters of late spring and summer.

Extremes of regime characteristics come into question when streams are classified as perennial, intermittent, or ephemeral. These terms are in common use but lack rigid definition. Whereas the middle and lower reaches of streams in humid regions rarely or never cease flowing and can properly be called perennial, almost every year many of their upstream feeders run dry where they are not fed by springs. In basins cut in impermeable bedrock, prolonged droughts can halt flow in most channel reaches. Karst (limestone country) that has some surface drainage often includes streams that are spatially intermittent; frequently it also contains temporally intermittent streams that flow only when heavy rain raises the groundwater table and reactivates outlets above the usual level. Temporally intermittent streams also occur in dry areas where, at low stage, only some channel reaches contain flowing water. There is a continuous progression from perennial streams through intermittent streams to ephemeral streams: the latter flow only in response to occasional storms, their channels remaining dry most of the time. Supplying storms may be more or less randomly distributed or may belong to the outermost limits of seasonal monsoon rains.

Long-term effects expressed in mean seasonal regimes and short-term effects expressed in individual peak flows are alike affected by soil-moisture conditions, groundwater balance, and channel storage. Channelled surface flow begins when overland flow becomes deep enough to be erosive; and depth of overland flow represents a balance between short-term precipitation and soil infiltration. Rate and capacity of infiltration depend partly on antecedent conditions and partly on permeability. Seasonal assessments are possible, however; numbers of commercial crops can take up and transpire the equivalent of 38 centimetres (15 inches) of precipitation during the growing season. In many midlatitude climates, the rising curves of insolation and plant growth during spring and early summer cause soil moisture depletion, leading eventually to a deficit that is often strong enough to reduce runoff and streamflow. Soil-moisture recharge during colder months promotes high values of runoff, frequently in the spring, quite independently of the influence of precipitation regime or snowmelt.

Groundwater and glacier effects

Storage of water in groundwater tables, stream channels, on floodplains, and in lakes damps out variations in flow, whereas snow and ice storage exaggerate peaks. For the world as a whole, groundwater contributes perhaps 30 percent of total runoff, although the proportion varies widely from basin to basin, within basins, and through time. Shallow groundwater tables in contact with river channels absorb and release water, respectively at high and low stage. Percolation to greater depths and eventual discharge through springs delays the entry of water into channels; many groundwater reservoirs carry over some storage from one year to another. Similar carryover occurs with glaciers and to some extent also with permanent snowfields; water abstracted by the icecaps of high latitudes and by large mountain glaciers can be retained for many years, up to about 250,000 years in the central Antarctic cap. Temperate glaciers, however, with temperatures beneath the immediate subsurface constantly near the freezing (or the melting) point, can, like their associated snowfields, release large quantities of water during a given warm season; their losses through evaporation are small.

Meltwater contributions to streamflow, however, can range from well above half the total discharge to well below the level of the snowline; they are vital to irrigation on alluvial fans rimming many dry basins, as in the Great Valley of California and the Tarim Basin of the Takla Makan Desert: meltwater is released during the planting or growing seasons. Within the limiting constraints of precipitation or meltwater input or both, and the outputs of evapo-transpiration and percolation, the actual distribution of rivers in nature is affected by available drainage area, lithology, and vegetation. Vegetation is obviously climate dependent to a large extent but might well be capable of reaching thresholds of detention ability that do not match recognized climatic boundaries: it is, moreover, liable to the influence of climatically independent factors where it has been disturbed by man. Runoff on the plainlands of northern Asia, expressed as a percentage of mean annual precipitation, ranges from about 75 in the tundra, through about 70 in the boreal forest and 50 through boreal forest with perennially frozen ground, down through less than 40 in mixed forest, to five in semidesert. Clear felling of forest increases runoff in the short and medium term because it reduces surface detention and transpiration. In areas of seasonal snow cover, forest considerably influences seasonal regime. But although there may be a jump in short-term runoff characteristics between areas of continuous vegetation (forest and grass sward) on the one hand and discontinuous vegetation (bunch grass and scrub) on the other, comprehensive general studies of precipitation–temperature-runoff characteristics suggest that mean annual runoff decreases, at a decreasing rate through the range that is involved, as temperature increases and as precipitation (weighted in respect of seasonal incidence) decreases.

Constraints of rock type and vegetation

Lithology is significant mainly in connection with permeability. The capacity of karst or limestone country to swallow and to reissue water is well-known, as is the role of permeable strata generally in absorbing water into groundwater tables. An extreme case of a special kind is represented by an artesian aquifer, which in favourable structural conditions can take water for a very long time from the surface and immediately connected circulations, returning it only if the artesian pressure becomes strong enough to promote the opening of flowing springs. Less directly, but with considerable effect or, infiltration and short-term runoff, the mechanical grade of bedrock or of surficial deposits can considerably affect the response to individual storms.

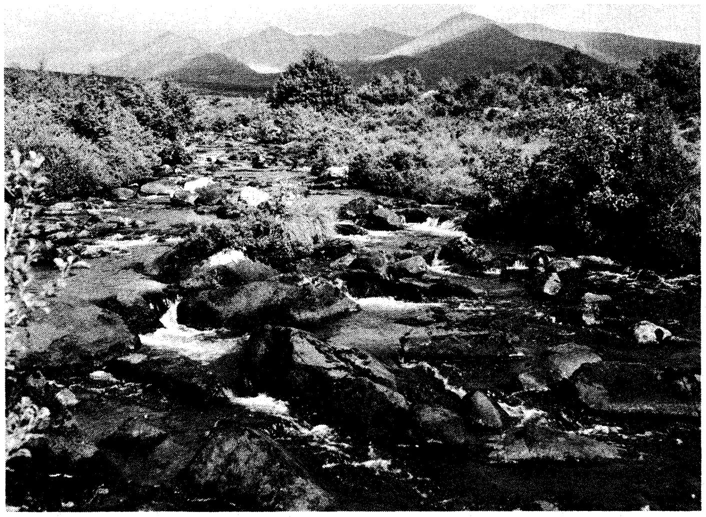

Figure 1: Boulder-bed stream, Ireland.

Both the ultimate possible extent of drainage basins and the opening of individual headwater channels are influenced by available drainage area. A hypothetical limit for very large basins could probably be constructed from considerations of stem length, basin shape, computed area, and continental extent: the Amazon probably approaches the hypothetical maximum. At the other extreme, basin morphometry (geometrical aspects of basins and their measurement) can be made to indicate the limiting average area necessary to sustain a given length of channel; in large areas of midlatitudes, the ratio is close to 2.25 square kilometres (1.4 square miles) of drainage area for a channel 1.6 kilometres (one mile) in length. Estimates for the conterminous United States, an area of about 7,770,000 square kilometres (3,000,000 square miles), give some 5,230,000 kilometres (3,250,000 miles) of channel length. These estimates include 1,500,000 unbranched fingertip tributaries—each having an average length of between 1.6 and 2.4 kilometres (1.0 and 1.5 miles).

DRAINAGEPATTERNS

Distinctive patterns are acquired by stream networks in consequence of adjustment to geologic structure. In the early history of a network, and also when erosion is reactivated by earth movement or a fall in sea level, downcutting by trunk streams and extension of tributaries are most rapid on weak rocks, especially if these are impermeable, and along master joints and faults. Tributaries from those streams that cut and grow the fastest encroach on adjacent basins, eventually capturing parts of the competing networks therein. In this way, the principal valleys with their main drainage lines come to reflect the structural pattern.

Dendritic, trellis, and radial patterns

Flat-lying sedimentary rocks devoid of faults and strong joints and the flat glacial deposits of the Pleistocene Epoch (from 2,500,000 to 10,000 years ago) exert no structural control at all: this is reflected in branching networks. A variant pattern, in which trunk streams run subparallel, can occur on tilted strata. Rectangular patterns form where drainage lines are adjusted to sets of faults and marked joints that intersect at about right angles, as in some parts of ancient crustal blocks; the pattern is varied where the regional angle of structural intersection changes. Radial drainage is typical of volcanic cones, so long as they remain more or less intact. Erosion to the skeletal state often leaves the plug standing in high relief, ringed by concentric valleys developed in thick layers of ash.

Similarly, on structural domes where the rocks of the core vary in strength, valleys and master streams locate on weak outcrops in annular patterns. Centripetal patterns are produced where drainage converges on a single outlet or sink, as in some craters, eroded structural domes with weak cores, parts of some limestone country, and enclosed desert depressions. Trellis (or espalier) drainage patterns result from adjustment to tight regional folding in which the folds plunge. Denudation produces a zigzag pattern of outcrops, and adjustment to this pattern produces a stream net in which the trunks are aligned on weak rocks exposed along fold axes and small feeder streams run down the sides of ridges cut on the stronger formations. Deranged patterns, in which channels are interrupted by lakes and swamps, characterize areas of modest relief from which continental ice has recently disappeared; these patterns may be developed either on the irregular surface of a till sheet (heterogeneous glacial deposit) or on the ice-scoured expanse of a planated crystalline block. Where a till sheet has been molded into drumlins (inverted-spoon-shaped forms that have been molded by moving ice), the postglacial drainage can approach a rectangular pattern. In glaciated highland, postglacial streams can pass anomalously through gaps if the divides have been breached by ice, and sheet glaciation of lowland country necessarily involves major derangement of river networks near the icefront. At the other climatic extreme, organized networks in dry climates can be deranged by desiccation, which breaks down the existing continuity of a net; the largely linear systems of ephemeral lakes in inland Western Australia have been referred to this process.

Spence Air Photos

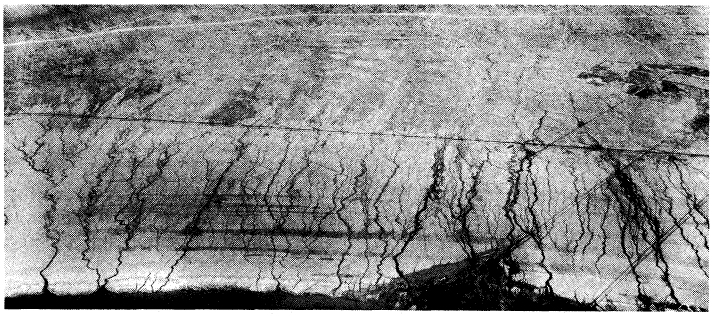

Figure 2: Dendritic drainage patterns in alluvium, Imperial Valley, California.

Adjustment to bedrock structure can be lost if earth movement raises folds or moves faults across drainage lines without actually diverting them; streams that maintain their courses across the new structures are called antecedent. Adjustment is lost on a regional scale when the drainage cuts down through an unconformity into an undermass with structures differing greatly from those of the cover: the drainage then becomes superimposed. Where the cover is simple in structure and provides a regional slope for trunk drainage, remnants of the original pattern may persist long after superimposition and the total destruction of the cover, providing the means to reconstruct the earlier network.

Stream order, stream number, and stream length

Horton's laws of drainage composition. Great advances in the analysis of drainage nets were made by R.E. Horton, an American hydraulic engineer who developed the fundamental concept of stream order: An unbranched headstream is designated as a first-order stream. Two unbranched headstreams unite to form a second-order stream; two second-order streams unite to form a third-order stream, and so on. Regardless of the entry of first- and second-order tributaries, a third-order stream will not pass into the fourth order until it is joined by another third-order confluent. Stream number is the total number of streams of a given order for **a** given drainage basin. The bifurcation ratio is the ratio of the number of streams in a given order to the number in the next higher order. By definition, the value of this ratio cannot fall below 2.0, but it can rise higher, since streams of greater than first order can receive low-order tributaries without being promoted up the hierarchy; some estimates for large continental extents give bifurcation ratios of 4.0 or more (see further SEDIMENT YIELD OF DRAINAGE SYSTEMS).

Although the number system given here, and nowadays in common use, differs from Horton's original in the treatment of trunk streams, Horton's laws of drainage composition still hold, namely:

1. Law of stream numbers: the numbers of streams of different orders in a given drainage basin tend closely to approximate an inverse geometric series in which the first term is unity and the ratio is the bifurcation ratio.

2. Law of stream lengths: the average lengths of streams of each of the different orders in a drainage basin tend closely to approximate a direct geometric series in which the first term is the average length of streams of the first order.

These laws are readily illustrated by plots of number and average length (on logarithmic scales) against order (on an arithmetic scale). The plotted points lie on, or close to, straight lines. The orderly relationships thus indicated are independent of network pattern. They demonstrate exponential relationships. Horton also concluded that stream slopes, expressed as tangents, decrease exponentially with increase in stream order. The systematic relationships identified by Horton are independent of network pattern: they greatly facilitate comparative studies, such as those of the influences of lithology and climate. Horton's successors have extended analysis through a wide range of basin geometry, showing that stream width, mean discharge, and length of main stem can also be expressed as exponential functions of order, and drainage area and channel slope as power functions. Slope and discharge can in turn be expressed as power functions of width and drainage area, respectively. The exponential relationships expressed by network morphometry are particular examples of the working of fundamental growth laws. In this respect, they relate drainage-net analysis to network analysis and topology in general.

Relation of morphometric parameters and river flow. The functional relationships among various network characteristics, including the relationships between discharge on the one hand and drainage area, channel width, and length of main stem on the other, encourage the continued exploration of streamflow in relation to basin geometry. Attention has concentrated especially on peak flows, the forecasting of which is of practical importance; and since many basins are gaged either poorly or not at all, it would be advantageous to devise means of prediction that, while independent of gaging records, are yet accurate enough to be useful.

Problem of predicting peak discharge

A general equation for discharge maxima states that peak discharges are (or tend to be) power functions of drainage area. Such a relationship holds good for maximum discharges of record; but conflicting results have been obtained by empirical studies of stream order, stream length, drainage density, basin size, basin shape, stream and basin slope, aspect, and relative and absolute height in relation to individual peak discharges in the shorter term. One reason is that not all these parameters have always been dealt with. In any event, peak discharge is also affected by channel characteristics, vegetation, land use, and lags induced by interception, detention, evaporation, infiltration, and storage. Although frequency–intensity–duration characteristics (and, in consequence, magnitude characteristics) of single storms have been determined for considerable land areas, the distribution of a given storm is unlikely to fit the location of a given drainage basin; in addition, the peak flow produced by a particular storm is considerably affected by antecedent conditions, seasonal and shorter term wetting and drying of the soil considerably influencing infiltration and overland flow. Nevertheless, one large study attained considerable success by considering rainfall intensity for a given duration and frequency, plus basin area, and main-channel slope expressed as the height–distance relationship of points 85 and 10 percent of stem length above the station for which predictions were made. For practical purposes, the telemetering of rainfall in a catchment, combined with the empirical determination of its response characteristics, appears effective in forecasting individual peak flows.

Evolution of drainage systems. To empirical analysis of the morphometry of drainage networks has been added theoretical enquiry. Network plan geometry is specifically a form of topological mathematics. Horton's two fundamental laws of drainage composition are instances of growth laws. They are witnessed in operation especially when a new drainage network is developing; and, at the same time, probability statistics can be used to describe the array of events and of forms which are produced.

Random-walk analysis

Random-walk plotting, which involves the use of random numbers to lay out paths from a starting point, can produce networks that respond to analysis as do natural stream networks: that is, length and number increase and decrease respectively, in exponential relationship to order, and length can be expressed as a power function of area. The exponential relationship between number and order signifies a constant bifurcation ratio throughout the network; and a greater constancy in this respect would be expected from a randomly predicted network than from a natural network, which contains adventitious streams that join trunks of higher than one additional order. The exponential relationship between length and order in a random network follows from the assumption that the total area considered is drained to, and by, channels; the power relationship of length to area then also follows. The implication of the random-walk prediction of networks that obey the empirically derived laws of drainage composition is that natural networks correspond to, or closely approximate, the most probable states (see further LANDFORM EVOLUTION).

THE GEOMETRY OF RIVER SYSTEMS

Hydraulic geometry. Hydraulic geometry deals with variation in channel characteristics in relation to variations in discharge. Two sets of variations take place: variations at a particular cross section (at-a-station) and variations along the length of the stream (downstream variations). Characteristics responsive to analysis by hydraulic geometry include width (water-surface width), depth (mean water depth), velocity (mean velocity through the cross section), sediment (usually, concentration or transport, or both, of suspended sediment), downstream slope, and channel friction.

Graphs of the values of channel characteristics against values of discharge usually display some scatter or departure from lines of best fit. One main cause is that values on a rising flood often differ from those on a falling flood, partly because of the reduction of flow resistance, and hence the increase in velocity, as sediment-concentration increases on the rising flood. Bed scour and bed fill are also related. Nevertheless, the variations for a given cross section can be expressed as functions of discharge, Q. For instance, width, depth, and velocity are related to discharge by the expressions: $w \propto Q^b$, $d \propto Q^f$, and $v \propto Q^m$, where w, d, v and b, f, m are numerical constants. The sum of the exponents $b + f + m = 1$, because of the basic relation—namely that $Q = wdv$.

Width, depth, and velocity of flow

Similar functions can be derived for downstream variations, but, for downstream comparisons to be possible, the observed values of discharge and of channel characteristics must be referred to selected frequencies of discharge. When data are plotted on graphs with logarithmic scales for each of two discharge frequencies at an upstream and a downstream station, the four points for each channel characteristic define a parallelogram (Figure 3), whereby the hydraulic geometry of the stream is defined in respect of that characteristic. The values of exponents in the power equations differ considerably from one river to another: those shown here are theoretical optimum values. One common cause of difference is that many gaging stations are located where some channel characteristics are controlled, whether naturally as by rock outcrops or artificially as by bridge abutments. Constraints on variation in width, for instance, are mainly offset by increased variation in depth.

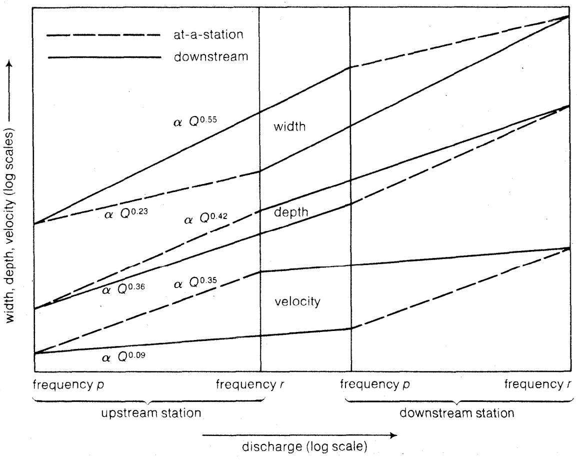

Figure 3: Hydraulic geometry for two frequencies of flow at an upstream and a downstream station, showing variation of width, depth, and velocity with discharge (see text).

Analyses of downstream variation in channel slope with discharge commonly reveal contrasts between field results and the theoretical optima. The discrepancy is probably due in considerable part to the fact that channel slope can vary in concert with channel efficiency, including channel habit, channel size, and channel form. Many past discussions of stream slope are invalidated by their restriction to the two dimensions of height and distance. In any event, the slopes of many natural channels are influenced by some combination of earth movement, change in baselevel, glacial erosion, glacial deposition, and change of discharge and load characteristics that result from change of climate. Consequently, although natural profiles from stream source to stream mouth suggest a tendency toward a smooth concave-upward form, many actually are irregular. Even without a change of baselevel, degradational tendency, or discharge, a change in channel sinuosity can produce a significant change of channel slope.

Down-stream changes of velocity

A marked downstream lessening of slope does not imply a decrease in velocity at a given frequency of discharge; reduction of slope is accompanied, and offset, by an increase in channel efficiency due mainly to an increase in size. The lower Amazon, with a slope of less than 7.6 centimetres per 1.6 kilometres (three inches per mile; less than 0.00005), flows faster at the bankfull stage than many mountain streams, at 2.4 metres (eight feet) per second. According to the assumptions made, an optimal velocity equation in hydraulic geometry can predict a slight increase, constancy, or a slight decrease in velocity downstream, for a given frequency of discharge. On the Mississippi, velocity at mean discharge (not a set frequency) increases downstream; velocity at the overbank stages of the five year and 50-year floods is constant downstream. Constant downstream velocity may well be first attained at the bankfull stage. The fact that relationships are highly disturbed at and near waterfalls and other major breaks of slope (the Paraná just below the Guaira Falls, for instance, runs at nine to 14 metres [30 to 45 feet] per second) has no bearing on the principles of hydraulic geometry, which applies essentially to streams in adjustable channels.

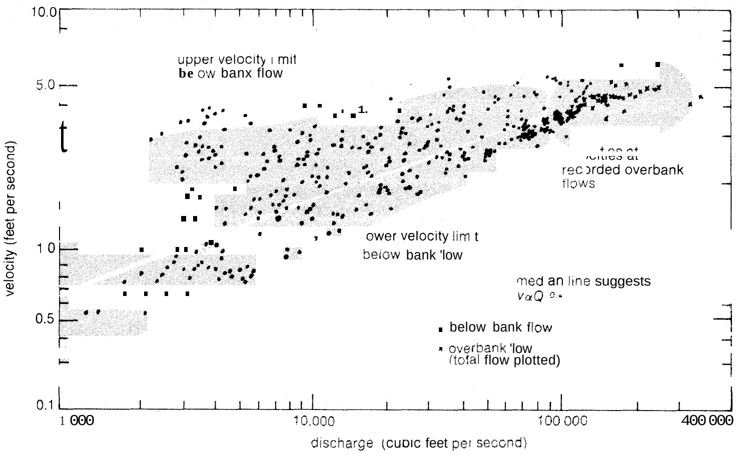

Figure 4: Variation of velocity with water discharge on the Red River at Fulton, Kansas.

The interrelationships and adjustments among width, depth, width–depth ratio, suspended-sediment concentration, sediment transport, deposition, eddy viscosity, bed roughness, bank roughness, channel roughness, and channel slope in their relation to discharge, both at-a-station and in the downstream direction, plus the tendency at many sections on many streams for variation to occur about some modal value, all encourage the conception of rivers as equilibrium systems. The designation quasi-equilibrium systems is usually used since not all variances can be simultaneously minimized, and minimization of some variances (for example, of water-surface slope) can only be secured at the expense of maximizing others (for example, channel depth).

River channel patterns. Distinctive patterns in the plan geometry of streams correspond to distinctive combinations of cross-sectional form, calibre of bed load, downstream slope, and in some cases cross-valley slope, ten-

dency to cut or fill, or position within the system. The full range of pattern has not been identified: it includes straight, meandering, braided, reticulate, anabranching, distributary, and irregular patterns. Although individual patterns repeatedly recur in nature and are given separate names, the total range constitutes a series of continua.

Straight channels, mainly unstable, develop along the lines of faults and master joints, on steep slopes where rills closely follow the surface gradient, and in some delta outlets. Flume experiments show that straight channels of uniform cross section rapidly develop pool-and-riffle sequences in their beds. Pools are spaced at about five bedwidths. Lateral shift of alternate pools toward alternate sides produces sinuous channels, and the spacing of pools on each side of the channel is thus about five to seven bedwidths; this relation holds in natural meandering streams.

River meanders and their cause

Meandering channels are single channels that are sinuous in plan, but there is no criterion, except an arbitrary one, of the degree of sinuosity required before a channel is called meandering. The spacing of bends is controlled by flow resistance, which reaches a minimum when the radius of the bend is between two and three times the width of the bed. Accordingly, meander wavelength, the distance between two successive bends on the same side —or four bend radii—tends to concentrate between eight and 12 bedwidths, although variation both within and beyond this range seems to be related to variations in the cross-sectional form of the channel. Because bedwidth is related to discharge, meander wavelength also is related to discharge.

Meandering channels are equilibrium features that represent the most probable channel plan geometry, where single channels deviate from straightness. This deviation, and channel division in general, is related in part to the cohesiveness of channel banks and the abundance and bulk of midstream bars. When single channels are maintained, however, the meandering form is most efficient because it minimizes variance in water-surface slope, in angle of deflection of the current, and in the work done by the river in turning. This least-work property of meander bends is readily illustrated by the trace, identical with that of stream meanders, adopted by a bent band of spring steel. Meander plan geometry is simply describable by a sine function of the relative distance along the channel bend. The least-work and minimum-variance properties of the plan geometry, however, are secured only at the expense of maximizing the variance in depth. The longitudinal profile of the bed of a meandering stream includes pools at (or slightly downstream of) the extremities of bends and riffles at the inflections between bends. Increased tightness of bend, expressed by reduction in radius and increase in total angle of deflection, is accompanied by increased depth of pool. Where riffles are built of fragments larger than sand size, they behave as kinematic waves: that is, the speed of transport of material through a given riffle decreases as the spacing of surface fragments decreases, and the total rate of transport attains a maximum where the spacing is about two particle lengths, as in moving traffic on a highway. Numerous sandbed streams in dry regions, however, fail to develop pool-and-riffle sequences, maintaining approximately uniform cross sections even at channel bends.

Irregularities in meanders developed in alluvium relate primarily to uneven resistance, which is often a function of varying grain size. Variations in total sinuosity are probably due in the main to adjustments of channel slope. The process of cutoff (short-circuiting of individual meanders) is favoured not only by the erosion of outer channel banks and by the tendency of meander trains to sweep downvalley but also by the stacking of meanders upstream of obstacles and by increases of sinuosity that accompany slope reduction.

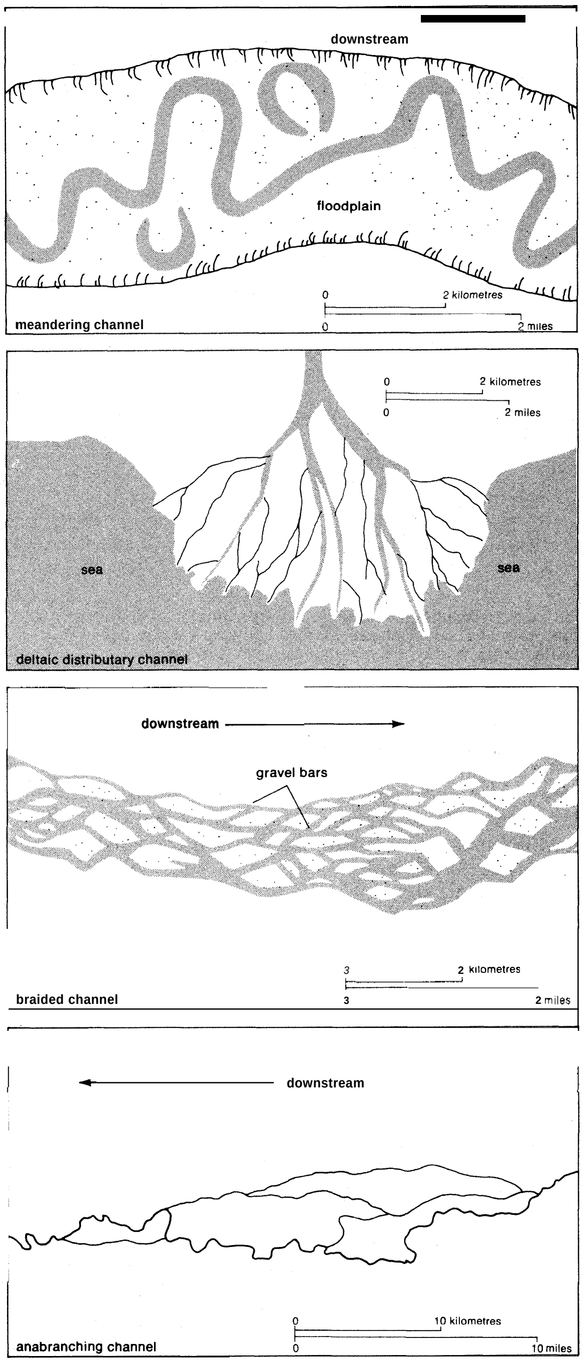

Figure 6: Common types of channel patterns.

Meandering streams that cut deeply into bedrock form entrenched meanders, the terminology of which is highly confused. It seems probable that, in actuality, the sole existing type of entrenched meanders is the ingrown type, where undercut slopes (river cliffs) on the outsides of bends oppose slip-off slopes (meander lobes) on the insides. For reasons not yet understood, lateral enlargement of ingrown meanders seems habitually to outpace downstream sweep, although the trimming of the upstream sides of lobes, and occasional cutoff, are well-known. Many existing trains of ingrown meanders belong to valleys rather than to streams, relating to the traces of former rivers of greater discharge. Reconstruction of the original traces indicates approximate straightness at plateau level, as opposed to the inheritance of the ingrown loops from some former high-level floodplain.

In a broader context, meander phenomena cannot be understood as requiring cohesive banks of the kind usual in rivers. Meanders, with geometry comparable to that of rivers, have been recognized in the oceanic Gulf Stream and in the jet streams (*q.v.*) of the upper atmosphere. In this way, stream meanders are classed with wave phenomena in general.

Braided channels

Braided channels are subdivided at low-water stages by multiple midstream bars of sand or gravel. At high water, many or all bars are submerged, although continuous downcutting or fixation, or both, by plants plus the trapping of sediment may enable some bars to remain above water. A single meandering channel may convert to braiding where one or more bars are constructed, as downstream of a tight bend where coarse material is brought up from the pool bottom. Each of the subdivided channels is less efficient, being smaller, than the original single channel; if its inefficiency is compensated by an increase in slope, that is, by downcutting, the bar dries out and becomes vegetated and stabilized. But many rivers that are largely or wholly braided along their length owe their condition to something more than local accidents. The braided condition involves weak banks, a very high width–depth ratio, powerful shear on the stream bed (implied by the width–depth ratio), and mobile bed material. Thus, braided streams are typically encountered near the edges of land ice, where valleys are being filled with incoherent coarse sediment, and also on outwash plains, as the Canterbury Plains of South Island, New Zealand; width–depth ratios can exceed 1,000:1. Studies on terraced outwash plains demonstrate that braided streams can readily excavate their valley floors: that is, they are by no means solely a response to valley filling.

Distributary patterns, whether on alluvial fans or deltas, pose few problems. A delta pass that lengthens is liable to lateral breaching, whereas continued deposition, both on deltas and on fans, raises the channel bed and promotes sideways spill down the least gradient. The branching rivers of inland eastern Australia, flowing across basin fills that range from thin sedimentary plains to thick riverine (fluvial) accumulations, have affinities with deltaic. distributaries although their patterns are only radial in part. A branch may run for tens of kilometres before joining a trunk stream, whether its own or another. Some channel plans change, notably at waterfalls, where multiple channels with high width–depth ratios above a fall are concentrated below the fall into a single gorge with a very low width–depth ratio. Outstanding examples include the falls of Khon (13 kiiometres, or eight miles wide; Mekong River), Guaira (Paraná River), Iguazu (tributary to Paraná), Victoria (Zambezi), and Niagara; channel width on the Iguazu below the fall is less than 2 percent of width at the fall lip.

STREAMFLOW AND FLUVIAL LANDFORMS

Stage-
discharge
relations

Peak discharge and flooding. Rapid variations of water-surface level in river channels through time, in combination with the occurrence from time to time of overbank flow in flat-bottomed valleys, have promoted intensive study of the discharge relationships and the probability characteristics of peak flow. Stage (depth or height of flow) measurements treat water level: discharge measurements require determinations of velocity through the cross-section. Although records of stage respond to frequency analysis, the analysis of magnitude and frequency is preferable wherever stage is affected by progressive scour or fill, and also where channels have been artificially embanked or enlarged or both. The velocity determinations needed to calculate discharge range from those obtained with portable Venturi flumes on very small streams, through observations with gaging staff or fixed Venturi flumes on streams of modest size, to soundings with current meters at intervals of width and depth at cross sections of large rivers. Frequent velocity observations on large rivers are impracticable. It is standard practice to establish a rating formula, expressed graphically by a rating curve. Such a curve relates height of water surface to the area of and velocity through the cross section, and thus to discharge. Secular changes in rating occur where a stream tends progressively to raise or lower its bed elevation. Short-term changes are common where the bed is mobile, and especially where the bed elevation–discharge relation, and thus the stage–discharge relation, differs between the rising and the falling limb of a single peak discharge curve. In such cases the rating curve describes a hysteresis loop. Rating curves for sandbed streams can include discontinuities, chiefly during rising discharge, that relate to behavioral jumps on the part of the bed.

Floods in hydrology are any peak discharges, regardless of whether or not the valley floor (if present) is inundated. The time-discharge or time–stage characteristics of a given flood peak are graphed in the hydrograph, which tends to assume a set form for a given station in response to a given input of water. The peak flow produced by a single storm is superimposed on the base flow, the water already in the channel and being supplied from the groundwater reservoir. Rise to peak discharge is relatively swift and is absolutely swift in small basins and on torrents, where the duration of the momentary peak is also short; on very large streams, by contrast, peak discharge can be sustained for lengths of days. Recession from peak discharge is usually exponential. The form of the hydrograph for any one station is affected by characteristics of the channel and the drainage net, and also by basin geometry, all of which can be taken as permanent in this context.

As already noticed above, flood-flow prediction that is based on permanent characteristics has hitherto achieved but partial success. Transient influences, also highly and at times overwhelmingly important, include the storage capacity of bedrock and soil, the interrelationships of infiltration, evaporation, and interception and detention (especially by vegetation), plus storm characteristics, which vary widely with respect to amount, duration, intensity, and location of rainfall with respect to the catchment.

Flood-
frequency
analysis
and the
annual
flood

In the longer term, flood-frequency analysis based on recorded past events can nevertheless supply useful predictions of future probabilities and risks. Flood-frequency analysis deals with the incidence of peak discharges, whereas frequency analysis generally provides the statistical basis of hydraulic geometry. Percentage frequency analysis has been much used in engineering: here, the 1 percent and 90 percent discharges, for instance, are those that are equalled or exceeded 1 and 90 percent of time, respectively. General observations of the flashy character of floods in headwater streams, in contrast to the long durations of flood waves far downstream, combine with analytical studies (as yet, restricted) to suggest, however, that percentage frequency is in some respects an unsuitable measure. Magnitude–frequency analysis, setting discharge against time, is directly applicable in studies of hydraulic geometry and flood-probability forecasting, although the best choice among types of probability is much debated. The accompanying example (Figure 7)

Adapted from *American Journal* of Science, vol. 251 (1953)

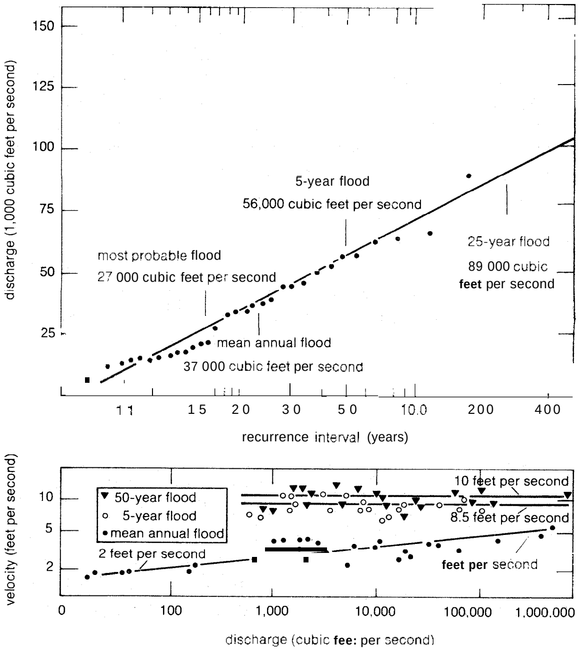

Figure 7: (Top) Magnitude of floods on the Sulphur River, Darden, Texas, and their probable recurrence interval. (Bottom) Relation of stream velocity and water discharge during floods of a given recurrence interval.

uses probability of extreme values to graph the annual series, wherein the peak discharge for each year of record is considered. Each recorded annual peak discharge is plotted against its simply computed recurrence interval. The 50-year flood has an average (but not regular) long-term spacing of twice in a century as an annual maximum; in any given year, it has a 2 percent chance of occurring as the annual maximum. On this scale, the 2.33-year flood is the mean annual flood. The most probable annual flood has a recurrence interval of 1.58 years (annual series); but, when floods lesser than, but independent of, the annual peak discharges are taken into analysis, it can be shown that the 1.58-year flood (annual series) has an average probability of occurrence of once a year.

Regional graphs of magnitude–frequency can be developed, given adequate records, for floods of any desired frequency or magnitude; but predictions for great magnitudes and low frequencies demand records longer than those usually available. Twelve years of record are needed to define the mean annual flood within 25 percent, with an expectation of correct results for 95 percent of time; and in general, a record should be at least twice as long as the greatest recurrence interval for which magnitude is desired.

Predictions of overbank flow, whether or not affected by artificial works, are relevant to floodplain risk and floodplain management. Notably in the conterminous U.S., floodplain zoning is causing risks to be reduced by the withdrawal of installations from the most flood-liable portions of floodplains or risks to be totally accepted by occupiers.

Catastrophic events

In the long geomorphic term, the transmission of sediment through the floodplain storage systems and through stream channels seems to result mainly from the operation of processes of modest magnitude and high frequency. Specifically, analyses suggest that total sediment transport by rivers is normally affected by flows approximating bankfull, over durations ranging down from 25 to 1 percent of total time. Infrequent discharges of great magnitude, such as are expectable on grounds of the probabilities of precipitation, snowmelt, and streamflow, range widely in destructive effect. Severe flooding is normally accompanied by great loss of life and property damage, the mean annual floods along the Huang Ho themselves affecting some 29,800 square kilometres (11,500 square miles) of floodplain, but geomorphic effects may be minimal, even with very large floods. The approximately 100-year floods of eastern England in the spring of 1947, fed bv unusuallv great and deferred snowmelt, scarcely affected either channels or floodplains. The 1955 floods in Connecticut. fed bv rains amounting to 58 centimetres (23 inches) in places, produced but spotty effects of erosion and deposition, even where floodplains were inundated to a depth of six metres (20 feet). For a given valley, there could be a threshold of inundation, river velocity, and sediment load, beyond which drastic changes occur. This is suggested, for example, by the catastrophic alluviation of valleys in eastern Australia and New Zealand during the last 4,000 or 2,000 years. Sudden catastrophes in the historical and geomorphic records relate to special events, mainly nonrecurrent: the 1841 Indus flood, which destroyed an army, the Gohna Lake flood of 1894 on the Ganges, and the 1925 Gros Ventre flood in Wyoming, accompanied the breaching of natural landslide barriers. The Lake Issyk (U.S.S.R.) flood of 1963, which caused widespread erosion and deposition, followed the overtopping of a landslide barrier by waves produced by a mudflow. The Vaiont Dam (Italy), although itself holding, was overtopped in 1963 by 91-metre (300-foot) high waves raised by a landslide: the floods downstream took more than 2,500 lives in 15 minutes. On the Huang Ho, the floods of 1887 took an estimated 900,000 lives. In late Pleistocene time, the overtopping of an erodible natural dam by the then existing Lake Bonneville eventually released nearly 1,666 cubic kilometres (400 cubic miles) of water; the maximum discharge of about 280,000 cubic metres (10,000,000 cubic feet) per second is comparable to the flow of the Amazon, but velocities were very high, perhaps ranging to 7.6 metres (25 feet) per second. The greatest flood peak so far identified is that of the ice-dammed Lake Missoula in Montana, which, on release, discharged 2,085 cubic kilometres (500 cubic miles) of water at an estimated peak flow of 8,500,000 cubic metres (300,000,000 cubic feet) per second, more than nine cubic miles per hour. Iceland is notable for glacier bursts, which are nonrecurrent where they result from subglacial eruptions but recurrent where they involve the sudden failure of ice dams, as with Grimsvotn, which periodically releases 8.3 or more cubic kilometres (two cubic miles) of water in floods that peak at 57,000 cubic metres (2,000,000 cubic feet) per second. Deposition by glacier-burst floods is illustrated by Iceland's Sandur plains.

Ice-dam flooding

Peak discharges that close the range between natural floods of great magnitude and low frequency on noncatastrophic streams and natural catastrophic floods of great magnitude and perceptible frequency include stormwater discharges from expanding urban areas. Because of the progressive spread of impermeable catchment and efficient runoff systems, such floods tend to increase both in frequency and in magnitude.

River floodplains. A floodplain, alluviated land of minor relief traversed by a river channel, is by definition liable to inundation. For convenience, the name is also applied to the alluvium itself. At the simplest, this forms a strip wide enough to accommodate the meander train, extending down to the depth of scour where bedrock is cleanly planed off; along the edges of the floodplain, the migrating meanders trim the valley walls into bluffs. As meander curves enlarge themselves, sweep downstream, and short-circuit themselves or one another, the alluvium is constantly reworked, being eroded from the outer sides of bends but redeposited on the inner sides as point bars. Rates of downstream sweep for alluvial meanders are poorly documented but are known to vary widely from stream to stream, and also in some streams along the length of the valley. Observations on the Rio Grande can be read as indicating sweep through a distance equivalent to one wavelength (distance between two meander extremities) in as little as 20 years; by contrast, some meander trains cut deeply into bedrock have shifted very little downstream in intervals as long as 500,000 years.

The minimum width for a completely developed floodplain equates with meander amplitude, which is to some extent controlled by the tendency of radius of curvature to equal two to three bedwidths, but many individual meanders are distorted by irregularities of composition in the floodplain alluvium, and in special cases the amplitude can be grossly exaggerated by the influence of bedrock structure. Many floodplains are in any case complex, being contained in older alluvium below the present depth of scour. Some, developed on deep and wide valley

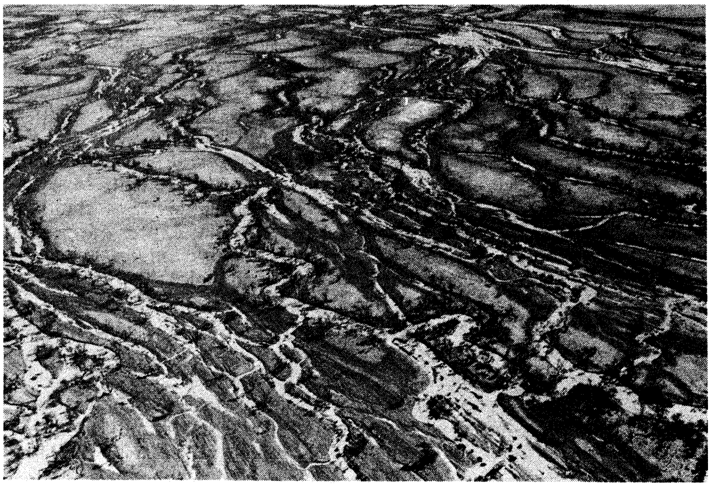

Figure 8: Australian channel country after seasonal rain has caused Cooper Creek to flood. The waters spread over a complicated network of rivers, channels, and swamps to form a natural irrigation area.

fills, are many times wider than the meander belt. Some floodplains possess natural levees, others none: the controlling difference may he a combination of sediment calibre with suspended-sediment concentration at times of overbank discharge. Natural levees tend to impede drainage on the outer parts of floodplains and to produce backswamps. Floodplains have been little studied in relation to other than meandering streams; both on these and on braided streams, floodwater can inundate low terraces on occasion.

Inundation and its effects

Magnitude–frequency analysis suggests that a stream that is neither raising nor lowering its profile at a significant rate will inundate its floodplain in about two years out of three. The geomorphic effects of inundation, including the inundation during high-magnitude, low-frequency floods, varies widely from valley to valley. In some valleys the bulk of the floodplain alluvium consists of point bar deposits, the deposition of which maintains channel width as a meander shifts, although the raising of the point bar surface to the general level of the floodplain may depend on encroachment by plants and their trapping of sediment. In such valleys the geomorphic influence of floods is minimal, despite the characteristic turbidity of floodwater; little sedimentation or valley-bottom erosion occurs during times of flood. In other valleys, botanical studies show that floodplains have been raised by vertical accretion. Trees rooted at former floodplain levels and toppled and covered by sediment during high floods can commence regrowth at the new levels of the raised alluvial surface, supplying markers in the history of buildup.

It is very difficult in general to separate natural from man-induced causes of floodplain alluviation. In some areas clearance, settlement, and cultivation have certainly been accompanied by alluviation of valley bottoms; but man's activities appear elsewhere merely to have accelerated natural processes, in response to which valley filling (including rise in floodplain elevation) alternates with valley clearing (including decrease in floodplain elevation). In some settings the whole matter is complicated by conversions to braiding, with steepening of gradients and much infilling, during ice-marginal or periglacial intervals or both, and reconversions to meandering, with lessening of gradients and excavation of valley fills, during interglacials.

River terraces. In one simple form, a river terrace is the remains of an old floodplain, cut through by the river and left standing above the present floodplain level. In this form the terrace has a flat depositional top and a steep fore-edge; it consists of alluvium. According to context, terrace can connote the upper surface, the combination of top and fore-edge, or the constituent material.

Paired terraces and their significance

A paired terrace is one where the terrace features (particularly the elevation and slope of the terrace surfaces) correspond across the valley. Sequences of paired terraces are common in the lower valleys of rivers that drain stable unglaciated areas. They relate to the sea-level stands of interglacial episodes, each successive stand being lower than the preceding, in consequence of the secular (cyclic) lowering of sea level on which glacial fluctuations were superimposed. Little is known in general of the rock floors on which such terraces rest; some terrace deposits are presumably shallow, representing simple floodplains, and the rock floors beneath evenly trimmed into planated benches. Because they are related to events of genetic significance, paired terraces have been much studied in connection with valley development; those of northwest Europe possess much archaeologic significance.

Where renewed downcutting has extended a new long profile part way up a stream, the head of the new profile and the remaining tail of the old profile intersect in a knickpoint. As already shown, however, a local increase in downstream slope results from causes other than renewed cutting. Where renewed cutting is responsible, the earlier forms, including floodplain deposits conveıted to terraces, can be used to extend the old profile downstream of the knickpoint; but no great success has attended efforts to fit equations to the curves of old profile plus terrace, and so to reconstruct past strandlines. Older, higher terraces are usually much eroded in lower valleys; allowances for local changes in former gradient are difficult to make.

Unpaired terraces display no cross-valley correspondence. They are most readily produced where a meandering stream is rapidly eroding a valley fill, while shifting its loops both downvalley and cross-valley. The terrace levels (except for the top of the fill) are now determined by the downvalley passage of single meanders, while the heights of terrace scarps depend on the extent of lateral channel swing.

Cut-and-fill sequences

Any climatic or other shift that causes intermittent downcutting, or a pair of shifts that cause filling to be followed by cutting, is likely to produce terraces. Intermittent uplift of the land or intermittent fall of sea level could bring identical suites of terraces into being, always provided that the stillstands (periods of stability) were long enough for floodplains to form. Many trains and sheets of outwash, deposited by the meltwater streams of land ice, have been subjected to intermittent clearance by braided streams, as notably on the Canterbury Plain of New Zealand; each new episode of cutting leaves part of the last wide stream bed as the top of a new terrace, terminating in a scalp where the rıver undercuts at the new, lower, level. A related form is the kame terrace, originally deposited alongside a wasting valley glacier and liable to be pitted by holes called kettles.

In some river systems the downstream relationships of terraces and present floodplain are complex. Where the upper basin was copiously supplied during glacial maxima with rock waste, either from glaciers or by periglacial action, stream gradients were increased by valley filling. Srmultaneously, gradients at and near the shore were increased by valley cutting in response to the glacial lowering of sea level. Many rivers affected in this way adopted braided habits. Reversion to interglacial conditions brought renewed cutting in the upper valley and filling in the lower valley, often with reconversion of the stream to meandering on a much reduced downstream slope. The steep fill surfaces of glacial times plunge seaward beneath existing floodplains; the sequence of cut and fill is inverted from the headward to the seaward valleys; and additional complications occur wherever a stream achieves net cutting between one interglacial and the next. Still further complications apply to streams that, developing a descending sequence of terraces in their upper valleys, experience deltaic subsidence at their mouths. The oldest former floodplain is represented by the highest terrace in the upper valley but is the most deeply buried in the delta.

A special type of terrace forms where a large meltwater stream draining from wasting land ice greatly raises its bed level and floods its tributary valleys with water and sediment. The sediment advances by delta-like progression into the lateral valleys, taking on remarkably horizontal top surfaces. When the trunk river begins to clear its valley fill and the tributaries are reactivated, the fills of the lateral valleys are cut through, their surviving portions forming backfill terraces. These are characteristically paired.

Climatic implications of cutting and filling

Alternations of cut and fill result from climatic shifts independent of, or in some areas additional to, glaciation, periglaciation, and strandline movements. Areas that are currently semiarid to arid have been especially studied in this respect. There is incomplete agreement on the working of the factors involved, except that these include changes in the amount (and probably also regime and intensity) of precipitation, changes in vegetal cover, and changes in temperature that are significant mainly for vegetation and evapotranspiration losses. Valley filling means an increase in stream slope: it implies an increase in sediment load, or at least a marked change in the calibre of load. Increased delivery of load implies increasing instability of the waste mantle on the hillslopes. Reversal to valley cutting requires reversal of some, or all, of the factors that promote filling. Studies in semiarid areas suggest that a shift either toward aridity or toward humidity would reduce total erosion; but the full combined effects of changes in climate, vegetation, and channel form and habit in relation to slope (and thus to cut or fill) may not yet be fully understood. It is clear, however, that quite small climatic changes in unstable environments can result in major changes from cut to fill or fill to cut. In at least some lately settled mountainous areas, the present gully cycle is independent of, although accelerated by, the activities of man in clearing and grazing.

Of necessity, visible terraces are less liable to flood than are floodplains; except in very large valleys, therefore, they usually give preferred locations of settlement, although very low terraces are exposed to occasional flood risk in some valleys. Little work has been done on the frequency of inundation of terraces proper, but recent investigations of valleys too narrow to contain terraces reveal series of small benches that relate to particular intervals or ranges of intervals on the magnitude–frequency scale. The predominant bench may relate to the frequency of the most probable annual flood; the causal connection, if any, between higher benches and channel-side berms (benches or ridges), on the one hand, and points on the magnitude–frequency scale, on the other, cannot yet be fully explained.

River deltas. The term delta originates from the A-like plan view of the exposed sedimentary accumulation at the mouth of the Nile. Deltas result from the outbuilding of alluvial deposits at river mouths; they frequently form seaward extensions of floodplains and in large instances of alluvial plains, which they themselves extend as they build oceanward. Delta plan geometry is simplest in small lacustrine deltas that build out from river channels fixed in bedrock: as such deltas rise, the channels on the delta repeatedly split, spilling down the lowest available slopes. The total effect is that the streams work back and forth across a cone-like surface, tending to produce an arcuate shoreline. Generally similar considerations apply to deltas formed in inland lakes, the Volga Delta at the entry to the Caspian Sea, for instance, attaining a surface area of almost 10,000 square kilometres (4,000 square miles); but the inland delta of the Niger, at its entry from the Fouta Djallon highlands to the Sud Plain, is a giant alluvial fan, correlative to the riverine accumulations of the members of the Murray–Darling system of southeast Australia where these leave the encircling highlands for the interior sedimentary plains.

Characteristics and changes of coastal deltas through time

Large coastal deltas also result from an excess of deposition over removal; and they too are typified by distributary channels. The visible areas—59,600 square kilometres (23,000 square miles) for the Ganges–Brahmaputra, about 25,000 to 35,000 square kilometres (9,500 to 13,500 square miles) for the Lena, Mississippi, and Niger, and a range of 24,600 to 12,200 square kilometres (9,500 to 4,700 square miles) for the Orinoco, Nile, Irrawaddy, and MacKenzie—represent only part of the depositional surface. Individual large deltas vary widely in plan, according to the interplay of deposition, shoreline processes, subsidence, general changes in sea level, and channel habit within the exposed parts. Unless they are advancing very fast, all great deltas locally concentrate enough sediment to depress the underlying crust; but the general tendency is one of progradation, that constructs a lengthening alluvial plain upstream of the delta proper. Long-continued deposition in a single area imparts lenticular cross sections to the sedimentary piles, whereas subsidence exerts a partial check on outbuilding; contemporary subsidence of the Po Delta offers a serious threat to the city of Venice. Submergence independent of subsidence results from deglacial rises in sea level; were it not for the latest rise, between about 15,000 and 5000 BP, coastal deltas would be commoner than they are and the visible deltas more extensive. Delta-building streams that are also levee builders can resist splitting, running far seaward before general breaching of the levees opens a new outlet. In the Mississippi Delta, levee breaching is followed by the formation of a new sedimentary lobe, but this sequence of processes appears untypical of large deltas generally. The Mississiyyi has initiated seven new lobes in the last 5,000 years. High tidal ranges do not inhibit delta building. Wave attack and longshore drift on a delta shoreline of moderate to high energy, on the other hand, can greatly modify the shoreline plan, checking extension of outlets and building spits perpendicularly to them; on some deltas, massive wave-built spits enclose lagoons.

Outbuilding lessens seaward gradients on the delta and also reduces the net gradients between upstream points in the valley and the advancing shore. In consequence, flood liability next upstream of the delta increases, unless the valley bottom is raised by sedimentation; and, within the delta, conditions are set for intermittent major diversions of the chief outlets. The latest 5,000 years in the Mississippi Delta have brought three major displacements of the main channel above the delta head, plus six marked relocations of the chief distributary system. The Huang Ho, artificially embanked for 725 kilometres (450 miles), has raised its bed in places more than ten metres (33 feet) above floodplain level. In some 4,000 years of record, bank failure has averaged one year in three and overtopping one year in ten. Seven complete changes of lower course roughly double the frequency observed on the Mississippi.

Ephemeral streams. Ephemeral streams, constituting the transition from perennial through intermittent to rare surface runoff, command much attention, especially because their effects in erosion, transportation, and deposition can be inordinately great and also because they relate closely to periods and cycles of gullying. Their channels generally have higher width–depth ratios than those of unbraided channels in humid areas; *e.g.*, 150:1 or more on small streams. In extreme cases, ephemeral streamflow merges into sheetflood. Stream beds, usually sandy, are nearly flat in cross section but contain low bars where gravel is available: these behave in many ways like riffles or braid bars elsewhere. Although beds and banks are erodible, the fine-material fraction is usually enough to sustain very steep channel banks and gully walls. Rapid downcutting produces flat-floored trenches, called arroyos, in distinction from the often V-shaped gullies of humid areas.

Geometry of arroyos

Discontinuous vegetation cover, well-packed surface soil, and occasionally intense rainfall promote rapid surface runoff, conversion of overland to channelled flow, and the multiplication of channels. Although reliable comparative data are scarce, it seems likely that ephemeral channel systems develop higher order ranking, area for area, than do perennial streams: channels as high as Ilth order are recorded for basins of about 1,300 square kilometres (500 square miles), whereas the Mississippi is usually placed only in the tenth order. This apart, geometry of ephemeral nets obeys the laws of drainage composition that apply to perennial streams: stream length, stream number, channel width, and water discharge can be expressed as exponential functions of stream order, and drainage area and channel slope as power functions, whereas slope and discharge can be expressed as power functions of width and drainage area.

At-a-station (a particular cross section) variations in width, depth, and velocity with variation in discharge in ephemeral streams resemble the corresponding variations in perennial streams; but differences appear when downstream variations are considered. For a given frequency of discharge, the rate of increase in width differs little between the two groups, but ephemeral streams increase the more slowly in depth, becoming increasingly shallow in proportion in the downstream direction. This effect is compensated by a more rapid downstream increase in velocity, which reflects high concentrations of suspended sediment and a resultant reduction of friction. Ultimately, however, the ephemeral flood may lose so much water by evaporation and percolation that the stream is dissipated in a terminal mudflow.

Trenching, the extension of gullies, and their conversion into arroyo systems, implies valley fills of erodible surficial material. Like streams of humid regions, ephemeral stream systems record complex histories of cut and fill: it is reasonable to expect comparable timing for climatically controlled events. Whatever the effect upon stream erosion of historical settlement in the western U.S., inland eastern Australia, and New Zealand, the present episode of gullying seems merely to have been intensified by man's use of the iand. Accelerated channelling frequently involves three processes not characteristic of humid regions: pipicg, headcutting, and the formation of channel profiles that are discontinuous over short distances.

Piping and discontinuous gullies

In piping, water that has penetrated the topsoil washes out the subsoil where this is exposed in section, forming small tunnels that may attain lengths of many feet. Collapse of tunnel roofs initiates lateral gullying and lengthens existing cuts headward. Headcutting is commonly associated with piping, because headcuts frequently expose the subsoil. A headcut is an abrupt step in the channel profile, some inches to some feet high; it may originate merely as a bare or trampled patch in a vegetated channel bed but will increase in height (like some very large waterfalls) as it works upstream. At the foot of the headcut is a plunge pool, downstream of which occurs a depositional slope of low downstream gradient. Formation of successive headcuts, say at an average spacing of 150 metres (500 feet), snd the construction of depositional slopes below each, causes the profile to become stepped; ephermeral streams with stepped profiles are called discontinuous gullies. Speed of headcut recession varies widely with the incidence and intensity of rainfall; but ultimately, when the whole profile has been worked along, and the bed widened, the original even slope is restored, although at a lower level than before.

THE RIVER SYSTEM THROUGH TIME

Natural river systems can be assumed to have operated throughout the period of geologic record, ever since continental masses first received sufficient precipitation to sustain external surface runoff. The Precambrian portion of the record, prior to 600,000,000 years ago, is complicated by the widely metamorphosed character of the surviving rocks, although even here the typical cross-bedding of shallow-water sands can be recognized in many places. The Cambrian and post-Cambrian succession of the last 600,000,000 years contains multiple instances of deposition of deltaic sandstones, which record intermittent deposition by rivers in many areas in many intervals of past time. The span since the Precambrian is long enough, at present rates of erosion, for rivers to have shifted the equivalent of 25 to 30 times the bulk of the existing continental masses, but the rate of erosion and sedimentation is estimated to have increased with time. Of necessity, river systems now in existence date from times not earlier than the latest emergence of their basins above sea level, but this limitation allows numbers of them to have histories 100,000,000 years or more in length.

Drainage diversion by stream capture

A river system of appreciable size is likely to have undergone considerable changes in drainage area, network pattern, and profile and channel geometry. Adjoining streams compete with one another for territory. Although competition is effectively nil where divides consist of expanses of plateau, or where opposing low-order streams of similar slope flow down the sides of ridges, it frequently happens that fluvial erosion is shifting a divide away from some more powerful trunk stream and toward a weaker competing trunk. In extreme cases, the height difference is so marked that a tributary head from one system can invade, and divert, a channel in the adjoining system: such diversion, usually named stream capture, has already been noted as a principal mechanism in the adjustment of network patterns to structural patterns. Close general adjustment to structure implies multiple individual adjustments, unless the stream network has developed solely by the headward extension of tributaries along lines of structural and lithologic weakness: the network predicated on a single regional slope is dendritic in pattern. By encroachment and capture, a successfully competing stream becomes yet more powerful, the headward extension of its basin increasing the discharge of the trunk channel and permitting reduction of slope; *i.e.*, additional downcutting. Seaward extensions of basins occur where deltas lead the outbuilding of alluvial plains, and where crustal uplift (and also at times strandline movements) result in emergence. Conversely, basin area is reduced along the seaward edge by submergence, in response to crustal depression or rise in sea level. The potential limits to basin size are fixed by available areas of continent with surface moisture surplus, in combination with theoretical optimum shape of basin; but actual basin shapes, for all large rivers, are to some extent affected by crustal deformation.

Glacial damming and isostatic rebound effects

Derangements other than the captures effected in stream competition include those due to nonfluvial invasion and deposition. Regional flooding by basalts, as during the Tertiary Period (65,500,000 to 2,000,000 years ago) in the Deccan of India and the northwestern part of the U.S., obliterates the former landscape and provides a new surface on which new drainage networks form. Major invasions by continental ice displaces fluvial systems for the time being; glacial deposits, especially till sheets, can conceal the preglacial topography and provide initial slope systems for postglacial streams. Individual diversions occur at and near ice fronts, also where preglacial divides in mountain country are breached by the ice of caps or impounded mountain glaciers. The full history of drainage derangement by continental ice is often complex, depending on the particular combinations of preglacial outlet directions, extent of glacial invasion, relation-"ship of regional slope to direction of ice advance, thickness of glacial sedimentation, amount and speed of postglacial isostatic rebound, and self-selection of postglacial outlet directions and drainage lines. The North American Great Lakes and Midwest areas, the Thames Basin in England, and the Eurasiatic plain all record intricate histories of damming during glacial maxima, with postglacial networks and outlets differing markedly from those of preglacial times. Glacial breaching of divides requires the passage cf thick ice through a preglacial notch or gap, with erosion severe enough to provide a new drainage line when the ice melts. The spinal divide of Scandinavia was breached by the ice cap centred over the Gulf of Bothnia, just as the highland rim of Greenland is being breached by effluent glaciers today. After deglaciation, areas of divide breaching display streams with anomalous courses through gaps in major relief barriers. Morphologically related to glacial breaching, especially with respect to indeterminate present-day divides, are the disordered drainage nets of formerly glaciated terrains where bedrock is widely exposed and where relief is subdued.

Changes through time in channel slope have already been partly treated in connection with terraces. In the long view, streams must tend to reduce their slopes as the basin relief is lowered, although isostatic (balancing) compensation for erosional reduction of load largely offsets the reduction of slope. The effects involved here are independent of, although necessarily associated with, glacial–deglacial changes in the strandline level, crustal warping, and isostatic rebound from glacial reduction of load. It can be argued that large river systems, removing large quantities of sediment and dumping them offshore, should promote intermittent isostatic uplift when yield thresholds are passed and, in consequence, promote the generation of new waves of erosion that, working upstream, are recorded in sequences of cyclic knickpoints. The implications of this conceptual view have been applied especially to the unglaciated shield areas (central and oldest part of continents, generally) of tropical latitudes and extratropical parts of the Southern Hemisphere, in all of which rivers descend in high falls or lengthy cascades across the edges of major erosional platforms. In the shorter term, severe and rapid erosion of a trunk channel can leave a tributary valley stranded at height. Channel geometry demands that tributary glacier troughs should hang above the floors of main troughs, while tributary stream valleys often hang above trunk valleys formerly occupied by long glacier tongues. Hanging valleys on shorelines are correspondingly due to the outpacing of channel erosion by cliffing.

Effects of climatic change

Climatic shifts are known to be capable of effecting fill or clearance of channels and valleys: they can also change channel habit. In addition to the alternation in some near-glacial areas between braiding during maximum cold and meandering during interglacial warmth, the record includes conversions of channel width and meander pattern. On numerous midlatitude streams, existing channels have been much reduced from their earlier dimensions; and on many, but by no means all streams, existing floodplains are contained in the floors of meandering valleys where the wavelength is determined by the plan of the floodplain as opposed to the existing channel. Valley meanders were cut by streams 20 to 100 times as voluminous as existing streams, at the bankfull stage. They illustrate only one variant, although a widespread one, of the underfit stream, which combines a former large with an existing reduced channel. Reduction to the underfit state is commonly, although not invariably, accompanied by the infilling of former large channels both laterally and from below, so that existing floodplains are contained in valley-bottom fills. Accidents of capture and glacial diversion apart, the underfit condition results generally from climatic shift. The last major shift responsible for channel shrinkage appears to have occurred in the interval 12,000 to 9,000 BP, or later in areas that were still ice-covered 9,000 years ago (see further CLIMATIC CHANGE). Involving a reduction of bedwidth to as much as one-tenth of earlier values, and in meander wavelength by similar proportions, channel shrinkage is known to have been succeeded in well-studied areas by lesser fluctuations that are recorded in episodes of partial clearance followed by renewed fill. Significant alternations between cut and fill during the last 10,000 to 20,000 years have perhaps averaged a periodicity of 1,000 to 2,000 years: there is no a priori reason to suppose that the corresponding periodicity differed from this value during the whole Pleistocene, 2,000,000 to 3,000,000 years in duration so far. Inferences about pre-Pleistocene fluctuations await detailed analysis of rates of deposition of graded beds, coral growth, and the like.

On account of the temporal–dynamic qualities that have been discussed, stream channels and river networks are to be regarded as open systems (those open to additions or subtractions of materials or energy through time), whether in relation to short-term adjustments to individual peak discharges, in relation to accommodation to the constraints of climate, vegetal cover, characteristics of infiltration and overland flow, or in relation to the long-term influences of crustal movement, interbasin competition, and land wastage. Channels and networks experience inputs and outputs of matter and energy. Some, but probably a small minority at any one time, and for a minor duration of total time in any one channel or network, act as open systems in disequilibrium. The general tendency seems to be for channel and river systems to attain steady-state conditions, wherein negative feedback tends to counter individual disequilibrium tendencies, and counteracting effects ensure variations about recurrent norms of form and behaviour. (G.H.D.)

LIFE IN RIVER SYSTEMS

The river as a biological environment. A distinction is often made between a zone of erosion and a zone of deposition in rivers, but it must be remarked that, whatever the size of the particle that is moved by a flood, it will be deposited when the flow is less. It is preferable to make the distinction between zones where the bottom has stones large enough for the biggest invertebrate animals to cling to and where the bottom is of sand or mud whose particles are so small that the larger invertebrates must burrow. If a river with a sandy or muddy bottom is shallow enough, rooted plants will grow in it. Between the two zones there will be an intermediate one where fine particles settle during low flow and are washed away by a flood, and the slope, or river bottom grade, may be such that this intermediate zone is longer than either of the other two. A river from source to mouth is a continuous whole, and attempts to divide it into zones must be arbitrary. Any classification system may prove useful for a particular purpose, without being a concept with fundamental significance for biologists.

Water emerging from deep underground layers is generally cold, often with but a small range of temperature change during the course of a year, but it may be warm if it drains shallow soil. The smaller the volume of water the warmer it will become in the sun and the more heat it will lose at night. Larger water volumes have less daily temperature fluctuation and they are never far from average air temperature. If there is not a big difference in altitude, headstreams may therefore reach a higher maximum temperature than the main river. This condition, of course, has importance regarding the type of life found in the various parts of a stream.

Oxygenation of streams

A torrential stream is nearly always well oxygenated. A slow river is often well oxygenated by day because of the activities of photosynthetic plants, but it may be depleted of oxygen by night, when only oxygen consuming and decomposition processes are active. Turbidity, the muddiness and cloudy condition of the water, generally increases steadily from source to mouth. Accumulated organic matter washed from the land is believed to be the main base of the food chain in running water, and therefore in hilly or mountainous regions the amount of material entering the stream that may become a source of food tends to increase as the area drained increases with distance from the source. The amount may decrease farther downstream where the carrying capacity of the river drops with reduced flow.

Biological classification of streams. An old and well-known method of dividing rivers into zones is based on the presence of one of four fish species commonly found in western Europe: *Salmo* (trout), *Thymallus* (grayling), *Barbus* (barbel), and *Abramis* (bream). Each zone as defined by these fish coincides with a given slope, though for any zone the wider the stream the more gentle the slope. Even in western Europe there is a certain inconvenience in designating the zones by species of fish, for some, notably grayling, are not widespread. Elsewhere other species must be sought. Running water systems have also been classified into zones called the rhithron, which is roughly the stony upstream region, having well-oxygenated water and with temperature rising to no more than 20" C (68° F), and the potamon, which is the downstream portion having a sandy or muddy bottom and temperature exceeding 20° C at the warmest time of year. Both rhithron and potamon are subdivided. Within any one subdivision, however, the composition of the living community may be changed by some factor unconnected with flow or temperature, and the terms therefore have no precise biological significance though they may be useful in a general sense.

Organisms in streams. The slower the streamflow, the more the composition of the living community resembles that of still water and, therefore, any discussion of peculiar features of running-water organisms must centre largely round those that have colonized the swifter flowing waters.

Stagnant waters fill and disappear but a watercourse must flow as long as there is precipitation to supply it. It is, therefore, not surprising to find in running water certain groups of organisms that have changed little during the millions of years in which others have evolved

Figure 10: Riverbed inhabitants.

From (a, d–g, i, k–n) T. Macan, *A Guide to Freshwater invertebrate Animals;* by permission of the author and Longman Group Ltd., (b) G. Pleskot, *Der Stand der Biologischen Fliesswasserforschung,* (c, h, j) C. Wesenberg-Lund, *Biologie der Susswasserinsekten*

and adapted. Most members of the insect order Plecoptera (stoneflies) and many of the order Ephemeroptera (mayflies) inhabit running water, and other primitive groups confined to it include the crustacean ***Anaspides*** and the caseless free-ranging caddis larvae of the insect family Rhyacophilidae. Moreover there are few groups of freshwater organisms that are not represented in running water. The exceptions are extreme specialists such as the phyllopod crustaceans (fairy shrimps and related forms), which must swim to feed and have survived only in temporary water where they are free from the predation to which this mode of life exposes them.

Hazards of the environment

Rapidly flowing water is well-oxygenated and a moving medium brings to its inhabitants a constant supply of oxygen and also salts, at the same time removing their waste products. It also carries a constant supply of food. The disadvantage of life in a moving medium is that any accidental displacement must always be in one direction. Even the organisms that live in the substratum (various layers of the stream bottom) are occasionally subject to this hazard when exceptional flow causes the substratum to shift. A further problem is the accomplishment by organisms of even colonization of a biotope (uniform habitat occupied by a uniform community of organisms) that may be very long and very narrow.

Plant communities. Stones and rock are covered by algae, many of which are single cells, though some are filamentous and traii in the water in tresslike tufts. There are many species of these and they are often scoured off their supports by sand and gravel when the rate of streamflow increases; there are marked changes in the communities with the seasons even when this does not happen. Algae tend to occur in irregular patterns varying considerably in species composition and abundance. It has not, therefore, so far proved possible to discern definite algae communities associated with given stream conditions, though it is known that temperature, light, substratum, and dissolved substances in the water are factors that influence the occurrence of certain species.

A stone or boulder that survives for a long time without being overturned, and that is not scoured by particles of sand and gravel, will become densely covered by mosses and liverworts.

Rooted plants grow thickly where substratum and water depth are suitable, but attempts to define communities comparable with those in still water have been unsucessful. This is partly due to the instability of the flowing water system. Once established, a tuft of vegetation impedes flow and facilitates the deposition of silt, which may alter the substratum until it becomes favourable for some other species. Eventually the vegetation may present so much resistance to streamflow that the whole mass is washed away. Many species of plants in temperate latitudes die down in winter and no longer protect silt that settled round them in summer. Copious plant growth interferes with water flow to such an extent that it often becomes necessary to cut and remove it from some streams to prevent flooding.

Animal adaptations. ***Life in the streambed.*** There is a zonation of animals in the substratum as may be seen in Figure 10. If bottom particles are not too fine, there is a rich and varied animal community down to a metre (3.3 feet) or more below the surface of the streambed. Certain crustaceans, mites, and nematodes are restricted to these deep habitats but also abundant may be tiny nymphs or larvae, the immature insects that, when they are larger, inhabit higher regions where the particles are coarser.

Stratification of life in the streambed

Nearer the surface, in sand and gravel, may be found various animals, notably segmented worms (of class Oligochaeta) and the larvae of certain families of flies (of the insect order Diptera) that, having come in from a similar habitat elsewhere, have been able to colonize running water with little change of form and habit. Nearer the surface still, but protected from the current by the large stones above, are many animals that show no structural adaptation to life in running water, though obviously without some modification of behaviour they would not survive. Most of the stoneflies (order Plecoptera), various caddis larvae (order Trichoptera) that make cases, and amphipods (shrimplike crustaceans) such as ***Gammarus*** are examples that are likely to be familiar over most of the world. Some of the stonefly nymphs are long and thin and consequently are well designed to live among the spaces between small stones and pieces of gravel. There is no rigid line of distinction between the inhabitants of the three zones mentioned.

Life at the surface of the streambed. Finally come the animals that colonize the large stones forming the surface of the streambed. Many are structurally modified for swift water environments. The freshwater limpets (family Ancylidae) have a simple conical shell that offers little resistance to the current and a foot that forms an efficient sucker. Larvae of the family Blepharoceridae, the net-winged midges, have six suckers provided with muscles that can create a powerful suction. Another similar adaptation is seen in several families of beetles and reaches its highest development in the water pennies, which belong to the family Psephenidae. The body is flat and wide, and the margin is pliable and beset with spines and hairs. It can be adjusted to fit the irregularities of the surface sufficiently to prevent any water flow underneath the larva, and the pressure on the rounded upper surface tends to press it against the substratum even though there are no suction-producing muscles. In certain Ephemeroptera (mayflies) modification of the nymph's gills produces the same effect. Such nymphs are frequently confined to running water because they cannot use their gills to create a current if necessary. For example, the mayfly genus ***Rithrogena*** has modified gills that respire less rapidly as current speed falls, whereas related genera that can move their gills consume as much oxygen in still as in flowing water. They occur on stony lakeshores and species of ***Rithrogena*** do not.

Nymphs of the mayfly family Ecdyonuridae (or Heptageniidae) have broad flat heads with veiy thin margins, and upper leg segments are of a similar shape though less acute at the margins. The body and legs are pressed against the surface, and, retaining its hold by means of sharp claws, the nymph can scuttle across a flat hard surface with great nimbleness. In the Southern Hemisphere this adaptation is found in members of the mayfly family Leptophlebiidae, which replace the Ecdyonuridae.

Adaptation to the running-water environment

Larvae of the fly family Simuliidae may perhaps be said to be the most highly adapted of all running-water animals because they not only anchor themselves in swift currents but make use of the flow to bring food. At the tip of the abdomen and on a proleg near the head are pads armed with concentric rows of hooks, of which the points can be directed outwards by pressure of the body fluid and retracted by muscles. The larvae can produce threads of silk, and these it lays over the surface of a stone, often where the current is swift. At intervals, tangled masses of silk are laid down. The larva can move across its silken lattice with a looping action, taking hold with fore and aft pads of hooks alternately. Most of the time it trails in the water with the rear hooks embedded in one of the tangled blobs of silk. It extends a rakelike apparatus, and when this has strained a mass of fine particles from the water the appendage is retracted and the mass is eaten.

Three families of caddis (of the insect order Trichoptera) utilize the current to bring food. None makes a case in the fashion of most caddis larvae but all spin nets. Members of two of these families feed on drifting organic matter, but the third is carnivorous and lives a life not unlike that of a spider on land. Members of this family occur in still water.

Adults of most beetles (Coleoptera) and bugs (Heteroptera) must come to the surface periodically to renew their store of air, a necessity that is plainly inconvenient in a medium flowing one way. It is not unexpected, therefore, that in swifter regions of rivers these two orders are represented mainly by families that have developed plastron respiration and can live permanently on the bottom (Elminthidae of the beetles and Aphelochiridae of the bugs).

Factors affecting communities in streams. Several factors influence the composition of the communities. It is impossible to separate the effects of streamflow and substratum. When current falls to a speed at which fine particles settle, the animals that inhabit the spaces between small stones and pieces of gravel are replaced by burrowing forms, of which the main groups are oligochaetes (worms), lamellibranchs (clams, mussels), and chironomid larvae (flies). Various mayfly nymphs such as the genera ***Ephemera*** and ***Caenis*** also burrow in sand and mud, and some dragonfly nymphs have also taken to this way of life, particularly in Africa.

Effects of flow velocity

A varied animal community is found in vegetation, if this develops. Animals with adaptations for life on a hard flat surface such as the mayflies of the family Ecdyonuridae or limpet-like mollusks do not occur, but less specialized forms such as the shrimplike ***Gammarus*** may continue in great numbers. ***Simulium*** (gnats and blackflies) and ***Baetis*** (mayflies) are two genera that are also abundant in both stony and weedy zones, though the species are generally different in the two.

Within one zone, rate of flow is probably not of great importance for most species since they live among stones, avoiding places exposed to the full force of the current. It is important to the net-spinning caddis larvae, which must find a place where current speed lies within a narrow range. It has been shown experimentally that a change in the pattern of flow is quickly followed by a change in the distribution of their nets.

Different kinds of rock break up into stones that differ in shape and size and texture, but whether this affects the communities that colonize them is not known. That the distribution of certain species that inhabit streambeds of fine particles is related to the size of the particles has been clearly established. In Europe the mayfly ***Ephemera danica*** inhabits sand, ***E. vulgata*** mud, and several similar examples have been described in North America. Stones that have been rounded by abrasion during transport by ice or water provide a difficult substratum colonized only by agile animals. Flat stones that move less easily harbour a more varied community, and it is richer still if, as generally happens, the stones become covered with moss.

Springs and the stretch immediately below them are often inhabited by species not found elsewhere, and some of these are confined there by their requirement of low temperature. One of the few species that has been thoroughly investigated, both in the field and in the laboratory, is the flatworm, ***Crenobia (Planaria) alpina.*** It is commonly confined to water whose maximum temperature does not exceed 15° C (59" F), though it can tolerate 25° C (77" F), provided it is not exposed to it for too long. Reproduction generally takes place only in water colder than about 12" C (54" F). Other animal species are confined to cold water not by physiological limitations but by their inability to compete with a rival in warmer water. Britain for example lacks the amphipods ***Gammarus fossarum*** and ***G. roeselii*** and instead ***G. pulex*** ranges in British streams from source to mouth. In Europe ***G. pulex*** is confined to the middle reaches of flowing waters and is apparently kept out of the upper ones by ***G. fossarum*** and the lower ones by ***G. roeselii.***

Effects of water pollution

Animal populations tend to be densest in those places where the configuration of the bottom produces areas of still water with consequent settling of debris. In addition some of the most notable changes in the composition of the population can be related to food supply. Below lakes the water is rich in floating algae and tiny drifting animals as well as suspended organic matter, and here the numbers of net-spinning Trichoptera and *Simulium* are much higher than elsewhere. They appear to exclude other species found under similar conditions of flow and substratum but without the augmented food supply. Slight enrichment by sewage leads to an increase in the number of flatworms and a decrease in the number of certain other species. It has been suggested but not proved that the flatworms eat them. In rivers enriched by the decomposition of sewage, great numbers of *Asellus* (a freshwater crustacean), leeches, mollusks and ***Sialis*** (alderflies) are found. Below the zone of enrichment these animals become progressively scarcer and are replaced by the community associated with similar conditions of flow and substratum in unenriched water. Again the full interrelationships have not been worked out. Decomposition of sewage is accompanied by lowered oxygen concentration in the polluted waters, and the typical inhabitants of stony rivers require a high concentration. There is also evidence that they are adversely affected by the bacteria that coat'the stones and indeed some of the animals themselves. In lakes, where water movement, in this case wave action, and substratum are more uniform, the most plansible explanation at present is that predation by the species favoured by enrichment leads to the elimination of the species typical of areas where there is no enrichment, and it is reasonable to postulate that this factor operates in running water too.

Life cycles of running-water animals are unexpectedly diverse and offer a rich field for experimental investigation. Nearly all the observations have been made in temperate regions. A number of animals, notably the larger ones such as leeches, snails, bivalve mollusks, and crayfish, take more than a year to reach maturity. Many are univoltine; *i.e.,* they take one year to complete development. Some species in the genera ***Baetis*** (Ephemeroptera) and *Simulium* (Diptera) and in the Trichoptera pass through two generations in a year. Quicker development is rare, ***Gammarus pulex*** being an outstanding example, completing its life cycle in less than two months.

Many of the univoltine species have a resting stage, which generally tides them over the warm period of the year. It is often the egg stage, sometimes the early nymphal stages, and sometimes, chiefly in Trichoptera, the last larval molting stage. The common European mayfly, ***Ephemerella ignita,*** apparently spends some ten months in the egg stage, at least in parts of its range; nymphs appear around midsummer, grow rapidly, and emerge in August or early September. In other species, the mayfly ***Baetis rhodani*** for example, some eggs remain unhatched for many months whereas others hatch .after a few weeks.

The phenomenon of drift

A net set so that water flows through it catches representatives of many of the species inhabiting the stream. Catches of most are much higher by night than by day and are often greatest just after dusk and sometimes again before dawn. This phenomenon, commonly referred to as drift, has been much studied and has provoked several controversies. The number of specimens drifting seems to bear some relation to the population in the stream and is at its highest during the period of most rapid growth. Therefore it probably represents to some extent a removal of surplus population. Drifting animals are likely to fall a prey to fish, but there is evidence that those that escape this fate do not travel far before regaining the safety of the bottom. Some of the larger adult caddisflies have been observed flying upstream to lay their eggs, but there is evidence that other insects do not maintain the population in the upper reaches in this way. Many have been shown to move against the current during the aquatic stage of their life cycles, particularly when small, and it is likely that uniform colonization of all suitable stretches of a watercourse is maintained in this way.

Detritus, drifting organic matter originating from dead leaves and other vegetable fragments that are blown or washed into the water from the land, is the main primary source of food in rivers and streams. The limpets, the flat nymphs of the mayfly family Ecdyonuridae, and larvae of various caddis species graze upon the algal felt that covers the upper surface of stones but probably subsist extensively on the detritus trapped in this. Detritus may also stick to the mucous trails left by flatworms or lodge in the irregularities of a rough surface. Little is known about the digestive powers of the various detritus feeders. That vegetable remains are not an easy source of food is indicated by the frequency with which they are passed twice through the same intestinal tract. It is likely that the actual source of food is the fungi and bacteria that are breaking down the vegetable tissue. The flatworms, the large stoneflies, some of the caddisflies and many fish are carnivores.

Biological productivity. In one study of total production of flesh by trout per year in the Horokiwi Stream in New Zealand, there were about 50 grams per square metre (*i.e.,* 500 kilograms per hectare, which is approximately 500 pounds per acre). An important point that came out of this investigation was the large contribution to production made by young fish, whose size was very small but whose numbers were large. Fish are comparatively easy animals with which to work, mainly because of their large size and the fact that the eggs hatch within a short period. Moreover the young do not live in the substratum. The trout establishes territories whose sizes depend on the configuration of the bottom and not on food supply. Fish, however, secure efficient exploitation of the resources of the environment by means of an indeterminate size at maturity. If food supply is poor the fish remain small, if it is good they grow much more rapidly, but sexual maturity is attained after a period that does not vary greatly with size, and the small fish reproduce just the same as normal adults. Furthermore, that calculations of production by populations of wild fish are of the right order can be confirmed by comparison with the extensive data obtained by commercial cultivators. Consequently there are reliable figures for the production by several species in the wild state.

Allen's paradox

Information about invertebrates is much less satisfactory. It was discovered how much the trout in the Horokiwi ate and it turned out to be some 17 times greater than the number of invertebrates apparently available as food. This observation, known as Allen's paradox, has been confirmed also in other parts of the world. In other words, production is underestimated. It is possible that unaccounted-for populations among running-water animals are to be found well below the surface of the substratum, where it is known that tiny nymphs abound and where most sampling instruments do not penetrate. They may also be washed down from the smallest tributaries, which are too shallow or too swift for fish to enter. This explanation of Allen's paradox is speculation, but it is plausible. What can be stated with confidence is that until an explanation has been provided and verified, calculations of production of invertebrates are premature.

Measurement of primary production by algae is difficult because any enclosing of them in containers, the technique that has been used extensively in lakes, alters the environment drastically by cutting off the current. Measurements of changes in the concentration of oxygen in a natural stream have been made, but the difficulty of ascertaining the amount of exchange between air and water has not been wholly overcome. Results suggest that primary production by algae is generally low. In contrast, that by rooted vegetation may be high. (T.T.M.)

Roads and Highways

The terms road and highway define those travelled ways on which wheeled vehicles, carriage animals, and men on foot have moved throughout recorded history. The most ancient name for these arteries of travel seems to be the antecedent of the modern "way." Way stems from the Middle English wey, which in turn branches from the Latin veho ("I carry"), derived from the Sanskrit *vaḥ* ("carry," "go," or "move"). The word highway goes back to the elevated Roman roads that had a mound or hill formed by earth from the side ditches thrown toward the centre, thus "high" "way." The more recent road derived from the Anglo-Saxon rad ("to ride") and the Middle English rode or rade ("a riding or mounted journey"). In modern usage highway refers to a rural travelled way as contrasted with the urban "street" derived from the Latin strata via ("a way paved with stones"). The word road is more generally used today to describe lesser travelled ways in rural areas, primarily those carrying small amounts of traffic or being of minor importance. In more recent years the terms freeway, expressway, and motorway and similar terms in other languages (autobahn, azrtostrada) have come into use to describe highways in both urban and rural areas for which there is full control of access. On these facilities points of entrance and exit for traffic are limited and strictly controlled.

This article is concerned with the development of major road and highway systems of the world. It reviews the major elements of highway building from financing to final construction and including the activities essential to the operation and maintenance of the system.

I. History and origin of roads and highways

ROADS OF ANTIQUITY

The first road builders probably practiced their art in southwestern Asia in the area bounded by the Black and Caspian seas, the Mediterranean Sea, and the Persian Gulf. People migrated east, west, north, and south from this area; presumably in their earliest travels they recognized the necessity of improving their paths and trails to facilitate the movement of their draft animals; this made the beginnings of trade possible. The first artificial roadways may have been constructed by levelling the high ground, filling the hollows, and transferring earth from the edges of the pathway to the centre, thus forming side ditches and providing for drainage.

Wheeled vehicles were probably first developed in a broad, roughly trapezoidal area with its longer base extending from north of the Black Sea to the Caspian and its shorter base the northern end of the Persian Gulf, with Lake Van in eastern Asia Minor as the centre. The earliest wheeled vehicles have been found within 600 miles (966 km) of the lake. The oldest archaeological evidence indicates that the wheeled vehicle came into existence somewhat earlier than 3000 BC. The earliest of these were probably two-wheeled wooden carts built by the Sumerians in the forested regions south of the Caucasus and Tarsus mountains. Four-wheeled vehicles with draft poles recently found north of the Caucasus Mountains in the U.S.S.R. date from about 2400 BC. The wheeled vehicle apparently was taken westward into Europe by people who travelled up the Danube River and north to the Balkans where there is evidence for wheeled vehicles going back beyond 2000 BC (see WAGONS AND CARRIAGES).

The role of trade in growth of roads

During the Bronze Age, the development of agriculture and trade, facilitated by the domestication of the horse, marked the beginning of civilization. Trade required better roads. The first serious road builders probably were the Mesopotamians, who developed a travel route from the Babylonian Empire west and southwest to Egypt. Processional loads (700–600 BC) connecting the temples and palaces (Figure 1A) of the ancient cities of Assur, Babylon, and Tall al-Asmar were paved roadways in which burnt brick and stone were lain in bituminous mortar. Such roads, while they did not serve the normal needs of caravan traffic, may have been the forerunners of the Roman system.

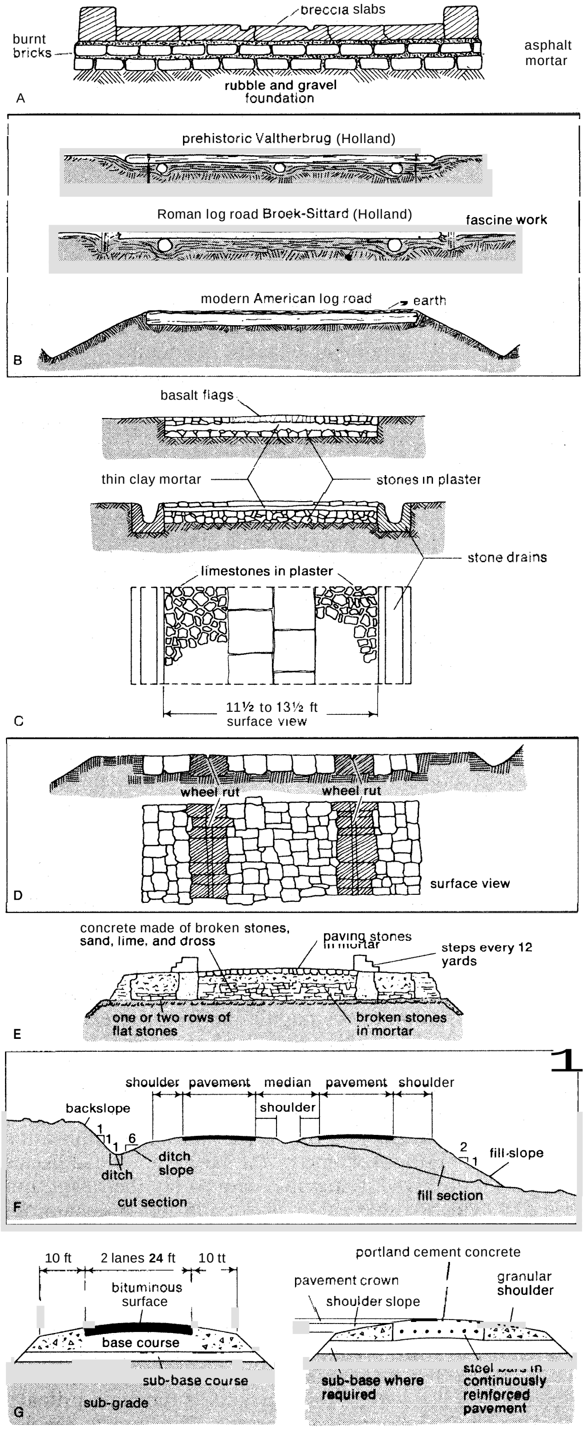

Figure 1: Cross sections of representative ancient and modern road and highway constructions (see text).

The oldest road. The modern highway systems are a natural outgrowth of the ancient road systems. The earliest long-distance road, in use from approximately 3500 to 300 BC was the Persian Royal Road, which began at Susa near the Persian Gulf, wound northwestward to Arbela and thence westward through Nineveh to Harran, a major road junction and caravan centre. The main road then continued northwestward to Samosata (modern Samsat) where it crossed the Euphrates River, and westward to Boghaz-Koi, the capital of the Hittite kings. From there travellers journeyed westward to Ancyra (modern Ankara) and Sardis where the road divided to twin termini at Smyrna and Ephesus. A branch went south from Harran through Palmyra, Damascus, Tyre, and Jerusalem to Memphis (Cairo) and another went westward from Harran to Tarsus, thence south to Caesarea and Tyre. From Susa an alternate route went westward to Ur and thence north through Babylon and Assur to Nineveh. From Boghaz-Koi one could travel northward to the Black Sea. The overland distance from Susa to Smyrna was 1,775 miles (2,857 kilometres), and Herodotus, writing in about 475 BC, put the time for the journey at 93 days.

"Amber Routes" of Europe. The earliest roads in Europe were the "Amber Routes" probably used between 1900 and 300 BC by Etruscan and Greek traders to transport amber and tin from the north of Europe to points on the Mediterranean and Adriatic. Four routes have been identified, the first from modem Hamburg southwestward by dual routes through Cologne and Frankfurt to Lyons and Marseilles. The second also passed from Hamburg south to Passau on the Danube and then through the Brenner Pass to Venice. The third began at Samland on the East Prussian Coast (where amber is still found) crossed the Vistula River at Thorn and thence continued southeastward through the Moravian Gate to Aquileia on the Adriatic. The fourth, the Baltic-Pontus road, followed the main eastern rivers, the Vistula, Saw, Sereth, Prut, Bug, and Dnieper. While these were not roads in the modern sense, they were improved at river crossings and over the mountain passes. In the same time period, evidence indicates, log roads (Figure 1B) were constructed extensively in northern Europe (modern The Netherlands, Germany, Poland, Latvia, Sweden, and White Russia) to carry traffic across wet and swampy areas. These roads were constructed by laying two or three strings of logs in the direction of the road on a bed of branches and boughs up to 20 feet (6 metres) wide and covering them with transverse logs 9 to 12 feet (2.7–3.6 metres) in length laid side by side. In the best log roads, every fifth or sixth log was fastened to the underlying subsoil with pegs. There is evidence that the older log roads were built prior to 1500 BC. The roads were maintained in a level state by covering with sand and gravel or sod, and the Romans used side ditches to reduce the moisture content and increase the carrying capacity.

Log roads

Imperial roads of China. The ancient road system of China, which paralleled in time the Royal Road, was a substantial and remarkable system. The Imperial roads played the same role in southeastern Asia as the Roman roads in Europe and Asia Minor. Many of the Chinese roads were wide, well built, and surfaced with stone; rivers were crossed by bridges or well-managed ferries; steep mountains were traversed by stone-paved stairways with broad treads and low steps. The Imperial road system, about 2,000 miles (3,200 kilometres) in total length, radiated from Sianfu, Nanking, and Ch'eng-tu. Except for short periods of time, however, the roads of China were not adequately maintained and fell into disrepair; it was said that in China a road was good for seven years and then bad for 4,000 years. Chinese roads differed markedly from the Roman roads in their crookedness, particularly in hilly areas.

Early roads of Malta and Crete. Unique "rut" roads were built on the island of Malta probably about 2000 to 1500 BC. These consisted of two V-shaped grooves about 4% feet (1.35 metres) apart cut into the coral sandstone of the island. The roads apparently were traversed by carts, drawn by human power, with the wheels running in the grooves. During the Minoan civilization on the island of Crete (3000 to 1100 BC), a road (Figure 1C) was built from Gortyna on the south coast over the mountains at an elevation of about 4,300 feet (1,300 metres) to Knossos on the north coast. Constructed of layers of stone, the roadway took account of the necessity of drainage by a crown throughout its length and even gutters along certain sections. The pavement was about 12 feet (3.6 metres) wide and the central portion consisted of two rows of basalt slabs two inches (50 millimetres) thick. The centre of the roadway seems to have been used for foot traffic and the edges for animals and carts. Guard houses were located at frequent intervals along the road.

India. The Indus civilization in Sindh, Baluchistan, and the Punjab probably flourished in the period 3250–2750 BC. Excavations indicate that the cities of this civilization paved their major streets with burned bricks cemented with bitumen. Great attention was devoted to drainage. The houses had drain pipes that carried the water to a street drain in the centre of the street, two to four feet (about a metre) deep and covered with slabs or bricks.

Evidence from archaeological and historical sources indicates that by AD 75 several methods of road construction were known in India. These included the brick pavement, the stone slab pavement, a kind of concrete as a foundation course or as an actual road surface, and the principles of grouting (filling crevices) with gypsum, lime, or bituminous mortar. Street paving seems to have been common in the towns in India at the beginning of the Christian era and the principles of drainage were well known. The crowning of the roadway and the use of ditches and gutters was common in the towns. Northern and western India in the period 300 to 150 BC had a network of well-built roads. The rulers of the Maurya Empire (4th century BC), which stretched from the Indus to the Brahmaputra and from the Himalayas to the Vindhya Range, generally recognized that the unity of a great empire depended on the quality of their roads. The Great Royal Road of the Mauryans began at the Himalayan border, ran through Taxila (near modern Rāwalpindi), crossed the five streams of the Punjab, and continued by way of Jumna to Prayag (now Allahābād). A "Ministry of Public Works" was responsible for construction, marking, and maintenance of the roads and rest houses and for the smooth running of the many ferries that carried the Royal Road across the wide rivers.

Egypt and Greece. Although Herodotus credits the Egyptians with building the first roads to provide a solid track upon which to haul the immense limestone blocks used in the pyramids, archaeological evidence indicates that road-building technology travelled southwest from Asia toward Egypt. The wheel arrived in Egypt at the relatively late date of about 1600 BC. There is little evidence of street surfacing in ancient Egyptian towns, though there is evidence of the use of paved processional roads leading to the temples. The ancient travel routes of Egypt ran from Thebes and Coptos on the central Nile east to the Red Sea and from Memphis (Cairo) across the land bridge to Asia Minor.

The early Greeks depended primarily on sea travel. There is evidence of the building of special roads for religious purposes and transport about 800 BC, but there is little evidence of substantial road building for travel and transport prior to the Roman system. The Greeks built a few ceremonial, or "sacred," roads, paved with shaped stone and containing wheel ruts (Figure 1D) about 55 inches (1.4 metres) apart, very similar to those built in Malta at a much earlier date.

Roman roads. The first scientific road builders were the Romans. By the peak of the Empire the Romans had built nearly 53,000 miles (85,000 kilometres) of road connecting the capital with the frontiers of the far-flung empire. Twenty-nine great military roads, the *viae militares,* radiated from Rome. The most famous of these was the Appian Way, started in 312 BC, following the Mediterranean coast south to Capua, then turning eastward to Beneventum, where it divided into two branches, both reaching Brundisium (Brindisi). From Brundisium the Appian Way traversed the Adriatic coast to Hydruntum, a total of 410 miles (660 kilometres) from Rome.

There are differences of opinion concerning the origin of the Roman road-building methods, but the consensus credits the Etruscans of northern Italy as Rome's principal teachers, though the Cretans, Carthaginians, Phoenicians, and Egyptians probably also contributed.

Roman road-building practice

Roman roads were remarkable for preserving a straight line from point to point regardless of obstacles. They were carried over marshes, lakes, ravines and mountains, and by their bold conception they have excited the admiration of modern engineers. In its highest stage of development the Appian Way was constructed by excavating parallel trenches about 40 feet (12 metres) apart to mark its exact location and to indicate the nature of the subsoil (Figure 1E). The foundation was then covered with a light bedding of sand or mortar on which four main courses were constructed; (1) a *statumen* layer of large flat stones 10 to 24 inches (250–600 millimetres) in thickness; (2) a *rudus* course of smaller stones mixed with lime about 9 inches (225 millimetres) thick; (3) the *nucleus* layer, about one foot (300 millirnetres) thick, consisting of small gravel and coarse sand mixed with hot lime; and (4) on this fresh mortar a *summa crusta*, or wearing surface, of flint-like lava about six inches (150 millimetres) deep. The total thickness thus varied from 3 to 5 feet (0.9 to 1.5 metres). The width of the Appian Way in its ultimate development was 36 Roman feet (35 English feet or 10.5 metres). The two-way central lane, heavily crowned, was 15% feet (4.7 metres) wide flanked by curbs 2 feet (0.6 metre) wide and 18 inches (0.45 metre) high on each side and paralleled by one-way side lanes 7% feet (2.3 metres) wide. This massive Roman road section adopted about 300 BC set the standard of practice for the next 2,000 years.

Classes of Roman roads

The public transport of the Roman Empire was divided into two classes: (1) *Cursus rapidi,* the express service and (2) *agnarie*, the freight service. In addition there was an enormous amount of travel by private individuals. The most widely used vehicles were two-wheeled chariots drawn by two or four horses and its companion, the two-wheeled cart used in rural areas. A four-wheeled *raeda* in its passenger version corresponded to the stage coaches of a later period and in its cargo version to the freight wagons. Fast freight *raedae* were drawn by eight horses in summer and ten in winter and, by law, could not haul in excess of 1,000 Roman pounds or 330 kilograms. Speed of travel ranged from a low of about 15 miles (24 kilometres) per day for freight vehicles to 75 miles (120 kilometres) per day by speedy post drivers.

The Silk Road. The trade route from China to Asia Minor and India, known as the Silk Road, had been in existence for 1,400 years at the time of Marco Polo's travels (*c.* AD 1270–90). but during this entire period incessant warfare and raiding by the Mongols and other nomads had kept it closed to traffic for all but 400 years. At its zenith in AD 200 this road and its western connections over the Roman system constituted the longest road on earth. The extreme western terminal of the Silk Road was at Gades (modern Cadiz, Spain) on the Atlantic Ocean; thence it ran northeastward across the Pyrennees north of Tarraco (modern Tarrasa) and around the shore of the Mediterranean through Genoa to Rome; from Rome south the road followed the Appian Way to Brundisium, where merchants took ship across the Adriatic, picking up the road again to cross the Balkan Peninsula to Byzantium (Istanbul) and continue southeastward through Ancyra (Ankara), with an alternate route through Antioch to Rhagae (near modern Tehrān) thence westward through Meshed, Bokhara, and Samarkand to Ferghana (Ush, the stone tower). From Ferghana the road traversed the valley between the Tien Shan and Kunlun Mountains through Kashgar where it divided and skirted both sides of the Takla Makan Desert to join again at Ansi. The road then wound eastward to Chia-yii-kwan (Su-chou) where it passed through the westernmost (Jade Gate or Yumen) gateway of the Great Wall of China. It then went southwest on the Imperial Highway to Sian and eastward to Shanghai on the Pacific Ocean. The Silk Road and its western connections bounds a globular rectangle 20" of latitude in height and 128" of longitude in breadth, a travel distance of 8,000 miles (12,800 kilometres) from Cadiz to Shanghai, for more than 2,000 years the longest road on earth. From Ferghana trade routes to the South passed over the mountains to the great trading centre of Eactria and to northern Kashniir.

Decline of roads: AD 200–1800. At the zenith of the Roman Empire overland trade joined the cultures of Europe, North Africa, Asia Minor, China, and India. But the system of road transport was dependent on the Roman, Chinese, and Mauryan empires, and as these great empires declined in the early Christian era the trade routes became routes of invasion. The road networks nearly everywhere fell into centuries of disrepair. Transport wagons gave way to pack trains, which could negotiate the badly maintained roads acd sufficed to carry the reduced stream of commerce. Eventually a commercial revival set in; by the 12th century old cities were reviving and new ones were being built, especially in western Europe. Some of the larger towns paved their principal streets. There was an awakened interest in better overland travel, better protection of merchants and other travellers, and the improvement of roads. Public funds, chiefly derived from tolls, were committed to road upkeep. The corvée, or road-labor tax, made an even more substantial contribution. Long-distance overland commerce increased rapidly and included a restoration of the trade route between Europe and China through Central Asia that Marco Polo travelled in the late 13th century.

Early paved town streets

During the 14th century the Black Death and other disasters brought a slowdown. During the 15th and 16th centuries street paving became more popular and wheeled vehicles increased in number and quality.

Inca roads of South America. Across the Atlantic,, the period witnessed the rise of another notable road-building empire, that of the Incas. The Inca road system, extending from Quito, Ecuador, to points south of Cuzco, Peru, consisted of two parallel roadways, one along the coast about 2,250 miles (3,600 kilometres) in length, the other following the Andes about 1,650 miles (2,640 kilometres) in length with a number of cross connections. At its zenith when the Spaniards arrived early in the 16th century, it served an area of about 750,000 square miles in which lived nearly 10,000,000 people. Some of the original Inca system was still in use in the 1970s. The Andes route was remarkable. The roadway was 25 feet (7.5 metres) wide and traversed the loftiest ranges with cutbacks and easy gradients. It included galleries cut into solid rock and retaining walls built up for hundreds of feet to support the roadway. Ravines and chasms were filled with solid masonry and suspension bridges with wool or fibre cables crossed the wider mountain streams. The surface was of stone in most areas and asphaltic materials were used extensively. The steeper gradients were surmounted by steps cut in the rocks. Traffic consisted entirely of pack animals (llamas) and people on foot; the Incas lacked the wheel. Yet they operated a swift foot courier system and a visual signalling system along the roadway from watchtower to watchtower. Interestingly, Inca roads resemble those of ancient China, which, it has been suggested, may indicate a direct cultural influence.

The Andes route

THE BIRTH OF MODERN ROAD BUILDING

The 17th and 18th centuries saw crude carts and wagons operating over rough, unimproved roads give way to regularly scheduled common-carrier stagecoaches and freight wagons running on stone-surfaced toll roads. The first engineering school in Europe, École des Ponts et Chaussées (the School of Bridges and Highways), was founded in Paris in 1747. Late in the 18th century Adam Smith in discussing conditions in England wrote,

> Good roads, canals, and navigable rivers, by diminishing the expense of carriage, put the remote parts of the country mote nearly upon a level with those in the neighbourhood of a town. They are upon that account the greatest of all improvements.

In the last half of the 18th century the fathers of modern road building appeared in France and England.

Up to this time the roads built had utilized, with minor modifications, the very heavy Roman cross section. In France in 1764, Pierre-Marie-Jérôme Trésaguet, an engineer from an engineering family, became engineer of bridges and roads at Limogs and, in 1775, inspector general of roads and bridges for France. In that year he developed an entirely new type of relatively light road surface, based on the theory that the subsoil, rather than the surface should support the load. His standard section, 10 inches (250 millimetres) thick, consisted of a course of uniform stones laid edgewise covered by a layer of walnut-sized broken stone. The roadway crown rose six inches (150 millimetres) in its 18-foot (5.4 metres) width and had a uniform cross section.

John Metcalf, the first of England's pioneer road builders, was a contemporary of Trésaguet. Born in 1717, he was blinded by smallpox at the age of six, but became an expert climber, horseman, and swimmer. About 1754 he launched a stagecoach route between Knaresborough and York and in 1765 built a portion of the turnpike authorized between Harrowgate and Boroughbridge. Over the next 37 years he built more than 180 miles (290 kilometres) of English turnpike roads and bridges. In his road building he emphasized the use of ditches for adequate drainage and special precautions for distributing the load by using baled brush as a subbase in marshy areas.

Thomas Telford, born of poor parents in Dumfriesshire, Scotland, in 1757, was apprenticed to a stone mason; intelligent and ambitious, he progressed to designing bridges and building roads. His Carlisle-Glasgow road was considered the finest road ever built up to that time (1816). Telford placed great emphasis on two features: (1) maintaining a level roadway with a maximum gradient of 1 foot in 30 feet and (2) building a stone-surfaced roadway capable of carrying the heaviest anticipated loads. His roadways were 18 feet (5.4 metres) wide, crowned only four inches (100 millimetres) and built in two courses, a lower course of 7 inches (175 millimetres) consisting of good quality stone carefully placed by hand (Telford base) and a second layer consisting of 7 inches of broken hardstone of 2% inch (62.5 millimetres) maximum size and a layer of gravel one inch (25 millimetres) thick.

The work of McAdam

John Loudon McAdam, born in 1756 at Ayr, Scotland, began his road-building career in Bristol, then the second city in England. The roads surrounding Bristol were in poor condition and in 1816 McAdam, chosen general surveyor of the Bristol municipality, had an opportunity to test his theory that road building could be reduced to a science based on fundamental principles. Like Trésaguet, he believed that a well-drained, compacted subgrade should support all the load while the stone surfacing should act only as a wearing surface and a roof to shed water. There is evidence that McAdam was indebted to others for many of his ideas. McAdam insisted on a roadway with adequate side ditches and a subgrade elevated above the surrounding ground surface and compacted with a crown of 3 inches (75 millimetres) in 18 feet (5.4 metres) to drain surface water rapidly. He believed that 10 inches (250 millimetres) of surfacing was adequate for any load of his time. His stone surfacing utilized two inch (50 millimetres) maximum size stone laid in loose layers and compacted under traffic. Weak spots were detected and replaced before the next layer was placed. Compaction under the wheeled traffic of the early 1800s proved to be very effective. McAdam's remarkable success was, however, due in large measure to his efficient system of administration.

By 1820 Britain had 125,000 miles (200,000 kilometres) of road, of which 20,000 miles (32,000 kilometres) were turnpikes. By 1836, 3,000 coaches operated on these roads; the rapid development of the railroads, however, brought road building virtually to a halt. Roadway improvements for the next 60 years were essentially confined to city streets.

Continental Europe and the U.S. had road-building histories virtually identical to Britain's, with a period of rapid construction of the new lightweight Trésaguet-McAdam type of roads followed by a sudden halt as railroads intruded on the transportation scene. The first engineered and planned road built in the United States was a privately constructed toll turnpike from Philadelphia to Lancaster, Pennsylvania, built between 1793 and 1794 at a cost of $465,000. Its 62-mile (100 kilometres) length with 9 toll-gates was surfaced with broken stone and gravel with maximum grades of 7 percent. The Cumberland Road, also known as the National Pike, was an even more notable road-building feat. It opened for traffic between Cumberland and Wheeling, West Virginia in 1818, and to Springfield, Ohio and part of the way to Vandalia, Illinois in 1838; total cost was about $6,825,000. The road was maintained by government appropriations and by tolls collected by the states. Specification requirements called for 2 66-foot (20 metres) right-of-way completely cleared. The roadway was to be covered 20 feet (6 metres) in width with stone 18 inches (450 millimetres) deep at the centre and 12 inches (300 millimetres) deep at the edge, the upper 6 inches (150 millimetres) was to consist of broken stone of 3-inch maximum size and the lower stratum of stone of 7-inch maximum size.

During the period 1840 to 1910, the era of railroad building all over the world, country roads everywhere remained virtually impassable in wet weather. The initial stimulus for a renewal of road building came not from the automobile, whose impact was scarcely felt before 1900, but from the bicycle, for whose benefit road improvement began in many countries during the 1880s and 1890s. Though the requirements of the lightweight, low-speed bicycle were satisfied by the old "macadamized" surfaces as the world entered the 20th century, the horseless carriage rather quickly rendered this type of road obsolete.

Road administration and financing

The responsibility for financing and building roads and highways has been both a local and a national responsibility of the nations of the world during many centuries. It is notable that this responsibility has changed along with political attitudes toward road building. English road building, for example, for centuries remained entirely local despite clear evidence that local responsibility was not providing adequate roads. Local authorities and private turnpike trusts dominated both British road building and maintenance throughout the 19th century, though the national government edged into the picture through increasing grants of funds, climaxed by the establishment in 1909 of a national Road Board authorized to construct and maintain new roads and to make advances to highway authorities to build new or improve old roads.

Except for the National Pike, early highway building in the United States was also carried on by local government. Toll roads, variously surfaced, were constructed in the first half of the 19th century under charters granted by the states. The Congress made a number of land grants for the opening of wagon roads but exercised no control over the expenditure of funds and, as in Britain, little road building was accomplished. Road labour to satisfy taxes was both unpopular and unproductive.

II. The automobile road

BASIC PROBLEMS

The automobile, and a little later the heavy truck, introduced totally new requirements for road and highway construction. Vehicle speeds increased rapidly; roadway alignment suitable for horse and buggy travel was completely inadequate, as were road surfaces, whose stones were torn loose by the heavily loaded tires. The early trucks, built with solid rubber tires, carried gross loads of 12,000 to 14,000 pounds (5,400–6,300 kilograms), which by the close of World War I had risen to 28,000 pounds (12,600 kilograms). The development of the pneumatic tire substantially reduced the destructive effect of truck loading on thin pavements intended for horse and buggy, but it was obvious that much stronger surfacing was required. Loads continued to increase, to gross weights of 40,000 pounds (18,000 kilograms) on tandem axles.

In western Europe and the United States, the world's principal automobile areas in the 1960s, approximately half of the total vehicle mileage travelled was travelled in urban areas. There was substantial amount of long distance travel both for business and pleasure, and the tonnage of intercity freight carried by trucks was increasing steadily, bringing a powerful demand for direct, long-distance express routes, including suitable links and bypasses in the metropolitan areas. In the late 1960s and early '70s increasing attention was being turned to the problem of safety in design of highways and their anxiliary equipment.

Highway planners and designers have had to take into account the speed and operating characteristics of the motor vehicles, wheel or axle loads, and the density and composition of vehicles in the traffic stream, as well as the safety, comfort, and convenience of the travelling public.

Classification and design standards

Depending upon the volume of traffic, composition of traffic, and major purpose, roads and highways may be divided into four functional classifications: (1) local roads and city streets; (2) collector and feeder roads, and secondary rural highways; (3) primary highways that carry relatively high volumes of traffic between population centres; and (4) expressways that serve major traffic flows.

In order to have reasonable uniformity in a given jurisdiction, design standards are usually established for each functional classification, taking into account the type of terrain in which the road or highway will be built (or rebuilt) classified as flat, rolling, or mountainous. Design standards are usually established on the basis of average daily traffic volumes, and it is common practice to set both a minimum standard and a desirable standard (Figure 1F). Design standards commonly provide for a right of way width, the speeds for which the roadway is to be designed, maximum permissible sharpness of horizontal cuives, maximum permissible vertical gradient in feet rise per 100 feet of horizontal distance, minimum width of roadway and surfacing (pavement), minimum nonpassing sight distance (the distance a driver a normal distance abcve the roadway can see an object six inches [150 millimetres] high on the roadway ahead), and the clearance and capacity of bridges. For the two higher functional classifications most nations have governmental or quasi-governmental agencies that establish design standards.

TYPES OF PAVEMENT

Pavements were first developed for use on city streets. The earliest city pavements were stone block, wood block, vitrified brick, and bitumen (*e.g.*, natural asphalt). The first bituminous pavement was laid in Paris in 1854 using a natural rock asphalt from Switzerland. The first portland cement concrete pavement was built in Inverness, Scotland, in 1865. At the beginning of the automobile era rural road surfacing, where it existed, consisted of broken stone or gravel. Such roads were too rough and dusty, and inadequate in strength for automobile traffic.

Highway pavement may be defined as the portion of the highway cross section above the natural earth or subgrade. Figure 1G illustrates a typical pavement cross section for a divided highway in a rural area and the elements (surfacing, base, and subbase) that make up the cross section. In some pavement sections not all of the three elements will need to be used and in others a given element may consist of several layers of differing materials.

Flexible pavement. Pavements are divided into two types: flexible and rigid. A flexible pavement consists of base and subbase layers of natural aggregate materials (sand and gravel), or crushed stone, and a surfacing of aggregates mixed with a bituminous material, commonly an asphalt extracted from petroleum or coal tar. In some areas of the world natural mixtures of asphalt and rock, called "rock asphalts," occur; these make excellent surfacing materials. Base and subbases for flexible pavements may also be made of "stabilized materials," in which natural soils or poor quality sand and gravel are mixed with such materials as lime, portland cement, chemicals, asphaltic oils, and coal tars in order to increase the strength of these materials and reduce their susceptibility to loss of strength with increasing moisture contents. The terms soil-lime or lime stabilization, soil-cement or cement stabilization, soil-asphalt or asphalt stabilization are used to refer to mixtures of this type. Beneficial effects can be obtained in many cases by mixing two soils, or a soil and an aggregate, together to instill the good qualities of both in the finished mixture.

The surfacing portion of a flexible pavement may be produced by a range of processes that yields surfaces of varying texture, thickness, strength, and quality. The major processes described below, are the surface treatment, macadam, mixed-in-place, and plant-mix types. The latter three processes are used for both the base and surfacing portions of the pavement structure.

Surface preparation

Surface treatment. In this installation the pavement is placed over a completed, compacted base course. The first step is to cover the base course with a thin asphaltic oil or tar sprayed on in sufficient quantity to fill cracks and crevices in the base without leaving excess oil or tar on the surface. After this prime coat has penetrated, the area is sprayed with a harder asphaltic oil or tar and covered with a layer of uniform-size gravel or stone chips, which is rolled to seat it in the bituminous material. A second, third, and even fourth layer of oil and stone may be applied to increase the pavement thickness. Surfacings so constructed are called single, double, triple, and quadruple surface treatments. Such surfaces are adequate for low volumes of traffic particularly in relatively arid climates.

Macadam construction. In this type of construction the surfacing is constructed by placing a layer of uniform size crushed stone or gravel in the size range of one inch (25 millimetres) to three inches (75 millimetres) on the completed and compacted base course. The layer thickness is somewhat greater than the maximum-size aggregate used. The stone layer is thoroughly compacted and is then bound together by one of several processes. In water-bound macadam a layer of stone screenings is worked into the surface by rolling, after which the surface is sprinkled with water and rolling is continued; the stone dust-water mixture forms a natural cement to bind the stone together. Water-bound macadam will not stand the abrasive effects of modern traffic and is seldom used today except for base courses. In penetration macadam, also referred to as asphalt or tar macadam (tarmac), the stone is impregnated with a substantial quantity of semisolid asphalt cement or tar heated to fluid temperaure and sprayed into the compacted stone. A layer of stone of such size as to fill the interstices in the first course is then rolled on. If the penetration macadam is the surfacing, it is completed with the application of a single surface treatment. In cement-bound macadam a cement-sand slurry is worked into the interstices of the compacted stone to provide the necessary cementing action.

Mixed-in-place surfacing. Mixed-in-place (road-mix) surfacing involves mixing aggregates in the roadway cross section with bituminous or other cementitious materials in order to obtain watertight and stronger surfaces. This kind of processing is used extensively for base courses and to a limited extent for subbase courses. In the 1920s and 1930s when many of the highways in western sections of the United States were surfaced in this manner, the natural gravel or stone surfaces were loosened and thoroughly mixed, after which asphaltic oils or liquid tars were added by spraying and worked into the loose aggregate with graders until uniformity was obtained. The resultant mixture was then compacted. Surfaces of this type last several years under light to moderate traffic and are easily repaired by loosening, adding material and recompacting.

Plant mix. Plant mix surfacings possess the necessary strength and waterproofing to carry the highest volumes of traffic and the heaviest wheel loads under severe climatic conditions. They also provide a high quality riding surface. The process involves the assembly of excellent aggregates in several sizes, from walnut size to dust, drying these aggregates, heating to temperatures of 300–400" F (150–200" C) and mixing, in a central plant, with the proper quantity of asphalt cement or semisolid tar also at elevated temperature. The resulting compound is hauled to the roadway where it is placed by a laying machine or paver and thoroughly rolled before the mixture cools. Such mixtures are placed in thicknesses varying from one to four inches (25–100 millimetres) and a given surfacing may consist of two or more layers. The resulting surface is smooth and if properly designed provides good frictional resistance for vehicles operating

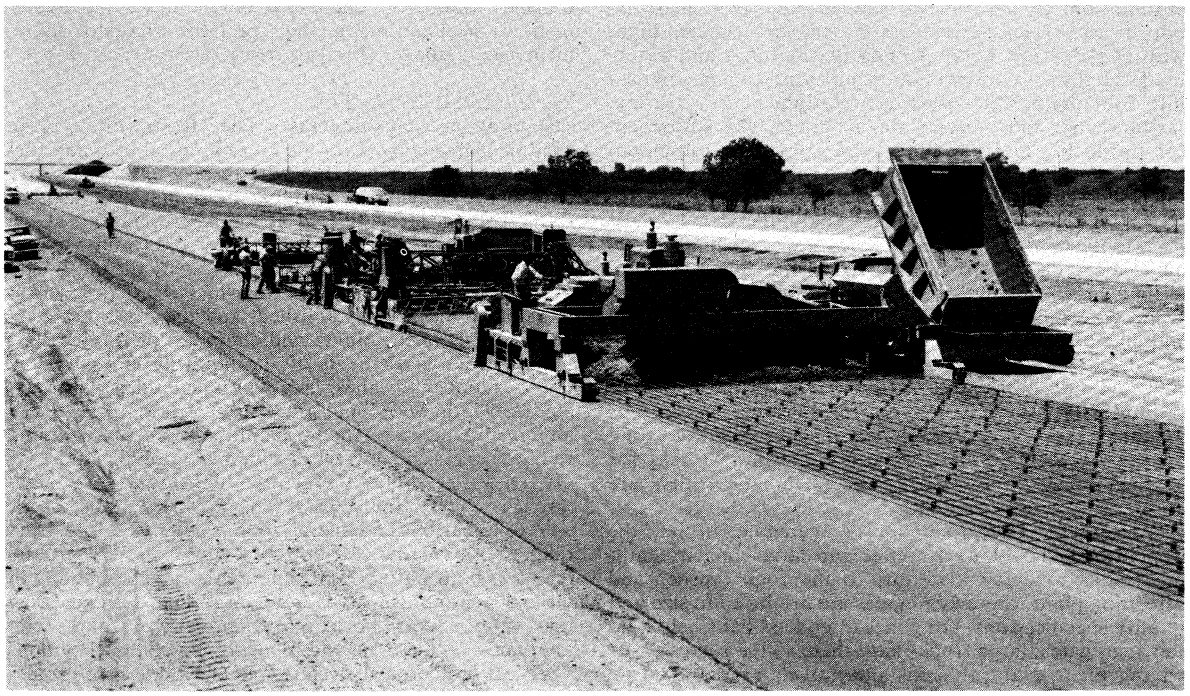

Figure 2: Three stages of concrete paving.

over it. Its repair is simple and the surface can be upgraded easily by adding another layer mixed and placed in the same manner.

Rigid pavement. Rigid pavement is portland cement concrete surfacing placed directly on the subgrade or on a subbase course or base course. The pavement thickness is in the range of 6 to 12 inches (150–300 millimetres) and is dependent on the volume and weight of truck traffic using the highway. This type of surfacing is produced by assembling graded aggregates and cement at a central location where they are carefully proportioned on a batch basis and then mixed with water to form concrete that will harden and yield adequate strength.

As the concrete changes from a plastic mass at placement to a hardened surfacing it undergoes a decrease in volume referred to as shrinkage. This shrinkage is accompanied by a tendency for the concrete to be pulled across the underlying layer, thus developing tensile stresses. In a continuous concrete mass the tension so developed exceeds the strength of the concrete and cracking occurs. The hardened concrete is also subject to volume changes and warping due to daily and seasonal temperature and moisture variations. As the temperature rises (or moisture content increases) there is an expansion of the surfacing while lower temperatures (or a decrease in moisture) cause contraction. In order to control these volume changes and the consequent cracking of the portland cement concrete pavement, three types of planned joints may be introduced. Contraction joints, spaced at intervals across the roadway, consist of grooves that extend partway through the pavement to insure that, when the concrete contracts, cracking will occur at these locations. Expansion joints, also transversely laid, consist of narrow openings through the pavement to provide room for expansion of the concrete. Elaborate measures are taken to keep these expansion joints water tight, and steel-rod dowels are provided across the joint to transfer part of the wheel loads from one slab end to the other. The third joint type is a longitudinal-tied joint used at the edge of the lanes and made by parting the pavement, as for contraction joints, and inserting steel tie bars under the parting strip to prevent the joints from opening. Such joints relieve the stresses caused by warping of the pavement slab due to temperature and moisture variations between the top and bottom. In the morning of a summer day the top of an 8-inch (200-millimetre) concrete pavement may be 25° F (14" C) hotter than the bottom. The weakened planes for the contraction and warping joints of concrete pavements were originally formed by hand methods, using a metal or fibre strip in the fresh concrete to produce the cut. However in recent years these joints have been formed after the concrete hardens by cutting the concrete to the desired depth and width with an abrasive circular saw blade.

Rigid pavement jointing

Maintenance problems of concrete pavements

Many of the maintenance problems in portland cement concrete pavements are associated with the jointing systems. It is difficult to keep the joints adequately sealed against water, dirt, and dust, and it is difficult to place dowel bars so that they permit expansion joints to open and close readily. For these reasons the continuously reinforced concrete pavement that does not require a jointing system has become increasingly popular. In this pavement (Figure 2) a continuous layer of steel bars is placed longitudinally at mid-depth of the pavement slab. The bars provide a steel area of about 0.5 percent to 0.7 percent of the cross section of the pavement. Shrinkage and temperature and moisture volume changes cause the concrete slab to crack transversely at intervals of 3 to 10 feet (1 to 3 metres) but the longitudinal steel absorbs the tension in the concrete so that the cracks are held tightly closed and no surface water can pass through. A small amount of transverse steel is used to hold the longitudinal bars in place and control longitudinal cracks. This method of construction permits the use of continuous slabs, several miles or kilometres long, with no jointing. Expansion and contraction of several inches may occur at the terminal ends of the continuously reinforced pavement and must be provided for in the design.

In deciding whether to use flexible or rigid pavement, engineers must take into account initial cost, probable life, probability of traffic disruptions for maintenance, riding characteristics, ease of repair, climatic conditions with their probable effects, and service to the travelling public.

MACHINERY AND EQUIPMENT

Highway construction in the developed nations has benefitted from rapid and spectacular developments in construction equipment technology. These developments have been marked by substantial increases in capacity per unit and decreases in manpower requirements through automation. In the underdeveloped countries where labour is less expensive and less skilled, sophisticated highway construction equipment is uneconomic and rarely used. Highway construction equipment can be divided into four major categories; (1) equipment for clearing, earthmoving, and building the subgrade; (2) equipment for producing and handling aggregates; (3) equipment for mixing and placing pavements, and (4) equipment for bridge construction.

Clearing and earth moving. The bulldozer is most commonly used for clearing vegetation and undesirable materials from the roadway. Earth moving is accomplished with bulldozers, hauling scrapers, and motorgraders. Compaction is accomplished with large tamping and pneumatic-tired rollers; sprinkling trucks are used to adjust the moisture content for compaction. Rock cuts and fills utilize the mobile wagon drill capable of drilling 200 feet (60 metres) for blasting, shovels, or draglines (very large excavating machines) for loading the excavated material, and very large dump trucks for hauling. Grid, steel-wheeled, and pneumatic rollers are used for rock compaction.

Aggregates. The production of aggregates utilizes the wagon drill, shovel, or drag line and large-capacity hauling trucks to carry materials to the rock crusher and screening plant where aggregates are produced to size and quality specifications. Draglines or endless belts help load the aggregates; large trucks haul them to the roadway, or paving plant. Natural sands and gravels are handled by draglines, washed if necessary, and screened to the desired size gradation. Compaction of base and subbase aggregates is accomplished by steel-wheeled rollers and pneumatic rollers.

Mixing pavements. Surface treatment and macadam pavements utilize a bituminous distributor that sprays the bituminous material, hot or cold, at the proper rate. Both steel-wheel and pneumatic-tire rollers are used for compaction. The roadway is swept clean by a rotary broom. Mixed-in-place pavements utilize truck-water distributors, bituminous distributors, blade graders, and special mixers. Alternately, road-mix machines excavate the roadway surface, apply the bituminous material or other liquid stabilizer, mix the materials, and return the mixture to the roadway. Special hauling units to transport and spread lime and cement are used in stabilization.

Bituminous paving

Bituminous paving operations involve equipment to assemble aggregates, storage tanks for asphalt and tar, cold bins for aggregate loaded by dragline or belt, a mechanical cold-materials feeder, a cylindrical drier to dry and heat the aggregates, hot bins to proportion the hot aggregates, an asphalt or tar metering system, and a mill *to* perform the mixing operation. Recent developments have eliminated hot bins in many plants. The mixed material is hauled to the roadway in dump trucks and placed in a paving machine that distributes it uniformly on the base course. Compaction is accomplished by steel-wheeled and pneumatic rollers.

In portland cement concrete-paving plants, aggregates are assembled, placed in bins by size, and proportioned by weighing; the cement is separately weighed and added to the batch after which the materials are loaded into a stationary or truck-hauled mixer where water is added and fresh concrete produced. If a central mixer is used the completed mixture is hauled to the roadway in agitator trucks or in ordinary trucks with a bathtub-type body. The concrete mixture is distributed on the compacted roadway and placed by a paver that forms and smooths the concrete. Steel side forms that were necessary a few years ago have been eliminated by the formless paver.

The steel in continuously reinforced pavements is made up in sections by tying the longitudinal bars to the transverse bars. It may be placed on the compacted roadway ahead of placement of concrete or continuously with the fresh concrete. Joints are cut with heavy duty circular saws. Dowel bars for contraction and expansion joints in plain concrete pavements are held in place by heavy metal supports.

***Bridge** construction.* Bridge building or viaduct building is a highly specialized operation using pile drivers, cranes, forming for concrete, riveting and welding equipment for steel and many other specialized types of equipment (see BRIDGES, CONSTRUCTION AND HISTORY OF).

DESIGN AND CONSTRUCTION

Highway location **and plans.** The design of a given road or highway involves the consideration of many factors and numerous decisions with respect to the necessary criteria for design. The designer must first establish the traffic volume to be carried at the beginning and at the end of the roadway's probable life. The number and loaded weight of trucks using the highway during its life must be determined. A speed for which the highway is to be designed must be established, and the maximum gradient decided. The volume and character of traffic determine the design elements of the highway cross section, that is, number of lanes, lane width, shoulder width and median width. Speed and gradient determine the vertical alignment, and speed the horizontal alignment, including radii of curves and degrees of superelevation on curves.

It is next necessary to match the highway to the terrain through which it must pass. The first step, thus, is the establishment of the general route. When this has been refined to a narrow corridor a map showing the ground features, both natural and man-made, and variations in ground contours must be prepared. The designer then lays out the exact horizontal alignment or route, with alternates, on the map, and by using the contours obtains a vertical profile on the centre line and transverse profiles at desired intervals. A grade line is then established and earth work quantities determined by comparing the finished roadway cross section with the ground cross section. The grade line is adjusted to balance the earth to be excavated with the fills to be made, to provide for moving the least amount of earth, and to satisfy the requirements for maximum gradient and minimum sight distances for vehicle operations. In setting the horizontal and vertical alignment the designer attempts to make the highway flow with the terrain so as to minimize the sense of tension with the driving environment.

New equipment, including a stereoscopic plotter utilizing aerial photographs for plotting points on a map and the computer, has taken much of the drudgery out of the work of highway design by permitting the automatic plotting of highway cross sections and the automatic computation of earthwork volumes. When the exact horizontal and vertical alignment has been established for the route selected, a set of plans is prepared showing the alignment details and the elements to be constructed. The required right-of-way is then purchased using location maps supplemented by ground surveys to establish precise ownership boundaries.

Soil analyses

Earthwork. In order to design the pavement it is next necessary to establish the characteristics of the subgrade soils over which the pavement is to be constructed. Certain soil features can be determined by expert study of the aerial photographs. Detailed soil information must, however, be determined on the ground and in the laboratory. Ground subsurface explorations are carried out by means of auger borings in which the soil strata are identified, classified, and samples obtained for laboratory analysis. The engineering properties of the soil encountered, including its strength, susceptibility of its strength to moisture increase, and amount of shrinkage and swell with moisture change are established. Soils completely unsuitable in the final roadway section are identified for removal; embankment and cut slopes are established, and the degree of compaction to be achieved in the field determined. The probable strength or capacity of the materials to resist the traffic loads is also determined.

After the construction contract has been let and surveys have established the exact location of the finished roadway in plan and elevation on the ground, with suitable line and elevation indicators, construction of the subgrade begins. The first step is to remove all vegetation from the roadway section, an operation in which the bulldozer plays a large part. Heavy earth-moving machinery then moves materials from cut sections into fill sections, where the material is placed in layers, brought to the proper moisture content, and compacted to the required density. In 1970, the unit cost of earthwork, including excavation, hauling, placement and compaction, was not substantially greater in Europe, the United States, and Japan than it had been a generation earlier, in spite of huge increases in other construction costs. Higher capacity equipment operating at greater speeds has prevented increases in costs per unit. It is generally considered desirable to perform the earthwork operations. including installation of the drainage pipes and culverts, as the first element of construction for most highways, followed next by the bridges, and finally the pavements. If it is possible to permit some traffic to operate over the completed earthwork, it is desirable to do so in order to detect weak spots in the grade prior to placing the finished pavement.

Drainage. Highway drainage includes those elements of the roadway that remove surface water (rain) from the roadway and carry flowing streams across the roadway as well as those used to control ground water. It has often been emphasized that adequate drainage is the most important element in road and highway construction; John McAdam was one of the first to grasp the fact. The major drainage is carried in the streams that continuously or intermittently cross the highway route. Surface water from the roadway, as well as from the surrounding lands, is carried in these streams.

"Design storm"

The highway designer must estimate the amount of water that will be carried in the stream at the highway location for the "design storm," which is either the most severe flood expected in a hundred years for a major stream, or merely that expected once in five years for a minor drainage channel on a low traffic-volume route. The elevation of bridges and the size of other drainage structures are fixed to carry this design storm without flooding the roadway. Hydraulic considerations are taken into account in the design of bridges and culverts, and construction may include work to increase the carrying capacity of the stream channel adjacent to the highway through channel changes, bank lining, and similar methods. In areas where land use is changing rapidly, particularly from agricultural to residential or business, attention must be given to the fact that ground water runoff and stream flow will materially increase as the area is covered with houses, drives, streets, business buildings, and parking lots.

The drainage of the roadway itself is an important consideration. Surface water drainage is insured by the crown in the pavement and the slope of the shoulders. Modern designs provide for surfacing the shoulders so that a complete waterproof surface is provided. It is important that all elements of the cross section, subgrade, subbase and base, as well as the surface, be crowned so that surface water entering the pavement system can drain outward to the ditch. Flat side slopes in the ditch section have two advantages. First they provide a better opportunity for vehicles leaving the roadway to recover without a serious accident occurring, and second, the ditch is further removed from the roadway laterally so that there is less opportunity for water in the ditch to penetrate and soften the subgrade. Both rounded V-bottom and trapezoidal ditch sections are commonly used. They must be sized to carry the maximum quantities at water elevations well below the elevation of the roadway shoulder.

In urban areas and at necessary locations in rural highways, particularly at intersections, the drainage of the highway pavement is accomplished by carrying the water laterally to shallow gutters at the edge of the shoulder, then along the gutter to storm-sewer inlets at frequent intervals. The water passes through these inlets into a pipe drainage system that carries it to a natural water course for discharge. For multilane freeways in areas of high rainfall the storm-drain system required is extensive and represents a substantial portion of the project cost.

Capillary water held in the pavement by surface tension is not subject to drainage. Where such water rises into the pavement and comes into contact with an overlying impervious layer, condensation occurs and may produce moisture problems. The use of impervious surfacing layers of appreciable thickness and free draining base and subbase courses minimizes this. If the ground water table is quite high relative to the elevation of the top of the pavement, capillary water problems can be severe; it may be essential to lower the level of the water table under the highway cross section by placing perforated drainage pipes, surrounded by free draining filters of gravel and sand, well below the water table. Ground water flows into the pipes, thus lowering the ground water table and reducing capillary moisture at the pavement elevation. The same procedure can be used to intercept ground water flowing under the highway cross section in pervious strata.

Drainage problems also occur when ground water can drain down the back slopes of cut sections and the fill slopes of higher fills. If these slopes are steep, severe erosion may occur. The usual solution is to flatten slopes so as to permit control through vegetstive cover. When this type of control is not feasible, the surface water is collected in shallow ditches or gutters at the top of the slope and carried along the roadway to a point at which it may be discharged into the ditch system or, alternately, carried down the slope in pipe drains to a suitable discharge point.

Design and construction of pavement elements. In order to design the elements of the pavement cross section the strength of the subgrade material must be determined in its condition of lowest probable strength or highest probable saturation. Strength is determined either by estimates based on experience with similar materials using routinely determined soil characteristics as an aid to judgment, or by means of laboratory test measurements. Materials tested are normally permitted to absorb water by capillarity prior to testing.

Designing roads for future needs

Where construction is to be in stages, the pavement section may be designed for the traffic to be carried during the early years, at the end of which added pavement material will be provided to increase the strength to that required for the next design period. Materials used for subbase and base courses must normally be located near the construction site to avoid high hauling costs. In some cases it may be advantageous to improve the strength of local materials by stabilizing with lime, cement, or bituminous materials. The subbase may also be constructed by stabilizing the top 6 to 12 inches (15–30 centimetres) of the subgrade. Operations involved in constructing the subbase and base courses consist of locating the materials to be used, processing these materials at the pit or quarry as necessary, hauling to the roadway, depositing in the proper quantities, mixing to provide uniformity, grading to proper elevation, adding water where necessary and compacting to the proper density.

Though, for many years concretz pavements were placed directly on the subgrade, it is now recognized that the destructive ejection of water through joints and cracks and along the pavement edge, can be avoided by providing granular bases or subbases or by providing stabilized bases under these rigid pavements. Most portland cement concrete pavements are now constructed over base courses stabilized with cement or bituminous materials. The thickness of the concrete pavement is determined an the basis of the strength of the concrete and the stresses induced by the heavier loads expected to use the pavement.

NOTABLE REBUILDING ACHIEVEMENTS 1920–1945

The parkway concept, forerunner of modern high-volume, high-speed, limited-access highways, was proposed first by William Niles White of New York as a part of the Bronx River protection program of New York City and Westchester County. The 15-mile (24-kilometre), four-lane drive known as the Bronx River Parkway was completed in 1925. Protected on both sides by broad bands of park land that limited access, the highway was located and designed so as to cause minimum disturbance to the landscape, and its use was restricted to passenger cars. The success of the concept led to the creation of the Westchester County parkway system and the Long Island State Park Commission. More parkways and expressways were built in the New York area, including the Merritt Parkway (1934–40), which continued the Westchester Parkway System across Connecticut as a toll road providing divided roadways and limited access.

The Italian autostrada system was started under Mussolini in the 1920s, beginning with an expressway from Milan to Varese. A national road board (Azienda Autonoma Statale della Strada) was given responsibility for the construction, maintenance, and repair of the state roads with advisory supervision over provincial and local roads. This body was assigned the funds from motor-vehicle taxes, and an annual matching grant of approximately the same amount from general tax funds. Superhighways were built primarily as toll roads under government supervision. The first of the major autostrada crossed northern Italy from Venice to Turin. The autostrada were built generally as undivided three-lane roadways with shoulders. All highway and railway grades were separated, access was limited, and there were restrictions on use of the highways by commercial vehicles.

The Inter-American (Pan American) Highway was conceived at the Fifth Conference of American States in 1923 and formalized by cooyerative agreements between the nations involved in 1928. Its route joined the highway system of the United States at Laredo, Texas, and went due south to Mexico City; thence southeast to Guatemala City, San Salvador, Managua, San José, and Panama City, a distance of 3,356 miles (about 5,400 kilometres). The U.S. Congress appropriated $1,000,000 for the highway in June, 1934, and construction began in 1935. Work on the highway in Mexico progressed rapidly but lagged on most of the remainder of the route until World War II, when a large U.S. appropriation permitted construction of a usable pioneer trail for the entire route.

The autobahn

The first fully modem highway system was the German autobahn network consisting of dual roadways separated by a substantial median area and providing for limitation of access. The idea of the motorway (expressway) was first conceived in Germany in 1926 and incorporated in the Cologne-Bonn roadway started in 1929 and opened to traffic in 1932. When Hitler came to power he implemented a plan for the construction of about 7,000 kilometres (4,350 miles) of an integrated highway network known as the "Reich Motor Roads". Construction began in 1934 on the Frankfurt-Mannheim-Heidelburg Autobahn. The entire system included three north–south routes and three east–west routes. The highway provided separate dual-lane roadways with a median strip of five metres, and one-metre shoulders. Clearly military in intent, the roads were designed for large traffic volumes and speeds in excess of 100 miles per hour, bypassing cities, and providing limited access. The whole system, of about 2,500 miles, was rushed to completion in a few years.

The Pennsylvania Turnpike Commission, established in 1937 to raise funds and build a toll road across the Appalachian Mountains, found an unusually favourable situation in the form of an abandoned railroad right-of-way, with many tunnels and excellent grades over much of the route. The turnpike provided a divided dual-lane highway with no cross traffic at grade and with complete control of access and egress at 11 traffic interchanges. Its alignment and grades were designed for high volumes of high-speed traffic and its pavement to accommodate the heaviest trucks. The favourable public reaction to this new type of highway provided the impetus for the post-World War II toll road boom in the United States, advanced the start of a major interstate highway program, and influenced highway developments elsewhere. The Pennsylvania Turnpike, originally running from Harrisburg to Pittsburgh, was later extended 100 miles (160 kilometres) east to Philadelphia and 67 miles (107 kilometres) west to the Ohio border, making it 327 miles (523 kilometres). An original feature of the turnpike, later widely copied, was the provision of restaurant and fuelling facilities.

The Alaska Highway was formalized in 1930 by a joint agreement between Canada and the United States. No funds were appropriated until the beginning of World War II when Alaska became an area of primary strategic importance, and an all-weather road link was needed to Fairbanks. In 1942 a pioneer road was cut from the Dawson Creek railhead northwest of Edmonton, Alberta, to Fairbanks. When complete, the motor-vehicle road was 20 to 24 feet wide and over 1,500 miles long. The road has been improved and has remained in continuous use since its pioneer days.

III. National highway and expressway systems

HISTORY

The Romans realized that a coordinated system of road ways connecting the major areas of their empire would be of prime significance for both commercial and military purposes. In the modern era the nations of Europe first introduced the concept of highway systems. In France, the State Department of Road and Bridges was organized in 1716 and by the middle of the 18th century the country was covered by an extensive network of roads built and maintained primarily by the national government. In 1797 the road system was divided into three classes of descending importance: (1) roads leading from Paris to the frontiers; (2) roads leading from frontier to frontier but not passing through Paris; (3) roads connecting towns. In the early 1920s this general plan remained essentially the same except that a gradual change in class and responsibility had taken place. At that time the road system was divided into four classes: (1) National highways (routes national), improved and maintained by the national government; (2) regional highways (routes *départementales*), improved and maintained by the Department under a road service bureau appointed by the Department Commission; (3) main local roads (*chemins* des *grandes* communications and chemins *d'intérêt commun*) connecting smaller cities and villages, built and maintained from funds of the communes supplemented by grants from the Department; and (4) township roads (chemins vicinaux ordinaires), built and maintained by the communities alone.

While the British recognized the necessity for national support of highways and a national system as early as 1878, the Ministry of Transport Act of 1919 first classified the roadway system and provided for 23,230 miles (37,168 kilometres) of Class I roads and 14,737 miles (23,579 km) of Class II roads with 50 percent of the cost of Class I roads and 25 percent of Class II roads to be borne by the national government. The need for a national through-traffic system was recognized in the middle 1930s and the Trunk Roads Act of 1939 followed by the Trunk Roads Act of 1944 created a system of roadways for through traffic. The Special Roads Act of 1949 authorized existing or new roads to be classified as "motorways" that could be reserved for special classes of traffic. The Highways Act of 1959 swept away all previous highway legislation in England and Wales and replaced it with a comprehensive set of new laws.

The U.S. road system

In the United States, New Jersey in 1891 enacted a law providing for state aid to the counties and established procedures for raising money at township and county level for road building. In 1893 Massachusetts established a state highway commission. By 1913 most of the states had adopted similar legislation but there was little coordination among the states. The Federal Aid Road Act of 1916 established federal aid for highways as a national policy, implemented by an appropriation of $5,000,000. The Bureau of Public Roads, established in the Department of Agriculture in 1893 to make "inquiries with regard to road management," was given responsibility for the program; and an apportionment formula based on area, population, and mileage of post roads in each state was adopted. Funds were allocated for construction costs up to $10,000 per mile and the states were required to bear all maintenance costs. The location and character of roads to be improved was left to the states, an arrangement that had some shortcomings. A national Good Roads Movement that had developed in the later years of the 19th century had long lobbied for a system of national roads joining the major population centres. This point of view was recognized by the Federal Aid Highway Act of 1921, which required each state to designate a system of state highways not to exceed seven percent of the total highway mileage in each state, and federal-aid funding was limited to this federal aid system. The system was divided into interstate roads, not to exceed 3/7 of the total mileage with the balance to be intercounty highway. Bureau of Public Roads approval of the system was lequired, and federal aid was limited to 50 percent of the estimated cost. The first map of the federal-aid system of 168,881 miles (270,210 kilometres) was published in 1923. The Federal Aid Highway Act and the Highway Revenue Act of 1956 provided funding for an accelerated program of construction on the Interstate System. A federal gasoline tax was established, the funds from which, with other highway-user payments, were placed in a Highway Trust Fund. The federal-state ratio for funding construction of the Interstate System was changed to 90 percent federal and ten percent state. It was expected that the system would be completed no later than 1971, but cost increases extended this time to about 1974–75. The system connects nearly all of the major cities in the United States and when completed will carry 20 percent of the nation's traffic on slightly more than one percent of the total road and street system.

An important element in the United States highway system, overlapping the Interstate network, is toll road mileage, most of which was built in the years immediately following World War II. A total of 3,500 miles (5,600 kilometres) of toll road has been constructed in the United States, most of it in the 1950s.

Canada and China are other nations that have formulated national highway policies. The Canadian Highway Act of 1919 provided for a system of 25,000 miles (40,000 kilometres) of highways and provided for a federal allotment for construction not to exceed 40 percent of the cost. The Trans-Canada Highway jointly financed by the federal government and the provinces has made good progress since World War II. China passed "The Regulation of Highway Improvement in China," establishing a National Highway Commission and a system of highways and village highways in 1920, but little has been done to implement the ambitious plan.

The Soviet road system

The Soviet Union has a 1,000,000-mile rural highway system that consists primarily of two-lane roadways. The cities have adequate street systems with very wide paved sections. Most highways radiate from the major cities and while some intercity routes are planned most are formed when two city systems intersect. In order to overcome this problem the Soviet Union is now planning and building several intercity highways, some four-lane divided and some with controlled accesses. It is estimated that 30% of the rural highway system was paved as the 1970 decade began. Funding is provided by an annual tax on cars and trucks, 2% of annual income from industrial plants and collective farms, and some state appropriations. In the future the profits from transportation enterprise are expected to provide much of the cost for new roads. The relatively small automobile population of the Soviet Union in proportion to its large land area generates little demand for highway improvements. As motor vehicle numbers increase strong pressures for more road building will undoubtedly develop.

Japan has a national expressway system of 2,480 miles (4,696 kilometres) most of which is on the island of Honshu. Three major toll roads, comprising about 400 miles, are major links in the system. The typical toll road section consists of two or three lanes in each direction separated by a 15-foot (4.5-metre) median. Because of land shortage in Tokyo and other major cities, urban expressway facilities are frequently double decked over existing streets or over rivers. In 1965 about one-fifth of Japan's national system was paved but good progress has been made since that time. The 117-mile (190-kilometre) Meishin toll expressway, Kōbe to Nagoya, was opened in 1969. Typical of expressway construction in Japanese cities is the 933-million-dollar construction program for the city of Osaka planned and partially completed to support Expo 70. The Osaka system includes a 35-mile (56-kilometre) ring highway, costing 135 million dollars, with 3 lanes in each direction and a 105-foot (32-metre) median. Almost one-third of the Osaka system is over water.

ADMINISTRATION AND FINANCING OF NATIONAL HIGHWAY SYSTEMS

Early road building was administered and financed on a local basis. The advent of the automobile created the necessity for integrated highway systems. Local roads and local streets are still generally administered by cities, townships, and counties or similar units of local government.

The major highway and expressway systems of a nation must, of necessity, have a national administrative base to guarantee continuity of routes and reasonable uniformity in design and construction. This responsibility may be shared with local units of government. In the United States current national highway policies are established by the Federal Highway Administration, an agency of the Department of Transportation. The local point of view is represented by advisory bodies of national policies and practices. notably the American Association of State Highway Officials. in England and Wales the Ministry of Transport, a cabinet-level department of national government, has authority over the motorways. the highest classification of highways, and the truck roads, the next highest, although this latter authority is often delegated to county or municipal authorities. In Scotland the secretary of state is the principal highway authority.

Financing of national roads

The financing of national 'highway systems is a national obligation. Before the automobile age, funds for highway systems were raised by general taxation in the form of labour taxes, by the issuance of bonds guaranteed by general tax revenues and to a limited extent by tolis charged against the users of highways and bridges. Since about 1920 the financing of highways has been almost entirely transferred to the highway user. A broad variety of taxes is employed, with motor-fuel taxes providing the largest single source of revenue. Vehicle licensing is common and trucks are usually licensed on a weight basis. Taxes on tires, rubber used in tires, lubricating oil, and on other motor-vehicle equipment items are widely applied for highway purposes. Excise and sales taxes on new car purchases more commonly accrue to general tax revenues. In periods of urgent demand for highways, for example, after World War II, governments employ credit financing for highway improvements, but the bonds are generally financed by highway-user tax revenues so the real source of funds does not change. Toll roads also become popular in periods of high demand, particularly over heavily travelled routes. The toll system permits rapid construction of a segment of the highway system through bond financing supported by tolls charged to the highway user. The toll, then, is in reality a special highway-user tax that assigns the tax to the particular highway. The toll system has proved effective in funding high-volume elements of national expressway systems.

SYSTEM PLANNING

Overall system study and planning. The planning of national expressway systems is an orderly, continuous process of assessing highway needs, determining the scope and requirements for a system, evaluating the required financing, and finally dealing with the complex relationships that occur among the various governmental units concerned with the system. The plan must provide for future extensions of the system, maintenance, and necessary rebuilding. System planning today is influenced by two major factors: the popularity of the automobile, which has provided new levels of mobility for many of the world's people; and the mass movement of people from rural areas to cities and from central cities to suburbs in the past quarter century, which has put great strains on urban expressway systems.

The need for transportation of both people and goods is closely associated with the physical location of most of the people. Consequently the major rural routes are easy to establish since they must join the major centres of population. The volume of traffic carried over such intercity routes is generally a function of the sizes of the terminal cities and the distances between them. Traffic volumes on intercity routes are established on the basis of current volumes and projections based on increasing population and vehicle ownership. Such volumes are customarily expressed in terms of the average daily traffic. For design purposes it is also essential that the traffic be classified by type with the heavy vehicles assigned to weight classification groups.

Determination of urban traffic volume

In urban areas the determination of traffic volumes assignable to various elements of the expressway systems is much more difficult. The automobile travel of individuals in urban areas is quite complex. Surveys of the origin and destination of present traffic are used to determine and project travel demands. In this procedure the travel of a percentage of the urban households and businesses is carefully studied with regard to trips made and their points of origin and destination. Future traffic is estimated on the basis of added demands as the city grows and on increasing use of the automobile. The result is a picture of the major travel-desire lines in the urban area and an estimate of the average daily traffic on each. The system must be designed to accommodate this traffic. While traffic-study techniques are constantly being refined and improved, the experience of the past 20 years is that urban traffic demands are chronically underestimated. In urban areas consideration must also be given to the parking of automobiles at their destinations. This problem involves both the quantity of parking area required and the methods for accepting and discharging the vehicles.

Rural expressways, urban expressways, and motorways are the most modern and expensive elements in the highway system of a country. Consideration must be given to the effect of this system on the lesser street and highway systems. Traffic must move to and from the expressways and motorways on these lesser systems; thus the proper design and operation of the whole requires careful attention to the needs of each of the system elements and to the proper connections between these elements. When the design and construction of a highway system element is the responsibility of several governmental agencies it is difficult to obtain proper coordination and proper consideration of the entire problem of traffic movement on a system basis. Only by the most effective use of all levels of highway facilities can the motoring public be served well. The result of a systems study for a nation or an urban area should be a network of roadways of varying complexity and traffic-service capability that will adequately serve the needs of the country or the urban area. For example, the Ministry of Transport plan for Great Britain's principal national routes calls for 720 miles (1,159 kilometres) of motorway (expressway) and 1,500 miles (2,400 kilometres) of other national routes. In September, 1950, most of the European countries adopted a system of major highways, totalling about 26,000 miles, (41,600 kilometres), to be improved and known as the "E" system. Completion of the system prior to the turn of the century is unlikely. Only Germany has completed a substantial portion of the routes to expressway standards. Many of the world's urban areas have comprehensive plans for highway development in the area. All of these plans must be continuously reviewed to accommodate changes in traffic needs.

Design engineering and testing. The highway designer starts with information on traffic volumes; types of traffic; vehicle, axle, and wheel loadings; and maximum speeds anticipated. His task is to design the highway cross section and to fix its alignment both horizontally and vertically. He has the further obligation of producing a design that can later be modified or expanded to meet increasing traffic demands. The design process is simplified and uniformity in the system is insured by the use of "standards" that are established for highways of various classifications. These standards are fixed by the highway building agencies. Most agencies with direct responsibility for the construction and maintenance of roads, streets, or highways also have standards for design, construction, and materials. Loadings to be used in the design of expressway systems are based primarily on actual loading measurements of vehicles using the facility. While vehicle weights and axle loads are usually prescribed by law, these legal weight limits are frequently exceeded, hence design loadings are based on actual wheel and axle load measurements and reasonable estimates of trends.

Because they carry large volumes of heavy traffic, expressways justify more sophisticated studies of the probable loading during the life of the pavement. Materials to be used in their construction, as well as for other highway systems, are specified and tested for conformity in accordance with standard specification requirements and test procedures. In addition, most major agencies constructing highways have special specifications and testing methods that apply to their special conditions. The multiplicity of specifications for materials used in highway construction causes problems for the materials-supplying industries and increases construction costs. A given aggregate supplier may furnish the national government, two states or provinces, and a number of local jurisdictions all having different gradation specifications for essentially similar materials. This condition forces the supplier to make and store several materials that have only insignificant differences in size.

Materials selection. A most important element in the design of the highway system is the selection of materials to be used in its various segments. Major factors considered in materials selection are the initial cost in place, estimated annual maintenance costs, service life, and suitability for the driving public. The latter factor is an important consideration for expressways, particularly in urban areas. The high volumes of traffic that use these expressways on a nearly continuous basis create difficulty in maintenance and renovation and for the drivers using the expressway during periods of repair or change. For this reason materials and methods of construction for expressways are selected to minimize maintenance and renovation; *i.e.*, the highest types of pavement produced with high quality materials.

Limited access and special requirements. A prominent feature of an expressway system is the basic premise that the expressway has the function of moving through traffic safely at reasonable speeds and with the maximum feasible limitation of points of access to and egress from the system. For expressways the land service function is relegated to a very minor role. All points at which traffic enters or leaves the traffic stream are points of traffic turbulence and particular attention must be given to designing these entrances and exits to facilitate traffic movement. Vehicles entering the expressway must ihcrease speed to that of expressway traffic and enter a gap in the traffic stream; this is accomplished by added lanes, called acceleration lanes, at points of entry. Similarly, deceleration lanes are provided at exit points.

The use of grade separation

Where two major expressways intersect, traffic flow is maintained uninterrupted by grade separation of the through traffic and the provision of separate lanes for each of the traffic movements from one expressway to the other, of which there are eight in all. The resulting pattern is commonly called a cloverleaf. Intersections of this type in urban areas often involve very complex problems, because of the unavailability of land, requiring compact intersections, and the need to accommodate traffic movements between the expressway and the street system. In such cases it is usually necessary to provide grade separations for some of the turning movements; three or four level grade separations may be provided by elevated bridge structures.

Urban expressways are also faced with the problem of clear separation of expressway traffic from that of the street system. This is accomplished either by depressing the expressway below ground and carrying the streets across the expressway on bridge structures or by elevating the expressway above the street system. The depressed expressway is generally better from the point of view of appearance but poses difficulty in maintenance of the back slopes, handling of storm water drainage, and construction in areas of high water table. The elevated expressway is expensive and often considered aesthetically objectionable, but its maintenance cost is lower and in areas of high water table or where large numbers of heavily travelled streets must be crossed it offers the most feasible solution to the traffic-separation problem. Expressway exits and access points in urban areas present difficult design problems for both the depressed and elevated freeways but are generally somewhat more difficult for the elevated system.

Expressways in urban areas require extensive lighting because of the movement of large volumes of traffic during the hours of darkness and the necessity for illumination to provide proper vision for the entrance, exit, and route-change movements. In addition to continuous lighting of the through lanes, special lighting and sign lighting is provided to accommodate entering and departing vehicles.

IMPACT OF THE NEW EXPRESSWAYS

Benefits. The new expressways and motorways have been very popular with the travelling public. Carrying large volumes of traffic at high speeds, they have excellent safety records due to the directional separation of traffic, absence of intersections, minimum interference from entering and leaving vehicles, more uniform traffic speed, and excellent visibility. Full control of access, as compared to no control, other conditions being equal, is responsible for an approximate 60 percent reduction in accident rates and 45 percent reduction in fatalities based on travel mileage. The greatest reduction occurs in suburban areas. Urban and rural expressways have only one-fifth the accident rate experienced on city streets and rural highways.

There is also a substantial saving in time and operating costs for all types of vehicles on the expressway in comparison to operating costs on normal rural highways or city streets. Studies made in Los Angeles in the early 1960s indicated operating and accident cost savings of 3% cents per mile for passenger cars, 10 cents per mile for trucks. Expressways, furthermore, provide much better driving conditions for the motoring public, so that trips are completed with less physical wear and tear. This has led to increased recreational and cultural travel.

Controversies and problems associated with expressways. The expressway, because of its greater traffic capacity produces problems of air pollution, noise, and, in the eyes of some, visual pollution. Air pollution due to vehicle operation has become a substantial problem in the larger urban areas of the world, particularly those in which common atmospheric conditions prevent rapid dispersion of the pollutants. Though this is not alone an expressway problem, the heavy concentration of vehicles on expressways makes them a major source of pollutants. The answer to the problem presumably lies in new technical developments that either will drastically reduce the volume of pollutants emanating from the internal-combustion engine or will facilitate the substitution of alternate, nonpolluting power sources for automobiles. Another possibility being explored in the early 1970s in Rome, New York City, and elsewhere in the restriction of vehicle use in the central city.

Urban expressways

The urban expressway and to a lesser extent the rural expressway are considered by many to be poor neighbours. A major intersection of urban expressways consumes tens of acres of land and the construction of thousands of linear feet of bridge structure. Such an intersection in a built-up area means a substantial disturbance of rhe neighborhood. The same is true to a lesser extent along the entire route in built-up areas. Strong objections are often raised to expressway locations in urban areas; public opposition has sometimes halted construction. Conservationists have objected to the location of expressways that utilize lands now in parks, golf courses, and other green areas, or which run adjacent to recreation areas such as beaches. The destruction of historic buildings and landmarks by expressway construction has drawn much criticism in Europe and the United States.

In rural areas the problems of expressway location are much less severe because of the availability of alternate locations and the smaller numbers of businesses and residences involved. Rural expressway intersections are generally designed to provide for turning movements at grade, thus eliminating the need for long bridge structures, although requiring large land areas. There have nevertheless been protests, not only from conservationists but from rural property owners whose lands and homes were affected. It has been alleged that highway designers give insufficient attention to aesthetics and create ugly scars on the landscape. Expressway designers of the 1970s are sensitive to these criticisms and are devoting much effort to design, location, and landscaping that fits the roadway to the countryside. In the United States the Highway Beautification Act of 1965 authorized the partial withholding of federal funds from states that do not take proper action to build and maintain aesthetically pleasing highways. Funds have been authorized for the control of billboards and junkyards adjacent to expressways. The appearance of expressways can be materially improved by good planning and design to fit the roadway to the terrain, the retention of native trees and shrubs and landscaping by judicious planting. Wide median areas of natural vegetation or landscaping are popular. The wider rights-of-way required are considered to be justified by the improvement in driving conditions as well as appearance.

Rivalry among highway users

Another area of controversy, principally in the United States, is the rivalry that exists among different elements of the transportation industry, particularly between the trucking and railroad industries. Unquestionably the expressways, which permit truck operations at high speeds and with few stops, substantially reduce the cost of operating these vehicles. In addition the trucking industry has argued for increases in allowable gross vehicle weights and dimensions, increases that are opposed by highway administrators and designers on the grounds that existing expressways are not designed to accommodate these heavier vehicles. Railroad interests and some highway administrators contend that the commercial trucks and buses do not pay their fair portion of the highway-user taxes and are, therefore, being subsidized by tax and highway-user funds from the general public. The question has never been settled, but it is generally conceded that higher taxes on commercial vehicles approximately cover the incremental costs involved in constructing the expressway. Highway cost allocation remains a thorny fiscal and philosophical problem that has occupied highway economists for many years; the approaches presented do not have the approval of all interests involved.

IV. Operation and maintenance

The glamorous phase of highway engineering is that of system planning, design, and construction of new highway facilities. Service to the driving public, however, is very much dependent upon operation and maintenance activities. The life of a highway is a function of the quality of maintenance and minor renovation, and long life provides the most important single element in highway economics.

The operation of traffic on roads and highways is subject to four types of control: (1) legal control, or the laws setting forth the rules of the road; (2) roadway signs and markings that provide instructions and information; (3) traffic light signals; (4) police action. Expressways are specifically designed to avoid the necessity for traffic signals, except on access or exit lanes, and police traffic control except in the case of traffic congestion due to accidents.

Maintenance consists of activities concerned with the condition of the pavement and shoulders, including surface conditions, structural integrity and adequacy, and the condition of the right-of-way areas outside the travelled way. It is also concerned with snow removal, debris removal, and the installation and care of pavement markings, signs, and signals.

OPERATION

Markings, signs, and signals. The marking of roadway surfaces with painted lines or types of permanent markers is standard practice throughout the world. While there are some disadvantages of pavement surface marking, notably high maintenance costs and problems in night visibility, it is generally accepted that the advantages far exceed the disadvantages. Interior lane lines and centre lines are marked with broken lines, either yellow or white, and dangerous conditions such as restricted sight distance and pavement edges are indicated with solid lines.

Signs are used to advise the driver of special regulations that apply at specific times and places and to provide information with regard to routes, directions, destinations, hazards, and points of interest. Expressway sign planning is particularly important because the driver who makes a mistake and misses an entrance or exit cannot recover quickly because of the limited access characteristic, which means that the next entrance or exit may be miles away. Signs are classified as: (1) regulatory signs, which provide notice of traffic laws and regulations such as speed-limit, stop and yield signs, and signs regulating traffic movement; (2) warning signs, which call attention to conditions in or adjacent to the roadway representing a potential traffic hazard such as turns, steep grades, low vertical clearance, or slippery pavement surface; (3) guide signs, which show route designations, destinations, distances, points of interest, and other similar information. In most nations signs have standard shapes and colours, with one shape used for the stop sign, another for warning signs, etc. Expressway directional signs, commonly mounted over the roadway on a sign bridge, are large in size for easy reading at high speeds and often have white letters and symbols on a green background. Special shapes and colours are used for route markers. A United Nations commission studied highway signs in 1951 and made recommendations for standard sign procedures that have been adopted by many nations. The commission found that the use of symbols is preferable to words; the advantage of wordless signs in Europe, with its large international traffic, is evident. The commission also found that three-colour signs are quite visible. European danger signs traditionally were triangular, but the commission recommended adoptions of the American diamond shape on the basis of better legibility and comprehension. Conferences in Bangkok (1967), Montevideo (1967), and Vienna (1968) were devoted to adoption of a convention for road signs and signals acceptable to most nations of the world.

Types of signs

The traffic signal has its primary use in traffic control in city street systems, but it also has a place on rural highways. At highway grade intersections accommodating large volumes of traffic the traffic signal is used to allocate the right-of-way to the various traffic streams. Systems known as traffic-actuated signals automatically monitor the demand in the traffic streams and allocate the green time or right-of-way correspondingly. Preference can be given to particular traffic directions by such signals. A recent development in expressway operation is the traffic-signal system to meter traffic entering on access lanes. These signals provide a red indication to entering traffic until a gap sufficient for entry occurs in the exterior expressway lane at which time the signal gives a green indication and the entering vehicle moves into the traffic stream. Signals are also used on expressways to indicate lanes open and closed ahead of the driver.

Rules of the road and speed limits. Legal rules governing the movement of traffic are an essential part of orderly movement on the highway. Such regulations may be nationwide, state- or province-wide, or local. In general the rules for operation of vehicles on the highway may be divided into three main categories. First are the rules applying to the vehicle and the driver such as vehicle and driver registration, vehicle equipment, accident reporting, and financial liability. Second are the general rules for drivers and pedestrians such as speed limits, right-of-way, and turn requirements known as the rules of the road. Third are those regulations which apply to limited roadway sections such as speed zones, one-way operations, and turn controls.

The important rules of the road are reasonably uniform throughout the world, except in two important aspects. First, the right-of-way is allocated to vehicles on the right-hand side of the highway in most nations, but on the left-hand side in a few, notably the U.K. This influences vehicle design since it is important that the driver be on the side of the vehicle adjacent to opposing traffic; *i.e.*, on the left side of the vehicle for the right-hand rule. The second major variation is in the regulation of vehicle speed by the use of speed limits. Speed limits on open rural highways and motor ways are not specified in many European countries. Police control judgments are made as to whether or not a driver's speed is compatible with driving conditions. In the United States and Canada speed limits are widely used. The limits set vary from 30 miles (48 kilometres) per hour for local service highways in built-up areas to 55–70 miles (88–112 kilometres) per hour on rural highways and expressways. Higher speed limits of 75–80 miles (120–128 kilometres) per hour are used in a few jurisdictions and on toll highways. An important aspect of the speed question is traffic speed differential, which should be minimal. There is much less interference in a nearly uniform traffic stream and consequently greater safety. For this reason minimum speed limits are established on many expressways, particularly in urban areas, with the lower limits set at 10 to 20 miles per hour below the upper limits.

Special regulations are important to the efficient movement of traffic in specific segments of the street and highway system. One-way street systems in congested urban areas provide safer driving conditions and increase the traffic-carrying capacity of the system. The prohibition of turns at intersections contributes to safety and reduces conflicts. Such regulations, however, may adversely affect some businesses. Speed zoning is used to establish localized speed limits in special zones. Reduced speed limits are commonly used on highways approaching built-up areas and on dangerous highway sections where lower speed limits are justified. Higher than normal speed limits may also be established on particularly safe sections of highway.

Highway policing. Highway patrols or highway police were inaugurated to help in solving the highway accident problem by enforcing driving regulations on the major highway systems. In urban areas traffic patrol and enforcement of traffic regulations is a responsibility of the police department. Most large cities have a traffic division in the police department. On heavily travelled expressways in rural areas adequate patrol requires one patrolman for each 4 to 5 miles (6.4–8 kilometres). In addition to patrolling to insure compliance with speed and other regulations, the patrolmen also investigate accidents, render assistance to disabled vehicles, and attempt to apprehend criminals.

Speed control methods

An important aspect of traffic regulations and accident prevention is the control of excessive speed. Speed is commonly measured by radar devices or by pacing with a patrol car. Speed traps that involve travel time measurements over a fixed distance are ordinarily not permitted. In accident investigation speed is determined by skid marks. Another important factor in highway accidents is the driver who is under the influence of alcohol or drugs. Tests for intoxication are now widely used. The determination of the alcohol content in the blood or other bodily fluids is probably the most conclusive indication of excessive use of alcohol, but such tests are not practical for police identification of excessive drinking. The most widely used test for police identification of the state of intoxication from alcohol is the breath test in which the driver blows up a balloon and his breath is run through a series of chemical contacts in an analyzer. The results indicate to the detaining officer whether or not the driver's condition is due to alcohol and the approximate blood alcohol content. The alcohol blood concentration that is presumptive of poor driving ability is not firmly established. Maximum levels of 0.15 percent have been widely used to prove alcoholic influence, but many authorities believe that a limit of 0.05 percent is more realistic and that 0.10 percent is the maximum reasonable upper limit.

In addition to the traffic control and policing function, highway patrols regulate traffic at the scene of accidents, provide information and are in this and other ways very helpful to the driving public. The primary work of various expressway emergency patrols is to assist in emergencies and to carry on activities to insure efficient movement of high volumes of traffic. New developments in recent years include the use of light airplanes and helicopters for patrol purposes. They are particularly effective in locating trouble spots causing traffic jams and relaying this information to patrol officers on the ground for corrective action.

MAINTENANCE

The proper and adequate maintenance of the highway after construction is one of the most important elements for proper functioning of the roads and highway system. Proper maintenance keeps the roadway safe, provides good driving conditions, and prolongs the life of the pavement, thus protecting the highway investment. Maintenance operations are carried on in all governmental jurisdictions by crews of men organized, trained, and equipped to carry out the maintenance function. Maintenance activities can be grouped into three major areas: (1) maintenance of pavements and shoulders; (2) maintenance of ditches, slopes. right-of-way areas, and drainage structures; and (3) maintenance of signs and markings and operations aiding traffic movement.

The three major maintenance activities

Maintenance of pavements and shoulders involves operations of the same type and involves use of much of the same equipment as for new construction. Maintenance of the ditches, slopes and right-of-way areas involves mowing operations to control vegetation and work to control and eliminate soil erosion. A major maintenance expenditure is involved in picking up and removing trash thrown or dumped in the ditch and right-of-way areas by the travelling public. Roadside containers for such trash provide only a partial solution to the problem. In the more rigorous winter climates substantial maintenance expenditures are required to remove snow and ice from the pavement including snow plowing, the spreading of salt for snow and ice removal, and spreading sand to provide traction.

V. Future highway trends

One of the major questions for the future concerns the desirability of continued construction of expressways in urban areas. In many high-population-density urban areas the transportation problem can probably be solved more economically and with lesser requirement for land by the use of mass transit, both bus and fixed rail. The operation of a Bay Area Rapid Transit System, in the San Francisco Bay Area, will provide an indication of the potential success of well-designed mass transit in attracting riders and reducing automobile traffic. At the same time it seems reasonable to predict that the automobile and truck will have a large place in the world's transportation for many years. In most parts of the world automobile use is steadily increasing. In urban areas continued development of more adequate expressway facilities in limited land area requires new approaches. One possibility is to take the expressway system underground in tunnels. The primary difficulties in this type of construction are the high cost of tunnelling and the ventilation problem. Another possibility is to move the expressway system to the second story level with direct access to buildings and parking garages at this level and the allocation of the street level to pedestrians and a few local service vehicles. If the automobile and bus are to continue to be the primary source of transportation of the people in urban areas, new approaches will be needed to integrate expressway systems into the total facilities of the central city.

Highway safety will continue to demand attention, much of which will be given to the design of roads and highways. More four-lane divided highways will be built to replace existing two- and three-lane roads. Recent developments of easy-breaking signs and light poles, along with impact attenuators to protect the vehicle that strikes rigid fixed objects such as piers and expressway gores, have reduced the severity of accidents involving vehicles striking fixed objects. Eetter roadway surfacing, alignments, and signing and marking will improve driving conditions and make highways safer.

A major safety feature under consideration is the development of an electronic highway in which vehicles entering the highway will be locked into a guidance system that will control its speed and path of travel. To be acceptable such a system will have to be absolutely reliable and provide a quality of travel that will insure the driver's willingness to give up his individual driving freedom.

Truck highways

Another potential development is the truck highway. There have been many examples of roads and highways on which trucks were prohibited, in particular the parkways around New York. Increases in transportation of goods by truck in the developed countries have led to truck traffic congestion on many highways. In some areas serious consideration will probably be given to the planning and construction of highways to be limited to truck traffic. Such highways would be financed by the trucks using them, thus eliminating the criticism that commercial vehicles are subsidized by automobile user taxes on the public systems.

One of the major question marks in the highway-building future is the outlook for the internal-combustion engine. Widespread problems of air pollution in major urban areas have led to the suggestion that the engine be legally regulated nut of use or that very rigid controls on emissions be established. If this trend continues and new types of engines or other devices to power the automobile and truck are adopted. the changes may require substantial changes in the design of highway systems. As an example major changes in acceleration rates would have a serious effect on the design of the highway system for passing and merging operations. Changes in other vehicle operating characteristics will have similar impact for other elements of the system.

(F.J.B.)

Robert I the Bruce, of Scotland

Robert "the Bruce," the 14th-century champion of Scottish independence from England, became king of Scots in 1306 and led the forces that freed Scotland from English suzerainty in 1328. Among the legends that later became attached to his name was the story that, when outlawed and hard pressed by the English, with his fortunes at low ebb, he derived hope and patience from watching a spider perseveringly weave its web.

The Anglo-Norman family of Bruce, which had come to Scotland in the early 12th century, was related by marriage to the Scottish royal family, and hence the sixth Robert de Bruce (died 1295), grandfather of the future king, claimed the throne when it was left vacant in 1290. The English king Edward I claimed feudal superiority over the Scots, and awarded the crown to John de Balliol instead.

The eighth Robert de Bruce was born on July 11, 1274. His father, the seventh Robert de Bruce (died 1304), resigned the title of earl of Carrick in his favour in 1292; but little else is known of his career until 1306. In the confused period of rebellions against English rule from 1295 to 1304 he appears at one time among the supporters of the rebel leader William Wallace, but he was later apparently restored to Edward I's confidence. There is nothing at this period to suggest that he was later to be the Scottish leader in a war of independence against Edward's attempt to govern Scotland directly.

The decisive event was the murder of John ("the Red") Comyn in the Franciscan church at Dumfries on February 10, 1306, either by Bruce or his followers. Comyn, a nephew of John de Balliol, was a possible rival for the crown, and Bruce's actions suggest that he had already decided to seize the throne. He hastened to Scone and was crowned on March 25.

Coronation on March 25, 1306

The new king's position was very difficult. Edward I, whose garrisons held many of the important castles in Scotland, regarded him as a traitor and made every effort to crush a movement that he treated as a rebellion. King Robert was twice defeated in 1306, at Methven, near Perth, on June 19, and at Dalry, near Tyndrum, Perthshire, on August 11. His wife and many of his supporters were captured, and three of his brothers executed. The King himself became a fugitive, hiding on the remote island of Rathlin off the north Irish coast.

In February 1307 he returned to Ayrshire. His main supporter at first was his only surviving brother, Edward, but in the next few years he attracted a number of others. The King himself defeated John Comyn, earl of Buchan, and in 1313 captured Perth, which had been in the hands of an English garrison; but much of the fighting was done by his supporters, who progressively conquered Galloway, Douglasdale, the forest of Selkirk and most of the eastern borders, and finally, in 1314, Edinburgh. During these years the King was helped by the support of some of the leading Scottish churchmen and also by the death of Edward I in 1307 and the ineptness of his successor, Edward II. The test came in 1314 when a large English army attempted to relieve the garrison of Stirling. Its defeat at Bannockburn on June 24 marked the triumph of Robert I.

Victory at Bannockburn

Almost the whole of the rest of his reign had passed before he forced the English government to recognize his position. Berwick was captured in 1318, and there were repeated raids into the North of England, which inflicted great damage. Eventually, after the deposition of Edward II (1327), Edward III's regency government decided to make peace by the Treaty of Northampton (1328) on terms that included the recognition of Robert I's title as king of Scots and the abandonment of all English claims to overlordship.

The King's main energies in the years after 1314, however, were devoted to settling the affairs of his kingdom. Until the birth of the future king David II in 1324 he had no male heir, and two statutes, in 1315 and 1318, were concerned with the succession. In addition, a parliament in 1314 decreed that any who remained in the allegiance of the English should forfeit their lands; this decree provided the means to reward supporters, and there are many charters regranting the lands so forfeited. Sometimes these grants proved dangerous, for the King's chief supporters became enormously powerful. James Douglas, knighted at Bannockburn, acquired important lands in the counties of Selkirk and Roxburgh that became the nucleus of the later power of the Douglas family on the borders. Robert I also had to restart the processes of royal government, for administration had been more or less in abeyance since 1296. By the end of the reign the system of exchequer audits was again functioning, and to this period belongs the earliest surviving roll of the register of the great seal.

In the last years of his life, Robert I suffered from ill health and spent most of this time at Cardross, Dumbartonshire, where he died on June 7, 1329, possibly of leprosy. His body was buried in Dunfermline Abbey, but the heart was removed on his instructions and taken by Sir James Douglas on a pilgrimage to the Holy Land. Douglas was killed on the way (1330), but, according to one tradition of uncertain value, the heart was recovered and brought back to Melrose Abbey. In later times Robert I came to be revered as one of the heroes of Scottish national sentiment and legend.

BIBLIOGRAPHY. The authoritative biography is G.W.S. BARROW, *Robert Bruce and the Community of the Realm of Scotland* (1965). This gives references to the sources and a full bibliography and supersedes all earlier works. The most important original authority for the life of Robert I is *The Bruce,* a poem in Scots by JOHN BARBOUR, probably completed in 1376; the most recent edition is by W.M. MACKENZIE (1909).

Robert Guiscard

A commander and statesman of exceptional ability, Robert de Hauteville, better known as Robert Guiscard (the Astute), was the remarkable leader of the Norman invasions of southern Italy during the last two-thirds of the 11th century.

Robert was born in Normandy around 1015, into a family of knights. Arriving in Apulia, in southern Italy, around 1047 to join his half brother Drogo, he found that it and Campania, though they were southern Italy's most flourishing regions, were plagued by political disturbances. These regions attracted hordes of fortune-seeking Norman immigrants, who were to transform the political role of both regions in the following decades.

Arrival in Apulia

In Campania, the Lombards of Capua were launching wars against the Byzantine dukes of Naples in order to gain possession of that important seaport. In Apulia, William (Iron Arm) de Hauteville, Robert's eldest half brother, having successfully defeated the Byzantine Greeks who controlled that region, had been elected count of Apulia in 1042. In 1046 he had been succeeded by his brother Drogo.

When Robert joined his brothers, they sent him to Calabria to attack Byzantine territory. He began his campaign by pillaging the countryside and ransoming its people. In 1053, at the head of the combined forces of Normans from Apulia and Campania, he defeated the haphazardly led forces of the Byzantines, the Lombards, and the Pope at Civitate. Guiscard now consolidated the riches of the Hautevilles. Because of the deaths of William and Drogo, and of his third half brother, Count Humphrey, in 1057, Robert returned to Apulia to seize control from Humphrey's sons and save the region from disgregating internal conflicts. After becoming the recognized leader of the Apulian Normans, Robert resumed his campaign in Calabria. His brother Roger's arrival from Normandy enabled him to extend and solidify his conquests in Apulia.

In his progression from gang leader to commander of mercenary troops to conqueror, Robert emerged as a shrewd and perspicacious political figure. In 1059 he entered into a concordat at Melfi with Pope Nicholas II. Until that time the papacy had been hostile toward the Normans, considering them an anarchist force that upset the political structure in southern Italy—a structure based on a balance of power between the Byzantines and the Lombards of northern Italy. The schism between the Greek and Latin churches in 1054 worsened the relations between the Byzantine emperors and the papacy, and eventually the papacy realized that Norman conquests over the Byzantines could work to their advantage. Guiscard's plan to expel the Arabs from Sicily and restore Christianity to the island also found favour in Nicholas' eyes. This expedition into Sicily, accompanied by an ever increasing religious fervour, got under way in 1060, as soon as the conquest of Calabria was completed. Guiscard entrusted the command of the expedition to his brother Roger; but on particularly difficult occasions—*e.g.*, the siege of Palermo in 1071—he came to his brother's aid.

Until this time, Robert's relations with Roger had not always been amicable, since Roger, aware of both his own talent and Robert's dependency on him, would not settle for the subordinate role allotted him. Their differences were resolved when Robert invested Roger, after he had recognized Guiscard's supreme authority, with "the County of Sicily and Calabria" along with the right to govern and tax both counties.

Expansion of the duchy

Robert continued to expand the small county left by Humphrey into a duchy, extending from the Adriatic to the Tyrrhenian seas. The capture of Bari in April 1071 resulted in the end of Byzantine rule in southern Italy. Guiscard turned next to the neighbouring territories of Salerno, controlled by the Lombards. Instead of fighting them, he dissolved his first marriage and in 1058 married the sister of Salerno's last Lombard prince, Gisulf II. Hostilities broke out between the two rulers, however, and Gisulf naively tried to bring about a Byzantine counteroffensive against Guiscard. Fearing that the Norman advances into Campania, Molise, and Abruzzi would threaten the papal dominions, Pope Gregory VII excommunicated Guiscard and gave Gisulf considerable military aid. The struggle came to a head when Gisulf, determined to display his power, advanced toward the prosperous city of Amalfi. Guiscard responded to the city's plea for help in 1073 and successfully defended it; in December 1076 he took Salerno from Gisulf and made it the capital of his duchy.

Robert was now at the height of his power. During his rise he repressed with an iron hand not only the claims of Humphrey's sons but also the uprisings of towns and lords fretting under the restraints imposed upon them. The harshness with which Robert dealt with these rebels was intended to mold a heterogeneous population into a strong, sovereign state.

When, in 1080, the conflict between church and state over the right to make ecclesiastical investitures had become more intense, Robert chose to reconcile himself with Gregory VII, entering into the Concordat of Ceprano, which confirmed the commitments of the earlier Council of Melfi, Even the Byzantine court drew closer to him and went as far as trying to establish a familial relationship with Guiscard. The Byzantine emperor Michael VII, in need of Robert's help to uphold his unstable throne, married his son, Constantine, to one of Guiscard's daughters, Helen. The opposition party, however, deposed Michael and confined Helen in a monastery. To guarantee Apulia against attack from the new rulers of Byzantium, Guiscard wanted the territories on the Adriatic coast of the Balkan Peninsula, and he began to build a large navy. Michael's ouster and Helen's confinement reawakened his unappeased spirit of adventure and hastened his long-considered expedition. Now his goal was even more ambitious: to march to Byzantium and crown himself emperor in place of the deposed Michael.

In 1083 Guiscard landed in Epirus with a well-trained army and immediately succeeded in defeating the Byzantines and their Venetian allies. The Pope, however, suddenly recalled him to Italy to help him oust the German king Henry IV, who was marching on Rome en route to claiming southern Italy for the Holy Roman Empire. Having returned home and suppressed the revolts of the lords hostile to himself and to Pope Gregory VII, Guiscard moved toward Rome, defeated the Pope's enemies, and escorted him to Salerno in the summer of 1084. Following this success, he returned to his campaign on the Adriatic coast. He died during the siege of Cephalonia on July 17, 1085.

Achievements

Physically attractive, endowed with an acute and unscrupulous intelligence, a brilliant strategist and competent statesman, Guiscard had begun to organize a state composed of diverse ethnic and civil groups: Latin and Germanic in Lombard territories and Greek in Byzantine domains. The new political structure was built on a monarchial–feudal framework characteristic of the time, but it was controlled by the energetic and uncompromising Guiscard, who tried to use his ducal power to create a powerful and prosperous state. The other base on which he built was Roman Catholicism, the religion of the conquerors and most of the conquered, which he used to reconcile the subjected peoples. An extremely religious man, Guiscard was distrustful of the Greek clergy because of their ties with Byzantium. On the other hand, his generosity toward the Latin Church was bountiful. He endowed it with territories and clerical immunities in order to tie it firmly to the feudal system. Splendid cathedrals and Benedictine abbeys were built in the hope that they would consolidate and diffuse Latin language and culture among the heterogeneous people and tie them into a new, unified state. Guiscard was kept from realizing this political vision only by his death.

MATHIEU (1961); F. CHALANDON'S classic work, *Histoire de la Domination Normande en Ztalie et en Sicile*, 2 vol. (1907); and E. PONTIERI, *Tra i Normanni nell'Italia meridionale,* 2nd ed. (1964).

(E.Po.)

Robespierre

Maximilien-François-Marie-Isidore de Robespierre, who was known to contemporaries as "the Incorruptible," played a leading part in the French Revolution, particularly the period of the Jacobin republic of 1793–94. A democrat, he thought, like Rousseau, that moral virtue was inseparable from the exercise of sovereignty. The strictness with which he adhered to his principles won him the approval of the French people, but eventually his realism led him to the belief that to save the country and the republic the government had to impose its will by means of coercion and "the Terror."

Early life. Maximilien was born at Arras on May 6, 1758, the son of a lawyer. After his mother's death, his father left home, and Maximilien, his brother, and his sisters were brought up by their maternal grandparents.

From 1765 Maximilien attended the college of the Oratorians at Arras, and in 1769 he was awarded a scholarship to the famous college of Louis-le-Grand in Paris. A brilliant student, he obtained his bachelor's degree in 1780 and, after taking his law degree the following year, became a lawyer at Arras, where he set up house with his sister Charlotte. He soon made a name for himself and was appointed a judge at the Salle Épiscopale, a court with jurisdiction over the provostship of the diocese. His private practice provided him with a comfortable income.

Lawyer in Arras

He was admitted to the Arras Academy for the advancement of the arts and sciences in 1783 and soon became its

R b pi e it by a n artist.
Ir the Musée t, ri
J.E. Bulloz

chancellor and later its president. Contrary to the long-held belief that Robespierre led an isolated and withdrawn life, he often visited local notables and mingled with the young people of the district. He entered academic competitions, and his "Mémoire sur les peines infamantes" ("Report on Degrading Punishments") won first prize at the Academy of Metz. He belonged to a literary society in Arras and wrote elegies in the fashion of the time. Though he was rumoured to be engaged to his cousin Antoinette Deshorties, he never married.

By 1788 Robespierre was already well-known for his altruism. As a lawyer representing poor people, he had alarmed the privileged classes by his protests in his "Mémoire pour le Sieur Dupond" against royal absolutism and arbitrary justice. When the summoning of the States General (a national assembly that had not been called since 1614) was announced, he issued an appeal entitled "To the people of Artois on the necessity of reforming the Estates of Artois." In March 1789 the citizens of Arras chose him as one of their representatives, and the Third Estate (the commons) of the bailiwick elected him fifth of the eight deputies from Artois. Thus he began his political career at the age of 30.

Membership in the National Assembly and Leadership of the Jacobins. Robespierre preserved his frugal way of life, his careful dress and grooming, and his simple manners both at Versailles and later in Paris. Despite his youth he quickly attracted attention in an assembly that included some distinguished names. He probably made his maiden speech on May 18, 1789, and was to speak more than 500 times during the life of the National Assembly. He succeeded in making himself heard despite the weak carrying power of his voice and the opposition he aroused, and his motions were usually applauded. Proofs of his growing popularity were the ferocious attacks made by the royalist press on this "Demosthenes," "who believes everything he says," this "monkey of Mirabeau's" (the Comte de Mirabeau, a politician who wanted to create a constitutional assembly). Robespierre was kept out of the committees and from the presidency of the National Assembly; 'only once, in June 1790, was he elected secretary of the National Assembly. In April he had presided over the Jacobins, a political club promoting the ideas of the French Revolution, of which he had been a member since it was first organized. In October he was appointed a judge of the Versailles district tribunal.

Robespierre, nevertheless, decided to devote himself fully to his work in the National Assembly, where the constitution was being drawn up. Grounded in ancient history and the works of the French philosophers of the Enlightenment, he welcomed the Declaration of the Rights of Man and of the Citizen, which formed the preamble of the French constitution of September 3, 1791, and insisted on observing it. He fought for universal suffrage, for unrestricted admission to the National Guard, to public offices, and to the commissioned ranks of the army, and for the right to petition. He opposed the royal veto, the abuses of ministerial power, and religious and racial discrimination. He defended actors, Jews, and black slaves and supported the reunion of Avigncn, formerly a papal possession, with France in September 1791. In May he had successfully proposed that all new deputies be elected to the next legislature so that as a completely new body, it would better express the people's sovereign will.

His passionate fight for liberty won him more enemies, who called him a dangerous individual—and worse: robber, murderer, spy, dictator. After the flight of Louis XVI (June 20–21, 1791), for which Robespierre vainly demanded his trial, the slanders of the revolutionary deputy became twice as violent. He hastened the vote on the constitution so as to attract "as many of the democratic party as possible," inviting in his ***Adresse aux Français*** (July 1791) the patriots to join forces. Martial law was proclaimed, and at the Champ-de-Mars (July 17) the National Guard, under the Marquis de Lafayette, a moderate who wanted to save the monarchy (and who had played an important role in the American Revolution), opened fire on a group demanding the abdication of the King. Robespierre, his life threatened, went to live with the family of the cabinetmaker Maurice Duplay. He managed to keep the Jacobin Club alive after all of its moderate members had joined a rival club. When the National Assembly dissolved itself, the people of Paris organized a triumphal procession for Robespierre, an honour repeated in Artois during a short stay there (October 1791).

The
Jacobin
Club

Although he had excluded himself and all his colleagues from the new Legislative Assembly, Robespierre continued to be politically active, giving up the lucrative post of public prosecutor of Paris, to which he had been elected in June 1791. Henceforth, he spoke only at the Jacobin Club, where he was to be heard about 100 times until August 1792. There he opposed the European war that his fellow revolutionary Jacques-Pierre Brissot was advocating as a means of spreading the aims of the revolution. He denounced the secret intrigues of the court and of the royalists, their collusion with Austria, the unpreparedness of the army, and the possible treason of aristocratic officers whose dismissal he demanded in February 1792. He also defended patriotic soldiers, such as those of the Châteauvieux regiment, who had been imprisoned after their mutiny at Nancy. When Brissot's supporters stirred up opinion against him, Robespierre founded, in May, a newspaper, ***Le De'fenseur de la Constitution,*** which strengthened his hand. He violently attacked Lafayette, who had become the commander of the French Army, whom he suspected of wanting to set up a military dictatorship, but failed to obtain his dismissal and arrest.

The reverses suffered by the French Army after France had declared war on Austria and Prussia had been foreseen by Robespierre, and, when invasion threatened, the people rallied to him. Although he had defined the aims of insurrection, he hesitated to advocate it: "Fight the common enemy," he told the *fédérés* (provincial volunteers) assembled in Paris, "only with the sword of law." When the insurrection nevertheless broke out on August 10, 1792, Robespierre took no part in the attack on the Tuileries Palace. But that same afternoon his ***section*** (an administrative subdivision of Paris), Les Piques, nominated him to the insurrectional Commune. As a member of the electoral assembly of Paris he heard the news of the September Massacres of imprisoned nobles and clergy by Parisian crowds. He exonerated the mob, and on September 5 the people of Paris elected him to head the delegation to the National Convention.

Work in the National Convention. The Girondins—the Revolutionary group that favoured political but not social democracy and that controlled the government and the civil service—accused Robespierre of dictatorship from the first sessions of the National Convention, but the Legislative Assembly did not concur. At the King's trial, which began in December 1792, Robespierre spoke 11 times and called for death. His speech on December 3 rallied the hesitant. With the help of of his new journal, ***Les Lettres à ses commettants*** ("Letters to His Constituents"), he kept the provinces informed. The King's execution did not, however, resolve the struggle between the Girondins and the Montagnards—the deputies of the extreme left. At the same time the scarcity of food and rising prices created a revolutionary mood. The treason of Gen. Charles Dumouriez, who went over to the Austrians, precipitated the crisis. A kind of "popular front" was formed between the Parisian sans-culottes, the poor, ultraleft republicans, and the Montagnards. On May 26, 1793, Robespierre called on the people "to rise in insurrection." Five days later he supported a decree of the National Convention indicting the Girondin leaders and Dumouriez's accomplices. On June 2 the decree was passed against 29 of them.

The democratic constitution of June 1793 contained several articles drafted by Robespierre. But his proposals to limit property rights, to proclaim the right to work for all, to establish a graduated tax and a league of nations seemed too bold. This constitution was never applied.

Role in the Committee of Public Safety and the Reign of Terror. After the fall of the Girondins, the Montagnards were left to deal with the country's desperate position. Threatened from within by the movement for federalism and by the civil war in the Vendee in the northwest, and threatened at the frontiers by the anti-French coalition, the revolution mobilized all its resources for victory. In his diary, Robespierre noted that what was needed was "une volonté une" ("one single will"), and this dictatorial power was to characterize the revolutionary government. Its essential organs had already been created, and now he set himself to the task of making them work.

On July 27, 1793, Robespierre took his place on the Committee of Public Safety, which had first been set up in April. While some of his colleagues were away on missions and others were preoccupied with special assignments, he strove to prevent division among the revolutionaries by relying on the Jacobin societies and the vigilance committees. Henceforward his actions were to be inseparable from those of the government as a whole. As president of the Jacobin Club and then of the National Convention, he denounced the schemes of the Parisian radicals known as the Enragés, who were using the food shortage to stir up the Paris ***sections.*** Robespierre answered the demonstrators on September 5 by promising maximum prices for all foodstuffs and a revolutionary militia for use in the interior against counterrevolutionaries and grain hoarders.

The Reign of Terror

In order to bring about a mass conscription, economic dictatorship, and total war, he asked to intensify the Reign of Terror. "It is our leniency towards traitors that is ruining us," he declared, and asserted the need for a "swift, harsh, and inflexible justice" that should be administered in accordance with laws against suspects. But he objected to pointless executions, protecting those deputies who had protested the arrest of the Girondins and of the King's sister. He was sickened by the massacres condoned by the ***représentants en mission*** (members of the National Convention sent to break the opposition in the provinces) and demanded their recall for "dishonoring the Revolution."

Robespierre devoted his report of 5 Nivôse, year I (December 25, 1793 [the French Republican calendar had been introduced in September 1793]), to justifying the collective dictatorship of the National Convention, administrative centralization, and the purging of local authorities. He protested against the various factions that threatened the government. The Hébertists, the Cordeliers, and the popular militants all called for more radical measures and encouraged de-Christianization and the prosecution of food hoarders. Their excesses frightened the peasants, who could not have been pleased by the decrees of 8 and 13 Ventôse, year II (February 26 and March 3, 1794), which provided for the distribution among the poor of the property of suspects. Reappearing at the Jacobin Club after a month's illness, Robespierre denounced the radical Revolutionist Jacques-René HBbert and his adherents, who together with some foreign agents were executed in March. Those who wanted, like Georges Danton, to halt the Reign of Terror and the war attacked the policies of the Committee of Public Safety with increasing violence. Robespierre, although still hesitant, led the National Convention against these so-called Indulgents. The Dantonist leaders and the deputies who were compromised in the liquidation of the French East India Company were guillotined in April.

A deist in the style of Rousseau, Robespierre disapproved of the anti-Christian movement and the "masquerades" of the cult of reason, In a report to the National Convention in May, he affirmed the existence of God and the immortality of the soul and strove to rally the revolutionaries around a civic religion and the cult of the Supreme Being. That he remained extremely popular is shown by the public ovations he received after Henri Admirat's unsuccessful attempt on his life on May 22. The National Convention elected him president, on June 4, by a vote of 216 out of 220. In this capacity he led the festival of the Supreme Being in the Tuileries Gardens on June 8, which was to provide his enemies with another weapon against him.

Declining Influence and authority

After the law of 22 Prairial (June 10) reorganizing the Revolutionary Tribunal, which had been formed in March 1793 to condemn all enemies of the regime, opposition to Robespierre grew; it was led by those ***représentants en mission*** whom he had threatened. His influence was challenged in the Committee of Public Safety itself, and the Committee of General Security, which felt slighted by the General Police Bureau directed by Robespierre, Georges Couthon, and Louis de Saint-Just, became even more hostile to him. In the cafes he was accused of being a moderate. And Joseph Cambon, the minister of finance, detested him.

Unremitting work and frequent speeches in the Legislative Assembly and at the Jacobin Club (a total of some 450 since the beginning of the session) had undermined Robespierre's health, and he became irritable and distant. Embittered by the slanders and by the accusations of dictatorship being spread both by the royalists and by his colleagues, the Montagnards, he stayed away from the National Convention and then, after June 28, from the Committee of Public Safety, confining his denunciations of counterrevolutionary intrigues to the Jacobin Club. At the same time he began to lose the support of the people, whose hardships continued despite the recent French victories. From his partial retirement Robespierre followed, dumbfounded, the unleashing of the Great Terror in the summer of 1794 and the progress of opposition.

Attempting to regain his hold on public opinion, Robespierre reappeared at the Committee of Public Safety on 5 Therrnidor (July 23) and then, on July 26, at the National Convention, to which he turned as his judge. His last speech was at first received with applause, then with disquiet, and finally the parliamentary majority turned against him. Despite his successful reception that evening at the Jacobin Club, the next day Robespierre's adversaries succeeded in preventing him from speaking before the Legislative Assembly, which indicted him together with his brother, Augustin, and three of his associates. Robespierre was taken to the Luxembourg prison, but the warden refused to jail him. Later, he went to the City Hall (the Hôtel de Ville), where he could, doubtless, still have continued the struggle, for armed contingents from some of the ***sections*** of the city had been summoned by the Paris Commune and were awaiting his orders. But Robespierre refused to lead an insurrection and eventually his loyal contingents began to disperse. Declared an outlaw by the National Convention, Robespierre severely wounded himself by a pistol shot in the jaw at the City Hall, throwing his friends into confusion. The soldiers of the National Convention attacked the hall and easily seized the wounded Robespierre and his followers. In the evening of 10 Thermidor (July 28), the first 22 of those condemned, including Robespierre, were guillotined amidst a cheering mob on the Place de la Révolution (now the Place de la Concorde). In all, 108 people died for their adherence to Robespierre's ideas.

Assessment. Robespierre's enemies credited him with dictatorial power, both in the Jacobin Club and in the

Committee of Public Safety, a power that he did not have. Counterrevolutionaries and the rich condemned his egalitarian ideas, while popular militants accused him of lacking boldness. After his death, his memory was relentlessly attacked, and a large part of his papers was destroyed. And so history mostly portrayed him as either a bloodthirsty creature or a timid bourgeois. But, following the ascendancy of the popular movements of the 19th century, both in France and abroad, homage was paid to this "persecuted patriot," and his most famous speeches were reprinted. His social ideal consisted in reducing extreme inequalities of wealth, in increasing the number of small property owners, and in ensuring work and education for all. He was a man of his times, of the Enlightenment, a patriot, a man with a sense of duty and of sacrifice, whose influence remains considerable.

Robot Devices

A robot device is an instrumented mechanism used in science or industry to take the place of a human being. It may or may not physically resemble a human or perform its tasks in a human way, and the line separating robot devices from merely automated machinery is not always easy to define. In general, the more sophisticated and individualized the machine is, the more likely it is to be classed as a robot device. Of 20th-century origin, the word "robot" was first used in the play *R.U.R. (Rossum's Universal Robots)* by the Czechoslovak dramatist Karel Capek, who had derived it from a Czech word *robota,* meaning "forced labour." An older word, automaton, has now come to be applied to a mechanical device that imitates a human or an animal, without necessarily performing useful work. The newer word android is restricted to human-like, not animal-like, mechanisms.

HISTORY

Modern robot devices descend through two distinct lines of development—the early automata, essentially mechanical toys, and the successive refinements and innovations introduced in the development of industrial machinery.

Early automata. Hero of Alexandria, a Greek savant of the 1st century, is reputed to have constructed birds that chirped, drank, and flew. The report may be exaggerated; certainly there were no known imitators for many centuries. But 18th-century Europe suddenly inspired an interest in automata among many technically gifted men. Preserved in a Vienna museum is a "writer" (1753), a mechanism capable of writing and drawing. The machinery controlling the hand is housed in a sphere that forms part of the base. Pierre Jacquet-Droz (born 1721) and his son Henri-Louis Jacquet-Droz (born 1752), French clockmakers, produced several mechanical men, which wrote, drew, or played musical instruments. Jacques de Vaucanson, a member of the French Academy of Sciences, is known from photos in the Musée des Arts et Métiers, Paris, to have made a mechanically animated duck that flapped its wings, drank water, pecked corn, and even "digested" or, at least, dissolved the corn. Another famous mechanical animal (in the Victoria and Albert Museum in London) is a tiger made by an unknown inventor for a customer in India. The tiger is in the act of mauling a prostrate European; when a handle is operated the tiger is made to growl by a worm gear and crankshaft connected to an organ inside, while at the same time the victim's arm moves. More recent examples of classic automata are modem animated toys, such as walking and talking dolls.

Industrial robot development. Possibly the earliest ancestor of industrial robot devices is the clepsydra, or water clock, which improved on the hourglass by employing a siphon principle to automatically recycle itself; Ctesibius of Alexandria is said to have made such a clock about 250 BC. Weight-driven, pendulum-controlled clocks were invented in the Middle Ages; the spring-driven clock did not come until the 18th century, which also witnessed the introduction of basic low-level automatic machinery in the textile industry. From the point of view of automation and robots, the most significant development of the Industrial Revolution was the punched-paper-tape-controlled Jacquard loom, an idea whose full exploitation had to await much further progress in technology.

Influence of the Industrial Revolution

The Industrial Revolution stimulated the invention of robotic devices to perfect the production of power itself. The steam engine inspired the governor (actuated by rotating weights), which, when it slowed under load, increased the flow of steam to the engine, and, when its load decreased, reduced it. The internal-combustion engine of the 19th century brought a recycling innovation in the form of pistons that repositioned themselves after each cycle. The later 19th and early 20th centuries saw a rapid proliferation of powered machinery in industrial operations. These at first required a man to position both the work and the machine, later, only the work, and still later, in mid-20th century, required no man at all. Antomatic cycle-repeating machines (automatic washers), self-measuring and adjusting machines (textile colour-blending equipment), and machines with a degree of self-programming (automatic elevators) followed, bringing the prospect of mechanical devices at least theoretically capable of semi-intelligent interactive operation.

The blend of automation development with the progress of automation and cybernetics began to take shape in the 1950s and 1960s. One line of development was represented by the synthetic robot, a computer simulation model of a human being. An example was SAMMIE, created at the University of Nottingham in England and displayed on a television tube. SAMMIE was designed to show how a human would perform in various environments, such as an aircraft cockpit. Another type of research involved the construction of such experimental automata as a mechanical horse built by a laboratory team at the General Electric plant, in Schenectady, N.Y., which could be ridden over rough ground at 30 miles (48 kilometres) per hour; and an android, constructed at Massachusetts Institute of Technology, which could be programmed to walk down a corridor, enter a room, position furniture so as to facilitate retrieval of a book, and return to its starting point.

MODERN ROBOT DEVICES

Only a few robot devices used in industry and elsewhere are android in character. Typically they depend on electronic components to process environmental information and permit prompt decision making and action. A familiar type of robot device that perceives a change, interprets the change in accordance with programmed instructions, and responds appropriately, is the room thermostat. As the room cools, the thermostat perceives a new environmental state, interprets it, and reacts by closing the electrical contacts to start up the heating unit. When the room has reached the programmed temperature, the thermostat again perceives, interprets, and acts.

Decision-making robots. Robots of a higher level are capable of adapting to changes in environment, but are also capable of making decisions by selecting the proper solution from among several alternatives stored in memory units. The traffic-control signal illustrates this higher level of robot activity. It may be time-switch-controlled on a fixed cycle (lowest level), or it may adjust its operation in response to information fed from sensors in the road surface about the number and timing of vehicles.

Automatic aircraft pilot and landing systems

A more complex robot device in modern transportation is the automatic aircraft pilot, which has progressed from the ability to maintain a set course to its present ability to operate as a complete control system capable of performing all routine in-flight steering and control manoeuvres. A complete flight, from takeoff to landing, is now possible without direct human intervention, as long as the aircraft can be brought within the effective range of a ground-based instrument-landing system. Such a system locates the aircraft in relation to the runway during the approach and makes automatic landings possible.

The reliability of aircraft instrument landing systems, the key to their successful application, depends on the duration of time for which the automatic device must operate. Typical figures for a system's probability of failure are 10^{-7} (or one failure in 10,000,000) for 30 seconds' operation in automatic landing, or perhaps 10^{-5} (one in 100,000) for a three-hour supersonic aircraft flight.

Advanced robotic control. Robotic control involves: (1) giving instructions (programming) to the device and storing information (memory) within it; (2) gaining knowledge of the state or position of the device and processing this information to decide a course of action (feedback); and (3) transforming this feedback data into action (response).

A high-level robot can accept and remember instructions. Basically mechanical in operation, they can also be constructed electrically to form electromechanical combinations. Programming or memory devices can also be electromechanical (electrical contacts, relays, completely electronic solid-state memorv devices), or magnetic (magnetic tape, and so forth).

An example of the application of programming and processing by robot-computer devices is seen in the navigation of spacecraft. Such vehicles require a degree of accuracy that far exceeds the capabilities of human coordination. Furthermore, in any event, complete stabilization and accurate control of rockets cannot be achieved by human hands in certain flight situations because the responses required are so rapid. Missiles and space vehicles in flight must, therefore, be controlled primarily by robot devices, although manual intervention on some levels can be interposed. Two types of robot navigators are installed in spacecraft. One, a celestial navigator, calculates position from star patterns. The other, an inertial navigator, receives responses from a gyroscope; any change of direction or velocity is sensed by the opposition of the gyroscope to such changes, and the path of the vehicle can be deduced by an appropriate summation of these reactions. Information from either navigating device is processed by a computer, making possible unmanned space flight and enormously facilitating manned space flight.

Analog and digital control systems

Control systems for advanced robots can be either analog or digital computer systems (see also COMPUTERS). Analog computers compare analogous functions with the variable over which control is required. A common analog device is the automobile speedometer, which relates electromechanical characteristics of the instrument to road speed of the vehicle. Digital control systems depend on counting. Computer digital systems work in binary form (*i.e.*, in pairs), in which information is presented as a pattern of two states or merely the presence or absence of a factor. This two-state system is used to make machine-processing of numerical information as simple as possible. An analog system is intrinsically less precise than a digital system. In the past, analog systems were common because of their low cost. Development of modern electronic components of direct digital monitoring has cut the cost of digital systems and led to their widespread adoption. Digital systems have the added attraction of being able to resolve complex equations more accurately and completely, and any changes (updating of information) can be accommodated more readily.

Industrial robots. A human worker, however superb a craftsman he may be, has certain physical limitations. He cannot work continuously in a hostile environment. He works at a relatively slow rate and possesses little physical strength. At best, he can work continuously at peak efficiency only for relatively short periods. Most significantly, from the economic point of view, he is in short supply and often expensive to hire. Modern industrial robot devices aim to substitute a machine for a man in hostile environments; cut costs by replacing expensive hand labour with cheap, dependable machines; and provide versatile all-purpose robots or mechanical handling devices at predictable cost. The alternative is a special device for each operation, with higher costs.

An example of a primary industrial robot is illustrated in Figure 1, which shows a single-arm robot that is polar in operation; that is, the single arm is attached at the centre like the hand of a clock, but is free to move in any direction. Another popular device able to carry out similar functions has a cylindrical movement. Numerous robots, based on these concepts, have been constructed. Figure 2 illustrates the working mechanism of a single-arm robot in polar operation; when the robot is operating, signals from the memory drum are compared with feedback signals to produce a control signal that actuates a special kind of valve. That device, in turn, directs the robot's arm and hand to repeat a specific sequence of movements. The drawing illustrates only one axis of motion. Other existing types of robots involve elbow movements for greater flexibility, but these have not met with much success in industry, doubtless because of the complexity of an elbow joint. Hydraulically operated heavier robots have successfully handled products weighing hundreds of pounds. Smaller robots, operated pneumatically, can handle loads from a fraction of an ounce to several pounds. The "hand" at the end of the operating arm can be a simple mechanical gripping device, or magnetic or suction pads to handle a variety of objects.

Industrial robots have been successful in operating forging presses, loading and unloading machine tools, stack-

ing parts into rectangular layers (as in loading kiln cars with bricks), spraying paint, controlling welding of automobile bodies in assembly plants (Figure 3), loading glass tubing into multilayer containers, galvanizing pails by dipping them into a molten zinc bath, unloading large injection-molding machines for making plastics, and heat-treating tractor parts by taking them through a complete furnace-to-quenching cycle. The use of robots in such jobs enabled the removal of men from toxic atmospheres, hot areas, and other hazardous or unpleasant surroundings and the easy performance of exhausting work.

Certain industrial operations that are too complex to be handled by existing robots can nonetheless effectively employ robots to simplify or modify a part of the operations. Robots can be tooled with sets of fingers designed for specific jobs. They can grasp, hold, and release light or heavy parts, and can push, pull, twist, raise, lower, and rotate parts as required. One such robot is capable of five individually controlled degrees of motion—twist, turn, rotate, up-down, and right-left. A sixth motion is used for grasping. This robot handles parts weighing up to 75 pounds (34 kilograms) and positions them within 0.05 inch (1.27 millimetre) of target position. Its memory can store as many as 180 sequential commands.

Robots in forging plants

The ability of robots to handle parts too hot for human handling is especially advantageous in forging plants. In one factory a robot plucks a connecting pin from a magazine feed (so-called because it works like the magazine of a gun), inserts it into a groove in the rotary hearth of a heating furnace, releases it, then grasps a red-hot pin, removes if from the furnace and signals the furnace door to close. The robot then places the hot pin in a quencher. The complete cycle takes about one minute. The robot is electrically prevented from loading pins into the furnace until it receives a signal that the furnace hearth has rotated to accept a pin and the furnace door is open. Similarly, the robot cannot load a pin into the quencher until the previously quenched part has been automatically ejected from it. The fact that the robot can perform its task repeatedly is due to a computer-like digital drum that can store 180 separate commands and send them back to the arm in the form of electrical impulses.

There are two ways to program, or give instructions to, a robot. In dynamic programming, the robot is led through its task while information about position and function are recorded simultaneously in its memory. The robot can then do what it has been taught by playing the recorded information back through its control system. Alternatively, the robot can be driven manually through its sequence of operations; a recording of the control responses generated is subsequently played back to operate the robot continuously.

Thus, to program the memory system described above, a plant worker takes the robot's arm in his own hand and leads it through the desired motions. At every step that calls for one of the robot's five motions, the worker pushes a "record" button to activate the memory drum. After one complete learning cycle the robot is ready to repeat the process endlessly.

Industrial robots such as these are still relatively low-level devices. They carry out their functions in a mechanical manner only after being programmed to do so. Apart from simple detection devices, such as photocells, which can be connected to them to sense the presence of objects and measure temperature, such robots are blind, deaf, dumb, and insensitive. They cannot sort out parts presented at random, and they must receive such parts one at a time in rigidly correct position for handling. Yet, in their own sphere of efficiency, they have proved so successful that applications have been suggested outside industry; for example, in household uses, such as table laying and clearing, washing, and bedmaking. **A** table-clearing robot has been successfully demonstrated by a team of researchers at Queen Mary College, London.

Experimental and scientific robots. In addition to robots with immediate practical applications in industry, scientists in the 1970s were working with a variety of robot devices, some planned for scientific-research applications, others simply with the aim of exploring the potential of the devices themselves. One of the most intriguing aspects of the robots' performance is their apparent potential for learning. A simple robot that illustrates the basic learning method is a mechanical rat that sequentially explores several paths in a maze, in a pattern of successive combinations of left and right turns. Its task is to reach a favoured position at the end of one of the channels. The rat uses a kind of trial and error process, sequentially adopting cyclic patterns of left and right turns. Eventually it ends up in the desired position, at which time a signal is injected, causing the machine to record the correct pattern. Henceforth, the machine travels quickly and accurately along the same track to accomplish any job that has been assigned.

The robot sailboat

Among a number of scientific-research applications for robots that have been proposed, an imaginative one is the robot sailboat developed by the Radio Corporation of America (RCA). An electronically controlled vessel, it is capable of carrying out a wide range of military, scientific, and commercial missions. Dubbed Skamp, for Station-

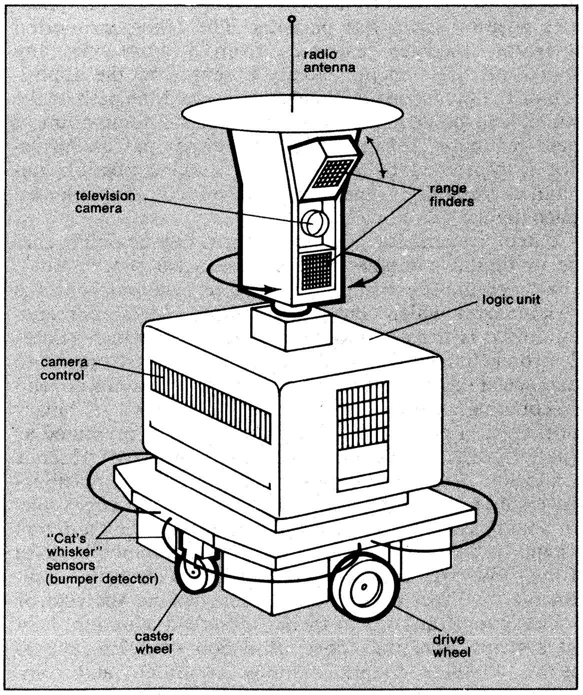

Figure 4: Shaky Robot device built by Stanford Research

Keeping and Mobile Platform, the circular, 8-foot-high plastic boat, which resembles a buoy with sails, theoretically could be sent to any point in the world's seas to radio back information. It is designed to receive orders from navigation satellites and to remain without a mooring within one-fifth of a nautical mile of its assigned position up to one year. Skamp might also serve as a navigation station for ships, submarines, or aircraft.

An example of the advanced android robots produced experimentally in the 1960s and 1970s is shown in Figure 4. Called Shaky Robot by its makers at Stanford Research Institute in California, it has perceptive capabilities and consists of a 3-wheel bogey, or base, with separate motor drives to each of the two drive wheels. Steering is achieved by driving the two main wheels at different rates; the third wheel has a caster action. The device does not carry its computational facilities within it, but communicates with a central computer over two radio channels. The swivelling head carries a television camera eye and range finder, to provide the capability for visual and positional recognition of a number of simple geometric shapes. "Cat's whisker" sensors around the robot operate microswitches, enabling it to take appropriate action if it encounters obstructions. Control circuitry in the cabinet (mounted within the device) processes commands radioed from the computer. Shaky Robot can be programmed to find simple objects, learn room boundaries as viewed by the television eye and range finder, and interpret such information numerically; problems involving object identification and position are solved by the computer through the use of projective geometry.

The humanoid robot

Another robotic device designed in the U.S. in 1969 for use in scientific fields has been called the first humanoid. A joint American design venture of the Atomic Energy Commission and the National Aeronautics and Space Administration, this mechanical man is intended to be guided by a computer for work in extreme or dangerous environments, such as retrieving highly radioactive materials and rescuing people in a contaminated area. The humanoid is equipped with artificial arms, TV camera, and sound pickup. Mounted on a flatbed vehicle, it uses a teletype machine for communication and is steered and controlled by microwave radio. Laser guidance, which would transmit more information in a tighter package, is under study for later installation. Its uses might extend to the testing of rockets during operation and the initial exploration of a planet. Case Western Reserve University in the U.S. has studied the possibility of having humanoids disassemble a nuclear reactor core, which is made up of thousands of individual fuel elements.

Such a robot is intended to improve man's senses, or add new ones, and then to do his bidding; its human features allow the operator to identify with it and thereby operate it more easily. A humanoid can be built to see via television, detect heat through thermal sensors, feel shapes with tactile devices, and transmit these sensations to the operator. Humanoids exceed humans in ultraviolet and infrared sensitivity and in magnifying images. The speed and precision of their responses is also superior to man's. The major problem facing designers of humanoids is that of communication, between the operator and the computer, and between the computer and the humanoid. In each case, human, computer, and humanoid, a different language is spoken (verbal, mathematical, and electrical), which requires translation.

Rock Deformation

Evidence of rock deformation today

The oldest rocks at the Earth's surface reveal abundant evidence of intense deformation, and analysis of the Earth's crust in all parts of the world demonstrates that spasmodic deformation has characterized all of geological time. Rock deformation continues unabated today. If it were not for continuing deformation, erosion would remove all the mountains within a few million years and reduce all land areas to sea level; the sediment produced would be accommodated easily in the ocean basins. Hence, the presence of mountains is strong evidence for geologically recent uplift. Earthquakes also reflect present-day rock deformation because they result from spasmodic, rapid slipping of major crustal blocks along fractures (fault planes).

Despite the importance of erosion by water, wind, and ice, rock deformation can still be considered the most important single factor controlling the environment at the Earth's surface. It results in the uplift of mountains like the Sierra Nevadas of California and the Alps and Carpathians of central Europe; in the growth of island arcs (curving chains of islands such as the Antilles of the Caribbean), and in foundering of rift valleys (fault-bounded troughs such as the East African Rift Valley). On a larger scale, although the evidence is not wholly unequivocal, many scientists believe that continental drift is continuing today. The continental drift hypothesis suggests that the American continents were contiguous with Europe and Africa some 60,000,000 years ago, and then separated slowly with the continents moving across the globe at perhaps one centimetre per year. This is yet another manifestation of rock deformation.

The development of major structural features of the Earth effects significant changes in climate and ecology. The specialized marsupial mammal fauna of Australia evolved and survived because of the deformation that effectively isolated their habitat from other continents. On a smaller scale, large mountain blocks can be raised rapidly (in a time interval of about 1,000,000 years) and these can drastically affect climatic patterns. The geologically young Sierra Nevadas in California effectively deplete the predominantly west to east air flow of moisture and create arid conditions east of the mountain mass.

The Earth's land areas can be divided into two parts: large continental shields, or cratons (areas that have been relatively stable and passive for millions--or even hundreds of millions—of years) and sinuous mobile belts (geosynclines) commonly one or two thousand kilometres long and 40 to 60 kilometres (25 to 40 miles) or more in width. These belts either occur along the margins of or transect the stable shield areas. Geologically rapid sedimentation, volcanic activity, and faulting and folding of rocks are integrated in these belts to develop intensely deformed zones. Until recently, the phases in the birth, development, and demise of mobile belts—a cycle lasting several tens of millions of years—were thought to have followed a fairly constant pattern throughout the world during the past 4,000,000,000 years of Earth history. Each cycle involves development and deformation of a geosyncline. Cratons (stable continental regions) such as the Canadian and Baltic shields comprise eroded remnants of ancient transecting mobile belts. The Canadian Shield extends southward and westward (in the United States and Canada) under a veneer of younger, mainly marine, sedimentary rocks deposited over the past 600,000,000 years, approximately. As the craton slowly oscillated up and down, periods of marine sedimentation alternated with uplift and erosion. Gentle folding, jointing (fracturing), and faulting (fracturing involving vertical or horizontal movements) accompanied these oscillations and were largely controlled by vertical movements on old joints and faults in the basement rocks. Examples are the Illinois, Michigan, and Williston basins, which are separated by broad arches and domes; each of these major structures is complicated by smaller folds and dislocations (faults). Because many of the veneer rocks (cratonic sediments) are oil and water reservoirs, their folding and faulting are of great economic importance.

The study of rock deformation

Structural geology involves the scientific study of the nature and development of deformed rocks in the Earth's crust, and also laboratory and theoretical attempts to simulate naturally deformed rocks. Interest ranges from the geometric interrelationships between crystalline grains at the microscopic or X-ray level to continental or oceanic units involved in global tectonics. Some of the oldest and unsolved geological problems concern the manner in which folds and faults form. Understanding of these problems would lead to more general concepts about the Earth's development and the nature of the most fundamental Earth processes. Initial scientific studies of fold and fault formation in the 19th century, for example, invoked compressive forces thought to result from contraction of the Earth. The essential importance of compression still pervades geologists' thinking, but during the 20th century there has come a realization that noncompressive forces are also significant, Many Soviet scientists contend that horizontal compression is a local, secondary phenomenon resulting from vertical movements of the crust and that the latter are really the fundamental movements involved. The correct balance between these extreme positions must await assembly of more factual data. Few early investigators dealt with folds and faults as prime objects of study; information accumulated incidentally during more general studies. In the last two decades, however, research aimed at understanding the mechanism of formation of folds and faults has been undertaken in several countries.

This article is concerned with the resnonse of rocks to imposed stresses, the several kinds of folding, faulting, and jointing that occur in nature, and the structural inteiference that results from the superposition of successive deformational events. For further information on the geologic and physiographic consequences of rock deformation, see MOUNTAIN BUILDING PROCESSES; MOUNTAIN RANGES AND MOUNTAIN BELTS; RIFT VALLEYS; OCEANIC RIDGES; CONTINENTAL DRIFT; SEA-FLOOR SPREADING; PHYSIOGRAPHIC EFFECTS OF TECTONISM. See also EARTH, STRUCTURE AND COMPOSITION OF; EARTHQUAKES; ISLAND ARCS.

STRESS AND STRAIN OF ROCKS

Response **to** stress. Essentially, all sedimentary, igneous, and metamorphic rocks are crystalline aggregates. When subjected to forces (stresses) in the laboratory, rock samples deform by fracture or distortion of their overall shape and internal structure or both. In nature, most rocks become deformed after their initial formation. Joints or fractures are almost ubiquitous. Shape distortion is most obvious when the initial rock contained features like bedding planes (visible surfaces on which sedimentation took place) or fossils; the present geometry of such markers is one measure of the degree of deformation. Initial horizontal bedding in sedimentary rocks may yieid simple folds that range in size from a few millimetres to several kilometres. Alternatively, rocks can be deformed and refolded to such an extent that all original structures are obliterated. Commonly, such penetrative deformation accompanies regional metamorphism (large-scale alteration of rocks under high temperatures and pressures) in mobile belts or the flow of extremely plastic rocks (*e.g.*, salt deposits) between rocks that are more rigid.

Stress components and the stress ellipsoid

Strain is the total change in volume, shape, and orientation resulting from stress. The stress (force per unit area) comprises body forces acting on every point in the rock equally (*e.g.*, gravity), and external or surface forces applied to the exterior of the rock unit. Stress commonly varies from point to point; theoretically, it can be calculated with respect to any plane through a rock. Normal stress, commonly designated *a* (sigma) is the component of total stress acting perpendicular to such a plane; tangential stress (shearing stress), commonly designated τ (tau), is the component parallel to the plane. Three mutually perpendicular (orthogonal) planes always exist such that the tangential stress τ equals zero, in which case the three normal stresses, designated $\sigma_1 > \sigma_2 > \sigma_3$, are the principal stresses. For a rock deformed deep within the Earth, the stress involves both confining pressure (an equal, normal stress across every possible plane as represented in Figure 1A) and shearing stress, which is conveniently resolved into three orthogonal normal stresses, σ'_1, σ'_2, and σ'_3, whose sum is zero. The shearing stresses can be represented by a stress ellipsoid (Figure 1C) with principal axes proportional to the magnitudes of *a*:, σ'_2, and σ'_3. Inclusion of confining pressure in Figure 1 adds a constant increment in every direction.

From (A,B) G. Wilson, "The Tectonic Significance of Small Scale Structures and Their Importance to the Geologist in the Field." Annals *of the Geological Society* of *Belgium*, vol. 84 (1961), (C) Proceedings of *the Geological Society* of *America* (1946)

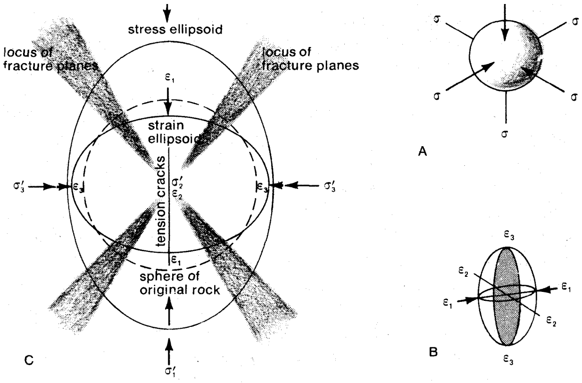

Figure 1: Relationship between stress and strain: (A) a spherical element of rock under confining pressure, with equal stress (σ) in every direction; (B) the strain ellipsoid, representing deformation of a sphere and the resulting strain axes (ε_1, ε_2, and ε_3); (C) relationship between stress and strain ellipsoids.

The response of rocks to stress is strongly affected by confining pressure, temperature, pore fluid pressure, rate at which strain is induced, length of time that stress is applied. and chemical environment. Granite and basalt, for example, are slightly ductile (can flow without fracture or faulting) at confining pressures of five kilobars at 300" C, or 570" F (average conditions about 21 kilometres [13 miles] below the Earth's surface; one kilobar [kb] equals 1,020 kilograms per square centimetre, or 14,504 pounds per square inch). Under experimental conditions of 150" C (300" F) in dry air the often used Solenhofen Limestone is brittle at 0.75 kilobar and ductile at one kilobar. Most rock deformation occurs beneath the Earth's surface where the average temperature increase with depth is approximately 1" C per 30 metres (1° F per 55 feet) and confining pressure increases at the rate of 0.23 kilogram per square centimetre per metre. At temperatures and pressures of modest depths, the strongest rocks flow and undergo permanent strain whereas, near the surface or when subjected to rapid strain rates, the same rocks may buckle or fracture.

Most theoretical stress–strain studies relate to elastic deformation (infinitesimal reversible displacements) in homogeneous substances. The actual strain of rocks, however, involves permanent deformation (finite strain) of heterogeneous media. Compositionally and structurally, the Earth's crust, whether considered on the scale of a continent or a microscope slide of a rock, is heterogeneous. When individual mineral grains are considered, the rocks containing them are always heterogeneous. In larger samples the' mineral variation becomes less important, however, and rocks approach homogeneity sufficiently to accommodate the principles that govern stress–strain relations in homogeneous rocks.

Elastic **and** plastic deformation. At the onset of stress, strain is in the elastic range, meaning that recoil to the original shape occurs with stress removal (except for minor residual strain due to pore-space collapse). Some rocks suddenly fracture (brittle failure) in this range. If brittle failure does not occur, additional stress carries the rock beyond the elastic limit (at the yield point) and plastic deformation produces permanent strain that persists after removal of the stress (*e.g.*, ε_1 or· ε_2 in Figure 2). For a given rock, yield-point stress is decreased by increased temperature, and increased by an increased

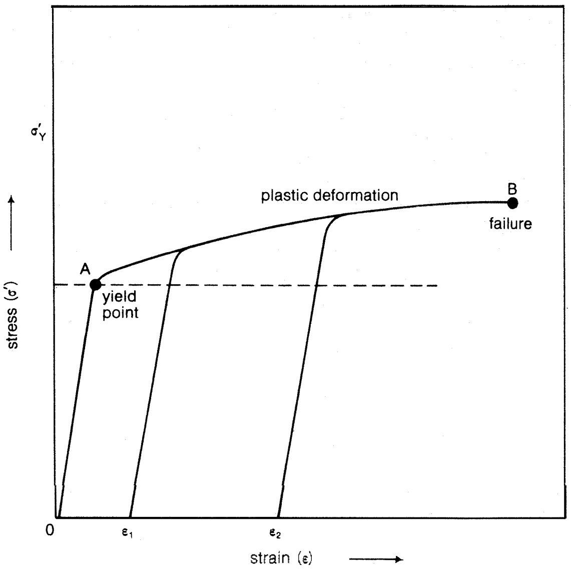

Figure 2: Generalized stress-strain relationships (see text),
From J.G. Ramsay, *Folding and Fracturing of Rocks*,Copyright 1967; used with permission of *McGraw-Hill Book Co.*

Effects of tempera- ture and time

confining pressure or strain rate. For a perfectly plastic body, the slope of AB (Figure 2) would be zero, but rocks exhibit strain hardening so that in order for plastic deformation to continue, the stress must increase beyond the yield-point stress. The mechanism of plastic flow varies: when the temperature is low, cataclastic flow by crushing, fracturing, and mechanical granulation occurs; when the temverature is moderate. distortion. bending, and crystal twinning occur, but no crushing or new grain formation take place; when the temperature is high, recrystallization and the growth of new grains with new orientations, shapes, and distributions occur—the rock behaves almost like a perfect plastic material.

Strain in rocks combines elastic, viscous, and plastic properties. Time-dependent deformation is creep. When stress is first imposed, the strain is elastic followed by fairly rapid primary creep (Figure 3). With increasing time, the rate of strain $d\varepsilon/dt$ becomes constant; during this secondary phase steady-state, or pseudoviscous, creep occurs. During the tertiary phase, creep rates increase to failure. Recoil associated with stress removal is indicated by broken lines in Figure 3. Directed stress in the Earth's crust may be maintained for many thousands of years (or even for millions of years); some authorities believe that under such conditions elastic, plastic, and other components are unimportant so that rocks essentially behave like viscous liquids. Materials in which viscous flow—as a steady-state process—is the only significant strain have been called rheids. Though this concept seems to explain many geological observations, it has been criticized by physicists. Unfortunately, it is difficult to account adequately for geologically significant time in experimental or theoretical work.

From J.G. Ramsay, *Folding and Fracturing of Rocks*, Copyright *1967;* **used** with permission of McGraw-Hill *Book Co.*

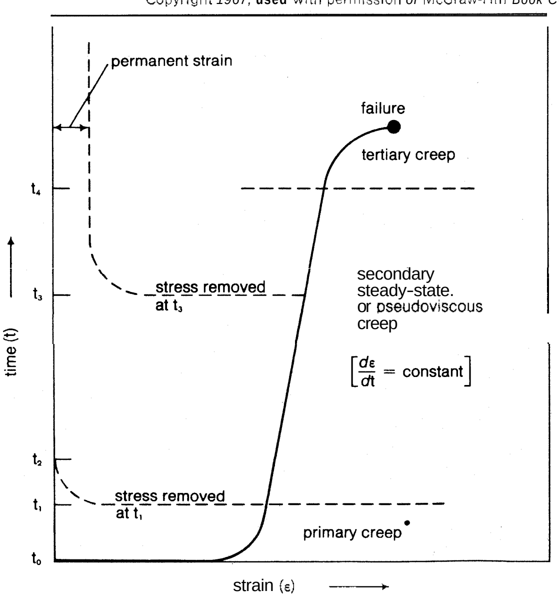

Figure 3: Generalized time-strain relationships with constant stress and with stress termination (see text).

The total strain results in changes in position (translation), orientation (rotation), volume (dilation), and shape (distortion). These are all geologically important. Translation and rotation are significant in mobile belts, for example, but observable evidence within rock samples is usually limited to dilation and distortion—*i.e.*, to pure strain. Pure strain can be considered in terms of the strain ellipsoid (Figure 1B), whose three principal axes are commonly designated by the Greek letter epsilon, $\varepsilon_1 > \varepsilon_2 > \varepsilon_3$ (which correspond to σ'_1, σ'_2, and oi); this ellipsoid is the shape assumed by an imaginary sphere of unstrained rock following the effects of stress (see Figure 1). The shapes of predeformation structures preserved in a deformed rock give the rock a geometric pattern that can be observed and described objectively and quantitatively. Though the movements of individual parts of the rock that resulted in the new geometry commonly can be reconstructed objectively, these kinematic movements cannot be directly observed. **A** unique set of forces produced the kinematic and geometric results but, being unobservable, the actual forces are commonly subject to considerable controversy. In consequence, knowledge of strain behaviour in rocks relies heavily on experimental laboratory work on rock samples and on mathematical analyses of idealized materials.

The strain ellipsoid

Numerous types of finite homogeneous strain are possible, but general strain is the most common in rocks. In this, pure strain (pure extension or compression along three orthogonal axes) is combined with pure rotation of the whole system about any axis or axes. Simpler strains are occasionally encountered in special, limited locations. Unrealistically, many geological analyses have been limited to two dimensions and based on plane strains in which strain was assumed to have occurred along only two orthogonal axes.

Wherever the strain is homogeneous, each part of the rock can be represented by the same strain ellipsoid; also a straight line, a plane, and a sphere become transformed into another line, a plane, and an ellipsoid, respectively. In most geological situations, heterogeneous, rather than homogeneous, strains occur (as in a simple fold). In a folded conglomerate (coarse-grained sedimentary rock), for example, the pebbles and the matrix are likely to have different physical properties and to be dissimilarly strained. In addition, mechanical heterogeneity causes the stress field to be uneven throughout the sample and this in turn produces additional strain dissimilarities. Commonly, smaller domains can be found in which strain is homogeneous; in many geological geometrical analyses, the first step involves identifying domains that are homogeneous with respect to structural properties of interest.

Analysis of grains in strained rocks

On the basis of extensive work in structural petrology, it is commonly believed that the symmetry of the stress factors is reflected in the symmetry of the strained rock. Each grain in a rock responds individually to a directed-stress field, so that the grains develop a preferred habit (shape) or lattice (molecular structure) orientation or both. According to classical concepts the process is believed to result from either direct componental movements (bodily rotation of existing grains) or indirect componental movements (recrystallization of existing minerals or growth of new, more stable, minerals with their molecular structure preferentially oriented with respect to the local directed-stress field). Electron microscopy, metallurgical research, and detailed consideration of the thermodynamic principles of solution and redisposition are currently shedding much light on the processes involved in lattice orientations and the development of the very common fine banding of recrystallized metamorphic rocks. Habit orientation is also a fundamental (though vexing) research topic of currency; it is discussed further in connection with foliation and cleavage development in the next section of this article.

FOLDING OF ROCKS

Types ***of tectonic folding.*** All rocks can be folded when the stress is sufficient to produce permanent strain, but folds are more obvious where original planar structures (such as bedding or schistosity) were deformed during the total strain. In the mobile belts, fold wavelengths (distance from crest to crest) vary from a few millimetres to several kilometres. Traditionally, most geologists have recognized three types of folding, but gradations between these are readily found in nature.

Flexure folding. The rock is structurally homogeneous (containing no planes of mechanical discontinuity) and no planes of discontinuity develop during flexure folding. A sheet of India rubber or modelling clay is an appropriate analogue—when folded, the concave side is compressed and the convex side is stretched without fracture development. Such strain is relatively rare in rocks.

Slip folding. The rock is structurally homogeneous but the stress induces a single set. of parallel slip planes (S') during slip folding. Folds of this type are common in slates where colour banding or very minor compositional differences define original bedding (S_0) that is folded by differential slip along innumerable new S' planes. The geometry can be illustrated with a deck of cards (Figure 4A). A heavy line can be drawn around the cards to represent bedding (S,), and it can be assumed that the cards are a solid homogeneous mass before deformation and that the planes (S') between the cards result from the stress; differential slip on these induced planes produces folds in S_0 that are variously called slip, similar, or bending folds. The genetic term bending fold implies folding caused by motion transverse to bedding that was not generated by compression along the rock layers (S,,).

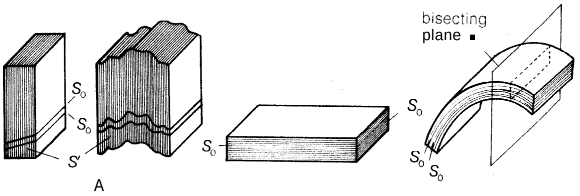

Figure 4: Simple fold models illustrated by decks of cards. (A) Slip folding of bedding S_0 along slip planes S'. (B) Flexural-slip folding of bedding S_0 (see text).

Flexural-slip folding. The initial rock has planes of mechanical discontinuity (*e.g.*, well-marked bedding planes) along which slip can occur during stress. A deck of cards can also illustrate such folding if the separation between the cards is assumed to correspond to original bedding (S,). Compression or shortening parallel to the layering (or bending of the layers) causes folding with slip (S') between the cards parallel to bedding (S,); the result is variously called flexural-slip, parallel, or buckling folds (Figure 4B).

Successive rock layers tend to be mechanically dissimilar during folding. Well-bedded sandstones, for example, may respond by flexural slip while interstratified silts and clays may develop slip-fold characteristics. Such complex relationships are common. Kock between the successive slip planes of flexural-slip folds is also strained during folding, but whether by flexure or by one of the other types of folding is not entirely clear.

From J. Ramsay, *Journal of Geology*, vol. 70 (1962); University of Chicago Press

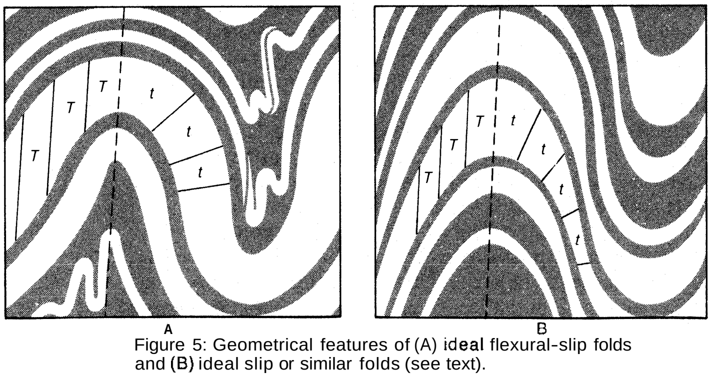

Figure 5: Geometrical features of (A) ideal flexural-slip folds and (B) ideal slip or similar folds (see text).

Theoretically, the geometries are simple and distinct. In ideal flexural-slip or parallel folds (Figure 5A), the orthogonal thickness (t) of each bed remains constant whereas "thickness" (T) measured parallel to the bisecting plane of the fold changes from point to point. By contrast, in slip folds the orthogonal thickness (t) varies while T remains constant (Figure 5B). It has generally been assumed that flexural-slip and slip folds are the dominant types in nature, with the former more common. These models have been recognized since 1896, but recently it has been noticed that few folds really have these geometries. In fact, most folds appear to depart markedly from the ideal *t* and T relationships, which calls into question the basic hypotheses about fold formation. In an attempt to explain this anomaly, it has been suggested that, after the initial fold formation, continued compression causes the structure to be flattened in the plane normal to the original maximum stress (*i.e.*, flattening approximately in the bisecting plane). Limited published *t* and T data for natural and experimentally produced folds make it difficult to evaluate the flattening hypothesis. If "flattening" is as common in numerous environments as has been suggested, most ideal fold shapes must be distorted.

Departure from ideal fold geometries

The terms flexural-slip, slip, and flexure fold clearly have genetic implications suggesting that the kinematic mode of formation is known unequivocally and that the folds conform to the *t* and T specifications. For this reason, many geologists use the older terms, similar and parallel folds, instead of slip and flexural-slip folds, respectively. The older terms refer to what now appears to be rare, idealized geometry; supposedly, in slip folds, successive folded layers have similar shape, whereas, in flexural-slip folds, boundaries between successive layers are parallel (Figure 5). Following the genetic terminology developed in strength-of-materials studies, some geologists prefer the terms bending and buckling folds.

The geological literature is burdened with dozens of terms descriptive of fold shapes. New terms accumulate rapidly and, in most cases, without the use of systematic concepts or usable operational definitions. Many terms overlap in meaning or are dissimilarly used by different geologists; some relate to purely geometrical characteristics, some to genetic concepts, and others to a mixture between geometric and genetic properties. A list of the descriptive terms for folds used in the principal English-language structural-geology textbooks (abnormal anticlinorium, abnormal synclinorium, accordion fold, allochthonous fold, ameboid fold, etc.) with brief definitions occupies 24 printed pages. Because a fold is a geometric form its description should be based on its geometry and not intertwined with the kinematic movements and dynamic forces (or both) that produced it.

Cylindrical and conical folds

When studied in units of convenient size, almost all folded rocks can be considered as cylindrical or conical geometric structures. Normals (perpendicular lines) to the sides of a cylinder are perpendicular to the cylinder axis; normals to bedding in a cylindrical fold are perpendicular to the fold axis. The fold axis is a direction (in three-dimensional space) but has no particular position; it is the imaginary line that, if moved parallel to itself, always remains within the folded surface. If the top and bottom of a sheet of ruled notebook paper are moved toward each other (so that the lines on the paper remain straight and parallel), the paper simulates a cylindrical fold with the fold axis parallel to each line on the paper. For standardization, fold shape is described in terms of the profile—the trace of the bed on a plane normal to the fold axis. An idealized cylindrical fold has identical profiles at all points along its axis. If, as commonly happens, the profile changes along the fold axis (at different rates in each fold), the geometry approaches that of a conical fold. A conical fold is the locus of a line constrained to pass through a fixed point; the fold axis is then the cone axis. A cylindrical fold is a special case of the conical fold in which the apical angle of the cone is zero. Although individual folds may be conical, when whole fold systems are considered, the folds are frequently approximately cylindrical; when seen in plan, such folds resemble a set of en echelon (parallel but offset) canoe-shaped structures. Thus, within a single system, folds of one size may be essentially cylindrical, and those of another size may be conical.

For complete description of a cylindrical fold, it is necessary to specify:

1. Fold axis orientation: usually in terms of trend and plunge. Trend is the orientation (in degrees east of north) of the projection of the axis on a horizontal surface (AB in Figure 6); plunge is the angle measured in a vertical plane between the fold axis and horizontal (angle between AB and AD in Figure 6).

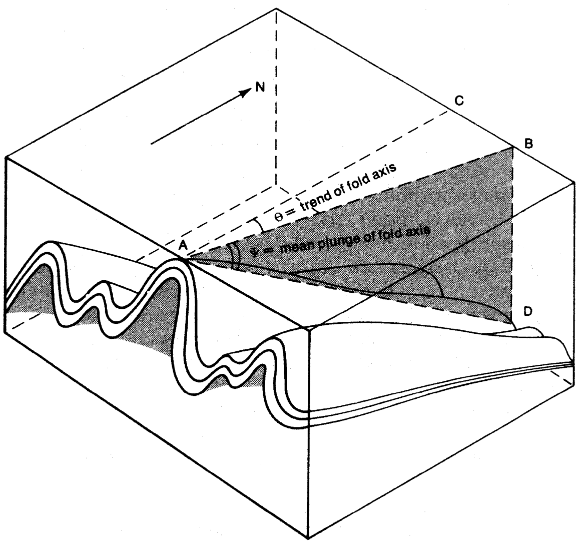

Figure 8: A group of plunging cylindrical folds, showing trend and mean plunge of one fold (see text).

2. Fold size: commonly, a wavelength measured on the profile.

3. Fold shape as seen in profile: qualitative descriptive terms are commonly used; although quantitative description techniques are being developed, wholly satisfactory methods are not yet available.

When several layers are folded together, the surface through successive fold crests is the axial surface (or plane), which may or may not coincide with the bisecting surface (or plane) defined by a dominant bedding plane. When successive beds are of different thicknesses and lithologies, folds developed in them tend to be of different sizes and of dissimilar profiles, although the axes are commonly approximately parallel (*i.e.*, homoaxial). The folds are disharmonic when profiles of successive layers are dissimilar. A fold whose limbs approach one another downward is called a synform; if the limbs diverge downward it is an antiform. Folds are upward facing when stratigraphically younger rocks are crossed in traversing upward along the bisecting plane. In intensely folded areas, the stratigraphic succession may be completely inverted so that folds face downward. If it is positively known that the folds are upward facing, they are properly called synclines and anticlines (instead of synforms and antiforms, respectively).

Very large folds within a mobile belt can be traced for several hundred kilometres, although structures of this size can be recognized only on the basis of careful mapping. When the wave length is a few kilometres, the entire structure can sometimes be seen simultaneously if exposure conditions are particularly good; air photographs are especially useful for studying such structures (Figure 7). Folds with wave lengths ranging from several tens of metres to a few centimetres can be seen readily in the field (Figure 8). With a hand lens, details of even smaller folds that commonly occur in more incompetent rocks can be seen. Not infrequently, smaller homoaxial folds occur on the flanks and in the cores of larger folds--this applies to structures of all sizes. In indifferently exposed terrain, the small folds—parasitic folds—assist in detecting the nature of major folds that can be interpreted only by mapping and piecing together information from numerous outcrops. Individual parasitic folds may be flexural-slip, slip, or flexure folds depending on the lithologies and other factors involved; the poor genetic term drag fold is frequently used for parasitic folds.

Foliation and lineation. Commonly, in rocks strained at all but very shallow depths, foliation (rock cleavage) has developed approximately parallel to the bisecting planes of folds. Foliation can be particularly obvious in rocks containing abundant phyllosilicates (chlorites, biotite~,etc.); the approximate parallelism of such flaky

From F.A Donath and R.B. Parker, "Folds and Folding " Bulletin of *Geological* Society *of* America, vol. 75 (1964); Geological Society of America, Inc.

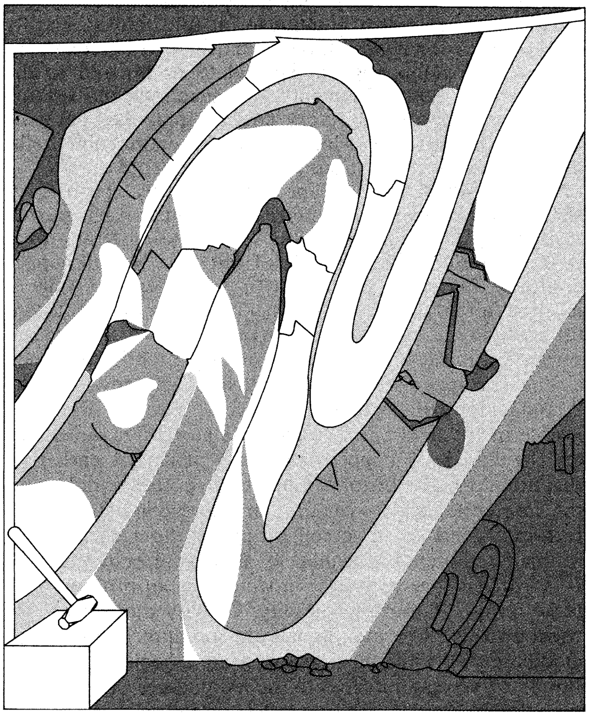

Figure 8: Flexural-flow fold in thick- and thin-bedded shales, Black Rock Mine, northwestern Queensland, Australia; hammer (lower left) provides scale.

minerals largely defines the foliation in hand specimens. If, as has commonly been supposed, such foliations develop perpendicular to either the maximum principal compressive stress that caused the strain or the direction of minimum total elongation (maximum shortening), it is difficult to explain why slip along *S′* is dominant in slip folds. This problem does not arise with the flexural-slip model, where both the bisecting plane and the foliation are approximately normal to the minimum total elongation for the whole fold. A satisfying explanation is not available. It has been suggested that in slip folds the *S′* planes are only approximately parallel, so that a small component of the greatest principal stress acts along each *S′* plane inducing differential slip. In varied clay, silt, and fine-sand formations folded at shallow depths, weak foliations have been attributed to the mechanical rotation of original clay minerals by pore water expressed during folding. Minor veinlets of sand parallel to the foliation and cutting through the silt and clay layers (and clay veinlets cutting the coarser grained units) support this hypothesis, but the theory may not adequately explain the axial-plane orientation of the veinlets and foliation.

Although most foliations form parallel to the fold axial planes, incompetent (weaker) beds located between more massive units frequently develop foliation (schistosity) parallel to bedding, due to shear during flexural-slip folding.

Various linear structures are generated in all strained rocks, except those deformed at very shallow depths. Structures within the parent rock become deformed during folding; for example, pebbles and carbonate ooliths (small, spherical particles) become elongate with their long axes approximately parallel so as to define a linear structure. Following intense deformation, individual grains may be strained sufficiently to show a distinct lineation in a hand specimen—viewed with unaided eye—especially on weathered surfaces; under the microscope, such preferred orientations can be detected and measured more easily and precisely. Such lineations tend to be parallel to the fold axes in metamorphosed rocks, whereas in less metamorphosed rocks they lie within the axial plane and normal to the fold axis. Lineations pervading the entire rock are penetrative, whereas nonpenetrative striations (slickensides) parallel to the slip direction (*i.e.*, normal to the fold axis) sometimes develop on bed surfaces subjected to flexural slip.

During flexural-slip folding of varied lithological sequences, the more competent units frequently develop a linear structure called boudinage on fold flanks; sharply defined necks or zones along which the bed is attenuated (necked) develop aligned parallel to or normal to the fold axis or both. Frequently, intersections of bedding and schistosity and the very small, ripple-like parasitic folds on the surfaces of large folds of metamorphic rocks define prominent lineations parallel to the fold axes.

Nappes and diapirs. Nappe is the general term for a sheet of rocks several kilometres in extent that has moved forward (for distances up to several kilometres) over rock formations beneath and in front of it. Not all nappes comprise individual folds, but a very large recumbent isocline (a fold with both limbs exhibiting a near-horizontal attitude) is one variety of nappe. Such structures are important in the architecture of ancient mobile belts such as the European Alps, the Scottish Highlands, and the Appalachian fold belt. In such areas, many of the folds visible in the field are second-phase structures developed on the flanks of nappes that were produced earlier in the mobile belt's history. Current hypotheses hold that the immense nappe structures are a response to gravity tectonics—that is, to creep or plastic flow of partially lithified sedimentary sequences shortly after deposition. It is implicit that very slow movements can produce very large strains if the time is long. Gravity movements toward a trough in a mobile belt are sometimes referred to as syntaphral; syntaphral tectonics are associated with the supply of creeping masses to the axial zones of a geosyncline. Such zones later become the axial zone of the tectonic orogen (mountain core) so that the early soft-sediment folds and nappes almost invariably become overprinted by younger deformation. The classical concept of folding being initiated by viselike compression is not applicable to gravity-tectonic or to syntaphral phenomena.

Gravity tectonics in mountain building

Diapirs, a special type of fold structure, appear to result from the ascent of a plastic core of less dense rock that pierces and dilates the overlying and surrounding rocks. Using a less dense, plastic medium below more dense material and simulating gravity operating over a long period with a centrifuge, a wide variety of naturally occurring diapiric structures have been simulated in the laboratory. In these experiments, a circular plug of the less dense medium typically ascends into overburden; the stalk connecting the plug to the buried parent layer attenuates so that an egg-shaped mass of the less dense material eventually separates from the parent layer completely and continues to rise upward (see further SALT DOMES).

Granitic diapirs

Aside from rock salt, the most common diapiric substance is granitic material. Numerous small (16 to 20 kilometres in diameter) granite masses (*e.g.*, Flamanville Granite on the northwest coast of France) have been emplaced by dilation of the enveloping rocks during magmatic intrusion—the ascent of hot, molten silicate material. In many Precambrian (older than 570,000,000 years) shield areas circular, dome-shaped granitic complexes abound. The so-called mantled gneiss (coarsely foliated metamorphic rock) domes of Karelia (Finland and the Soviet Union) and the Vredefort Dome (near Johannesburg, South Africa) are good examples. Although their origins are controversial, a diapiric origin, with relatively low-density granitic material rising plastically through more dense material, appears reasonable in the light of recent studies. The examples cited seem to occur at axial culminations (intersections of major perpendicular antiformal structures) that facilitated and localized diapir formation. Analogous structures have been mapped over large tracts of Rhodesia; the Canadian Shield of Saskatchewan and Manitoba has numerous comparable structures.

Nontectonic folding. The development of small, nontectonic folds in relatively unconsolidated surficial rocks and recently deposited sediments is also important. Submarine sliding and slumping is widespread and more important; the process produces small folds contemporaneously (or nearly so) with sedimentation. Gravitational slip along bedding planes prior to additional sedimentation means that the folds affect only a metre or two of sediment; the underlying strata and the overlying (as yet undeposited) strata are unaffected. Lithified examples seen in outcrop can look deceptively like tectonic folds. Following tectonic deformation, the superposed tectonic folds make it difficult to recognize the earlier soft-sediment structures; a good example of this situation was described in graywackes (a type of sandstone with a muddy matrix) from the Appalachian mobile belt of Newfoundland. Gravitational creep and flow in sedimentary rocks that are exposed in deeply dissected terrain on land causes crumpling and folding in disturbed zones up to a few metres thick, several good examples from the Italian Apennines have recently been described.

Under special conditions, numerous other soft-sediment folds can develop in largely unconsolidated sediments. For example, differential compaction, extrusion of water during compaction and dewatering, and decay of ice bodies within periglacial areas are examples of conditions that can induce minor fold structures.

FRACTURE IN ROCKS

Rock units at the Earth's surface are always intersected by fracture and rupture surfaces. As pointed out earlier, rocks respond to stress either by plastic deformation or by failure (fracture), depending on pressure, temperature, and other conditions. The fractures commonly result from stress imposed during earth movements and tectonism; however, thermal contraction of igneous rocks and dessication of sedimentary rocks also produce fractures, as do residual stresses within rocks formed at depth in the crust but brought to the surface as erosion slowly strips away the overlying rocks. Individual fractures range from minute structures visible under the microscope to some of the largest recognized geological structures in the Earth's crust. These fractures fall into two main categories—joints, which are fractures along which little or no displacement has occurred, and faults, which are fractures along which significant displacements have occurred.

Economic and geologic importance of joints

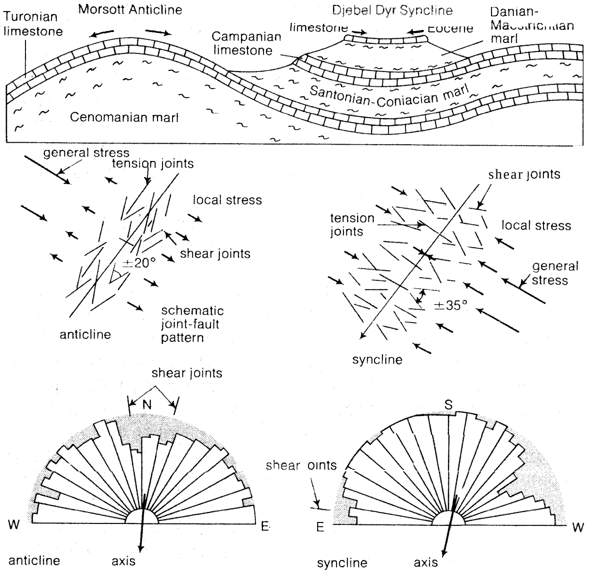
Joints, joint sets, and joint patterns. Because they facilitate easy flow within relatively impervious rocks, joints afford excellent groundwater, oil, and gas reservoirs of considerable economic importance. In addition, joints are exploited in quarrying and mining operations, and stone masons customarily utilize the many invisible planes of weakness that are parallel to the visible fractures. For water wells, some success has recently been achieved in locating the intersections of master joints on air photographs (even in country blanketed by a few metres of soil or other overburden). If the host rock is a compact limestone, for example, appreciably better water flow is obtained by sinking wells to intersecting joints. Small explosive charges are sometimes used at the bottom of a well to shatter the surrounding rock and to provide access to the natural joint system. Solution of limestone by groundwater circulating through joint systems commonly results in pot holes and extensive underground cave systems (enjoyed by speleologists) and eventually leads to development of karst topography and impressive gorges (see further CAVES AND CAVE SYSTEMS).

Joints are probably brittle fractures in which displacement (zero to several centimetres) normal to the fracture surface is characteristic; sometimes, the dilation appears to be greater, but many of the very open joints in surface outcrops were enlarged and widened by surface erosion. Commonly, two or more sets of regular, parallel, closely spaced joints—systematic joints—are clearly visible in outcrops; scattered, non-systematic joints of more variable orientation and not crossing other joint sets are not uncommon.

In laboratory compression tests of rock samples, brittle-fracture surfaces form either parallel to or oblique to the maximum compression axis and produce extension fractures or shear fractures (or faults), respectively. In simple tensile tests, the fracture surfaces form approximately perpendicular to the tensile-stress axis. High pore-water pressures reduce the rupture strength of rocks and offset the stress due to the weight of the overlying rock column. Despite these simple experimental results, the origin of natural joints is not well understood and different authorities hold quite dissimilar views. None of the numerous theories for joint development is wholly acceptable. One immediate problem is that there are few detailed studies of the nature and variability of joints, although joints are visible in essentially every outcrop and air photograph. Second, there are probably numerous dissimilar mechanisms that induce brittle fractures in rocks, so that a single genetic theory is inadequate. Analysis of natural joints is complicated by the common superposition of successive, unrelated joint sets. Slight offset of one joint set by another sometimes permits the relative ages to be established.

Relation of joints and faults to folding

It is widely believed that joints and faults have as a common origin the deformative stress that occurs during a phase of folding. Many cylindrical and conical folds are associated with well-developed cross joints (normal to fold axis) and longitudinal joints (parallel to axial surface). Less pronounced diagonal joints occur as paired (conjugate) sets symmetrical to the cross and longitudinal joints but more closely inclined to the former. Joints tend to be of two types: (1) tension fractures characterized by clean granular breaks (sometimes with plumose, or radiating, patterns reflecting the spreading fracture through the rock) oriented parallel to the maximum-stress axis and perpendicular to the minimum-stress axis; (2) shear fractures occurring as conjugate sets with slight offsets and slickensided (below) surfaces; these joints or faults develop in planes parallel to the median stress direction, and they have an acute angle between them that is bisected by the maximum-stress direction. Slickensides are grooves or striations on joint or fault surfaces produced parallel to the last direction of forceful movement of one face across the other. Close relationships between joint sets and fold geometry are widespread and, when actually established, fracture-pattern analysis can have far-reaching significance in determining the orientation of tectonic forces responsible for regional structures (*e.g.*, anticlines and mountain uplifts). Close agreement to theory is illustrated by an example from southeastern Algeria (Figure 9).



From L.U. do Sitter. *Structural* Geology, 2nd ed. (1964); McGraw-Hill Book Co.

Figure 9: Origin of joint and fault patterns in adjoining anticline and syncline, adapted from aerial photographs of adjacent structures in southeast Algeria, with frequency diagrams of the strikes of joints and faults.

Where there appears to be a clear genetic interrelationship between joints and folds, the fracture density tends to be greater in thinner rock units and in the more brittle rocks. Fracture frequency is commonly correlative with the degree of bed curvature, so that fold flanks have fewer fractures than the closures; such fractures, seen on fold profiles, have sometimes been called fracture cleavage, but they are true joints and should be differentiated from cleavage or foliation. Foliation, unlike joints, is characterized by a splitting parallel to a preferred mineral orientation (*e.g.*, schistosity or slaty cleavage). Occasionally, this type of fracture and slaty cleavage grade into each other; this is additional evidence for foliation and folding being concomitant and genetically related. In metamorphic rocks, tensional-joint formation is commonly aided by the foliation, which customarily parallels the fold axial surfaces.

Propagation of basement joints

In many other situations, joints appear to be independent of the stress field that previously effected strain of the rocks. Sedimentary rocks on stable cratonic areas, for example, are commonly almost unfolded or folded only very mildly. Such rocks are invariably jointed, however, and the joint patterns remain remarkably constant in orientation over vast areas, although varying in frequency from one rock type to another. Similarly, the highly folded and metamorphosed shield areas are characteristically transected by regional joint sets bearing no easily discerned relationship to the local structural geometry. Such joints apparently reflect major regional stress phenomena. Sometimes consistent offsets suggest shear components. More commonly, three mutually perpendicular (orthogonal) joint sets are dominant—two nearly vertical and one approximately horizontal. This suggests that basement joints—those in the oldest crystalline rocks at the bottom of the sequence—were propagated into the overlying cratonic rocks (and even into Pleistocene sedimentary rocks) by either (1) continuation of the processes that produced the original basement joints or (2) relatively small vertical movements on the old joints causing extension of those joints up into the overlying rocks. Detailed observation in Finnish mines east of the Gulf of Bothnia reveals continuing small movements on Precambrian joints; these particular movements probably reflect continuing isostatic readjustment following melting of the Pleistocene ice sheets. It has been demonstrated that movement on old basement joints is widespread and has dominated the map pattern in Finnish basement rocks (particularly in the Orijarvi area). Similar posthumous movements appear to be characteristic of the southern Canadian Shield. Such movements probably initiated jointing in the Paleozoic sedimentary rocks of the north central United States that blanket the southward extension of the Canadian Shield. This mode of joint development soon after deposition of sedimentary rocks is probably a common phenomenon. Some geologists believe that such regional joints are fatigue fractures, resulting from continued cyclic elastic strain of the rocks due to periodic waves affecting the whole Earth's crust. Seismic waves and solid earth tides have been cited, but numerous other significant periodic stresses affect the crust. It seems unrealistic at present to attribute the regional joint sets to any one of these possible causes because of the lack of knowledge that prevails.

Joints do not persist downward indefinitely because eventually the domain of plastic deformation is reached. Frequently joints are much more open at surface outcrop and more appressed (or only incipient) a few metres below the surface. It has been argued that joints are brittle fractures caused by stresses developed in rocks raised from within the Earth's crust by uplift and erosion. During such uplift a body of rock must undergo a lateral expansion simply because the Earth is spherical and this, on geometric grounds alone, might be expected to produce more open joints near the Earth's surface. It also has been suggested that uplift and erosional unloading induce formation of vertical conjugate shear joints and, at shallow depth, vertical extension fractures.

Desiccation and cooling patterns

Many joints are the product of nontectonic forces. During the desiccation of clays and silts on playa lake beds, shrinkage produces vertical tension fractures in a polygonal plan. Individual polygons are usually 0.2 to 0.6 metre (0.7 to two feet) across and, with continued desiccation, the joints extend downward. Aerial photographs show that major joints also develop on playa lake beds defining polygons 100 to 200 metres (330 to 660 feet) across. Some geologists have suggested that, during dewatering and lithification of many primary sediments, joints develop perpendicular to bedding. This is possible, though not as yet proven.

Distinctive joint patterns characterize igneous rocks and are generally attributed to tensional stresses during post-crystallization cooling and contraction. Dikes and sills, which are tabular intrusive bodies, and many lava flows tend to develop columnar joints; the latter define polygonal columns perpendicular to the cooling surfaces. Individual columns range from seven to eight centimetres (2.75 to three inches) to as much as six metres (20 feet) in "diameter." The column "diameter" seems to be controlled by the cooling rate; a zone of smaller columns occurs at the base and surface of thick lava flows, whereas much thicker columns characterize the centre. Characteristically, curving tensional joints occur perpendicular to the column length. At Giant's Causeway in northeastern Ireland, basalt flows of Early Tertiary age (about 55,000,000 years old) are exposed in sea cliffs and provide an excellent three-dimensional view of columnar jointing. The extensive basaltic lava flows of the Columbia Plateau, Washington, are equally impressive. Although very common, these simple polygonal joints are not universal. For example, basalt flows in southern Nevada are well exposed, capping mesas around the edge of which the joints appear to be columnar. In detail, the joint patterns are complex and not infrequently dominated by rectilinear vertical joints many of which are parallel to and physically continuous with the more widely spaced, but regionally developed, joints of the underlying sedimentary rocks that are significantly older.

Joint sets in large igneous bodies

In major igneous intrusions three mutually perpendicular joint sets are characteristic, with two sets roughly vertical. Many plutons (large intrusive bodies) have distinctive planar preferred orientations of the component mineral grains. In many cases, these planar structures are nearly vertical and are interpreted as products of flow during intrusion and crystallization. The vertical orthogonal fractures comprise cross and longitudinal joints that are roughly perpendicular to and parallel to the planar structure. Also, less well developed, conjugate, vertical fractures (diagonal joints) are symmetrically disposed to the flow structure. Joints of granitoid batholiths (very large masses of igneous rock) probably arise from cooling and contraction of the crystallized magma. Early formed joints sometimes become annealed prior to formation of the present fractures; for example, annealed old fracture planes, demarcated solely by iron pyrite, occur in some Front Range granites of Colorado. Joint faces (or the whole joint cavity) in many igneous rocks are encrusted with secondary minerals, formed after crystallization of the principal rock mass. Late stage veins and dikes cutting plutons commonly utilize previously formed joints. Many intrusions have additional fractures, however, some of which may be responses to postcrystallization deformation. Some batholiths even have well-developed orthogonal joints that are apparently unrelated to the internal mineral orientations; for example, the Older Granite of Donegal in northwestern Ireland is characterized by strongly developed north–south and east–west vertical joints and a subhorizontal set, which disregard well-defined flow-structure orientations.

Faults **and faulting.** Faults are fractures along which the rocks on opposite sides have moved so as to produce significant displacement. Such displacements range from a few millimetres or less up to several hundred kilometres. An initial rupture surface or plane of failure in the rock provides the plane along which fault displacement occurs. When strain in homogeneous rocks is involved, there is little problem in differentiating between joints, faults, and folds. With natural heterogeneous rock units, however, transitions between faults and folds abound. Numerous, small shear planes characterize the small internal structures of many folds. Faults large enough to be shown on a map may die out and grade into folds. Similarly, there appears to be a complete gradation from small joints to major faults, although this may be misleading because there are many different types of joints and, apparently, an even greater diversity of fault types.

The net slip or total length of displacement on a fault can range from essentially zero (as in joints) up to perhaps 600 kilometres (400 miles). The distribution of faults is very uneven; some large areas are almost unfaulted, and others are cut by innumerable faults of varying size. Movement on many faults has been or is very spasmodic with rapid movements (lasting a few seconds) of up to a few metres being separated by intervals during which stress builds up and is eventually released when frictional forces along the fault plane are overcome. Rapid release produces an earthquake. Movement on some currently active faults, however, seems to be by continuous creep rather than spasmodic jumps. Many faults were active for only a brief period, whereas some others moved spasmodically and played a major role in Earth history over hundreds of millions of years.

The three types of faults

Three types of faults can be distinguished on the basis of theoretical stress systems that can be resolved into three orthogonal principal components $\sigma_1 > \sigma_2 > \sigma_3$, based on a model in which one component is approximately vertical and the fracture planes are inclined 15° to 45" to the largest principal stress component (σ_1). The three generally accepted possibilities involve: thrust faults, wrench, tear, or transcurrent faults, and normal or tension faults (Figure 10). Reverse faults are also common in some areas but they are unexplained by this model. This system can readily be extended to joint formation, however, especially if a fourth category is added, namely tension joints (equivalent to fissures or gash fractures) developed parallel to the principal stress.

Normal faults. Normal faults appear to occur when the least principal stress (often actual tension) is horizontal and the largest principal stress (gravity) is approximately vertical. Subparallel normal faults with the down-

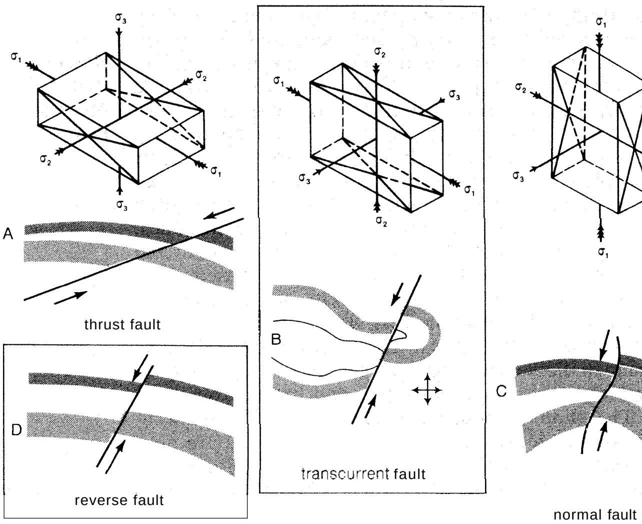


Figure 10: The three principal types of faults based on the orientations of the stress axes (σ_1, σ_2, and σ_3).

Adapted from E. H. Timothy Whitten, Structural Geology of Folded Rocks, © 1966 by Rand McNally and Company, Chicago, p. 133. Fig. 109.

thrown side facing the same direction give a steplike structure. Facing normal faults, with a downthrown block between them, produce a rift zone; rifts range from a metre or two in width to structures a few kilometres wide and several hundred kilometres long (*e.g.*, the East African Rift Valley). Horsts—upthrown blocks bounded by outward facing normal faults—rarely exceed a few kilometres. The dip of normal fault planes is usually greater than 45°, although they are sometimes steeper (about 60" to 80°) near the surface and shallower at depth; also, fault planes are usually less steep in soft, incompetent strata. Hanging wall and footwall (old mining terms) are names used to designate the blocks on either side of a normal fault.

Transcurrent faults. Transcurrent or tear faults produce structures of major significance in the Earth's crust. Their planes are characteristically almost vertical, so that the fault traces on a map are essentially straight. Horizontal compression apparently induces two intersecting fractures at an acute angle to the maximum compressive stress; friction between the rock masses can produce extensive slickensided surfaces, fault breccias (coarse fragmental rocks), mylonites (rocks produced by intensive crushing and shearing), or even ultramylonites along the fault planes. In many cases, one transcurrent fault direction is dominant, and the conjugate set is not obviously developed. Examples are the San Andreas Fault Zone, California (Figure 11), and a widespread set of northeast–southwest faults that cut the Scottish Grampian Highlands. In the latter area, a major fault and an associated breccia zone of great width resulted in erosion of the Great Glen (Inverness to Fort William); the net slip (movement) was some 96 kilometres (60 miles), but to the south numerous subparallel faults with smaller slips ranging up to seven or eight kilometres (four to five miles) have been mapped (*e.g.*, along mid-Strathspey). These Scottish faults are left lateral (or sinistral) because, looking across the trace of the fault, the opposite side moved to the left. The opposite movement sense is termed right lateral or dextral.

Scottish and midocean examples

John S. Shelton and Robert C. Frampton

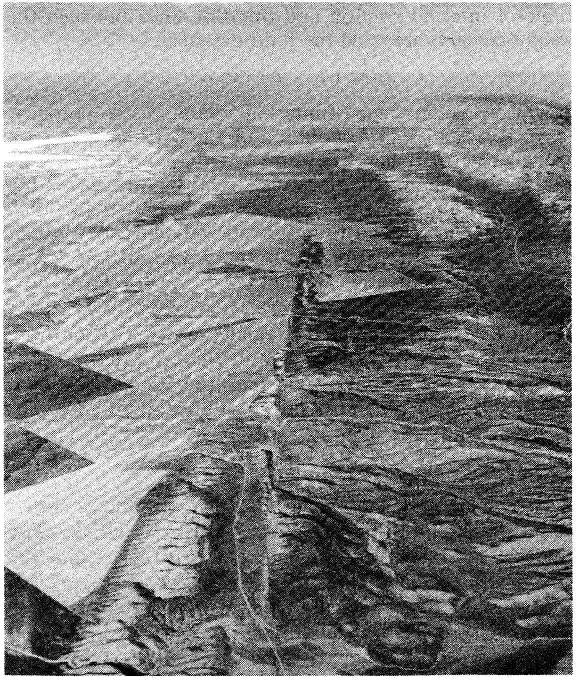

Figure 11: San Andreas Fault looking northwest from Elkhorn Hills. California.

Transcurrent faults in ocean basins are widespread and are responsible for repeated offset of midoceanic ridges (*e.g.*, Mid-Atlantic Ridge, which has the dimensions of a major mountain range). Many of these are thought to be transform faults; that is, the transcurrent movement terminates sharply where it is transformed into a structure of another type. The hypothesis involves unusual geometry because these transcurrent faults transect midoceanic ridges interpreted to be zones of active oceanic growth and outward spreading (see further OCEANIC RIDGES; SEA-FLOOR SPREADING).

Thrust faults. According to the model referred to above, thrust faults involve horizontal maximum compression and near-vertical least compression. The model involves a fault plane inclined less than 45°. This widely quoted model is too simple to explain fully a large proportion of actual thrusts, or the locally important although relatively small (less than a few hundred metres) reverse faults with dips greater than 45°. Some horsts are upthrust blocks between two reverse faults. Most thrusts tend to be steep near the surface but flatten to a nearly horizontal attitude at depth and over most of their extent. Many authorities distinguish overthrusts as thrust faults with an initial dip of less than 10° and a net slip measured in kilometres. The first overthrusts were identified in the 19th century in Switzerland and near Dresden, Germany.

In zones of apparently strong compression within the Appalachian fold belt (eastern United States and Canada) many geologists still support the classical concept that folding occurred where competent rock units overlie weaker shales and other incompetent rocks, whereas thrusting occurred where incompetent members were underlain by competent units (see Figure 12). Thrusts are

extremely important structural elements of major geosynclinal or mobile belts. In Alberta and Kentucky, for example, oil wells have frequently penetrated the same horizon three or four times where several thrust slices overlie each other. Thrust faults have frequently been considered to be convincing evidence of crustal shortening in tectonic zones of compression; many authorities now reject this hypothesis, which, in some mobile belts, would involve incredible distances (several hundred kilometres) of crustal shortening. In addition, many of these thrust slices are only a few tens of metres thick but several kilometres long (parallel to the movement direction), and it is difficult to conceive that brittle fracture, followed by transmission of stress through such a lithic unit, could move it up a thrust plane--especially if the rocks involved are relatively incompetent. There is considerable difference of opinion about whether thrusts continue into the local basement or whether they are restricted to the "thin skin" above the basement. Several dissimilar types of major thrusts exist in the Earth's crust, although currently textbooks tend to emphasize one type to the virtual exclusion of others. For illustration, three tectonically dissimilar types are discussed here, with examples of each type:

Types of major thrust faults

(1) Marginal to many deformed mobile belts (foothill belts), oil wells commonly penetrate numerous thrusts and then one major sole fault (main fault surface) before entering essentially undeformed strata. The basement is apparently not involved; the rocks are essentially unmetamorphosed and contain few, if any, small folds. Examples were exhaustively studied during petroleum search in the Rocky Mountain foothills of Alberta. In the European Alps and Carpathians, thin thrust-bounded slices are termed nappes (or decken); many nappes comprise gigantic recumbent isoclines (folds with near-horizontal limbs and bisecting planes). Such structures involve décollment, meaning that the sedimentary rocks become detached from and thrust across underlying, undeformed basement. The surfaces between nappes resemble the "slides" in the Scottish Grampian Highlands; subsequent to development of these slides, the whole sequence was regionally metamorphosed and concomitantly subjected to several superposed phases of folding.

(2) Some thrusts cut the basement, causing introduction of crystalline rock slices into overlying sedimentary sequences. The Scottish Northern Highlands provide an excellent example. Here, Lewisian gneisses crystallized about 1,600,000,000 years ago; following profound erosion, these basement rocks were overlain by some six to seven kilometres of Moine shales and sandstones about 900,000,000 years ago. The earliest recognized folding of the Moine rocks involved intimate isoclinal interfolding with the Lewisian basement (as at Glenelg, east of Skye). Current interpretation of the region farther northeast (*e.g.,* Scardroy) is that several thrusts brought basement slices up into the Moine sequence during the initial deformation (prior to intense folding and metamorphism of the Moine rocks). Such thrusts possibly characterize a more central zone of mobile belts than does the preceding type.

(3) The Scottish Northern Highlands yield a classic example of another thrust type. Several folding and metamorphic events (more than 570,000,000 years ago) affected the Moine rocks before deposition of the Cambrian and Ordovician quartzitic and dolomitic sediments. The Moine Thrust Zone (excellently exposed in the Assynt area of northwestern Scotland) shows unmetamorphosed Cambro-Ordovician rocks overridden by Moine metamorphosed rocks. Several major thrust planes are involved. Moine rocks were thrust westward several tens of kilometres. Local but intense folding was induced in the underlying Cambro-Ordovician and overlying Moine rocks bordering the thrust surfaces.

The mechanisms by which these three thrust types (and other possible tectonically distinct types) were generated are not fully understood, although two hypotheses that help to avoid the need for extreme crustal shortening in mobile belts have gained much support in recent years.

Possible thrust mechanisms

(1) The voids between sediment grains are full of water at deposition; continued sedimentation causes loading and compaction of underlying sediment and, not infrequently, the pore-water pressure builds up more rapidly than water can be expelled. Water pressure above the hydrostatic pressure forces grains apart, reducing internal friction and viscosity of the sediment and facilitating gravitational flow down gently inclined slopes. Local, or general, vertical tectonism during development of geosynclinal mobile belts apparently causes gravity gliding of recently deposited sediments out onto adjacent zones. Continuing rise of central areas (more rapidly than the flanks) would promote lateral spreading off raised welts toward the bounding craton. This activity produces nappes and recumbent folds of semiconsolidated sedimentary materials, together with thrusts at the junction of the deeper-water and shallow-water zones of sediment accumulation, (respectively, the eugeosynclinal and miogeosynclinal belts). The gliding would laterally compress the flanking portions of the geosynclinal belt. Such concepts are now widespread, and Russian authors have championed the idea that vertical movements, rather than crustal shortening and crustal compression, are the dominant cause of folding and faulting.

A few geologists place emphasis on syntaphral tectonics, which involve basinward gravity sliding. Slumping of unconsolidated wet sediments and penecontemporaneous folding are examples, although much larger examples appear to develop on slopes of only a degree or two. It is argued that troughs in developing geosynclines receive creeping masses, compressive foldings, nappelike sheets, and turbidity flows separated by "thrust" surfaces (that could be preserved and misidentified as early orogenic phenomena). A sheet one kilometre *(0.6* mile) thick and 10,000 square kilometres (4,000 square miles) in area travelled many kilometres on the Grand Banks off eastern North America; study of this sheet suggested that a significant part of the deformation of Alpine-type geosynclines occurred while sedimentation was continuing and before tectonic forces began to uplift the geosyncline. Evidence of extensive troughward gravity sliding in the central Appalachian fold belt also is germane; the sliding occurred in the form of widespread wedges—small thrusts (one to four metres) on which one thinly bedded sedimentary member rode up and over itself.

(2) Another mechanism invoked is that of high water pressures to reduce frictional resistance and to facilitate movement on major thrusts. The weight per unit area, S, of a block is supported by a solid stress σ plus the interstitial-fluid pressure p. The critical shear stress, τ, required to slide a block is then the product of the tangent of the angle of internal friction and the difference between the weight per unit area and the fluid pressure:

$$\tau = (S - p) \tan \phi$$

in which ϕ is the angle of internal friction; as p approaches S, corresponding to flotation of the overburden, τ approaches zero. It has been claimed that, under tectonic compression, if maximum stress is horizontal, p readily equals S. Fluid pressures approximately equal to 0.9 S and greater have been found in oil wells in geosynclinal basins and in areas probably now tectonically compressed. Such pressures permit formation of large, low angle overthrusts. For the western Wyoming overthmst belt, it has been calculated that, if the geosyncline limb sloped at 2.5" to 3°, a fluid pressure–overburden ratio of 0.91 to 0.92 would have been required for gravitational sliding, which there must have totalled about 80 kilometres (50 miles).

STRUCTURAL INTERFERENCE

Events of several ages generally have produced superposed strains in all but the most recent rock bodies. The kinds of geological phenomena that may occur and the time spans associated with them are shown in Figure 13. Superposition of tectonically induced strains makes analysis of the individual events difficult.

Superposed-fold geometry within metamorphosed mobile belts has been studied intensively for 15 years. Folding and metamorphic events within a belt tend to be

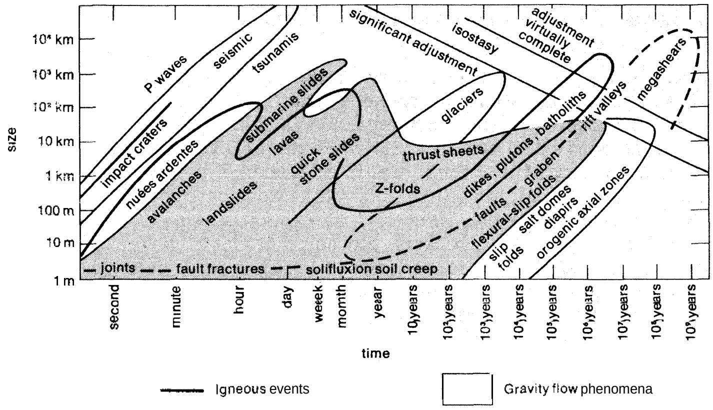

Figure 13: A size-time model for geotectonic phenomena, showing the kinds of events that may occur and their associated sizes and time spans.

Superposed folding events

spasmodic in space and time. Remarkably similar but not synchronous events may occur at locations parallel to a geosynclinal axis. In the Caledonian mobile belt of Scandinavia, Scotland, and Ireland or in the Appalachians of eastern North America, major nappes apparently formed during initial deformation prior to major metamorphism. Without detailed lithologic mapping over hundreds of square kilometres, such nappes are difficult to detect. Two or three subsequent phases of slip, flexural-slip, or flexure folding (interspersed with metamorphic episodes) produced the folds that are readily seen in the field. Dating methods used in the Caledonides have shown that despite the similarity of the folding events in the Dalradian rocks of western Ireland and of the eastern Grampian Highlands (Scotland), they were not synchronous. During the waning deformation, mobile belt rocks commonly become less plastic and small, angular, kink folds are commonly superposed on earlier folds.

Compression of planar beds commonly produces cylindrical or conical folds with subparallel axes, although the axial orientation depends on the original bedding orientation with respect to the compressive stress. Superposed refolding does not produce a single new fold axis, but a differently oriented fold axis for each differently oriented portion of the original fold. Succeeding fold systems thus tend to produce smaller folds on the flanks of earlier structures; exceptions occur if all old structures are obliterated by transposition and a new schistosity is produced and folded, or if the new folding is of a much larger wavelength (*e.g.*, gentle regional warping of a range). The theoretical geometry of superposed slip and flexural-slip folding has been described, but unravelling superposed folds in the field is very complicated. Several hundred papers describe field relationships in different parts of the world, but few give unequivocal geometrical solutions. Current methods require analysis of thousands of field measurements. Complications stem from: (1) inadequate three-dimensional exposure, (2) the fact that although superposed slip and flexural-slip folding produce dissimilar geometries it is often uncertain which was involved or whether a hybrid of both mechanisms occurred, and (3) factors like flattening that may have significantly distorted the theoretical strain models. It has proved effective for deciphering complex superposed fold geometry (when enough data are available) to subdivide the region into smaller, homogeneous domains in which specified linear structures are approximately parallel. This identifies domains in which bedding (or schistosity) was planar after the first folding. Extrapolation to adjacent areas would be important for prospecting (*e.g.*, Precambrian iron ores, Quebec), but currently it is extremely difficult. Where two simple and open fold phases are superposed, structural culminations (domes) at antiformal intersections and depressions (basins) at synformal intersections commonly occur. Because the domes and basins tend to be arranged on a checkerboard pattern some predictions are possible. This model was used successfully to predict another cratonic basin of gold-bearing Witwatersrand rocks east of the known subsurface goldfields near Johannesburg, South Africa; drilling proved the existence of the predicted basins.

Superposed joints and faults

Relatively little work has been done on fracture sets in areas of superposed folding, although joints specifically related to superposed folds are usual. Superposed joint and fault sets are common even where folding has not been induced, but the regional significance of superposed fracture systems has been evaluated in only a few cases. Renewed stress may induce a new joint set or accentuate or cause movement along old joints. Analysis of the offsets, mineralization, or dike-swarm intrusion along certain joints can sometimes produce a chronology. Central Scotland provides an excellent example. During the waning phases of the Caledonian orogeny (episode of mountain building), a dike swarm intruded northeast–southwest trending fissures; in late Paleozoic time (about 275,000,000 years ago), transcurrent faults (*e.g.*, Great Glen Fault) cut the Central Highlands. The latter probably reflect north–south compression (Hercynian orogeny?), and release of this stress may have accounted for intrusion of the east–west dike swarm. Later, the Tertiary basaltic dike swarms occupied new northwest–southeast fractures, although across parts of the Donegal Granite (northwestern Ireland) Tertiary dikes alternately occupy short dilated sections of the old north–south and east–west joints to maintain the regional northwest–southeast trend.

Currently, great interest centres on global and plate tectonics (the concept that the outer part of the Earth consists of a small number of great plates that shift about and abut each other), subjects that received impetus from the implications of extensive continental drift and concomitant growth of the ocean basins by upward and outward flow along the midoceanic ridges. These hypotheses are not universally accepted, although their advocates marshal1 impressive arrays of supporting evidence and have begun to develop an integrated picture of crustal development and evolution. On the continents, it is increasingly clear that many old structures continue to control structural development of younger features. Major basement fractures may remain active and significantly affect younger sedimentation. Evolution of cratonic basins and domes of southern Africa and North America supports the hypothesis that basement fold structures may control the pattern of cratonic basins and sedimentation during all succeeding periods, unless they become involved in mobile belt geosynclinal activity.

Rockets and Missile Systems

Rocket is the generic term used broadly to describe a variety of jet-propelled missiles, research vehicles, thrust devices, fireworks, and space-launch vehicles. Forward motion results from reaction to the rearward ejection of matter, usually hot gases, at high velocity. The propulsive jet of gases usually consists of the combustion products of solid or liquid propellants. Stored, high-pressure cold gas, heated hydrogen gas, or ions can also be used.

Rocket propulsion is a unique member of the family of jet-propulsion engines that includes turbojet, pulse-jet, and ramjet systems. The rocket engine is different, however, in that the elements of the propulsive jet (fuel and oxidizer) are self-contained within the vehicle. The thrust produced is independent of the medium through which the vehicle travels. Other kinds of jet-propulsion engines carry only their fuel and depend on the oxygen content of the air for burning. Thus these varieties of jet engines are called air breathing and are limited to operation within the Earth's atmosphere. The upper limit of travel for air-breathing jet engines is about 90,000 feet (27 kilometres). A rocket engine is necessary for flight beyond the atmosphere into the immense reaches of space.

A guided missile is broadly any military missile that is capable of being guided or directed to a target after having been launched. Modern guided missiles are powered by some type of jet propulsion, usually rocket propulsion. There are numerous kinds of guidance systems as well as range and functions of such missiles. Accuracy is of prime importance. Explosive warheads may be high explosive or nuclear.

Rocket power has been used in crude form for hundreds of years for military purposes, signalling, and fireworks displays. During the first half of the 19th century, several European armies had rocket brigades, but interest waned with improvement in accuracy and range of artillery. Guided missiles had their origin during World War I but were not then developed to operational use. During World War II, however, rocket power and guided missiles were extensively developed, primarily by Germany. Since then, most technologically capable nations have developed rocket-propelled guided missiles for military purposes and for space research.

Nearly a century ago it was recognized that rocket power was the key to exploration of space beyond the Earth's atmosphere. Technology, however, did not reach the point at which such investigations were possible until mid-20th century. In 1957 man opened a new era of exploration by applying the laws of celestial mechanics through the use of rocket power.

This article is outlined as follows:

I. Development of rockets and guided missiles

EARLY HISTORY

There is no reliable early history of the "invention" of rockets. Most historians of rocketry trace the development of rockets to China, a land noted in ancient times for its fireworks displays. In 1232, when the Mongols laid siege to the city of K'ai-feng, capital of Honan Province, the Chinese defenders used weapons that were described as "arrows of flying fire." There is no explicit statement that these arrows were rockets, but some students have concluded that they were because the record does not mention bows or other means of shooting the arrows. In the same battle, it is reported, the defenders dropped from the walls of the city a kind of bomb described as "heaven-shaking thunder." From these meagre references some students have concluded that by 1232 the Chinese had discovered black powder (gunpowder) and had learned to use it to make explosive bombs as well as propulsive charges for rockets. Drawings made in military documents much later show powder rockets tied to arrows and spears. The propulsive jet evidently added to the range of these weapons and acted as an incendiary agent against targets.

In the same century rockets appeared in Europe. There is indication that their first use was by the Mongols in the Battle of Legnica in 1241. The Arabs are reported to have used rockets on the Iberian Peninsula in 1249; and in 1288 Valencia was attacked by rockets. In Italy, rockets are said to have been used by the Paduans (1379) and by the Venetians (1380).

Nature of early rockets

There are no details of construction of these rockets, but it is presumed that they were quite crude. The tubular rocket cases were probably many layers of tightly wrapped paper, coated with shellac. The propulsive charge was basically a mixture of finely ground carbon (charcoal), saltpetre (potassium nitrate), and sulfur. The English scientist Roger Bacon wrote formulas for black powder about 1248 in his Epistola. In Germany, a contemporary of Bacon, Albertus Magnus, described powder charge formulas for rockets in his book *De mirabilibus mundi.* The first firearms appeared about 1325; they utilized a closed tube and black powder (now referred to as gunpowder) to propel a ball, somewhat erratically, over varying distances. Military engineers then began to invent and refine designs for guns and rockets on a parallel basis.

The French historian Jean Froissart suggested that firing rockets from tubes would give them better direction. An Italian writer conceived a number of novel weapons based on rocket propulsion, including a rocket-driven car, designed to breach walls or gates, and a naval torpedo, designed to skim across water and ram its spiked nose into ships. Many other ideas were suggested in print, such as rockets with parachutes and underwater explosive rockets. The extent to which many of these designs were reduced to working models or weapons is not known. By this time rockets were used also for signalling and, especially by pirates, for setting fire to the tarred rigging of sailing ships. They had many names, such as flying fire or wild fire. There is reason to believe that some of these devices were hurled or catapulted incendiaries rather than actual rockets, particularly in night attacks.

Of considerable interest are the historical origins of rocket designs that were to be employed many years later: the staged (or step) rocket, the clustered rocket, and the winged rocket. These designs evolved both from applications and requirements of fireworks and their adoption by ordnance masters. The earliest records of these concepts are contained in a manuscript by Conrad Haas, an artillery officer and chief of the arsenal at Sibiu, Romania, in the 16th century. In 1590 a German fireworks expert published a small illustrated book reproducing Haas's designs. A Polish artillery expert published essentially the same designs (see Figure 1) in a book translated into French, German, English, and Dutch, but practically no use was made of these concepts for clustered, winged, and step rockets for several hundreds of years, except perhaps in fireworks displays.

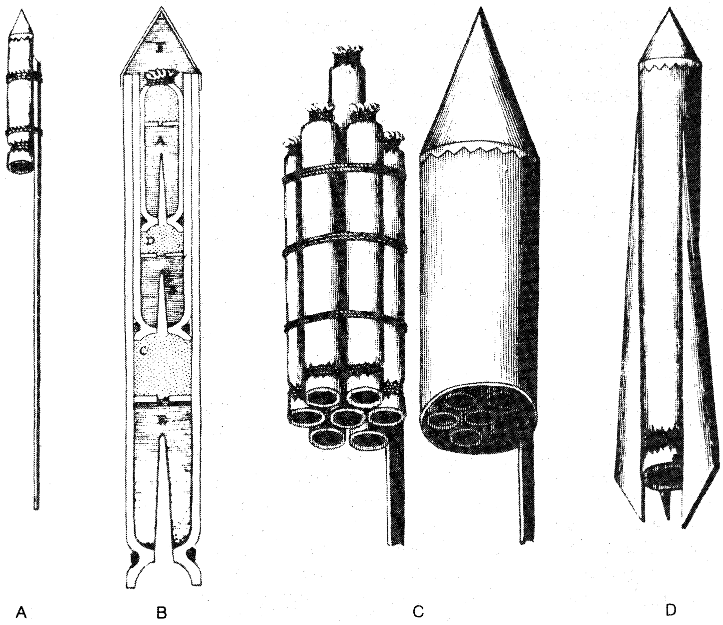

Figure 1: Historical examples of rockets.
(A) Conventional stick-guided war rocket or fireworks skyrocket; some early design concepts of (B) a step rocket, (C) a clustered rocket, and (D) a fin-stabilized glide rocket. Drawings by Casirnirus Siemienowicz from *Artis* magnae *artillerae*, pars prima, 1650.
By courtesy of M. Subotowicz (Poland)

By 1668 military rockets had increased in size and performance. In that year, a German colonel designed a rocket weighing 132 pounds (60 kilograms); it was constructed of wood and wrapped in glue-soaked sailcloth. It carried a gunpowder charge weighing 16 pounds (seven kilograms). Nevertheless, the use of rockets seems to have waned, and for the next 100 years their employment in military campaigns appears to have been sporadic.

Hyder Ali's metal-clad rockets

A revival commenced late in the 18th century in India. There Hyder Ali, prince of Mysore, developed war rockets with an important change: the use of metal cylinders to contain the combustion powder. Although the hammered soft iron he used was crude, the bursting strength of the container of black powder was much higher. Thus a greater internal pressure was possible, with a resultant greater thrust of the propulsive jet. The rocket body was lashed with leather thongs to a long bamboo stick. Range was perhaps up to three-quarters of a mile (more than a kilometre). Although individually these rockets were not accurate, dispersion error became less important when large numbers were fired rapidly in mass attacks. They were particularly effective against cavalry and were hurled into the air, after lighting, or skimmed along the hard dry ground. Hyder Ali's son, Tippu Sultan, continued to develop and expand the use of rocket weapons, reportedly increasing the number of rocket troops from 1,200 to a corps of 5,000. In battles at Seringapatam in 1792 and 1799 these rockets were used with considerable effect against the British.

19TH-CENTURY DEVELOPMENTS

The news of the successful use of rockets spread through Europe. In England, William Congreve began to experiment privately. The fact that his father, of the same name, was comptroller of the Royal Arsenal at Woolwich undoubtedly facilitated his efforts.

Several important improvements in rockets were made by Congreve. First, he experimented with a number of black-powder formulas and set down standard specifications of composition. He also standardized construction details and used improved production techniques. Also, his designs made it possible to choose either an explosive (ball charge) or incendiary warhead. The explosive warhead was separately ignited and could be timed by trimming the fuse length before launching. Thus, air bursts of the warheads were feasible at different ranges.

Congreve's metal rocket bodies were equipped on one side with two or three thin metal loops into which a long guided stick was inserted and crimped firm. Weights of eight different sizes of these rockets ranged up to 60 pounds (27 kilograms). Launching was from collapsible A-frame ladders. In addition to aerial bombardment, Congreve's rockets were often fired horizontally along the ground.

These side-stick-mounted rockets were employed in a successful naval bombardment of the French coastal city of Boulogne in 1806. The next year a massed attack, using hundreds of rockets, burned most of Copenhagen to the ground. In the Battle of Leipzig and the siege of Danzig, which led to the surrender of that city, rockets played a significant role.

Rockets in the War of 1812

During the War of 1812 between the United States and the British, rockets were employed on numerous occasions. The two best known engagements occurred in 1814. At the Battle of Bladensburg (August 24) the use of rockets assisted British forces to turn the flank of the American troops defending Washington, D.C. As a result, the British were able to capture the city. In September, the British forces attempted to capture Ft. McHenry, which guarded Baltimore harbour. Rockets were fired from a specially designed ship, "Erebus," and from small boats. The British were unsuccessful in their bombardment, but on that occasion Francis Scott Key, inspired by the sight of the night engagement, wrote "The Star Spangled Banner," later adopted as the United States national anthem. "The rockets' red glare" has continued to memorialize Congreve's rockets ever since.

In 1815 Congreve further improved his designs by mounting his guide stick along the central axis. The rocket's propulsive jet issued through five equally spaced holes rather than a single orifice. The forward portion of the guide stick, which screwed into the rocket, was sheathed with brass to prevent burning. The centre-stick-mounted rockets were significantly more accurate. Also, their design permitted launching from thin copper tubes.

Maximum ranges of Congreve rockets were from one-half mile to two miles, depending upon size. They were competitive in performance and cost with the ponderous ten-inch mortar and were vastly more mobile.

Congreve wrote a brief but classic work, ***The Details** of the Rocket System* (1814), detailing the deployment and use of his rockets. Recognizing the importance of massed fire for maximum effect, he recommended the simultaneous firing of 50 rockets at a time, and never less than 20. Volleys could be fired as rapidly as every 30 seconds.

The use of Congreve rockets spread rapidly through Europe. Rockets based on Congreve designs were developed in France, Denmark, Spain, Italy, Switzerland, Sweden, Austria, and Russia. One interesting rocket design of the Swedish Rocket Corps was a stickless, delta-winged glide missile that was fired from a hand-held launcher.

The next significant development in rocketry occurred about the middle of the 19th century. William Hale, a British engineer, invented a method of successfully eliminating the deadweight of the flight-stabilizing guide stick. By designing jet vents at an angle, he was able to spin the rocket. He developed various designs, including curved vanes that were acted upon by the rocket jet. These rockets, stabilized by means of spin, represented a major improvement in performance and ease of handling.

Manufacturing techniques and materials had improved, too. The use of improved steel and rivetted rocket bodies permitted pressures as high as 23,000 pounds per square inch.

Decline in use of rockets

Even the new rockets, however, could not compete with the greatly improved artillery with rifled bores. The rocket corps of most European armies were dissolved, though rockets were still used in swampy or mountainous areas that were difficult for the much heavier mortars and guns. The Austrian Rocket Corps, using Hale rockets, won a number of engagements in mountainous terrain in Hungary and Italy. Other successful uses were by the Dutch colonial services in Celebes and by Russia in a number of engagements in the Turkistan War.

Hale sold his patent rights to the United States in time for some 2,000 rockets to be made for the Mexican War. 1846–48. Although some were fired, they were not particularly successful. The U.S. Ordnance Manual of 1862 lists 16-pound Hale rockets with a range of 1.25 miles (two kilometres).

Rockets were used in a limited way in the American Civil War (1861–65), but reports are fragmentary, and apparently they were not decisive.

During the 19th century two important peacetime applications of the war rocket developed: the lifesaving rocket and the whaling rocket.

In the era of sailing ships many lives were lost in the grounding and breakup of ships a short distance offshore, particularly during storms. The idea of using a rocket to carry from ship to shore or shore to ship a light line, which then could haul a heavier lifesaving line to aid passengers and crew to reach shore, was developed fiist by Henry Trengrouse of Cornwall, in England. In 1807, after watching the loss of 100 crewmen in a shipwreck near the coast, he built a series of line-carrying rockets. The first lives were saved by a line-carrying rocket in 1832. John Dennett modified a small Congreve rocket and in that year was able to save 19 persons from the "Bainbridge" aground on Atherfield Rocks. By mid-century numerous other designs had appeared (see Figure 2).

By courtesy of Mitchell R Sharp

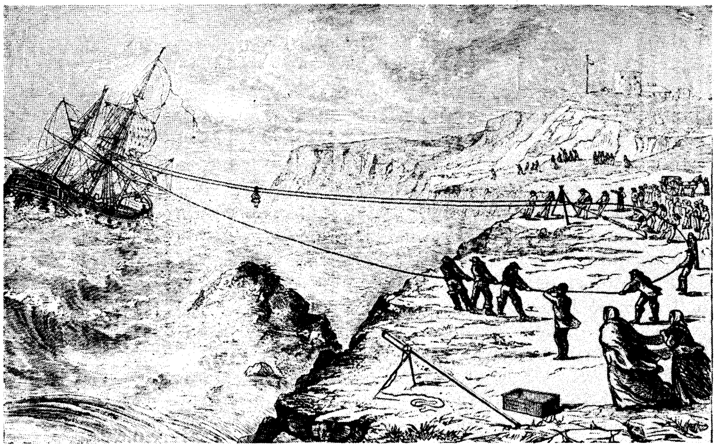

Figure 2: Rescue operation using lifesaving rocket, from a drawing of the 1870s. The light line carried to the ship by the rocket (centre foreground) has been replaced by a heavier line, and a breeches-buoy transfer is in operation.

Lifesaving rockets spread to maritime nations and to the United States. Records kept of their use in Great Britain alone list at least 15,000 lives saved between 1871 and 1962.

As steam and diesel power replaced sails, the need for lifesaving rockets declined. In the late 1960s, however, The Netherlands still maintained coastal stations from which special trucks could rush line-throwing rockets to the nearest point on shore to aid a grounded ship.

Rocket-propelled harpoons

Rocket propulsion was first applied to whaling harpoons in 1821. The most successful concept was that of Capt. Thomas W. Roys, of the United States, whose design of a rocket harpoon carried an explosive warhead. The harpoon was fired through a tube launcher from a small boat. If the aim, burning time of the rocket, speed of flight, and distance travelled were correct, the explosive bomb killed the whale quickly and affixed a toggle and rope in the carcass. These devices enjoyed only a brief lifetime, however.

Both the United States Army and the British Navy conducted experiments with rocket-propelled torpedoes in the period 1860–80, and several ingenious devices were designed. Nevertheless, none of this work led to a real weapon. One of the fundamental problems of the rocket torpedo, as pointed out by William Hale, was that as the powder in the rocket motor was consumed, the torpedo grew lighter, making it difficult to hold the torpedo at constant level below the surface.

Meanwhile, there were individual enthusiasts and inventors in nearly every country. Largely unknown, and sometimes considered a dangerous nuisance, they achieved varied success and recognition. In the early 19th century Claude Ruggieri, a prominent Italian fireworks maker, staged a number of shots in Paris in which rats and mice were sent aloft by rockets and returned by parachute. It is reported that Ruggieri even planned to send up a small boy, using a rocket cluster, but the police intervened.

In 1881 a Russian explosives maker, Nikolay Ivanovich Kibalchich, imprisoned for his part in an assassination attempt on Tsar Alexander II, conceived a rocket airplane that functioned by successive explosions of compressed powder candles. Kibalchich was executed and his writings remained in prison archives until the Revolution in 1917.

A few years later a German inventor, Herman Ganswindt, conceived of an intermittent-firing propulsion system similar to that of Kibalchich but employing steel cartridges loaded with dynamite. Ganswindt went further. He wanted to give his vehicle sufficient speed to attain escape velocity; *i.e.*, to leave the Earth. Apparently, Ganswindt was the first to connect rocket propulsion with space flight. But in Russia in 1895 a young mathematics teacher published his first article on space travel. Konstantin Eduardovich Tsiolkovsky was among the first to grasp the importance of exhaust velocity and the reason that rockets had been limited by black-powder formulas. He saw that by using liquid propellants (*e.g.*, liquefied hydrogen and oxygen) much greater efficiencies would result. Tsiolkovsky made important contributions to the theory of space vehicle design, including the concept of a closed biological cycle, utilizing plant life to produce oxygen on long voyages. The fact that he wrote in Russian, combined with his retiring nature, left him scarcely known abroad for many years.

Importance of exhaust velocity

20TH CENTURY TO WORLD WAR II

In Sweden, about the turn of the century, Wilhelm Unge invented a device described as an "aerial torpedo." Based upon the stickless Hale rocket, it incorporated a number of design improvements. One of these was a rocket motor nozzle that caused the gas flow to converge and then diverge. Another was the use of smokeless powder based on nitroglycerin. Unge believed that his aerial torpedoes would be valuable as surface-to-air weapons against dirigibles. Velocity and range were increased, and about 1909 the Krupp armament firm of Germany purchased the patents and a number of rockets for further experimentation.

In the United States, meanwhile, Robert Hutchings Goddard was conducting theoretical and experimental research on rocket motors at Worcester, Massachusetts. Utilizing a steel motor with a tapered nozzle, he achieved greatly improved thrust and efficiency. Another of Goddard's concepts was a high-altitude research rocket whose motor was fired in pulses. Somewhat similar to the pulsed-momentum principle suggested by Kibalchich and Ganswindt, the impulses were to have derived from charges of solid fuel injected into the combustion chamber in rapid succession. In 1916 Goddard approached the Smithsonian Institution for financial support. It was forthcoming in a few months.

During World War I Goddard developed a number of designs of small military rockets to he launched from a lightweight hand launcher. By switching from black powder to double-base powder (40 percent nitroglycerin, 60 percent nitrocellulose), a far more potent propulsion charge was obtained. These rockets were proving successful under tests by the United States Army when the Armistice was signed; they became the forerunners of the bazooka of World War II. Goddard's main interest, however, was in utilizing the new potential of rockets to reach high altitudes. His notebooks ultimately revealed such imaginative concepts as a circumlunar rocket to carry a camera to photograph the far side of the Moon, ion and nuclear rocket propulsion, and manned and unmanned interplanetary exploration.

Backed by the Smithsonian Institution, Goddard switched from solid to liquid propellants and launched

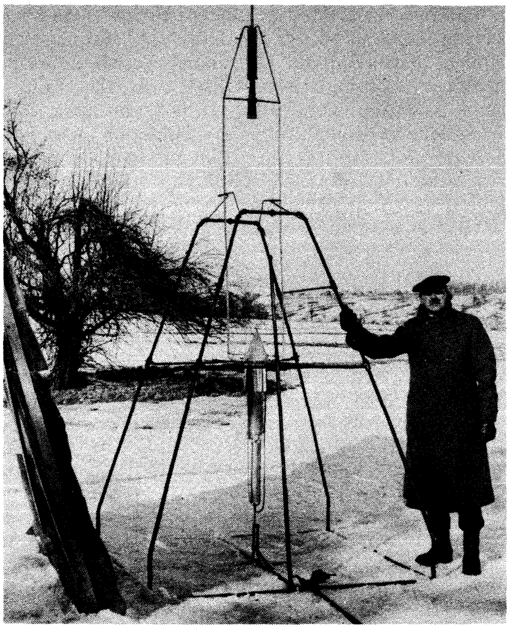

Figure 3: R.H. Goddard, U.S. rocket pioneer, with the liquid-propellant rocket he designed and launched in 1926.
By courtesy of Mrs. Robert H. Goddard

the first liquid-propellant rocket (liquid oxygen and gasoline) on March 16, 1926 (see Figure 3). It reached an altitude of only 41 feet (12 metres) and landed only 184 feet (56 metres) away, but the significance was as great as the few feet flown by the Wright brothers at Kitty Hawk.

Picking up the pieces, Goddard modified the motor nozzle length, increased the throat diameter, strengthened the launching stand, and flew the apparatus again on April 3. No public report of this success was made.

Later, supported by Clark University and Guggenheim Foundation funds, Goddard developed further research rockets in Roswell, New Mexico. Although he never achieved the results he knew were possible, Goddard was a brilliant inventor. His later designs utilized both turbine-driven pumps and gyroscopic stabilizers. Vanes were used to deflect the rocket exhaust to correct deviations from the planned flight path.

In his paper "A Method of Reaching Extreme Altitudes" Goddard discussed the possibility of a rocket reaching the Moon with a payload of flash powder to signal its arrival to astronomers. The significance of this work, like that of Tsiolkovsky's, was that the suggestions were made not by an exuberant inventor or enthusiast but by a thoughtful scientist with a sound academic background.

World War I actually saw little use of rocket weapons, despite successful French incendiary antiballoon rockets and a German trench-war technique by which a grappling hook was thrown over enemy barbed wire by a rocket with a line attached. Many researchers besides Goddard used the wartime interest in rockets to push experimentation, the most noteworthy being Elmer Sperry and his son, Lawrence, in the United States. The Sperrys worked on a concept of an "aerial torpedo," a pilotless airplane, carrying an explosive charge, that would utilize gyroscopic, automatic control to fly to a preselected target. Numerous flight attempts were made in 1917, some successful. Because of interest in early military use, the U.S. Army Signal Corps organized a separate program under C.F. Kettering in Ohio late in 1918. Seventy-five aircraft were ordered built just before World War I ended.

Features of the Kettering design

The Kettering design used a gyroscope for lateral control to a preset direction and an aneroid barometer for pitch (fore and aft) control to maintain a preset altitude. A high angle of dihedral (upward tilt) in the biplane wings provided stability about the roll axis. The aircraft was rail-launched. Distance to target was determined by the number of revolutions of a propeller. When the predetermined number of revolutions had occurred, the wings of the airplane were dropped off and the aircraft carrying the bomb load dropped on the target.

The limited time available to attack the formidable design problems of these systems doomed the programs, and they never became operational.

In Britain, even earlier, A.M. Low conceived of a similar project, but two tests made in 1917 had little success. Following World War I the British continued a small development program of radio-controlled seaplanes, with known flights being made in 1927 and 1930. In the United States the Sperry automatic control system was utilized in work from 1920 to 1926.

In 1923 an obscure German mathematics teacher, Hermann Oberth, published ***Die Rakete zu den Planetenräumen*** ("The Rocket into Interplanetary Space"). In this thin pamphlet was set forth, with a grasp remarkable for his time, the potentialities of rockets to achieve great velocity and to provide the means for manned space exploration. In ***Wege zur Raumschiffahrt*** ("Way to Space Travel"), in 1929, Oberth not only set forth design concepts for immense interplanetary space vehicles utilizing clustered liquid-propellant motors but also included a chapter on electric propulsion and the ion rocket (see below ***Electrical propulsion systems)*** predating actual development work on electrostatic propulsion by 30 years.

The decade that followed was an exciting one. Germans such as Walter Hohmann and the Austrians Baron Guido von Pirquet and Hermann Noordung published technical studies on rocket power and space vehicles. In France, the famous aviator and test pilot Robert Esnault-Pelterie lectured and wrote on high-altitude rockets and interplanetary flight. It was Esnault-Pelterie who first used the term astronautics. In 1929 Esnault-Pelterie and the French banker André Hirsch established an annual astronautics award for the experimenter who had done most to further space flight. In the Soviet Union, researchers were interpreting and expanding Tsiolkovsky's work. In the period 1927–33 rocket and space flight societies were formed in Germany, Austria, the Soviet Union, the United States, and Great Britain. These groups provided a meeting place for discussion and experimentation, and their journals became a means of disseminating information.

Formation of rocket and space flight societies

As World War II approached, minor and varied experimental and research activities on rockets and guided missiles were underway in a number of countries. But in Germany, under great secrecy, there was concentrated effort. In the Soviet Union, experimental sounding rockets were built by enthusiasts in Moscow and Leningrad. Minor financial support was given by the government. Liquid-propellant motors were designed and tested, and in 1936 a sounding rocket altitude of more than three miles was reported. Other research was conducted on an engine for a rocket-powered airplane designed by S.P. Korolev, who later became the leading Soviet space vehicle designer.

In the United States, Goddard was at Roswell, working with a small crew of technicians, making many improvements in his sounding rocket design. There he constructed and launched 31 rockets, reaching 2,000 feet (600 metres) altitude in 1930 and 7,500 feet (2,300 metres) in 1935. Goddard was a brilliant innovator. He worked under self-imposed secrecy, and few details of his work were known until after World War II.

Elsewhere in the United States, the American Rocket Society conducted a number of rocket engine and flight tests in the vicinity of New York City. At the California Institute of Technology, under Theodore von Kármán, a number of graduate students started a program of rocket research and development in 1936. Backed by Guggenheim Foundation funds, detailed scientific studies of solid- and liquid-propellant rocket technology were made, and with military support solid-propellant formulations were developed. Rockets also were studied for the purpose of assisting the takeoff of heavily loaded aircraft.

In France, Esnault-Pelterie and others were receiving some military support on small liquid- and solid-propellant rocket motors. Across the Channel in Great Britain, amateur rocket enthusiasts were prevented from experimentation by stiff laws relating to explosives. Military rocket research was confined to utilizing smokeless cordite powder.

Rocket development in Germany

But in Germany, successful flights as high as one mile with gasoline–oxygen-powered rockets were made in 1931–32 by the German Rocket Society. Funds for such amateur activities were scarce, and the society sought support from the German Army. The work of Wernher von Braun, a member of the society, attracted the attention of Capt. Walter R. Dornberger. Von Braun became the technical leader of a small group developing liquid-propellant rockets for the German Army. By 1937 the Dornberger–Braun team, expanded to hundreds of scientists, engineers, and technicians, moved its operations from Kummersdorf to Peenemiinde, a deserted area on the Baltic coast. Here the technology for a long-range ballistic missile was developed and tested (see below Surface-to-surface: guided missiles).

Two other prewar German activities deserve mention. One was the rocket engine design and development work of the Austrian Eugen Sanger. A brilliant engineer, Sänger had built and tested rocket motors at the University of Vienna. The German Air Force invited Sanger to build a rocket research establishment at Trauen near Hannover.

The other development was the work of Hellmuth Walter, who developed hydrogen peroxide rocket motors. An experimental Heinkel aircraft powered by such an engine made a successful flight in February 1937.

II. Military Systems—World War II to present

World War II saw the expenditure of immense resources and talent for the development of rocket-propelled weapons. Except in the case of Germany, the greater part of the effort was in development of unguided rockets. As German resistance collapsed in 1945, the Allies avidly sought details of rocket and guided missile development. Particularly sought were the key personnel, who had years of experience in the design, development, and testing of missile system components: propulsion, airframe, guidance, and warheads. More than 100 specialists, headed by the foremost expert, Wernher von Braun, surrendered to the U.S. Army and moved to the United States in 1945

MILITARY ROCKETS AND GUIDED MISSILES

The four major categories of military rockets and guided missiles are: surface-to-surface, surface-to-air, air-to-surface and air-to-air. Free flight, or unguided military rockets are included in appropriate surface- or air-launch categories. Submarine- (underwater-) launch missiles are included in the surface-to-surface launch category. In the following summation, the developments relating to each of the four categories are taken up in turn.

Surface-to-surface. Free-flight rockets. Germany used widely a battlefield rocket, the Nebelwerfer, of 15-centimetre (about six-inch) and 21-centimetre calibre, from six-barrelled launchers. The 15-centimetre rocket was about 40 inches (100 centimetres) long, weighed about 80 pounds (35 kilograms), could be fired at the rate of one per second, and carried a high-explosive warhead. Maximum range was more than 6,000 yards (six kilometres).

The Rheinbote

Other German developments included the Panzerfaust and Panzerschreck, hand-held tube-launched rockets. One other noteworthy rocket was the Rheinbote, a four-stage, solid-propellant rocket. It weighed nearly two tons, was about 40 feet (12 metres) long, and had an impressive range—135 miles (220 kilometres). The payload of 88 pounds (40 kilograms) of high explosive, however, could not compete with other weapons such as aircraft bombardment and the V-2. The Rheinbote was significant, nevertheless, in that practical recognition was made of the value of the step principle suggested by Haas almost 400 years before.

In Great Britain, a five-inch rocket with a 30-pound explosive warhead was developed. Its range was two to three miles. These rockets, fired from specially equipped naval vessels, were used in heavy coastal bombardment prior to landings in the Mediterranean. Firing rates were 800–1,000 in less than 45 seconds from each ship.

The United States did not commence active development of rockets until mid-1940. At that time, the National Defense Research Committee (NDRC) authorized a program under the direction of C.N. Hickman, who had worked with Goddard on the tests of hand-launched rockets at Aberdeen in 1918. Hickman supervised the development of a refined design, known as the bazooka. About 20 inches long and weighing 3.5 pounds, the rocket was fired from a shoulder launcher that weighed 14.5 pounds. The bazooka was used extensively against tanks. Its maximum range was short (600 yards) and it travelled slowly, but it carried a potent shaped-charge warhead.

Another United States Army development was the Calliope, a 60-tube launching projector for 4.5-inch rockets mounted on a Sherman tank. The launcher was mounted on the tank's gun turret, and both azimuth (horizontal direction) and elevation were controllable. Rockets were fired in rapid succession (ripple-fired) to keep the rockets from interfering with one another as they would in salvo firing. Other launchers were developed for trucks and jeeps.

Close liaison was established between the U.S. committee and similar research groups in Great Britain. Advantage was taken of earlier rocket developments by the British. In this cooperative effort the United States developed an antisubmarine rocket-propelled weapon, known as Mousetrap, based upon a similar British design, Hedgehog.

Other conventional rockets developed in the United States included a 4.5-inch barrage rocket with a range of 1,100 yards and a five-inch rocket of longer range. The latter was used extensively in the Pacific theatre of war from launching barges against shore installations, particularly just before landing operations. The firing rate of these flat-bottom boats was 500 per minute. Other rockets were used for smoke laying and demolition. Because the United States had great industrial capacity, unhampered by air raids, and urgent needs for its own forces as well as for its Allies, its production of solid-propellant rockets increased to a high rate by the end of the war. The United States produced more than 4,000,000 of the 4.5-inch rockets and 15,000,000 of the smaller bazooka rockets during the war.

Soviet barrage rockets

As far as is known, Soviet rocket development activity during World War II was limited. Extensive use was made of barrage, ripple-fired rockets. Both A-frame and truck-mounted launchers were used. The Soviets mass-produced a 5.1-inch rocket known as Katyusha. From 16 to 48 Katyushas were fired from a boxlike launcher known as the Stalin Organ, mounted on a gun carriage.

After World War II, the impetus of advanced rocket designs of free-flight rockets continued at a much slower pace. By 1950 the United States Army had begun development of the Honest John rocket; it became operational in 1955. The Honest John is 24.8 feet (7.6 metres) long, about 30 inches (75 centimetres) in diameter, and weighs 4,700 pounds (2,100 kilograms). It has a range of about 23 miles (37 kilometres) and can be equipped with either a high-explosive or nuclear warhead. The rocket is both spin-stabilized and fin stabilized. After it leaves the launcher, small rocket motors located forward of the head of the sustainer engine (but arranged tangentially to it) fire and impart a slow spin to the rocket. The four large stabilizing fins at the aft end of the rocket are set at a slight angle to maintain the spin.

A smaller version, Little John, was developed especially for use with airborne infantry divisions. Unlike the larger rocket, Little John is spin stabilized by the launching rail as it is fired; the spin is maintained by slightly offset fins.

Following World War II the Soviet Union produced its Frog series of large, solid-propellant, ballistic free-flight rockets. (In the absence of public designation of Soviet missiles, the code names [*e.g.*, Frog] used by the North Atlantic Treaty Organization are used in this article.) The Frog 1 missile, in service since about 1957, is a single-stage spin-stabilized rocket 31 feet (nine metres) long with a body diameter of about two feet (0.5 metre), a bulbous nose, and six fins with a span of three feet three inches (one metre). The gases exhaust through a cluster of seven nozzles. The missile is carried on a tracked armoured vehicle and is believed to be capable of delivering either a conventional or a nuclear warhead a distance of about 15 miles (25 kilometres). The latest version is the Frog 7, displayed in 1965. This appears to be a much cleaner design, cylindrical in shape, with four small fins and a main nozzle ringed by 12 small nozzles. It is rail-launched and carried by a wheeled transporter erector.

Between the end of World War II and 1960 the development of smaller solid-propellant rockets spread to other countries, primarily because of the effectiveness of such weapons. Thus by the 1960s all major powers were developing and producing antitank and battlefield-support rockets.

Guided missiles. In Gerniany, as mentioned above, the army was developing a long-range ballistic missile at Peenemiinde. The A-4 (popularly known as the V-2, for Vergeltungswaffen Zwei, "vengeance Weapon Two") was a remarkable engineering achievement (see Figure 4).

Camera Press—Publix

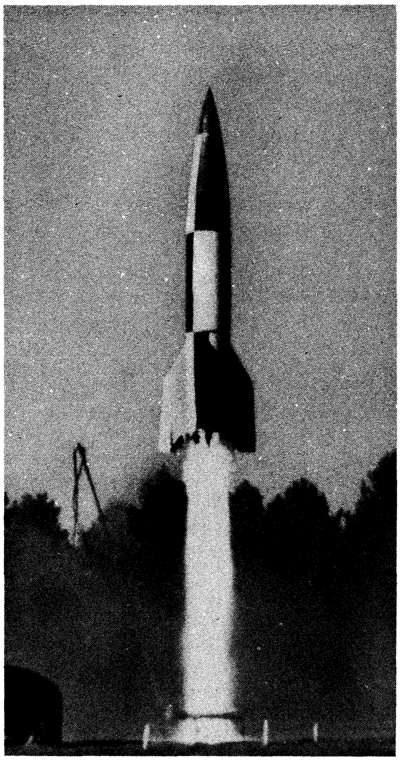

Figure 4: German V-2, nearly 47 feet long, a 13.5-ton missile with a 200-mile range. First fired in 1944, it carried a conventional warhead weighing one ton.

The V-2 rocket was nearly 47 feet (14 metres) long, had a cylindrical diameter of 5.5 feet (1.5 metres), and weighed about 13.5 tons at takeoff, including the one-ton warhead. Propellants were liquid oxygen and a 75 percent ethyl alcohol–water mixture. Approximately 8,400 pounds of alcohol and 10,800 pounds of oxygen were burned at a rate of 300 pounds per second. The rocket motor produced a 55,000-pound thrust for about one minute, after which the engine was shut off. Propellant supply was by turbopump (see below *Propellant supply system*). Yaw and pitch control was accomplished by two pairs of graphite carbon vanes in the rocket exhaust. Ignition of the alcohol–liquid oxygen propellants was effected by a pyrotechnic pinwheel inserted in the motor. Maximum range was about 200 miles (320 kilometres).

The first operational V-2 was fired against Paris on September 6, 1944. Two days later, the first of more than 1,000 missiles was fired against London. The missile travelled on a ballistic arc trajectory, reaching a maximum speed of more than one mile per second and an altitude of 60 to 70 miles. Since it approached the target faster than the speed of sound, there was no warning of its approach. By the end of the war about 4,000 of these missiles had been launched from mobile bases against Allied targets. During February and March 1945, only weeks before the war in Europe ended, an average of 60 missiles was launched weekly.

V-2 fired against London

Although the V-2 did not become a decisive weapon, it was a landmark achievement in rocketry. Large rocket motor developments after World War II, in both the United States and the Soviet Union, drew heavily upon V-2 engine design.

The only other relatively long range, surface-to-surface guided missile to see action in World War II was the V-1, or "buzz-bomb," a development of the German Air Force. The V-1 has been called, from an engineering point of view, an aerial counterpart of the naval torpedo. The analogy is striking in several ways. Once the V-1 was launched, its course could not be corrected, being determined by a preset guidance system. An accelerometer, a sensitive instrument for detecting accelerations, sensed deviation to the left and right of the programmed flight path and sent correcting signals to the control surface actuators. The missile's altitude was sensed and maintained in a similar manner by a barometer, and range was determined by the number of revolutions turned by a small propeller in the nose of the missile. When the requisite number of revolutions, corresponding to a linear range, had been made, a signal was sent to the aerodynamic control surface actuators to cause the V-1 to dive vertically onto the target. The average range was 150 miles. Launching ramps and a hydrogen peroxide-powered catapult boosted the V-1 to flying speed.

Pulse-jet engine in the V-1

The V-1 used a unique pulse-jet engine that found later employment in early post-World War II Soviet and U.S. missiles. Air enters a diffuser through a series of spring-loaded flapper valves that open as the air passes through them and then close when the air is in the combustion chamber. At this point in the firing cycle, kerosene from a gas-pressurized tank is sprayed into the chamber and ignited by a spark plug. As the chamber pressure of the burning gas rises, the flapper valves close and the exhaust gases are forced through the nozzle of the motor. The V-1 warhead was a 2,200-pound charge of high explosive set off by an impact fuze.

A final but significant weapon under development by the Germans during World War II, and one that spurred investigation in Great Britain, France, the Soviet Union, the United States, and Switzerland, was the X-7 antitank missile. Although this missile was not developed in time for combat, its technology set the pattern for practically all antitank guided missiles developed during the next 20 years. The X-7 was a solid-propellant winged rocket with a shaped-charge warhead and a range of about half a mile. This missile was to have been guided in flight by means of signals sent over two wires connected to control surfaces located on the wings, similar to the X-4 air-to-air missile (see below). The operator visually followed the missile in flight and sent guidance correction signals by manual control.

When World War II came to a close in August 1945, development and production of rockets was a massive enterprise in the United States and Great Britain. Despite a few ingenious uses of rocket power, however, the major effort was along conventional lines, adapting technical improvements to existing weapons. Nowhere else was there the depth of appreciation and scope of plans for tactical guided missiles or long-range ballistic rockets that there was in Germany. Recognition of the potential of rocket power by the Allied powers came too late in the war to enable them to catch up with German developments.

Appreciation of the potential importance of German technical efforts was indicated by the speed with which technical intelligence teams followed close behind front-line troops as they moved across Germany. These teams obtained masses of technical data, design drawings, and missiles. They also interrogated key scientists and missile engineers. The top planning and technical staff of Peenemiinde, headed by Dornberger and von Braun, fled south in the last few days of the war in order to surrender to U.S. troops. The Soviet troops that captured Peenemiinde found mostly wreckage and had orders to destroy what was left. Soviet forces, however, took many German technicians to the Soviet Union. Thus, the U.S., France, Great Britain, and the Soviet Union all had the benefit of information on rockets and guided missiles captured in Germany. In general, early postwar development of rockets followed most of the lines suggested by German work. Rockets were used to propel all types of guided missiles, competing successfully in these missions with air-breathing jet engines.

The United States obtained not only the services of top German rocket experts but also, from the underground V-2 factory at Niedersachswerfen, enough V-2 components for about 100 complete vehicles. About 70 V-2s were fired during the period 1946–51 at White Sands (New Mexico) Proving Ground. These firings provided much experience in the handling and launching of large rockets.

V-2 firings in the U.S.

The long-range ballistic missile was not a major development in the United States until 1954. Until that time air-breathing subsonic missile developments such as the Snark and Navaho were counted upon by military planners to supplement and supersede long-range, strategic-bomber aircraft. These vehicles were essentially unmanned, turbojet- or ramjet-engine-powered, high-speed aircraft equipped with warheads. The Corporal (75-mile range), with a mobile launcher, developed by the U.S. Army, was operational by this time as a battlefield support weapon.

By the 1960s the Pershing missile (400-mile range) replaced the Corporal. Capable of carrying either a conventional or nuclear warhead, Pershing is deployed in Europe.

Numerous wire-guided antitank rockets presently operational have been built by the United States, Great Britain, France, and many other countries.

In 1954 two developments put the intercontinental ballistic missile (ICBM) in a new light. One of these developments was the thermonuclear bomb, with destructive power measured in megatons (millions of tons of TNT equivalent). The other was the miniaturization and refinement of inertial guidance systems (see GYROSCOPE), so that they became sufficiently accurate to place the warhead of the ICBM close to a target 5,000 miles or more away.

The first ICBM authorized in the United States was the Atlas, followed later by the Titan. The Atlas was a one and one-half-stage vehicle. Whereas a two-stage vehicle drops both first-stage rocket engine and tankage, the one and one-half-stage vehicle drops only the rocket engine, and the second stage continues to use the original tankage. The first Atlas was fired full range from the Cape Canaveral (now Cape Kennedy, Florida) missile range in November 1958. The Titan I ICBM was a conventional two-stage vehicle. First successful tests of the Titan were made in 1959. Both the Atlas and Titan burned liquid oxygen and hydrocarbon fuel (similar to kerosene).

A major logistic problem in ballistic missiles using cryogenic (extreme low-temperature) propellants such as liquid oxygen is the necessity for fuelling just prior to launching. This weakness, which means delay in defensive, retaliatory fire, can be eliminated by the use of solid propellants or storable noncryogenic propellants. A later version of Titan, Titan II, used a higher performance propellant combination of nitrogen tetroxide and hydrazine-based fuel. This propellant combination permits the missile to stand ready, fully loaded for firing.

Development of solid propellants to a level of performance near that of liquids achieved such progress by 1958 that a solid-fuelled ICBM, the Minuteman, was authorized.

For greater defense against attack, the Minuteman was designed to be launched from a 90-foot underground concrete silo. Minuteman I was first launched in 1961. Consisting of three stages, the missile was 54 feet (16 metres) long. In September 1964, 650 Minuteman I missiles were in place and an improved Minuteman II was in development. By 1971 a further improved Minuteman III was test launched. A recent version is nearly 60 feet long and has the capability of carrying MIRV warheads (see below Warheads). Range is over 7,000 miles.

In 1947 the United States Navy demonstrated that a V-2 could be launched from the deck of a ship at sea. The problems associated with the production and storage of liquid propellants aboard ships soon turned the navy toward a quest for a solid-propellant IRBM; the result was the two-stage Polaris, first tested in 1958 and fired underwater in 1960.

The Polaris missile

Launching of Polaris missiles is accomplished by compressed air. The first-stage rocket motor fires only after the missile is in the air, above the surface. Sixteen Polaris missiles are carried in two parallel rows of eight on each of the nuclear-powered United States fleet ballistic missile submarines. In 1971 a program to replace Polaris missiles with the longer, wider diameter Poseidon missile (see Figure 5) was begun. The Poseidon, like Minuteman III, is capable of carrying MIRV warheads.

By courtesy of the U.S. Navy

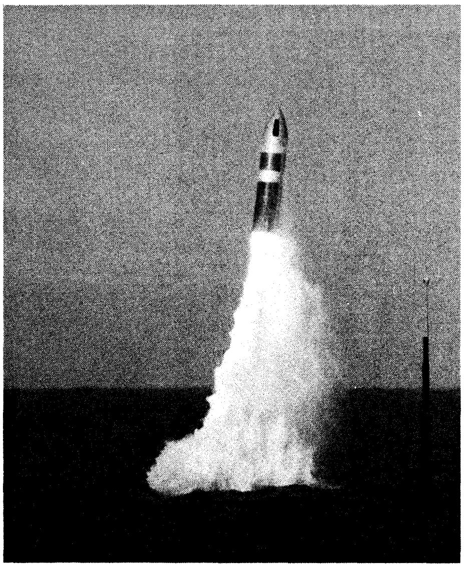

Figure 5: U.S. Poseidon missile being launched from a nuclear- ower red submarine.

Another submarine-launched missile is the antisubmarine Subroc. Launched submerged, the missile breaks the surface and is rocket-propelled on a ballistic trajectory toward an enemy submarine. Re-entering the water, the missile assumes the role of a homing torpedo.

Ten years after World War II, the United States Air Force and Army each undertook the development of an IRBM. The air force Thor and the army Jupiter used the same liquid-propellant engine, and each had a range of 1,600 miles (2,600 kilometres).

Great Britain commenced development of the Blue Streak IRBM but cancelled it in 1960. France, after a late start, began development of a three-stage, solid-propellant, 2,000-mile-range ballistic missile, but progress has been slow. The technology has been used also for the French space launch vehicle, Diamant.

Developments in IRBM and ICBM design in the Soviet Union paralleled United States efforts in the years immediately following World War II. The Soviets fired several captured V-2 missiles from the rocket proving ground at Kapustin Yar in 1946 and 1947.

Early Soviet surface-to-surface guided-missile developments borrowed heavily from German technology, but later Soviet weapons were original designs. The Scud A is a liquid-fuelled, single-stage missile that appears to derive from the German Wasserfall surface-to-air missile. This missile and its successor, the Scud B, are both believed to have a range of about 50 to 100 miles and probably are guided by radio commands.

The first Soviet IRBM's were the Shyster (700-mile range), Sandal (1,200-mile range), and Skean (2,000-mile range), all single-stage vehicles. The Shyster is basically a stretched and uprated version of the German V-2 rocket and is fuelled by liquid oxygen and kerosene. The Sandal and Skean are powered by storable propellants and appear to be essentially original Soviet designs. The Sandal was the missile deployed to Cuba in 1962 and withdrawn after crisis negoiiaiions.

The Soviet Scud missiles

Soviet tactical and medium-range missiles are highly mobile, mounted on cross-country vehicles that allow them to advance with combat troops. They can be concealed in wooded country, making detection by aircraft and satellites more difficult. Scud is an example. Two variants of this storable-liquid-propellant missile are known. Scud A travels on a tracked vehicle of the type used for the unguided missile Frog, while the larger Scud B is carried on a fully enclosed cross-country vehicle of the type first shown in November 1965. Each is placed on a simple launch platform at the rear of the vehicle by a tubular cradle that elevates into a vertical position. It is believed that guidance is achieved by a preset inertial system acting upon steerable tail fins.

Scapegoat is carried by a tracked transporter-erector, the full weapon system being designated Scamp in NATO nomenclature. The 35-foot missile appears to be the top two stages of Savage, the Soviet silo-based solid-propellant ICBM.

Scrooge, also mobile on a heavy tracked transporter, is concealed within a cylinder 62 feet long. This launch tube is raised vertically behind the vehicle, and the missile is fired directly from it.

Weapons of this type can be moved effectively along the entire frontier of the Soviet Union, providing coverage of western Europe, the Middle East, and Southeast Asia. Scrooge has been reported deployed as far east as the Chinese border near Buir Nuur in Mongolia. Estimated range is 3,000 to 3,500 miles.

The first Soviet ICBM is believed to be a dual-purpose vehicle used both as an ICBM and as the basic booster for much of the Soviet space program. It was displayed publicly for the first time at the 1967 Paris Air Show, where it was placarded as the booster for the Vostok spacecraft, but it has probably been in use since the late 1950s. The vehicle is parallel staged, with a central sustainer core to which are attached four large, tapered boosters. The sustainer and boosters are powered by clusters of thrust chambers, all of which ignite upon launching; midway in the powered flight the four-booster tank and engine combinations are detached while the sustainer continues burning. The propellants are liquid oxygen and a hydrocarbon, and the engines develop a total sea-level thrust of about 1,000,000 pounds.

In 1964 and 1965 the Soviets displayed the Sasin and Scrag, both tandem, liquid-propellant, long-range rockets. Scrag, which has three stages separated by interstage trusses, was described as being from the same family as the vehicles that placed Soviet cosmonauts into orbit. It does not appear, however, to have become operational as an ICBM.

The premier Soviet missiles in this class are the SS 11, SS 13 Savage, and SS 9 Scarp. The SS 11 is reported to employ storable liquid propellants, but by 1971 it had not been publicly displayed by the Soviet authorities. Savage, solid-fuelled, follows the format of the U.S. Minuteman ICBM but is somewhat larger. The liquid-fuelled Scarp is much larger, on the lines of the U.S. Titan ICBM. The first stage has six fixed-thrust chambers and four swivel-mounted vernier rocket motors, small auxiliaries used for trajectory correction. It can be used both as a conventional ICBM launched across the Northern Hemisphere or as a fractional orbit bombardment system (FOBS) weapon (see below *Military* space vehicles).

In the FOBS application the Scarp could be launched almost to orbital velocity to attack the United States over the Southern Hemisphere, thus avoiding the Ballistic Missile Early Warning System (BMEWS) radar stations in Britain, Greenland, and Alaska.

By the spring of 1970 the number of SS 11 and SS 13 ICBM's deployed were stated by the U.S. secretary of defense to be around 800. Also deployed were about 220 SS 9s, each capable of carrying a warhead of some 25 megatons yield.

The Soviet Sawfly

In 1962 the Soviets displayed a 48-foot-long missile, Sark, describing it as a submarine-launched missile, although its very heavy construction and large size made it seem unsuitable for operational use in submarines. Two years later the smaller Serb was displayed and also credited with a submarine application. The 33-foot-long missile is similar in configuration to the U.S. Polaris. It has two solid-fuelled stages with a range of less than 1,000 miles. A submarine-launched ballistic missile that has recently become operational is Sawfly. First displayed in 1967, the two-stage missile is 42 feet (13 metres) long and about five feet nine inches (1.75 metres) in diameter. The four first-stage nozzles are gimbal-mounted, permitting the stages to be moved freely so that their direction (thrust vector) can be controlled. Range is reported to be around 1,300 miles (2,100 kilometres).

The most advanced Soviet nuclear-powered submarine in the early 1970s was the Y-class, which has 16 launch tubes for missiles of the Sawfly family.

Regardless of the country of origin, all IRBM's and ICBM's are equipped with either nuclear or thermonuclear warheads, because (1) it is economically impractical to use such an expensive missile to deliver a relatively small amount of high explosive; and (2) the unavoidable inaccuracies in range and direction make essential the far-reaching effects of a nuclear explosion.

Table 1 gives information on representative surface-to-surface missiles of various nations.

Surface-to-air. The major purpose of the class of surface-to-air weapons is to intercept and destroy enemy aircraft, particularly at altitudes beyond the effective capability of conventional anti-aircraft artillery. During World War II high-altitude bombing above this range necessitated the development of rocket-powered weapons.

In Great Britain, initial effort was aimed at achieving the equivalent destructive power of the three-inch and later the 3.7-inch anti-aircraft gun. Single, double, and then multiple launchers were produced.

Two important innovations were developed by the British in connection with the three-inch rocket. Both devices were directed against German dive bombers. One was a rocket-propelled aerial-defense system. A parachute and wire device was rocketed aloft, trailing a wire that unwound at high speed from a bobbin on the ground. Altitudes as high as 20,000 feet were attained. Several versions of this were used, quite successfully, from ships. The other device was a type of proximity fuze utilizing a photoelectric cell and thermionic amplifier. A change in light intensity on the photocell caused by light reflected from a nearby airplane (projected on the cell by means of a lens) triggered the explosive shell.

The only significant anti-aircraft rocket development by the Germans was the Taifun. A slender, six-foot liquid-propellant rocket of simple concept, the Taifun was intended for altitudes of 50,000 feet. The design embodied coaxial tankage of nitric acid and a mixture of organic fuels. This weapon, though planned for mass production, never became operational.

Wasserfall supersonic missile

During World War II Germany made efforts to produce effective surface-to-air missiles. Three of those under development were subsonic (less than the speed of sound): the Schmetterling and Enzian resembled stubby midwing aircraft, and the Rheintochter had cruciform wings. All used solid-propellant boosters, or takeoff rockets, and sustainer motors, except that there was a liquid-propellant version of the Rheintochter. Altitude capability was about 50,000 feet. The Wasserfall was a superior weapon designed to operate at supersonic (greater than the speed of sound) speeds. A single-stage missile weighing 7,800 pounds at takeoff, this weapon was powered by a 17,000-pound-thrust motor and reached a velocity of 2,500 feet per second. Maximum altitude was 60,000 feet, and the weight of the warhead was 330 pounds. Propellants were nitric acid and an organic liquid, vinyl isobutyl ether. All of these weapons would have been effective against enemy aircraft flying at 15,000 to 30,000 feet. Although none

became operational, their development reached a point of experimentation that proved that missiles could be guided by radar beams.

Two anti-aircraft missiles were designed in the United States in the latter days of the war: the Lark and the Little Joe. The former was a 14-foot-long liquid-propellant weapon with semi-active radar homing. Weighing 1,200 pounds, it was accelerated to operational speed by two solid-propellant jato (jet-assisted-takeoff) units. It could deliver a 100-pound warhead to a range of 38 miles. The Little Joe was an 11-foot-long solid-propellant missile with a range of 2.5 miles. Its payload was a 100-pound warhead designed to counter Japanese kamikaze attacks on U.S. Navy ships. Neither weapon became operational.

Following World War II the major nations continued the development and refinement of anti-aircraft guided missiles. In the United States the navy initiated a research program the purpose of which was to develop a ramjet engine suitable for use in a high-performance anti-aircraft missile. Ultimately the Talos missile resulted. Thirty-three feet long, this ship-launched missile has a slant range of about 75 miles. Other U.S. Navy surface-to-air missiles are the Terrier, Tartar, and Sea Sparrow. The Standard missile is replacing Terrier and also has a surface-to-surface capability.

The United States Army concentrated its efforts in the field of anti-aircraft weapons on the Nike group of missiles. The first of these was the Nike Ajax, which was first test-fired in 1951 and which remained deployed with the army until 1961. The missile was 21 feet (six metres) long and weighed 2,455 pounds (1,115 kilograms). With a range of 25 miles (40 kilometres), it had a liquid-propellant engine and a velocity of 1,500 miles (2,400 kilometres) per hour.

An advanced version of the Ajax was conceived in 1953, known first as Nike B, later as Nike Hercules. The Hercules was 41 feet long and weighed 10,000 pounds. It had a solid-propellant motor, could carry both nuclear and high-explosive warheads, and had a range of 85 miles. Both the Nike Ajax and the Nike Hercules employed radar-command guidance.

Safeguard anti-ballistic missile system

Out of the early experience in the Nike program also grew the possibility for an antimissile missile. The U.S. version was the Safeguard antiballistic missile (ABM) system. Safeguard consists of two missiles, the 55-foot Spartan for high-altitude missile interceptions and the 27-foot Sprint for low-altitude operations. Both are designed to carry nuclear warheads. This system was under final development in the early 1970s.

The U.S. Air Force Bomarc is ramjet powered and capable of interception at ranges as great as 400 miles. Solid-propellant boosters are used on ramjet-powered missiles to bring the engine up to operational speed of flight.

Other significant current U.S. surface-to-air missiles include the Hawk, capable of intercepting low-flying aircraft, as is the shoulder-launched Redeye. Both have homing devices.

The Soviet Union has shown numerous surface-to-air missiles: Guild, Guideline, Goa, Griffon, Gainful, Ganef, and Galosh. Of these, Guideline has been widely deployed in the Soviet Union, in Warsaw Pact countries, and in certain Middle East countries, as well as in Cuba, Indonesia, and North Vietnam. It has been used in Vietnam against U.S. aircraft with limited success.

In Egypt, during the Six-Day War of 1967, an advanced version of Guideline was used against the Israeli Air Force. The weapon, similar in many respects to the U.S. Nike Ajax, has a solid-fuel booster and a liquid-propellant (nitric acid–kerosene) sustainer. Later versions are reported to have a slant range of about 28 miles, an altitude ceiling above 60,000 feet, and a maximum speed of mach 3.5 (3.5 times the speed of sound).

Goa, first displayed in 1964, is a low-to-medium-altitude weapon mounted on a twin launcher. Used on ships of the Soviet Navy, it has also been developed as a field weapon and appeared in Egypt in 1970.

Guild was an early surface-to-air missile. Solid-fuelled, it was about 39 feet long and appeared in Moscow parades mounted on an articulated trailer behind a truck.

Another low-level weapon is Gainful, first displayed in 1967. Three of the 19.5-foot-long solid-fuel missiles are carried, on a tracked vehicle for the defense of Soviet units in the field.

As a surface-to-air weapon, Ganef is unique among Soviet missiles in its use of a ramjet for main propulsion. Four small, strap-on, solid-fuel boosters provide initial velocity. Two missiles are carried on a tracked vehicle, and the system depends on command guidance.

Novosti Press Agency

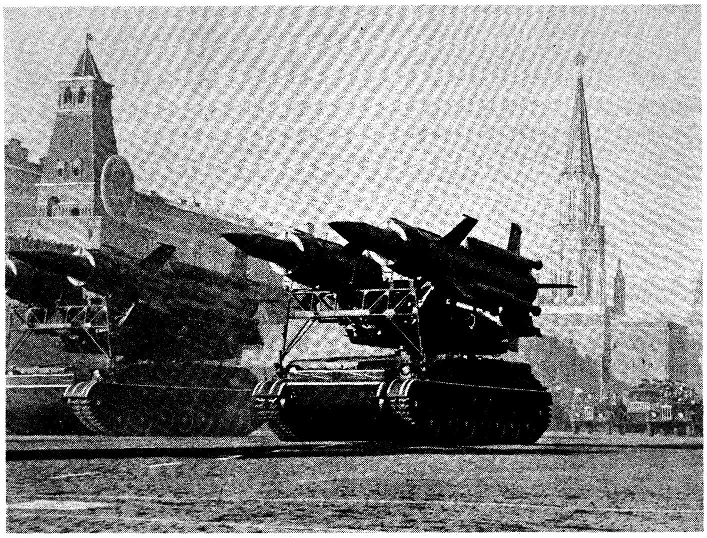

Figure 6: The Ganef, a Soviet mobile air defense weapon.

Griffon, a long-range anti-aircraft missile, is also stated to have an antimissile capability.

The more definitive antimissile missile is Galosh, a cone-shaped weapon first shown in 1964 within a tubular container measuring 67 by nine feet. The first stage has four rocket nozzles. Launching is from fixed emplacements under radar command. First sites were being established on the perimeter of Moscow in 1967.

Table 2 provides additional information on representative surface-to-air missiles.

Air-to-surface. *Free-Bight rockets.* In World War II, Great Britain, Germany, the Soviet Union, Japan, and the United States all developed airborne rockets for use against surface as well as aerial targets. These were almost invariably fin stabilized because of the effective aerodynamic forces when launched at speeds of 250 miles per hour and more. Tube launchers were used at first, but later straight-rail or zero-length launchers, located under the wings of the airplane, were employed.

One of the most successful of the German rockets was the two-inch-diameter R4M. The tail fins remained folded until launch, facilitating close loading arrangements.

The U.S. achieved great success with a 4.5-inch rocket, three or four of which were carried under each wing of Allied fighter planes. These rockets were highly effective against motor columns, tanks, troop and supply trains, fuel and ammunition depots, airfields, and barges.

Whereas British and German aircraft rockets were fin stabilized, the U.S. designs were spin stabilized, resulting in greater accuracy. The largest such rocket was the Tiny Tim. Slightly over 10 feet long, it carried 150 pounds of TNT. The solid-propellant motor developed 30,000 pounds of thrust for one second. More than 7,000,000 aircraft rockets were produced in the U.S. during 1940–45.

Glide bombs

A variation on the airborne rocket was the addition of a rocket motor and fins to conventional bombs. This had the effect of flattening the ballistic trajectory, extending the range, and increasing the velocity at impact, useful against concrete bunkers and strengthened (hardened) targets. These weapons were called glide bombs, and the Japanese had 224-pound and 815-pound versions. The Soviet Union employed 56-pound and 220-pound versions, launched from the Stormovik fighter aircraft.

***Guided** missiles.* Among the first air-to-surface guided missiles developed by the Germans was the radio-controlled, armour-piercing Fritz-X, which sank the Italian battleship "Roma" after its surrender to the Allies in 1944. Another was the Hs 293 winged bomb. More than 11 feet (three metres) long and weighing about 2,300 pounds (800 kilograms), this radio-controlled weapon destroyed a number of merchant ships in Allied convoys. Although these early versions of glide bombs required optical tracking (and, therefore, clear weather), plans were under way for television viewing of the target by the weapon and radar spotting for nighttime and foul-weather use. The U.S. developed a controlled glide bomb called the Bat, similar to the Hs 293.

The Hs 293 was a radio-guided bomb with a rocket engine using hydrogen peroxide as a propellant. This chemical was decomposed into steam by the use of aqueous potassium permanganate as a catalyst. A crew of three, a pilot, an observer, and a bombardier, were necessary to launch and direct the Hs 293 to its target. The observer's duty was to set the gyroscope that established a reference plane for the missile, and the bombardier piloted the bomb by remote control after its release from the aircraft. It was especially adaptable to targets at sea and found its greatest use there, sinking many merchant ships.

The United States Bat had a much greater range—up to 20 miles. In guidance it was in advance of the Hs 293, since it employed an active radar homing device. The Bat was a glide bomb, however, having no propulsion system. It weighed 1,000 pounds and was 12 feet long, with a wing span of ten feet. Developed primarily as a weapon for use against ships, the Bat was to be released from an airplane at an altitude of three to five miles. The bomb's velocity of 300 miles per hour was considerably slower than the 470-mile-per-hour Hs 293. Built in considerable numbers before the end of the war, the Bat was not actually used until April 1945, when it was credited with sinking a Japanese destroyer at the maximum range of 20 miles.

After 1945 the U.S. Air Force explored more complex versions of the air-to-surface missile. One of these was the Rascal, a liquid-propellant missile with inertial guidance and a range of 100 miles. By the mid-1950s development turned to achieving longer ranges. This effort was aided by the advent of lighter weight nuclear warheads. Two of the weapons developed, the United States Hound Dog and the British Blue Steel, had ranges of about 500 miles. The U.S. Skybolt missile, cancelled in 1963, was to have had a range of 1,000 miles. The cause of the cancellation was essentially the difficulty in guidance from an aerial launch; development was stopped in favour of alternative weapons, such as the fixed-base ICBM.

By the early 1970s the United States had seven operational air-to-surface missiles. Systems utilizing a basic missile, with modification for either air or surface launch, such as the Standard missile, were gaining favour.

The Soviet Union has displayed a variety of air-to-surface missiles on bomber aircraft that have been given the NATO designations Kangaroo, Kennel, Kipper, Kitchen, and Kelt. The first three have turbojet propulsion; the last two appear to have liquid-plopellant rocket engines.

The largest of these missiles is the 50-foot-long, swept-wing Kangaroo carried by the Tu-20 aircraft. Its range probably exceeds 300 miles.

Kennel, another aircraft-launched missile, is carried by the Tu-16 Badger aircraft. Powered by a turbojet, it is about 28 feet long with a wing span of about 16 feet. Its role is antishipping. A variant, Kelt, is rocket-powered with an enlarged radome.

Kipper, another antishipping missile, is also launched by the Tu-16. Turbojet-powered, it has a range of about 120 miles.

Kitchen, a more advanced Soviet air-to-surface cruise missile, is powered by a liquid-fuelled rocket engine and carried by the Tu-22. Range is probably about 200 miles.

The complexity and expense of air-to-surface missiles is great. Particularly difficult is the guidance problem. At extreme ranges, programmed and command systems generally are not feasible, and it is necessary to rely on such delicate and exacting systems as inertial guidance.

Table 3 lists representative air-to-surface missiles.

Air-to-air. ***Free-flight rockets.*** As might be suspected, aircraft-launched rockets can be used against aerial as well as ground targets, provided that the aerial targets are propeller-driven aircraft with a speed of 400 knots or less. Near the end of the war the German Me 262 jet fighter carried 48 such rockets. On one sortie, six Me 262s shot down 14 B-17 bombers during a daylight raid, without the loss of one fighter aircraft.

Rockets launched by Me 262 aircraft

After World War II the United States fitted many aircraft with 2.75-inch Mighty Mouse and Aeromite folding-fin rockets. Firing could he singly or in clusters. Another postwar development by the U.S. was a version of the army's five-inch, spin-stabilized rocket loaded by belt and fired from within the wing of the navy Skyraider aircraft.

Other countries fitted airborne rockets to aircraft for air-to-air weapons, notably Sweden (Gerda, three inches, 15.5 pounds), Italy (2.4 inches, 7.9 pounds), and Switzerland (3.15 inches, 22 pounds).

Guided ***missiles.*** As in the case of other guided missiles, Germany led in the development of the air-to-air category, although, similarly, the weapon, called the X-4, never reached operational use. An ingenious design, the X-4 was 6.5 feet (two metres) long, 8.6 inches (21.8 centimetres) in diameter, and weighed 132 pounds (60 kilograms). It had two sets of cruciform wings and fins. Two opposing wings carried pyrotechnic guide flares, and the other two carried streamlined bobbins, which trailed as much as four miles of fine copper wire. Along these wires travelled corrective directional signals that automatically imparted drag to the rear fins while the vehicle, travelling almost 600 miles (950 kilometres) per hour, spun slowly. The X-4 was powered by a rocket motor using nitric acid–hydrocarbon fuel and carried a 44-pound warhead.

After World War II the first U.S. air-to-air guided missile was the Firebird. It was ten feet long and had a solid-propellant booster and a liquid-propellant sustainer motor. It was aimed initially by radar from the launching aircraft, and it homed on the target, guided by an on-hoard radar system. First test-launched in 1947, the Firebird was considered obsolete three years later. It was replaced by more sophisticated supersonic missiles, such as the Sparrow, Falcon, and Sidewinder.

Increased range of air-to-air missiles

By the 1970s air-to-air missiles had become increasingly sophisticated. Although short-ranged (two miles) missiles such as Sidewinder 1A were still in operational use, supersonic aircraft required longer range missiles. Ranges have grown to ten to 12 miles, and the Phoenix and Falcon (AIM-47A) have ranges as great as 100 miles.

The Soviets have displayed five air-to-air missiles, NATO-coded as Alkali, Anab, Ash, Atoll, and Awl. Atoll, which resembles the U.S. Sidewinder, is widely used by the Soviet Union and by Warsaw Pact countries. It has also been exported to Afghanistan, Egypt, Cuba, Finland, India, Indonesia, Iraq, North Vietnam, and Syria.

Anab, in both infrared and semi-active radar homing versions, arms a number of all-weather interceptors. The much larger Ash, again with alternative infrared and radar homing versions, is carried by the Tupolev Tu-28 Fiddler long-range interceptor.

The earlier Alkali missile arms the all-weather MiG-17 and MiG-19 aircraft.

Table 4 gives information on representative air-to-air missiles.

MILITARY SPACE VEHICLES

Military applications of space flight are discussed in this section. For nonmilitary applications see SPACE EXPLORATION.

Following the launch of Sputnik 1 in 1957 by the Soviet Union, there was public concern that nuclear bombs might be placed in orbit for an indefinite period to be called down at will. Such concern is uninformed, however, since a bomb in orbit follows a fixed path. Hitting a planned target may require a waiting period of hours or days. On short notice such a bomb might not be able to strike a useful target. Further, a bomb system in orbit is subject to malfunction, and space maintenance is still a matter for the future. A bomb in orbit may be precisely located and therefore is subject to interception by another space power. Thus ground-based or submarine-based missile systems are capable of greater command and control, and continual testing and maintenance of silo-launched ICBM's is feasible. For these reasons the U.S.

and Soviet Union experienced no great difficulty in agreeing to a treaty to ban weapons of mass destruction from Earth orbit and from other celestial bodies.

The general uses of Earth orbital flight for military purposes are reconnaissance and surveillance; satellite inspection and interception; for securing communications; and as part of the fractional orbit bombardment system (FOBS).

The United States Air Force and United States Navy military satellites are launched by Scout, Thrust-Augmented Delta (TAD), Thor-Agena, Atlas-Agena, and Titan IIIC launch vehicles.

Soviet space launch vehicles

The Soviet military space program, as in the case of the U.S., has relied primarily on modified military ballistic missiles for space launch vehicles. Thus the Sapwood, Sandal, Skean, and Scarp have been used for more than 400 Earth orbital launches. All of the Soviet military launches are included in their Cosmos series program.

In 1968 and again in 1970 the Soviet Union apparently launched "inspector–destructor" satellite vehicles. In each case, a spacecraft was manoeuvred in orbit to the vicinity of a previously launched Cosmos satellite, then moved away, after which an explosion into many bits of debris occurred. From these observations it is generally conceded that the Soviets possess at least a rudimentary capability of satellite inspection and destruction.

FOBS is an alternative system for conventional ICBM trajectory. Instead of a trajectory on the shortest great circle path, the Soviet Union has launched test vehicles into orbit and caused the re-entry vehicle to land in the Soviet Union just before the end of the first orbit. Such a strategic ballistic missile system would have the advantage of nullifying the United States Ballistic Missile Early Warning System (BMEWS) radar watch, which "looks" north from Alaska, Greenland, and England. The Soviet SS 9, Scarp, has flown several flights that would seem to indicate interest in such a system. Inherent in FOBS would be a certain loss in accuracy because of the greater distance flown as well as a smaller warhead. The U.S. does not have an FOBS program.

DRONES, DECOYS, AND TEST VEHICLES

This category contains a variety of special-purpose vehicles closely related to guided-missile systems.

Drones. A drone is basically a pilotless aircraft, usually under radio-command guidance and widely employed as a target for anti-aircraft weapons. Powered by propeller or by turbojet, ramjet, or rocket engines, a large number of these manoeuvrable vehicles have been developed, with operating velocities as high as four times the speed of sound. Recovery, if the drone is not destroyed, is effected by controlled landing or by parachute.

Drones in reconnaissance

Another application for drones is military reconnaissance. Equipped with photographic or television cameras, the drone may be shifted from radio control to programmed inertial guidance and flown over targets at a relatively low speed and low altitude under operationally hazardous conditions.

Other applications of drones are electronic communications, surveillance, antisubmarine warfare (detection equipment and depth charges are carried by a drone helicopter), and even the rescue of downed airmen at sea.

An example of a drone target vehicle is the United States Army Roadrunner. This 25-foot, swept-wing, unmanned aircraft is powered by a ramjet engine. Boosted to flight velocity by a solid-propellant rocket, the Roadrunner can fly 30–40 minutes at speeds as great as mach 1.5. It flies at low altitude and is used to train personnel to operate Hawk surface-to-air missiles and to evaluate performance of other defense missiles.

Decoys. The decoy is a device designed to simulate by electromagnetic radiation an aircraft or ballistic-missile warhead. The purpose is to divert defensive anti-aircraft or antimissile fire. Thus a relatively small decoy can be made to appear, by electromagnetic techniques, as large as a bomber on radar screens. Or it can emit infrared and other radiation to simulate a re-entering ICBM warhead. For military reasons, details of such devices are not released to the general public.

Test vehicles. The term test vehicle covers a variety of special-purpose rockets and missiles designed to produce data on components or design features that will ultimately be used in much more expensive missiles and rockets. They must be scaled-down versions of the eventual rocket or missile. After World War II, for example, many aerodynamic shapes were tested at subsonic and supersonic velocities under dynamic flight conditions by affixing them to the front of solid-propellant rockets. Data were obtained by optical tracking and telemetry. In the development of a satisfactory design for ballistic missile re-entry vehicles, a five-stage rocket vehicle carried a scale model of the test shape to high altitudes; the final stage was then fired toward the Earth, achieving the re-entry velocity of an ICBM. In Project Fire, the National Aeronautics and Space Administration (NASA) in a similar manner achieved velocities equivalent to those of a lunar vehicle returning to Earth. Another special test vehicle is the Little Joe solid-propellant booster. It was developed to launch the Mercury and (a larger version) the Apollo spacecraft to an altitude at which the parachute recovery system could be tested.

The ingenious design and use of such special-purpose vehicles built from available components can reduce costs significantly, confirm design concepts, and save time.

GUIDANCE AND CONTROL

Most free-flight rockets require stabilization of some sort to minimize flight-path deflection caused by wind, nonuniformity of rocket structure, rocket-jet misalignment, and other factors.

Methods of stabilization

In the case of some barrage-type rockets launched by the thousands, dispersion errors may be accepted because of the overlapping explosive effect in the target area. Aircraft rockets are often stabilized by fixed fins located at the rear of the rocket. Folding fins that open by inertia after firing are also used. Short-range bazooka rockets and ballistic rockets of five- to ten-mile range are usually fin stabilized. Spin stabilization is used on some rockets. In these designs, the rocket nozzle is replaced by a series of smaller nozzles, canted at an angle to impart torque as well as thrust.

A unique method of wire control, based upon the German air-to-air X-4 rocket, has been used. This technique is utilized in some antitank rockets of about one-mile range. Fine wire is trailed from a pair of bobbins on the fins of the rocket, and command signals are given by the operator observing its flight through a telescope.

If a rocket is designed to operate at high altitudes, as in the case of sounding rockets, satellite launchers, and ballistic missiles of ranges greater than 100 miles, aerodynamic forces are no longer available for control because of the low density of the air. One technique, employed first by Goddard, is to place carbon or molybdenum deflection vanes within the rocket exhaust. Usually two pairs are employed for corrections about all three axes; one pair for pitch, the other for yaw and, in opposition, for roll. In flight, deviations from flight path are sensed by gyros within an automatic control (autopilot) system, and corrective signals are sent to motors that operate the vanes. This deflection system may be used also to program the tilt from vertical launch to ballistic flight path. Radio command also may be used to initiate the tilt program.

A modification of the jet vane method is the "jetevator," a ring-shaped deflector mounted at the nozzle periphery that rotates slightly into the edge of the rocket jet as required. Gimbal mounting of the engine, permitting the motor to swivel a few degrees in any direction, is widely used for flight-path control. This system was developed for the U.S. Viking and has been used successfully on IRBM'S and ICBM's.

Injection of high-pressure gas in the rocket nozzle to create a local shock wave and differential pressure is a further technique of jet deflection in use. This technique is known as thrust vector control (TVC). Magnetohydrodynamic (MHD) deflection of a rocket jet is another possible flight-control concept; since a rocket jet may be highly ionized, it is conceivable that a magnetic field may induce deflection of the exhaust gases without physical contact.

Roll control (*i.e.*, rotation about the long axis) is sometimes required, particularly on larger ballistic missiles. Small jets mounted transversely on the side of the missile are commonly used for this purpose.

Details of guidance systems in modern missiles are, of course, secret, particularly frequencies of operation, since electronic "jamming" or confusion by deliberate transmission of spurious signals by the enemy may be possible. Pulse-cdded directional signals (see TELEMETRY) have been used to avoid jamming. Some missiles carry their own small radar systems and are launched when the missile is electrically "locked-on" to the target. A ship may utiiize its large radar to track the target aircraft or vessel and continuously compute the range and bearing of the target while sending flight-correction signals to the missile in flight. Some air-to-surface missiles use television guidance, maintaining the image on the scanning screen in the same relative position after launching.

Sometimes the target may emit a signal that a missile can sense and track. Some missiles can lock on to the exhaust jet of an enemy aircraft, others on enemy radar transmitting systems.

The Snark was an early United States postwar intercontinental guided missile that utilized stellar navigation, comparing the position of stars and correcting an on-board inertial guidance platform. Powered by turbojet engines, this missile became operational in 1958 but was superseded by the Atlas ICBM. Long-range ballistic missiles have a flight time of about 30 minutes. The guidance system for these missiles is invariably inertial, using gyros and accelerometers to sense variations in velocity in each of the three axes: roll, pitch, and yaw. Having sensed a variation, the system gives correction to the flight controls to place the missile back on the programmed trajectory. Travelling along a preplanned launch path, the final-stage rocket engine is shut down at the precise moment when required velocity (about 15,000 miles per hour) and direction are achieved. The warhead and final stage continue to travel upward and follow a ballistic trajectory to the target.

Inertial guidance in ICBMS

WARHEADS

Rocket and missile warheads are conveniently divided into three categories: (1) high-explosive, (2) nuclear, or atomic, and (3) special-purpose. The first of these is generally employed on short-range tactical weapons. While it is possible to design such warheads to produce damage by either concussion (blast) or fragmentation, most depend upon some form of fragmentation. The efficiency of high-explosive warheads is a function of the size, number, weight, and velocity of the fragments produced, and the reliability of the warhead is largely a function of its fuzing system. The spray pattern of the fragments is also important and is established by the geometry of the high-explosive charge and the arrangement of the fragments upon it. Nonfragmenting high-explosive warheads for antitank weapons usually incorporate the shaped charge principle to achieve maximum penetration by concentrating the blast at one point. Nuclear warheads are used primarily, but not exclusively, on the IRBM'S and ICBM's, since it would be uneconomical and inefficient to use high-explosive heads on these long-range missiles. Typical of such missiles are the U.S. Titan, Minuteman, and Polaris. Very long range air-to-surface missiles (particularly the so-called standoff bombs), some air-to-air missiles, as well as certain short-range tactical or battlefield rockets and missiles also may employ nuclear warheads. The nuclear warheads may be either fission or fusion types; in the latter case they are called, popularly, H-bombs. The power of nuclear warheads is indicated by comparing the release of energy of a certain weapon to an equivalent weight of TNT. Thus a ten-kiloton warhead or bomb has the same explosive force as 10,000 tons of TNT, a five-megaton device has the force of 5,000,000 tons of TNT (see also NUCLEAR WEAPONS).

Because of the development of antiballistic missiles and tracking radar that can locate and identify an incoming warhead, several further refinements of warhead systems should be noted. One concept is a rocket-powered re-entry vehicle that would cause the warhead to change course to a target. By the mid-1960s, as a result of the development of antiballistic missile (ABM) sites around Moscow and other cities, the United States pressed the development of MIRV—multiple independently targeted re-entry vehicles. This system embodies a multiheaded ICBM, one that has three separately targeted nuclear warheads sent on their independent ways after the main propulsion stages of the ICBM have shut down. Installation of MIRV warheads on Minuteman III ICBM's is reported to have commenced in May 1971. U.S. Navy Poseidon fleet ballistic missiles are also scheduled to carry MIRV warheads.

Development of MIRV

III. Rocket-propulsion systems

PRINCIPLES OF ROCKET PROPULSION

Jet propulsion—of which the rocket is one type—is based upon reaction of a body to the rearward thrust of a jet of gas. The physical principle involved was set forth by Sir Isaac Newton in 1687. Newton's third law of motion states, in its simplest form, that for every action there is an equal and opposite reaction.

A simple example of reaction propulsion is the brief flight of a toy balloon after it has been filled with air and released. The forward motion of the balloon results from the rearward expulsion of air from the balloon. The thrust does not result, as sometimes erroneously presumed, from the jet pushing against the surrounding air. The force imparted by the jet is equivalent to the product of the mass flow of the air and the velocity of the jet expanded to atmospheric pressure; see equation (2), below. In the case of a chemical-propellant rocket, the jet is composed of the gaseous combustion products of the propellant mixture, which is burned inside a thrust (combustion) chamber and ejected at supersonic velocity through a nozzle. The gas velocity in a properly designed converging–diverging nozzle is sonic at the throat (most narrow) portion of the nozzle and becomes supersonic as it travels through the diverging (exhaust) end of the nozzle.

The concept of propulsive force

The concept of propulsive force (thrust) and specific impulse is best explained by the aid of simple mathematics. The propulsive force, or thrust, is basically equal to the momentum of the gas, which in turn is equal to the product of the weight of the exhaust gas and its velocity. In mathematical terms, this propulsive force is expressed as

$$F = \frac{\dot{W}}{g} \times V_e \qquad (1)$$

in which F represents thrust in pounds, W the propellant flow rate in pounds per second, g the acceleration of gravity in feet per second per second, and V_e the nozzle exhaust velocity in feet per second. For greater precision, another term must be added; the difference between the exit and ambient pressures multiplied by the nozzle exit area. The complete equation, then, becomes

$$F = \frac{W}{g} \times V_e + (P_e - P_o)A_e, \qquad (2)$$

in which P_e is the exit pressure, P_o ambient pressure, and A, the nozzle exit area. Since P_o decreases with altitude and is equal to zero in a perfect vacuum or in outer space, it may be seen that rocket engine performance increases with altitude. Thrust ratings of upper-stage rocket engines are often given both at sea level and at operating altitudes; the latter rating is always higher. Effective exhaust velocity c may be expressed

$$c = \frac{Fg}{\dot{W}} = V_e + \frac{P_e - P_o}{\dot{W}} A_e g. \qquad (3)$$

Inspection of equation (1) shows that thrust can be increased by increasing the jet velocity or the mass flow of propellant gases, or both.

Limitations on mass flow of propellant gases arise from such design considerations as maximum temperatures and pressures feasible within permissible engine weights.

Since the kinetic energy in a rocket jet is derived from conversion of the chemical energy of combustion to directed kinetic energy, high thermochemical energy per unit weight of propellant is desired. In practice, the kinetic energy of the rocket exhaust jet may be only 40 to 70 percent of the theoretical heat energy from combustion of the propellant. Minor losses arise from incomplete combustion and heat lost to the thrust chamber walls. Larger efficiency losses come from unavailable thermal energy that leaves the exhaust nozzle.

An important rocket term is specific impulse, I,,, which is the thrust per pound per second of propellent burned:

$$I_{sp} = \frac{F}{\dot{W}} \frac{\text{lb}}{\text{lb/sec}}. \qquad (4)$$

Similarly, from equation (3),

$$I_{,,} = \frac{c}{g} \frac{\text{ft/sec}}{\text{ft/sec}^2}. \qquad (5)$$

Since the pound and foot units cancel out, I,, is given in units of seconds.

Further calculations show that specific impulse is increased by increased chamber pressure and combustion chamber temperature and lowering of molecular weight of exhaust gases.

As a rocket-powered vehicle moves, the weight (mass) of the vehicle continuously decreases as the propellant is consumed and disappears to the rear as exhaust jet. In the design of efficient long-range rockets, every effort is made to reduce structural weight to a minimum and increase to a maximum the percentage weight of the propellant. In the case of the V-2, 69 percent of the takeoff weight was propellants. Modem lower-stage boosters have values as high as 94 percent. Takeoff acceleration may vary from several g's to a few tenths of a *g* in large rockets taking off vertically.

The technique of staging

The final velocity of a rocket-powered vehicle can be increased, theoretically, to any desired value by the technique of staging; *i.e.*, setting a series of rockets one on top of the other and firing them successively. Thus each successive stage is smaller and commences firing at a higher initial velocity. In practice, however, the complications of duplicating mechanical items, cost, and reduction in reliability have set a practical limit to the number of stages that are employed.

The Bumper-WACprogram conducted in the U.S. in 1948–50 is an example of the benefit of staging. A WAC/Corporal rocket placed on top of a V-2 was fired after burnout of the V-2. Whereas a V-2 alone achieves a maximum altitude of about 100 miles and a maximum velocity of 3,500 miles per hour, the Bumper-WACsent the WAC/Corporal to a velocity of 5,000 miles per hour and a peak altitude of 250 miles. All long-range ballistic missiles and space launch vehicles are staged. In the case of the Saturn 5, the S-1C (first stage) reaches a cutoff velocity at 5,350 miles per hour and separates; the S-2 (second stage) brings the vehicle to 14,750 miles per hour and separates; the S-4B (third stage) delivers thrust until an orbital velocity (at 103 nautical miles) of about 16,600 miles per hour is reached and shuts off (see also SPACE EXPLORATION).

A rocket-propelled vehicle is highly inefficient at low speeds. Efficiency increases from zero at rest to a maximum when the velocity of the vehicle is the same as the jet exhaust velocity.

A rocket motor or thrust chamber assembly is composed of a combustion chamber and nozzle (see Figure 7). The injector head is considered a part of the combustion chamber in the case of a liquid-propellant motor. The term rocket engine (liquid-propellant only) refers to the motor plus the associated propellant and feed system, propellant lines, valves, regulators, mounting lugs, igniter, etc. A rocket power plant refers to the complete propulsion system, including propellant tankage, pressurizing system. gimbal mounting (or jetevators, vanes, etc.), tankage-level sensing devices, and associated computers.

Conventional rocket motors burn chemical propellants, either solid or liquid. Combustion of the propellants provides the hot gas, which is exhausted in a jet through a convergent–divergent nozzle to the rear. Other types of rocket motors employ hybrid systems (liquid propellant burned in a solid-propellant core) and air turborockets, which utilize some ram air for part of the combustion process. Two nonchemical types of rocket propulsion systems are nuclear and electrical. These systems have received serious attention only since World War II and have particular application for space flight missions.

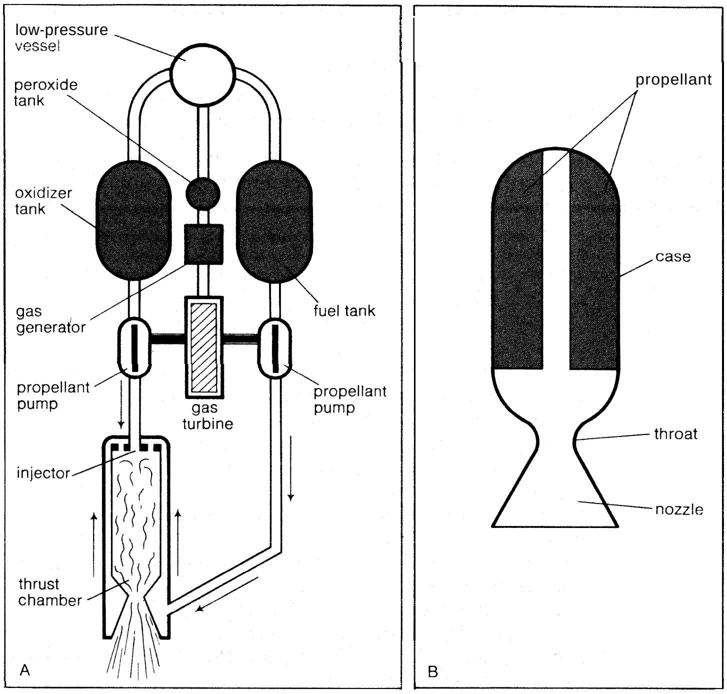

Figure 7: Representative design of (A) liquid-propellant, regeneratively cooled rocket power plant and (B) solid-propellant rocket motor.

SOLID-PROPELLANT ROCKET MOTORS

Characteristics. The outstanding feature of solid-propellant motors is their relative simplicity of configuration and state of readiness for use. All of the propellant is contained in the combustion (or thrust) chamber, to which is attached an exhaust nozzle. An electrical or pyrotechnic igniter fires the propellant charge.

Disadvantages arise from a somewhat lower specific impulse range at sea level compared with liquid-propellant motors, performance variation caused by storage temperature, and heavier rocket casing to contain combustion gases at a typical pressure of 1,000 pounds per square inch.

The design configuration and chemical composition of solid-propellant charges vary widely. The charge (or grain) may burn from one end only, as does a cigarette. Or the grain may be a hollow cylinder or have a star-shaped interior burning surface. Important elements in solid-propellant charge design are surface area and the burning rate of particular propellant mixtures.

Generally speaking, a solid-propellant rocket motor may be designed to wide performance specifications, with individual motors operating from a fraction of a second to 30 seconds or more. Current motor designs range from a few pounds to more than 1,000,000 pounds. Although modern motors are generally made of high-strength alloy steel of tubular construction, glass-fibre-wound motor cases are also used.

The largest solid-propellant rocket motors in use in the United States are the two strap-on booster motors ten feet in diameter and 86 feet long, on the air force Titan IIIC space launch vehicle. The thrust of each of these two rocket motors is 1,200,000 pounds. Each motor weighs 500,000 pounds.

Solid propellants. Various formulations of black powder (gunpowder) were the only source of propellant for rockets until nitroglycerin was discovered late in the 19th century. Saltpetre (KNO,) was the oxidizer in this mixture, while the sulfur (S) and charcoal (C) served as fuel. This exothermic (heat-releasing) reaction may be written approximately

$$2KNO_3 + S + 3C \rightarrow K_2S + 3CO_2 + N_2$$
$$+ \text{ 550 calories per gram of mixture reacting.}$$

Specific impulse from black powder

In a rocket motor, black powder yields a specific impulse (I,,) of 50–70 seconds, depending upon chamber pressure and formulation (typical, by weight: 75 percent KNO_3, 15 percent C, and 10 percent S). The flame temperature of gunpowder is about 1,500"–3,000" F (800"–1,600" C), and the mixture burns smoothly even below combustion chamber pressures of 100 pounds per square inch. The volume of gas produced is about 400 times the original volume of the charge.

With the advent of nitro explosives there arose new possibilities of obtaining high-temperature gases smoothly and reproducibly. Motor design changes were required to accommodate the higher combustion temperatures and pressures. Rocket propellants based upon nitrocellulose (guncotton) are known as single-base propellants. Mixtures of nitrocellulose and nitroglycerin are known as double-base propellants. These double-base mixtures are similar to smokeless powders for firearms. To improve the physical and chemical properties of double-base propellants, small amounts of additives are usually present as stabilizers. These additives prevent decomposition in storage or improve combustion characteristics and bond the propellant to the motor casing.

Double-base propellants require a minimum operating chamber pressure of about 500 pounds per square inch for smooth burning. Lower pressure results in irregular burning and oscillatory combustion. Flame temperature is of the order of 5,000" F (3,000" C). Heat yield is of the order of 850–1,200 calories per gram. Specific impulse is about 180–210 seconds. The volume of gases produced from double-base propellants is about 1,500 times initial propellant volume.

Solid propellants are considered to be divided into two main classes: "homogeneous" is applied to solid-propellant mixtures in which the propellant or mixture of propellants is intimately associated. Single- and double-base propellants are examples of homogeneous propellants. In composite (or heterogeneous) propellants, the substances, although finely ground, are in distinctly separate phases. An example of composite propellant is gunpowder.

Nitrocellulose or nitroglycerin is different from gunpowder with respect to the process of chemical combustion. The molecules of saltpetre, sulfur, and carbon in gunpowder must be intimately mixed in order to react. Nitrocellulose contains within each molecule sufficient fuel and oxidizer for complete reaction without the addition of other substances.

Advances in composite propellants

During World War II, a number of important new composite propellants were produced. One of these was the GALCIT series, which was a mixture of 75 percent potassium perchlorate and 25 percent asphalt oil. Another series consisted of the NDRC mixtures; a typical example of these was about 46 percent each of ammonium picrate and sodium nitrate mixed with 8 percent plastic resin binder.

Other composite mixtures use ammonium nitrate as oxidizer, and still others utilize synthetic rubber as fuel. An important advantage of composite propellants is that they can be cast directly in the case.

In the early 1970s both double-base and composite propellants were in operational use in missiles and space launch vehicles. In the composite mixtures, ammonium perchlorate was the standard oxidizer. The fuels (and binding agents) most used were polyvinyl chloride, polyurethane, and synthetic rubber, sometimes with finely divided aluminum as an additive.

LIQUID-PROPELLANTROCKET MOTORS

In this class of rocket motors, the liquid combustibles (*i.e.*, the propellants) are contained in tanks and are fed into the thrust chamber through an injector head by a propellant supply system. Most liquid-propellant rockets use two combustibles (bipropellant system), such as liquid oxygen and liquid hydrogen. Monopropellant systems that depend upon the exothermic (heat-r-leasing) decomposition of a substance, such as high-strength (90–95 percent) hydrogen peroxide, are in use. Such systems usually have lower performance ratings but are simpler to design and may be used for auxiliary propulsion systems.

The chief advantages of liquid-propellant rocket engines are the preciseness of control and restart capability that can be achieved. Also, liquid engines can be checked out, fired, and calibrated precisely before use. Further, the range of specific impulse is higher than for solid-propellant systems. Finally, only liquid-propellant motors are capable of burning for several minutes.

Elements of design of a liquid-propellant rocket engine include the combustion chamber, cooling techniques, exhaust nozzle, injector head, propellant supply system, propellant tankage, and the liquid propellants.

Combustion chambers. As in the case of all components of a rocket vehicle, a premium is placed on reduction of weight to the minimum adequate to perform the necessary function reliably. Combustion chambers are usually made of high-strength steel alloy and are usually cylindrical, although sometimes bell shaped. Solid-propellant motors are uncooled because the walls of the motor are protected from the combustion flame, since burning is from the core outward. Further, the duration of burning is relatively short. The length and volume of a liquid-propellant combustion chamber is related to the length of time for the propellants to mix and burn before passing through the nozzle.

Cooling techniques. Motors that operate for a fraction of a second to a few seconds only (such as in attitude-control systems) may be uncooled, radiating absorbed heat. Liquid rockets may be required to run five or more minutes, however. The conventional method of cooling is known as regenerative cooling.

Regenerative cooling

In this technique, one of the propellants flows along the outside of the nozzle and thrust chamber wall before it is injected into the motor. The heat that the propellant thus absorbs is not lost but is added to the heat of combustion in the thrust chamber. Design of the cooling flow passages is critical, since it is necessary to prevent boiling of the propellant and yet obtain a lightweight structure and low pressure drop. A high pressure drop results in greater design weight and higher pressure flow systems. Because the heat transfer rates to the walls are greatest in the narrow neck of the nozzle, the coolant flow rate is usually highest at this point.

In the early 1960s a new technique, ablative cooling, was developed, using materials similar to those employed as heat shields for re-entering space vehicles. Rocket chamber liners and entire chambers were made of these materials, which absorb and dissipate large amounts of heat as they vaporize and are lighter than comparable regeneratively cooled systems. They are also useful when propellant flow rate may be insufficient for regenerative cooling (*e.g.*, at low thrust levels) or when neither of the propellants has inherent sufficient cooling capacity to protect the rocket engine from heat damage.

Ablative-cooled motors have been used on both the descent and ascent stages of the Apollo Lunar Module.

Other cooling techniques that were tried in early developments were ceramic liners and film cooling, wherein a portion of one of the propellants was admitted through holes in the chamber providing a cooling film on the wall.

Exhaust *nozzle.* Exhaust nozzles are designed to expand the combustion gases to ambient pressure. In the case of a sounding or ballistic rocket, the ambient pressure decreases with altitude. For operation at high altitudes or in the vacuum of space, the diameter of the nozzle exit becomes very large and the construction weight prohibitively high. Thus nozzle design is usually subject to compromise, and certain reductions in efficiency (nozzle losses) are accepted.

Injector head. The injector head meters the propellants at a predetermined rate and mixture ratio and atomizes and combines the mixture within the combustion chamber so that burning takes place smoothly and completely. If the pressure drop across the injector is too great, an excessive burden is placed upon the propellant supply system and the weight of construction is increased unnecessarily. On the other hand, if the pressure drop is too low, oscillatory combustion will result. Good injector design reduces to a minimum the volume and length of a combustion chamber. A number of types of injectors have evolved. In the impinging spray type, propellant streams in pairs or clusters are injected to intersect at high velocity so that they break up into small droplets, evaporate, and burn. In the showerhead type, concentric rows of holes spray the propellant into the chamber. The rows of sprays may or may not impinge. Sometimes concentric slots are used to produce intersecting conical sheets of propellant sprays.

Impinging spray injectors

A World War II German design utilized a splash plate within the thrust chamber on which liquid-propellant streams played. Good mixing is obtained in this design, but hot spots may occur on the splash plate. Premix injectors have been tried wherein mixing is accomplished just prior to injection into the thrust chamber. Since rocket propellants by their nature are high-energy substances, this type of design is subject to explosion. Swirl-type sprays are another approach to injection configuration. Shop producibility, critical tolerances, and cost enter into injector head considerations, and some compromises in performances are usually accepted.

Often related to injector head dynamics is the phenomenon of oscillatory combustion instability in the combustion chamber. This is usually accompanied by audible effects of chugging and screaming. High-speed pressure differentials can destroy a rocket motor within seconds.

Because the mixture ratios of different propellants vary widely, a rocket motor is tailored for specific propellants, and it is not generally possible to operate an engine efficiently on propellants different from those for which it was designed.

Gas pressurization

Propellant supply *system.* The simplest method of forcing liquid propellants into the combustion chamber is by gas pressure. An inert gas is used, such as helium or nitrogen. Because the combustion chamber pressure is usually 300 pounds per square inch or more, the pressurizing gas must be higher to overcome frictional losses in propellant lines, valves, the thrust chamber cooling jacket, and the injector head. This high pressure necessitates heavy tanks. Gas pressurization is a simple and reliable system, however. For small vehicles helium gas at several thousand pounds pressure may be used, with operating pressure being reduced through a regulating valve. Another source of pressurizing gas is the reaction of small quantities of the propellants themselves in a special gas generator or even within the propellant tanks. In turbopump systems a source of high-velocity gas drives a turbine wheel, which in turn drives centrifugal pumps between the propellant tanks and the rocket motor. High-strength hydrogen peroxide (95–98 percent) is commonly decomposed by a catalyst bed within a gas generator. The decomposition products, oxygen and steam, are led through a nozzle and impinge on the turbine blades. The main propellants themselves may be used to provide turbopump power, simplifying the system.

The propellant pumps are usually centrifugal. They may be located on opposite ends of the turbine shaft or, in cases of large pumps, may be driven by a gear train. A certain pressure head is necessary to prevent cavitation (the formation of a partial vacuum at the blades). This is supplied from a lightweight high-pressure storage bottle through a pressure regulator to the propellant tanks. Other turbopump-drive systems utilize a high-pressure stored gas start cycle and then bleed a portion of one of the pumped propellants to an expansion jet to drive the turbine. This turbine gas exhaust may then be burned in the combustion chamber, utilizing its thermochemical heat content.

Valves for rocket engines offer design problems from the nature of the propellants and requirements for high reliability and precise operation. Many rocket flights have failed because of sticking valves. Valves are usually electrically, pneumatically, or hydraulically actuated.

Ignition of the propellants upon entry into the combustion chamber must be rapid to prevent a buildup of combustibles. The ignition of some propellant combinations such as Aerozine 50–nitrogen tetroxide is hypergolic; that is, it ignites spontaneously when the components are brought together. Otherwise, as in the case of hydrogen–oxygen systems, a source of flame or spark; or a hot wire or pyrotechnic igniter is required.

Propellant tankage. Tankage for propellants has evolved in recent years to integral systems, wherein the thin wall of the tank is the skin of the rocket vehicle itself. In addition to the weight of the propellant, rocket tankage must be able to withstand a certain amount of gas pressure for turbopump systems and several hundred pounds of pressure for gas-pressurized propellant supply systems.

Liquid propellants. The early rocket pioneers all recognized the advantages of liquid hydrogen and liquid oxygen as rocket propellants; however, such substances were in short supply and expensive. Goddard used liquid oxygen and commercial gasoline in his historic rocket test flight in 1926. The Germans used liquid oxygen and diluted alcohol in their V-2. Other German missiles used concentrated nitric acid and hydrocarbons such as vinyl isobutyl ether or a mixture of xylidine and triethylamine.

Common bipropellants

By the early 1970s the most common bipropellants in use in the United States were: liquid hydrogen and liquid oxygen (upper stages of Saturn 5); liquid oxygen and RP-1 (Atlas and first stage of Saturn 5); Aerozine 50 and nitrogen tetroxide (Titan II and Apollo Command, Service, and Lunar modules). RP-1 is a hydrocarbon similar to kerosene. Aerozine 50 is a 50–50 mixture of hydrazine and dimethylhydrazine.

Monopropellants in use in auxiliary rocket systems are high-strength hydrogen peroxide and hydrazine. Decomposition occurs by forcing the propellant through a catalyst of silver or platinum.

Considerable research and development effort has been expended on liquid propellants of higher energy, such as liquid fluorine and borohydrides.

Although experiments have been performed on thousands of fuels and a lesser number of oxidizers, no completely ideal propellants have emerged. Each propellant has some disadvantages that must be weighed against the particular design application and mission; for example, the problems of corrosivity and toxicity of fluorine or the low density of hydrogen may be accepted to obtain their high performance in space applications. Or the lower specific impulse of solid propellants may be accepted to obtain the advantages of readiness in antimissile defense systems.

In evaluation of liquid propellants the following properties are of engineering importance to the rocket designer: heat of reaction, average molecular weight of combustion products, stability (*e.g.*, to heat, shock), speed of reaction, ignition characteristics, density, viscosity, vapour pressure, specific heat, and corrosivity. For regenerative cooling—and all large, long-burning engines are so cooled—at least one of the propellants must have sufficient stability, specific heat capacity, thermal conductivity, and high saturation temperature to serve as a coolant. Despite its low temperature of —297" F (—183" C), for example, liquid oxygen is an unsatisfactory regenerative coolant. To improve cooling ability in the V-2, the ethyl alcohol fuel was diluted to 75 percent with water.

The logistic and handling qualities of liquid propellants must be taken into consideration. For bulk storage and transfer of propellants, corrosivity, stability, and vapour pressure are important, as are the freezing point and inflammability. Toxicity is important to personnel. Cost and bulk availability are also important considerations to program planners.

OTHER PROPULSION SYSTEMS

Nuclear propulsion systems. The development of reliable nuclear fission reactors has led to consideration of nuclear energy as a source of power for rockets. In this case the energy does not derive from the heat of combustion of a chemical reaction but from fission of nuclear

Design problems of nuclear systems

particles. Although the amount of energy potentially available is very much greater, the conversion to kinetic energy in a rocket exhaust jet is more complicated. Several nuclear rocket systems have been studied, including the rather audacious notion, suggested shortly after World War II, of obtaining impulse by a series of small nuclear explosions, an idea that was soon abandoned. The more conventional approach to a nuclear rocket is to use the heat of a fission reactor to heat a working fluid and expel the hot gas through a nozzle. Since the nuclear products are in a closed cycle, no radioactive particles are in the exhaust. The most obvious working fluid is low-molecular-weight hydrogen. The working fluid, or propellant, in this system would not be burned but simply heated and ejected. Some of the major problems associated with the design of a nuclear reactor are related to the design of an efficient heat exchange to transfer heat energy from the reactor to the propellant; cooling the thrust chamber walls; shutdown and restart; and nuclear radiation. The range of specific impulse (*i.e.*, pounds of thrust per pound per second of propellant flow) achievable with such nuclear rockets is estimated in the order of 700–1,000 seconds. Chemical propellants have a limitation of about 430 seconds at sea level. In the early 1970s work was proceeding on a flight-weight engine that would develop 75,000 pounds thrust and weigh 16,000 pounds.

Electrical propulsion systems. Whereas chemical-propellant rockets are characterized by high thrust for short durations, a number of electrical systems have been proposed that would yield a low thrust (in the order of a thousandth to a millionth of a pound) over a long period of time. Specific impulses of such systems range from about 1,000 to 10,000 seconds and more. Several approaches to electrical thrust systems are under development. All such systems, because of low thrust, must be carried to a low-altitude orbit by conventional rocket-powered systems. From this orbit these devices will operate in pulsed fashion or continuously for weeks, months, or even years in the case of distant interplanetary flight. Electric power to operate these thrust devices would be obtained from direct conversion of solar energy (solar batteries) or from nuclear electrical generators, as in a plasma thermocouple. Since specific impulses of 1,500 to 5,000 seconds are optimum for space missions from low-altitude Earth-satellite orbit (22,300 miles), additional flight time (of extra days or weeks) is not necessarily important. The advantages of using electrical propulsion are, however, truly significant. Earth takeoff weights may be reduced as much as one-half over the weight using chemical rocket propulsion throughout. In the particular case of a communications satellite payload, which could utilize the electrical power supply of the propulsion system, Earth takeoff weight might be reduced to one-third.

Among the electrical thrust devices under development is the electrothermal arc jet. This utilizes an electric arc to heat the propellant, or working fluid, which is expelled through a rocket nozzle to the rear. Another device studied accelerates the plasma, produced by the electric arc, by means of a magnetic field. Still other electric thrust devices operate in a pulsed fashion and utilize magnetohydrodynamics (MHD) to accelerate high-temperature gases.

Ion propulsion systems

Best known of the electrical thrust devices is the ion rocket. In this system electrostatic fields rather than electromagnetic fields are used to accelerate dust particles or positively charged ions such as metallic cesium. Specific impulse ranges of this device are estimated at 5,000 to 100,000 seconds. In 1971 two systems reported being investigated were a mercury bombardment engine (0.001–0.025 pound thrust) and a colloid accelerated system (8×10^6 pound thrust). Although in the early 1970s a few ballistic and orbital test flights had been made of rudimentary ion thrust motors, their operational use appeared to be some years in the future.

Interestingly enough, Robert H. Goddard conceived the use of accelerated charged particles for space propulsion and conducted related laboratory experiments as early as 1916–17, and Hermann Oberth independently proposed ion propulsion in 1929.

Future space propulsion systems. There are two other rocket systems proposed for space propulsion. One is the so-called hydrogen heater. In this concept, solar energy is concentrated by hemispherical reflectors onto a heat exchanger, which in turn heats hyrdogen to a high temperature; the hydrogen is then accelerated through a rocket nozzle to the rear. Finally, mention should be made of the photon rocket, wherein energy is converted to light and expelled as such. Such a system is wholly theoretical at this time, since the extremely high temperatures (nuclear fission range) required are not compatible with currently available materials.

TESTING

Cost of testing facilities

Many tests are required in the development of a rocket motor design. The term static test is used to describe operations wherein the motor is bolted to a test stand and fired. Static test stands provide for measurements of thrust, propellant flows, and a variety of significant temperatures and pressures. Control is maintained from within a reinforced concrete bunker or blockhouse. The rocket firing is viewed by means of mirrors or periscopes or at a distance through bulletproof glass. Closed-circuit television may also be used in the case of large motors. In liquid-motor development, so-called battleship (heavyweight) propellant tankage is employed, and gas pressure often is used to force the propellants into the thrust chamber. In initial chamber-design tests, water cooling provides a large safety factor over regenerative cooling. Flow measurement tests of injector heads and gas generator and turbine pump development usually proceed separately. Eventually all components are combined for system tests. When missiles are in the final stages of development, the entire vehicle is mounted in other test stands and fired. These are known as captive tests. The cost of rocket test facilities, with associated plumbing, tankage, propellant storage, and the necessary safety provisions of reinforced concrete and large safety distances, is naturally great. Because of the initial large cost of such facilities, particularly for large missiles and space launch vehicles, they represent a major investment and national asset of spacefaring nations.

AUXILIARY ROCKET SYSTEMS

In addition to the main propulsion systems of sounding rockets, guided missiles, and space launch vehicles, there are a wide variety of other rocket motors used to provide thrust for specific purposes during flight. These are called auxiliary, or secondary, propulsion systems.

At high altitudes and in space, small rocket motors (vernier motors) are used to provide attitude control about the three axes of flight: pitch, yaw, and roll. Two motors mounted on opposite sides of the missile can provide forces required to maintain correct flight path as directed by the inertial guidance system. Four quadrants of four motors each are installed on the Apollo Lunar Module for attitude control and manoeuvring. In the case of the Apollo Command Module a requirement exists for reliable, precise control of attitude to position the craft for atmospheric re-entry. Two sets of six rocket motors, flush-mounted on the command module, are provided. The thrust of each motor is 93 pounds. The second set of motors is redundant to provide for malfunction of the first system.

Ullage rockets

Under conditions of weightlessness between stage firings on launch or while in orbit, the liquid propellants float freely in their tankage. It is necessary before firing a rocket engine to have the outlet of the propellant tanks covered with fuel and oxidizer, respectively, so that continuous flow of propellant may occur. Thus an auxiliary rocket motor, known as an ullage rocket, is fired to impart a small amount of thrust to the space vehicle, causing the liquids to move to the lower end of the propellant tanks. Rocket motors that are used to provide spin (for flight stabilization) for missiles are usually of the solid-propellant type. Other small spin (or despin) motors are used on some satellites. Tiny rocket motors are sometimes used to control attitude of satellites operating automatically or upon command. Stored high-pressure inert gas is used occasionally for this purpose rather than more common monopropellants; *e.g.*, hydrogen peroxide or hydrazine. A small rocket motor may be used to separate a satellite from the final stage of the launch vehicle.

IV. Applications of rocket power

The role of rockets in space exploration is treated in SPACE EXPLORATION. In addition to the space applications, and the military applications described above, rockets have been used for a wide variety of other purposes.

SOUNDING ROCKETS

Atmospheric sounding--or vertical probe—rockets have become an important research tool for scientific investigation of the upper atmosphere. Despite their short lifetime, as compared with satellites, they have valuable characteristics. They are relatively much cheaper and simpler in design, and they offer flexibility in making meteorological measurements at times and locations desired by the scientist. Of foremost importance, however, is the fact that sounding rockets offer the only means of lifting scientific instruments to altitudes of 50–100 miles—higher than balloons or aircraft can reach and below the altitude at which satellites can function, because of atmospheric drag. Also, these versatile vehicles are used for operational checkout of instruments designed for use in research satellites. Sounding rockets have investigated such phenomena as cosmic rays, solar ultraviolet radiation and X-rays, auroral particles, stellar astronomy, and micrometeorites.

Before 1946 all upper-atmosphere research had been conducted from balloon sondes or aircraft. Beginning in 1946, various kinds of physical sensors were carried aloft in the nose cones of captured and reassembled V-2s to heights above 100 miles. Recovery of the instruments and data was by parachute after separation from the rocket.

More than 60 V-2s were launched, including the Bumper-WAC,a V-2 fitted with a second-stage WAC/Corporal rocket, which reached a 250-mile altitude in 1949. The WAC/Corporal was a liquid-propellant research rocket developed by the Theodore von Kármán research team at the California Institute of Technology near the end of World War II. The WAC/Corporal was 16 feet long; the rocket motor developed 1,500 pounds of thrust for 45 seconds. Propellants were red-fuming nitric acid and aniline mixed with 20 percent furfuryl alcohol.

Features of the Viking sounding rocket

By 1947 the United States Naval Research Laboratory commenced development of the Viking sounding rocket. First launch of this upper-atmosphere research rocket was in September 1949. A single stage vehicle, 41–47 feet long and weighing 9,650 pounds, it was powered by a 20,000-pound-thrust liquid oxygen–alcohol rocket motor. The fully gimbaled motor control system was unique. Another innovation was the integral propellant tank construction, in which the tank walls were the skin of the rocket. Payload weight was 400–500 pounds. Twelve Vikings were built, one reaching a 158-mile altitude in 1955. Some Vikings were launched from the USS "Norton Sound." Others were fired from White Sands Proving Ground in New Mexico.

Another sounding rocket of this period was the Aerobee, a Navy Bureau of Ordnance program. Nearly 19 feet long, this single-stage sounding rocket was an improvement of the WAC/Corporal design and could carry a 150-pound payload to an altitude of 72 miles (116 kilometres).

An exciting period of research developed with these new scientific tools, despite the technical problems associated with the developing rocket technology. Cosmic radiation measurements were made; photographs of the Earth were taken from space; mice were photographed under conditions of weightlessness; and the chemical composition of the upper atmosphere was studied.

Typical of experiments performed by sounding rockets is one begun in 1954 that determined regions of intense turbulence and strong shear winds below the altitude of 60 miles and extremely high winds above that altitude. These conditions were observed by Nike Asp sounding rockets that released trails of sodium vapour into the atmosphere between 60 and 120 miles above the Earth. Temperature measurements at high altitudes are made by timing the arrival of the sound of exploding grenades ejected from sounding rockets at altitudes between 38 and 65 miles. By the early 1970s much of the knowledge of the temperature and pressure of the atmosphere, as well as the composition of the ionosphere, was based on data from sounding rocket experiments.

Sounding rockets range in size, performance, and cost from a simple, single-stage, solid-propellant rocket such as the 66-pound Arcas, which can lift a 12-pound meteorological payload 37 miles, to the two-stage, solid-propellant, 11,500-pound Astrobee 1500, which can lift a 50-pound payload to 2,000 miles.

French rockets in IGY

Liquid-propellant sounding rockets are also used extensively. The French Vdronique rockets proved valuable during and after the International Geophysical Year (IGY). First flight-tested in 1952, these rockets were subsequently flown at the French missile test range at Colomb-Béchar, Algeria. In its IGY flights the VCronique used an 8,820-pound-thrust engine burning nitric oxide and turpentine. The rocket weighed 2,962 pounds and could lift a payload of 166 pounds to an altitude of 140 miles. The VCronique was 24 feet long and fin stabilized. A later version, the Véronique 61, was 30 feet long, weighed 4,310 pounds, and could lift a 440-pound payload to an altitude of 162 miles (261 kilometres).

Cooperative worldwide efforts during the International Years of the Quiet Sun resulted in the 1960s in several dozen coordinated rocket soundings of the upper atmosphere, which yielded new scientific understanding of solar effects upon the Earth.

During the solar eclipse of 1970, 31 sounding rockets were launched to obtain upper-atmosphere data on effects of the eclipse. Nearly half of these rockets were launched during a 20-minute period (see also METEOROLOGICAL MEASUREMENT).

Representative sounding rockets are listed in Table 5.

Table 5: Representative Sounding Rockets

	name	payload (lb)	altitude (mi)
Argentina	Rigel	66	135
Australia	HAD	20	80
Australia	HAT	35	47

AIRCRAFT PROPULSION

The first aircraft to fly on rocket propulsion alone was a glider built by Fritz von Opel of Germany; it flew on September 30, 1929. Black-powder rockets were used for launching and a brief sustained flight. The first aircraft powered by a liquid-propellant rocket engine was a Heinkel design, in 1937. During World War II the Messerschmitt Me 163 rocket-powered interceptor became operational. It was powered by a hydrogen peroxide engine and achieved speeds of more than 600 miles per hour.

First supersonic flight

After the war the United States built the first supersonic research aircraft, the Bell X-1. It was powered by a four-barrelled, 6,000-pound-thrust, pressurized, liquid oxygen–alcohol engine. Each of the four 1,500-pound-thrust rocket motors could be fired independently or in combination. Launching was from a mother B-29 aircraft, which carried the X-1 underneath. Supersonic flight was achieved October 14, 1947. A later version, the X-1A, had a turbopump rocket engine, carried more propellant, and reached 1,650 miles per hour at 90,000 feet in 1953. Meanwhile, the U.S. Navy, in cooperation with the National Advisory Committee for Aeronautics (NACA) developed the Douglas D-558. This research aircraft reached mach 2 (twice the speed of sound). The Bell X-2 design, with a 15,000-pound-thrust engine, reached mach 3.3 and 126,000 feet. The North American X-15, with a 50,000-pound-thrust engine, flew a new aircraft speed and altitude record—mach 6.7 and 67 miles. Much valuable knowledge and hypersonic flight data were obtained in this program in 199 flights flown by three aircraft.

In postwar France and Great Britain, consideration was given to rocket-powered interceptor aircraft. Although a number of experimental aircraft were built and flown, no nation is known to have military rocket-powered aircraft in operational use.

OTHER APPLICATIONS

During World War II both the United States and Germany developed jet-assisted takeoff units for aircraft. Both solid and liquid propellants enabled land planes and seaplanes to take off with a shorter run or with increased loads, or both. Development continued after the war, particularly in the United States, where the units were also produced for the commercial market. Jet-assisted takeoff units are sometimes designed as a fixed installation in aircraft, but otherwise are intended for parachute drop after takeoff.

Rockets have been used to propel supersonic sleds along a twin-rail track. These sleds serve as beds for acceleration tests of various components such as parachutes, aircraft ejection seats, and nose cones. Important aeromedical tests on men have also been performed with rocket sleds. Accelerations as high as 100 gravity (*g*), decelerations of 150 *g*, and velocities up to 4,600 feet per second are possible. Both liquid- and solid-propellant rockets are used. Braking is accomplished by a parachute or, more often, by extending a scoop beneath the sled into a trough of water between the track rails.

Buried land mines were attacked in World War II by rocket-propelled devices. One of these devices, known as the Infantry Snake, pulled a 100-foot train of skis, linked together and carrying TNT or explosive-filled pipes known as Bangalore torpedoes.

A unique device based upon a German development was the Wedge, also called Donnerkeil. It used a powerful rocket to drive a six-foot-long rod, one inch in diameter, into the ground. By pulling out the rod and inserting and detonating a length of cord filled with explosive (primacord), a hole 10 to 12 inches in diameter was created. Since the hole made would accommodate a telephone pole, it was sometimes called a portable posthole.

Other wartime rocket-propelled devices included smoke bombs that, in barrage firing, could swiftly erect a smoke screen. Antiradar rockets, used in the Allied invasion of Normandy, released metal foil strips, called window, at the peak of their trajectories. These strips caused spurious radar reflections and appeared as swarms of aircraft on radar screens. Grapnels and rope ladders have been boosted over heights by rockets in commando operations. Rockets designed to carry thin cables aloft as anti-aircraft devices and mortar-fired rockets have been developed.

Solid rocket propellants have been used for turbojet engine starters, to furnish gas pressure to power small gyroscopes or electric turbogenerators for guided missiles, and to pressurize flame throwers. Solid-propellant charges have been fired in specially designed tools in oil wells to create high pressures that fracture the earth and increase oil production. Rocket jets have been used to drill holes through earth and rock. Rocket motors provide a high-temperature jet that is useful for materials tests, such as those carried out in the development of ballistic missile nose cones.

The possibility of delivering troops and equipment accurately and at long ranges with long-range ballistic missiles has been proposed. Even rocket boost of individual soldiers for hundreds of yards has been achieved by the use of a device known as a rocket belt.

Rockets have been attached to automobiles, boats, gliders, iceboats, motorcycles, railcars, and even to a man on ice skates. These experiments, many of which were carried out in the 1920s and 1930s, were generally more ingenious and publicity-seeking than efficient. Nevertheless, rocket motor technology, an extremely broad field of engineering involving chemistry, physics, materials technology, and fluid dynamics, has considerable promise in the future of transportation.

(F.C.D.III)

Rock Magnetism

The phenomenon of magnetism was first discovered in rocks. Early inhabitants of the Middle East and China knew of deposits of lodestone, an iron-bearing rock that attracted pieces of similar rock and that pointed toward the north and south if freely suspended. These unusual characteristics gave rise to myths about the heavens, the polar regions, and special lodestone mountains that were not dispelled until the 17th century.

It was also recognized that an unusual "field" existed in the vicinity of magnetic rocks. Iron objects or iron-bearing rocks that were unmagnetized would themselves acquire magnetism when placed in this field, and in many cases they would remain magnetized after removal from the original field. Magnetism, which is created in a substance by the presence of a magnetic field and which is retained after the original field is removed, is called ***remanent magnetism;*** most of the permanent magnets used in modern technology are made in this general manner. Magnets can also be made from coils carrying electric currents; these types are referred to as electromagnets. The main magnetic field of the earth is believed to result from the circulation of electric currents near the earth's core. The crust of the earth is thought to be free of such currents; it appears to have been magnetized by the main field of the earth.

The strength and direction of the remanent magnetism of crustal rocks are related to the strength and direction of the ambient field that induced the magnetic state. Accordingly, the remanent magnetism of rocks can be used to study the magnetic field that originally magnetized them. Some rocks, especially those that are iron bearing, are more strongly magnetized than are others in the same ambient field. This results from differences in the chemical or mineralogical composition of the materials. Temperature plays a key role because at elevated temperatures, the remanent magnetism characteristics will be markedly altered. Upon cooling in a magnetic field, an entirely new set of characteristics may be acquired.

Because magnetism is a quantity posseasing both direction and strength, precise information about the orientation of the field that caused remanent magnetism can be obtained. For example, if the direction of the inducing field is known and a different direction is measured in a rock outcrop, it is possible to reconstruct the motion through which the rock has been mechanically turned since it was magnetized. **A** major interest in rock magnetism is the determination of such rotations by assuming a knowledge of the original-field direction or inferring the direction of the original field by assuming that the rotation is negligible.

Advances in the technology of measuring the remanent magnetic properties of earth materials have permitted earth scientists to work with materials other than those commonly thought of as magnetic rocks. Although very weakly magnetized, many sedimentary rocks and soft sediments can be measured with sensitive instruments.

This article treats the ways in which rocks acquire magnetism, the determination of this property, and some interesting aspects of paleomagnetism, such as sea-floor spreading. For further information on this latter point, see CONTINENTAL DRIFT; and SEA-FLOOR SPREADING. See also MAGNETISM; EARTH, MAGNETIC FIELD OF; EARTH, STRUCTURE AND COMPOSITION OF; and ROCKS, PHYSICAL PROPERTIES OF for discussions of relevant information on magnetism in the earth and in the rocks of the earth's crust.

MAGNETIZATION OF ROCKS

Kinds of magnetization and magnetic materials

The magnetic moment (product of pole strength and distance between poles) of rock material is caused by the orbital and intrinsic spin motion of electrons in constituent atoms. In most materials there is little interaction between the magnetic moments of adjacent atoms. The vector directions of the moment are randomly distributed so that a specimen of material has no net magnetic moment in the absence of an external field. When an external field (H) is applied, however, there will be a weak interaction between the neighbouring atoms, and at this instant vectors will align themselves along the axis of the external field. If the alignment reinforces the field, the material is said to exhibit paramagnetic susceptibility. The magnitude of the susceptibility k (a measure of the ease of magnetization) is on the order of one-millionth of the external field (10^{-6}). If the alignment opposes the field, the susceptibility is diamagnetic. The common rock-forming minerals quartz and feldspar are diamagnetic materials. Pyroxene, biotite, and amphibole are paramagnetic.

In certain other materials, there may be additional effects that give rise to very strong magnetic interactions of neighbouring atoms. For these materials the crystal lattice of the structure is such that atoms with very strong intrinsic magnetic moments (particularly iron) are in a spatial configuration that allows them to become aligned permanently, relative to the crystal lattice. This ordering is due to a very powerful intramolecular magnetic field and results in spontaneous magnetization of the material. The region of the material over which this ordering occurs is called a magnetic domain and is on the order of 10^{-4} centimetres. The energy required to produce the ordering is termed the exchange energy. If the magnetic moment vectors in a domain are all parallel to one another, the material is ferromagnetic. Antiferrornagnetism refers to an arrangement of vectors in two equal antiparallel sublattices so that the net magnetization is zero. If the sublattices are antiparallel but not of equal magnitude, giving rise to net magnetization, the material is termed ferrimagnetic. If the sublattices are of equal magnitude but not exactly antiparallel, the material exhibits parasitic antiferromagnetism. The minerals iron, pyrrhotite, magnetite, and hematite, respectively, are examples of each of these types of domain orderings.

Intensity and components of magnetization

The magnetic moment per unit volume of material is called the strength or intensity of magnetization. It is a vector quantity and usually expressed by the letter J. The total magnetization J may contain both induced I and remanent components $\boldsymbol{R}$. These add vectorally to give $J = \boldsymbol{R} + I$ The induced magnetization is dependent on the direction and strength of the ambient magnetic field and the susceptibility k of the material. The value of k is a function of the mineralogical composition of the material. This relation can be expressed as: $I = \mathrm{k}H$. $\boldsymbol{R}$ is dependent on the above and on the thermal, chemical, and physical history of the material. A specimen that already has a remanent magnetization may acquire a new magnetization, This new magnetization may not erase the original but may add to it, vectorally, to produce a new total magnetization. Thus if R_{A} and I_{A} are the original remanent and induced components and a new remanent component R_{B} is added to it, the resultant total magnetization will be

$$J_{\mathrm{AB}} = R_{\mathrm{A}} + R_{\mathrm{B}} + I_{\mathrm{A}}.$$

If a new magnetization I_{B} is simply induced by an ambient magnetic field H_{B} that is different from the original ambient field H_{A}, then the new magnetization will be

$$I_{\mathrm{B}} = \mathrm{k}H_{\mathrm{B}},$$

and the total magnetization will then be given by

$$Jan = R_{\mathrm{A}} + In,$$

in which the I_{A} is lost and replaced by **In.** A portion of the magnetism induced in this fashion may or may not be retained as a remanent magnetization R_{B}.

A rock from the surface of the earth may have several remanent component magnetizations such as R_{A}, **Rn,** R_{C}, etc. It is possible by various laboratory techniques to remove the magnetization attributable to certain of these components one at a time. This selective removal of magnetic components is termed demagnetization. It can be accomplished by heating the rock or exposing it to strong alternating fields. The values of magnetization found in nature vary from the smallest value that instruments can measure, about 10^{-7} electromagnetic unit per cubic centimetre (emu/cc) for limestones and shales, to about 10^{-2} electomagnetic unit per cubic centimetre for lava flows and iron ores.

Iron oxide or sulfide minerals commonly exhibit properties of ferromagnetism and can be classified into two types. The first type includes the more strongly magnetized cubic oxide minerals: magnetite, maghemite, and the titanomagnetite series. The weakly magnetic rhombohedra] minerals, hematite, ilmenite, and pyrrhotite, constitute the second type.

The major parts of most rocks do not possess remanent magnetism, but in localized regions certain magnetic minerals may form small grains. In magnetite-bearing rocks the grains are usually large enough to constitute domain clusters. For rocks containing hematite, the grains are usually of such small size that each grain represents a single domain that is easily disordered by thermal agitation. Although these rocks may appear to be strongly magnetized in the presence of an applied magnetic field, they show low magnetic remanence when removed from the field.

Temperature and magnetization

The rocks most strongly magnetized are those of igneous origin, namely those rocks thrust up to the earth's surface in a molten state. Volcanic extrusions of lava and intrusive dikes (tabular bodies that penetrate pre-existing rocks and structures) are examples. These materials contain relatively large amounts of iron oxide minerals and are commonly formed at temperatures greater than about 1,000"

C. This temperature is much above the Curie temperature of the magnetite minerals (575" C), above which ferrimagnetic minerals lose their remanent magnetic characteristics. Hematite loses its remanence above *675"* C. This is called the Neel temperature in antiferromagnetic minerals. Upon cooling at the earth's surface these minerals become strongly magnetized in the direction of the ambient earth's magnetic field. The temperature at which the rock acquires its magnetization upon cooling in a magnetic field is the blocking temperature. The blocking temperature depends largely on the size and shape of the magnetic domains. Such rocks are said to have acquired thermoremanent magnetization (TRM) because the magnetization is retained after the temperature falls to that of the surface environment and the field is removed. This magnetization is very stable and subsequent exposure of rocks with TRM to magnetic fields several orders of magnitude stronger than the magnetizing field cannot appreciably change the original magnetization.

Acquisition of magnetization

There are several ways in which a specimen may acquire magnetization in an ambient magnetic field, these include:

1. Thermoremaneut magnetization (TRM) is as described above.

2. Isothermal remanent magnetization (IRM) is a weak magnetization acquired in a strong magnetic field at constant low temperature, much below the Curie temperature, and in only a matter of minutes. This magnetization is considered soft (less stable) as compared to TRM.

3. Chemical remanent magnetization (CRM) is acquired in a weak magnetic field when new magnetic mineral grains are formed during such chemical reactions as oxidation and dehydration. These reactions occur at low temperatures much below the Curie temperature. The CRM is much like TRM in its strength and stability characteristics.

4. Viscous remanent magnetization (VRM) is acquired at constant low temperature in a weak magnetic field over a time period on the order of millions of years. It is a relatively strong and hard magnetization compared to IRM. The regular thermal agitation of the magnetic domains eventually orders the mineral grains to produce a coherent magnetization.

5. Detrital remanent magnetization (DRM) arises when small magnetic grains that already possess remanent magnetization fall through the earth's atmosphere or through water and are subjected to the earth's ambient magnetic field. The grains align themselves to produce an appreciable magnetic effect that is quite stable.

Less frequently encountered types of magnetization include piezoremanent magnetization (PRM), which arises when stress is applied to a specimen in a magnetic field; inverse-type thermoremanent magnetization (ITRM), due to anomalous changes in crystal structure with temperature in the presence of a magnetic field; and anhysteretic remanent magnetization (ARM), which sometimes arises in rock specimens when an external alternating magnetic field is decreased from a maximum value to zero in the presence of a constant magnetic field. In addition many materials acquire a strong magnetization when they are struck by lightening. It is important to note that an existing magnetic field must always be present when a rock is magnetized, regardless of the method.

The total magnetization of a rock may be due to the sum of any or all of these types of remanent magnetization and to a nonremanent (induced) magnetization as well. The ratio of the strength of remanent to induced magnetization is called the (Koningsberger ratio) Q. This ratio has been found to be nearly zero for some sedimentary rocks and characteristically high, approaching 100, for certain marine lava rocks.

The primary or original magnetization of most igneous rocks is generally considered to be TRM. The magnetization of sedimentary rocks is more complex. Certain sediments are believed to contain both CRM and DRM components of primary magnetizations. The former probably results from chemical changes shortly after the sediments are deposited on the sea floor, whereas the latter is acquired as the sediment particles slowly accumulate. The primary magnetization is believed to be acquired in most rocks soon after the rock is formed. Determination of the age of a rock and its primary magnetization therefore permits inferences to be drawn about the ancient geomagnetic field. Such studies of paleomagnetism are of great significance in terms of elucidation of earth history.

Sampling and study of rocks

In the study of rock types on land, a number of practical problems arise. The first is the question of whether the rock formation has been reoriented since it was magnetized. Sedimentary strata may have been tilted or severely folded, for example, by geologic forces. The observed angles for the magnetization vector must be corrected for any postdepositional tilting to obtain information about the original magnetic field direction. If there have been intrusions of magma (molten material within the earth) into a pre-existing rock mass, it is possible that thermal and pressure effects (metamorphism) will alter the magnetic characteristics of the older mass. Such problems can be overcome by careful inspection of the sampling locality and by taking many samples in the general vicinity. It should be recognized that even when all necessary corrections are made, the primary magnetization direction of rocks generally does not agree with the earth's present field direction. It appears that deviation from the present earth's field increases with the age of a given rock.

The sampling of rocks and sediments from the ocean floor is associated with different problems. The chief difficulty in dredging hard rocks at sea is that the recovered rock sample may be part of the sea floor proper but also may be an erratic fragment transported to that locality by icebergs or other natural means. The age and geologic history of the rocks, therefore, are not usually known. Secondly, there is the problem of determining the orientation of the recovered specimen. New types of ocean floor rock drills have permitted some oriented samples to be obtained by a surface ship, and some research submarines carry experimental drills for taking oriented samples. Soft deep-sea sediment samples generally are obtained by a coring device, a hollow tube that penetrates the bottom and is then recovered with the entrapped sediment sample (Figure 1). There is usually some question about the azimuthal orientation of the coring tube and thus some uncertainty about the declination (horizontal

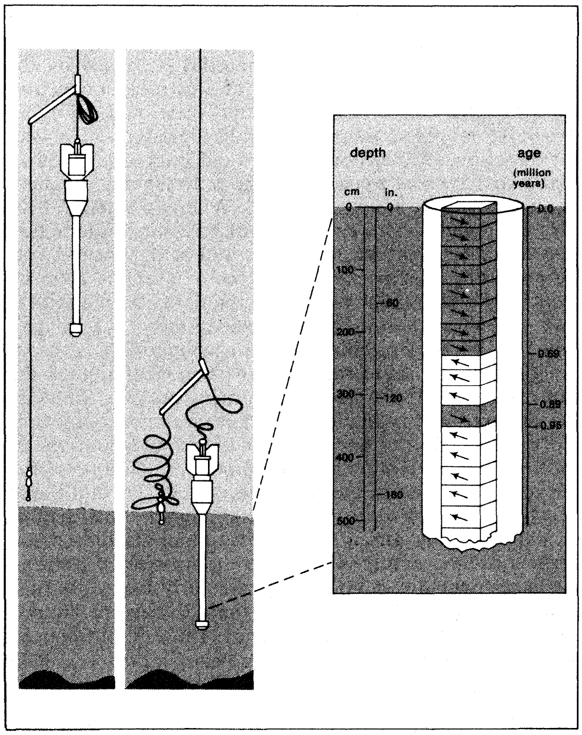

Figure 1: (Left) Recovery of ocean-floor-sediment column by deep-sea coring technique. (Right) Core of sediment. Arrows represent sediment magnetization vector directions. Dark and light cubes show expected sequence of normal and reversed magnetic polarity intervals as a function of depth beneath sea floor.

bearing) of the measured magnetization with respect to north. Fortunately, because the tube falls vertically downward in taking the sample, the inclination (departure from the horizontal plane) does not have to be corrected. Most sedimentary bedding planes on the ocean floor are horizontal or very nearly so. Sea-floor sediment samples also are usually weakly magnetized compared to the hard rocks and this constitutes another difficulty. The use of high sensitivity magnetometers has permitted measurement of the magnetic properties of rocks in recent years, however.

Measuring a rock's magnetism

The magnetization of a rock is measured in either of two ways. When an astatic magnetometer is used the specimen generally is positioned near a standard magnet system that is suspended vertically by a thin fibre. The specimen's external magnetic field causes the magnet to rotate, and the deflection of the magnet is noted, The specimen is then repositioned about a second axis and third axis; the three axes are oriented at right angles to each other. In each case the deflection is noted, and the magnetization is calculated from the three measurements.

In the second method, the sample is spun at high frequency near a signal pickup coil wound of fine wire, and the phase and amplitude of the induced voltage are noted. The sample is then repositioned with respect to the coil face and spun about a second and third set of axes. The magnetization can then be calculated by a procedure somewhat similar to that above. The instrument used is called a rock generator or spinner magnetometer.

THE EARTH'S PALEOMAGNETIC FIELD

The overall strength and direction of the earth's magnetic field can be expressed by its magnetic dipole moment. One hundred and fifty years ago the earth's dipole moment was 6 percent greater than at present. Fifteen hundred years ago it was 50 percent greater, but 5,500 years ago it was only about one-half of the present dipole moment. Various measurements made on samples as old as 500,000,000 years suggest that the field strength at that time was as little as one-quarter of its current value, although the variations through geologic time do not follow a very smooth curve.

In order to determine the strength of the paleomagnetic field, it is necessary first to measure the magnetic properties of an ancient rock sample. The sample is then heated above its Curie point to destroy its magnetism; finally it is cooled in a known magnetic field, and the new thermoremanent magnetization intensity is compared to the value it had before heating. If it is not the same the heating must be repeated followed by cooling in a different field. In this fashion, almost by trial and error, the strength of the original magnetizing paleomagnetic field is determined. The method is fraught with difficulties. Viscous magnetic effects and other irreversible changes, possibly of a chemical nature, cannot be accounted for. Nevertheless, the method has been applied to geologic samples, to the lining of kilns used by the Romans, and to hearths from early civilizations with apparent success.

Geomagnetic polarity reversals. Great strides have been made in understanding in detail how the earth's magnetic field has changed direction in the past. The most remarkable change in the field is the complete reversal of its polarity. It appears that within a relatively short period, probably less than 10,000 years, the field may reduce to a very small intensity and then re-establish itself with approximately equal intensity in exactly the opposite direction.

Naturally occurring rock sequences such as lava flows and sedimentary strata show sections that are reversely magnetized relative to the earth's present field direction. For many years it was believed that a rock could somehow automatically reverse its magnetization and, consequently, that there was little point in studying such an unstable characteristic of rocks. In 1960 it was indeed found that a special ilmenite–hematite mixture could become magnetized in a direction opposite to that of the applied field. Such mixtures are extremely rare in nature, and reversely magnetized rocks are not now believed to be due to any such cause. Rather the reversely magnetized specimens are thought to be due to their having been magnetized at a time in the geologic past when the earth's magnetic field had a polarity opposite from that which it has today. The idea of reversals of the earth's field was long considered hypothetical, but it is now accepted as fact by most geophysicists.

Volcanic rocks and the geomagnetic time scale

The most convincing evidence for polarity reversals of the earth's main magnetic field has come from recent studies of volcanic rocks collected from all parts of the world. Extensive field sampling programs have been carried out in the basalt flow regions of Iceland, Hawaii, California, southern Europe, East Africa, Australia, and India. Thick sheets of Pliocene and Pleistocene basaltic lavas exposed over large outcrop areas in these regions have been particularly useful. Such exposures yield rock samples that possess exceedingly stable remanent magnetism (TRM) in a flow sequence where the relative rock ages are clear.

The potassium–argon radioisotope decay technique is generally employed to determine absolute ages of rock specimens. Because the method is precise to about 3 percent of the age of the rock, a detailed chronology for the absolute age of lava flows extruded over the last 4,000,000–5,000,000 years has been determined. The time scale for geomagnetic polarity reversals can thus be inferred simply by noting the magnetic polarity of a lava flow and its absolute age. By analyzing a number of flows whose ages span appropriate time intervals, a catalog of age versus polarity can be developed. Because a single volcanic region generally contains lava flows extruded over a relatively short time interval, compared to the duration of a polarity state, it has been necessary to sample many volcanic regions to get a complete time se-

quence. Fortunately, nearly overlapping basalt flow chronologies, each spanning several polarity states, have been developed from the late Tertiary and Pleistocene Icelandic, Columbia River, and Hawaiian lava fields. Comparison of polarities measured from rocks of the same age collected in different parts of the world show remarkable agreement as would be expected if the geomagnetic field polarity does reverse itself through time. In fact, it is now possible to erect a detailed history of geomagnetic polarity reversals for the last 4,500,000 years. Figure 2 shows the sequence of normal and reversed states with the names assigned to the short events and the more comprehensive epochs. When the epochs were originally named and their dates established, they were thought to be long duration unipolar states. It was not known that they would contain several states of both polarities. Accordingly, the resulting system of naming epochs and events is partly redundant and somewhat ambiguous. Although several hypotheses related to changes in the electric-current pattern at the core–mantle interface have been advanced to account for the reversal phenomena, a satisfactory explanation is not available at this time.

Marine sediments and the geomagnetic time scale

The study of the magnetization of sediment layers from the sea floor yields the same sequence of polarity reversals as that found on land. In dating the subbottom horizons, each reversal in magnetization is related to a dated geomagnetic field reversal as determined from terrestrial volcanic rocks (Figure 1). The sedimentation rate can then be inferred and the sediment layer dated at various points on the sea floor. The coring technique, by which undisturbed bottom samples are obtained, has not permitted verification of the reversal time scale or the dating of material older than about 4,500,000 years. An interesting aspect of the reversal chronology observed in deep-sea cores is the apparent correlation of the extinction and first appearance of certain marine fossil organisms with reversal boundaries. It has been speculated that this is a causal relationship resulting from an increased influx of cosmic radiation during a polarity reversal. Such an influx may have accelerated evolutionary processes by causing extinctions and by increasing the rate of gene mutations. Much more work remains to be done in this area before definitive results will be available, however.

It is now believed that the field has had its present polarity for about the last 700,000 years, although there is some very recent evidence to suggest that one or a few very short periods of reversed polarity may have occurred within this 700,000-year period. Each such episode lasted no more than 10,000 to 20,000 years.

Historical departure of the magnetic and geographic poles

Polar wandering. Another important aspect of directional changes of the field is the implied migration of the magnetic pole across the earth's surface. The recent changes appear to be rather smooth and predictable. Current magnetic charts used by navigators show yearly correction factors that must be applied to the declination. Over the last 300 years observatory records at Paris and London show that the position of the magnetic field pole has completed nearly half a circle of rotation about the earth's geographic or rotational pole. The field direction has changed by about 7° in inclination and 35° in declination (Figure 3). Studies on archaeological specimens indicate that over the last 2,000 years the declination and inclination at various sites in England may have varied by as much as 20 to 30 degrees to either side of their present values.

The general configuration of magnetic lines of force of the earth appears to have a westward drift, to judge by the recent observatory records. Whether this trend will continue is problematical, but the magnetic dipole axis, now inclined some 11° to the geographic axis, might be expected to move slowly about the earth so that its average from the geographic or rotational axis will be zero over a few thousand years, say 10,000 years.

On a somewhat larger time scale the declination indeed appears to average near zero over a few thousand years. For example, ocean sediments deposited at a rate of one centimetre in a few thousand years provide core specimens a few centimetres in dimension for measurements on spinner magnetometers. Each specimen thus spans a time interval of 1,000 to 10,000 years and in most cases shows a magnetization close to the present rotational pole. The misalignment of the present geomagnetic dipole and the rotational pole therefore is probably a transient situation on the recent end of the geologic time scale.

Polar departures during geological time

In contrast to these rather minor magnetic and geographic discrepancies of pole position, directional changes observed in rocks on the order of tens and hundreds of millions of years old show marked deviations from the present geographic pole. The remanent directions appear to be offset from the present field because of slow wandering of the magnetic pole with respect to the present rotational pole. The directions may also be different for another very important reason: the entire continent upon which the rock lies may have moved or drifted. Continental drift, once considered extremely controversial, is now accepted by most earth scientists. A most important observation that led to the acceptance of the theory was the smooth angular displacement of the paleomagnetic poles for rocks of different ages taken from the same continent. Also rocks of the same age from other continents showed a consistently different displacement path. By shifting the continents, the displacement paths could be superimposed, and similar geologic features along the margins of the two continents would also match. In any event, the resulting magnetic-pole path during geologic time does not match the present rotational pole. In fact, the indicated north magnetic pole appears to have moved slowly across the earth's surface from equatorial latitudes 200,000,000–300,000,000 years ago to its present position in the Arctic Ocean. Some earth scientists believe that the ancient rotational poles also have wandered over the earth's surface with the magnetic poles.

Magnetic anomalies over the continents and oceans. Variations in the magnetic properties of the earth's crust are commonly used to locate and define ore bodies of economic value. Iron ore deposits are particularly well suited to magnetic-exploration methods. Because the hard rock basement in most areas is more magnetic than the overlying sediments (a magnetization contrast on the order of 1,000 usually exists), the sharpness of the magnetic effects on the surface also gives an estimate of the depth of burial of the basement and information about the configuration of the basement. Quantitative procedures exist for obtaining the most likely geometry of buried structures, but it is never possible to determine from the magnetic data alone the exact configuration of the basement. The configurations of many magnetic bodies can give rise to the same anomalous values on the surface.

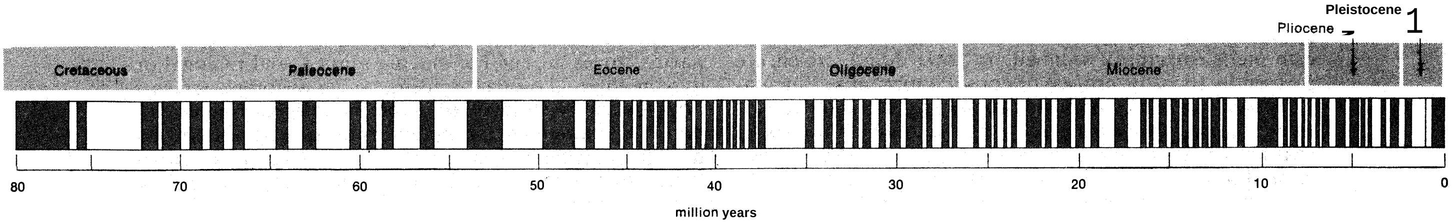

Figure 4: Geomagnetic polarity reversals time scale for the last 80,000,000 years as inferred from magnetic anomaly profiles across oceanic ridge crests. Black and white bands represent periods of normal and reversed polarity respectively.

Nevertheless, magnetic surveys are useful for estimating the depth of sedimentary basins.

Anomalies over oceanic ridges

An analysis of the spatial fluctuation of magnetic values shows that wavelengths of up to about 100 to 200 miles are due to the. earth's crustal features. Wavelengths greater than 1,000 to 2,000 miles are part of the earth's main field and arise at the core-mantle interface within the earth. There are relatively few wavelengths between 200 and 1,000 miles.

The pattern of anomalous magnetic values (magnetic anomalies) is, in general, quite irregular over the continents, the continental shelves, and marginal seas such as the North Sea and the Mediterranean Sea. Over much of the ocean, on the other hand, the pattern is more simplified and exhibits characteristic linear trends. Except for relatively isolated disturbances caused by volcanic seamounts, the ocean is dominated by linear magnetic anomalies that are related to the midocean-ridge system in all the oceans. Basaltic submarine lava flows near the sea floor are believed to be responsible for most oceanic anomalies. These rocks typically show a very high Q-ratio (ratio of remanence to induced magnetization).

The midocean-ridge system is an enormous mountain range that extends down the full length of the Atlantic Ocean, continues around Africa into the Indian Ocean, and, after branching, goes south of Australia and up the eastern part of the Pacific Ocean. The strength of the magnetic field is alternately anomalously high and low with increasing distance out from the axis of this ridge system. The anomalous features are almost symmetrically arranged on both sides of the axis and parallel the axis, creating bands of parallel anomalies.

Sea-floor spreading

According to the sea-floor-spreading theory, these linear anomaly trends are underlain by alternating bands of normally and reversely magnetized basaltic rocks on the sea floor. These rocks are thought to have been created at the axis of the midocean ridge, where they acquired a thermoremanent magnetization as they cooled. The polarity of their magnetization depended upon the polarity of the geomagnetic field at the time they cooled. It appears that the older rocks spread out to each side of the ridge as new igneous material continuously wells up along the ridge axis. Because the sea floor is thought to spread at a relatively constant rate, the history of geomagnetic field reversals is believed to be recorded in rocks of the ocean floor. If spreading rates are on the order of one to ten centimetres per year (10 to 100 kilometres per 1,000,000 years), then the history of reversals matches the geomagnetic polarity time scale determined from terrestrial volcanic rocks very closely. Observed magnetic profiles are calibrated by matching them with computer-simulated anomaly profiles formed by spreading during the Gauss epoch, 3,370,000 years ago. The spreading rate is considered constant throughout the last 4,500,000 years. A comparison of the polarity time scales determined by this method and the volcanic-rock method is shown in Figure 2.

When the different spreading rates in the oceans of the world are considered, the sequence of normal and reversely magnetized rocks is remarkably similar in all the ocean floors. Initially an arbitrary number was assigned to the anomalies for identification, but absolute dates now have been assigned to the magnetic anomalies; these signify both the age of the ocean floor and the date of the magnetic reversals of the field.

The assignment of ages to magnetic anomalies has been made by assuming that the particularly distinctive magnetic anomaly associated with the Gauss geomagnetic normal polarity epoch about 3,370,000 years ago can be recognized in the magnetic profiles. Measurement of the distance of this anomaly feature from ridge crests thus permits determination of the spreading rate over the last 3,370,000 years. By extrapolating this rate to the outer ridge flanks, anomalies older than 3,370,000 years can be dated. On the basis of profiles across the South Pacific and South Atlantic oceanic ridges, a time scale for the last 80,000,000 years, approximately, has been developed (Figure 4); its verification was provided by recent deep-sea drilling in the south Atlantic Ocean. The age of sea-floor lava rock obtained at varying distances from the ridge crests showed that the spreading rate inferred from magnetic profiles is essentially correct.

Rock Metamorphism, Principles of

Metamorphism means change, and in petrology the term refers to the physical and chemical alteration of rocks that are subjected to the elevated temperatures and high mechanical stresses that occur in the earth's crust. This article describes the kinds and degrees of metamorphism that are known and the relations between the important causative variables and rock compositions and structures. For information on the specific rock types involved see METAMORPHIC ROCKS; for information on the conditions that lead to metamorphism see EARTH, STRUCTURE AND COMPOSITION OF and MOUNTAIN BUILDING PROCESSES; see GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES for the geochemistry involved.

Petrologists divide rocks into three broad classifications: igneous rocks (*q.v.*), those that have solidified from silicate melts (magmas); sedimentary rocks (*q.v.*), which are formed by the slow process of consolidation of sedimentary deposits; and metamorphic rocks (*q.v.*), which constitute a major part of the earth's crust and which are rocks that originally belonged to the other groups but that were altered in various ways. The alteration consists in part of chemical reactions among the minerals in the rocks or between incoming fluids and the original minerals. These changes in physical and chemical properties of rocks, under the new environmental pressures, transform them into new species. For example, clay sediments change to shales and slates at temperatures around 100°–200° C. At higher temperatures in the earth's crust, clay may change to mica schists or various types of gneisses. Limestones, originally formed as sedimentary rocks from the calcareous shells of primitive animals, change to marbles by the chemical reactions and recrystallization that occur during metamorphism.

Mechanical deformation of rocks is another common occurrence in metamorphism. This deformation is partly plastic; the rock yields more or less like metal under crustal stresses. These crustal stresses can sometimes crush rocks to fragments varying from pieces a foot long to fine powder (see ROCKS, PHYSICAL PROPERTIES OF).

Alterations of a physical and chemical nature are also caused by weathering (*q.v.*) of rocks in·contact with the atmosphere and surface water and by diagenesis of sediments, but such changes are generally not included in the term metamorphism. Weathering and diagenesis occur at temperatures below those at which true metamorphism takes place. On the other hand, temperatures above 600°–900" C, depending on rock type, cause silicate rocks to melt and thus the realm of magmatism and magmatic rocks is created. Rocks exposed to these extreme physical conditions are called ultrametamorphic.

METAMORPHIC ALTERATIONS

All kinds of rocks may be exposed to metamorphic alterations. Alterations without change of bulk chemical composition of the rocks are called isochemical metamorphism. If change of bulk chemical composition is involved, the term allochemical metamorphism applies.

Some chemical constituents are very mobile in rocks undergoing metamorphism. The content of mobile constituents such as water and carbon dioxide is rarely constant in a rock during metamorphic alterations. Thus, a gabbro that consists of two anhydrous minerals, plagioclase feldspar and pyroxene, picks up several percent of water if metamorphosed at low temperatures because hydrous minerals such as chlorite and hornblende are formed. On the other hand, a sedimentary rock containing hydrous clay minerals loses large amounts of water when metamorphosed at high temperatures (above 500" C), at which essentially anhydrous minerals become stabilized. Similarly, rocks may readily gain or lose carbon dioxide because at high temperatures, calcite and other carbonate minerals react with quartz or silicates to form calc-silicates and carbon dioxide gas, which escape from the altered rocks.

Rocks containing calc-silicates such as wollastonite, diopside, and anorthite often develop carbonates at low-temnerature metamoryhism. This means considerable introduction and gain of carbon dioxide. An example of reactions involving carbon dioxide is as follows:

low temperature		high temperature	
$CaCO_3$ +	$SiO_2 \rightleftharpoons$	$CaSiO_3$ +	CO,.
calcite	quartz	wollastonite	carbon dioxide

The right-hand side of this metamorphic mineral reaction corresponds to high temperature and loss of carbon dioxide, the left-hand side to low temperature and gain of carbon dioxide.

Many rock-making chemical constituents other than water and carbon dioxide are mobilized during metamorphism, thus making change of bulk chemical composition a common phenomenon.

Types of metamorphism. Metamorphism is conveniently classified as contact metamorphism, which occurs in narrow zones around hot magma masses, and regional or dynamothermal metamorphism, which encompasses vast complexes of rocks involved in the evolution of fold mountains. The latter type of metamorphism is not caused by heat from molten magmas but rather by tectonic, or structural, stresses in the earth's crust and a regional rise in crustal temperature. The reason for such regional rises in crustal temperature is not known for certain, but it is probable that it is caused by the dissipation of the potential energies that create fold mountains (see ROCK DEFORMATION).

Contact metamorphism. Rocks altered by contact metamorphism show little or no sign of strain such as plastic flowage or mylonitization or crushing of minerals. In contact metamorphic rocks, recrystallization (for example, formation of coarse-grained marble from limestone or quartzite from sandstone) and neomineralization (the formation of new mineral assemblages more stable than the old ones) are the most prominent features. Such rocks are generally called hornfels.

Regional metamorphism. Regional metamorphic rocks bear signs of mechanical strain in addition to recrystallization and neomineralization. The strain is seen as schistosity or foliation and other kinds of anisotropic structures in the rock bodies, much like the structures found in rolled metal plates and drawn wires. Crystalline schists such as mica schists and greenschists, many marbles, most gneisses, certain soapstones, amphibolites, and granulites are regional metamorphic rocks.

Progressive and regressive metamorphism. Rock alteration taking place at increasing temperature (and pressure) is called progressive metamorphism (for example, clay sediment altered to mica schist). Alteration at decreasing temperature is called regressive metamorphism or diaphoresis (for example, greenschist formed from basic lava).

Polymetamorphism. A polymetamorphic rock is one that has been exposed to two or more periods of metamorphism. Such rocks may carry proof of their complex history in the form of structural or mineralogical relics from earlier states in their evolution. The term palimpsest (from the Greek for scratched or scraped, that is, marked again) structure was coined for features of this kind.

GRADES OF METAMORPHISM

Metamorphic rocks provide an illustration of the fact, established by atomic science, that the concept of "dead matter" is an illusory one. Exposed to changing geological conditions in the lithosphere, rocks respond by mineralogical, structural, and chemical alterations and, thus, tend to develop mineral assemblages or recurring combinations and structures best suited—*i.e.*, most stable—under the conditions of temperature, pressure, and anisotropic stress that affect rocks during their evolution.

The principal processes taking place in rock bodies during metamorphism are recrystallization and neomineralization. referred to above. The change of mineral assemblages in response to varying temperature and pressure conditions makes it possible for geologists to distinguish among various grades or degrees of metamorphism. The different grades are determined by the occurrence of characteristic minerals or mineral assemblages that represent, and presumably are stable at, unlike pressure and temperature (P,T) conditions.

Grades and depths. The Swiss petrologist Ulrich Grubenmann (1850–1924), in his classification of crystalline schists, distinguished among three grades of metamorphism, the epi (upper), meso (middle), and kata (downward) zones. Grubenmann believed that depth of burial in the earth's crust was the chief reason for unlike grades of metamorphism because pressure obviously increases with depth and, generally, so does temperature, as shown by the geothermal gradient, or increase in temperature of the earth from the surface toward the interior, averaging about 3° C per 100 metres (see EARTH, HEAT FLOW IN).

Epizonal rocks were regarded as products of shallow depths because their mineral content was characteristic of low temperature (chlorite, talc, serpentine, and other hydrous minerals).

Mesozonal rocks carry minerals generally formed at moderate temperature (300" C to 400" C). Such rocks were consequently believed to have developed at intermediate depth in the crust.

Katazonal rocks consisting mostly of anhydrous minerals such as garnet, kyanite, hypersthene, cordierite, feldspar, etc., were considered ambassadors from the deepest portions of the earth's crust, now exposed by erosion.

Unlike grades and constant composition. G. Barrow, working in Scotland, demonstrated that the grade of regional metamorphism changed in horizontal direction across the Caledonian fold-mountain chain, which extends in a northeast-southwest direction through the Highlands. Zones of rocks exposed to the same grade of metamorphism are approximately parallel to the axes of the mountain chain, low-grade rocks generally occupying marginal zones and high-grade rocks central zones, with rocks of intermediate grade between. Similar conditions are encountered in other areas of more or less eroded fold-mountain chains, such as the Caledonian chain in Scandinavia and many Precambrian, deeply eroded mountain chains in Fennoscandia (the Baltic Shield), Canada, west Greenland, and other areas. Barrow chiefly studied alterations of argillaceous (clay-rich) sediments, which are very responsive to changing pressure and temperature. Certain index minerals were used to identify certain grades of metamorphism; one index mineral would change over to another along a more or less curved boundary line in the field. Such a line is termed an isograde and represents the intersection between the earth's surface and a boundary surface separating two neighbouring zones of metamorphism. Such boundary surfaces between adjacent but unlike zones of regional metamorphism are curved surfaces that often but not always show fold axes more or less parallel to the axis of the mountain chain. Chlorite, biotite, garnet, kyanite, staurolite, and sillimanite were minerals used by Barrow to indicate increasing grades of regional metamorphism.

Goldschmidt's studies

Constant grade and unlike compositions. V.M. Goldschmidt was the first to apply extensively physicochemical principles in a study of metamorphic rocks. His treatise of the Oslo (Kristiania) area in Norway has become classic. In this area numerous magmatic bodies of Permian age have intruded a sedmentary complex of sandstone, limestone, and argillaceous schists. These sediments have been exposed to high temperature in a contact zone of varying thickness around the intrusive magmatic rocks. At a constant distance out from the rim of a given magma body the temperature in the surrounding sediments has been constant. Therefore Goldschmidt was able to study in great detail how rocks of unlike bulk chemical composition (sandstone, limestone, claystone, etc.) responded to a given temperature as determined by the solidifying magma. In other words, Goldschmidt studied the effect of a given grade of metamorphism (the grade of contact metamorphism, or the pyroxene hornfels facies of P. Eskola, discussed below) on a number of rocks of unlike chemical composition. Barrow had studied the effect of unlike metamorphic grade on rocks of nearly constant composition. Later, P. Eskola combined both by studying the effect of various grades of metamorphism on rocks of various bulk composition.

Chemical equilibrium and the phase rule. The important Oslo-area work led to the conclusion that chemical equilibrium had been approached rather closely in sediments baked in the heat from intrusive magmas. Subsequent studies have shown that chemical equilibrium among minerals in rocks generally is attained also during regional metamorphism, probably more commonly than under contact metamorphism. The laws of chemical equilibrium in heterogeneous systems are consequently applicable to metamorphic rocks, a fact largely responsible for the recent progress in metamorphic petrology. Metamorphic rocks frequently obey the chemical phase rule: $P + f = C + 2$, in which P stands for phases, which in petrology correspond to minerals, f means degrees of freedom, and C components. In silicate rocks simple oxides are conveniently counted as components; if sulfides are present sulfur is an additional component.

The chemical phase rule

Under isochemical metamorphism, rocks are closed systems not permitting communication of chemical constituents with the environment. Two degrees of freedom have then generally prevailed inasmuch as pressure and temperature are independent variables, and the so-called mineralogical phase rule is valid: $P = C$. That is, a metamorphic rock formed under equilibrium conditions should have the same number of different minerals as it has components. It is noteworthy that metamorphic rocks very rarely have more minerals than components, counted in terms of simple oxides, such as those of potassium, calcium, magnesium, silicon, etc. Indeed, in most metamorphic rocks the number of minerals is fewer than the number of components. For example, many amphibolites, which are common metamorphic rocks in terrains of gneisses and crystalline schists, contain only the two minerals plagioclase and hornblende, yet chemical analyses may show ten or more simple oxides. The reason for this apparent discrepancy is in part that many minerals are mixed crystals in which several atoms or ions can substitute for one another in identical structural positions. Sodium and calcium are interchangeable in plagioclase and so are silicon and aluminum to some extent. In hornblende a great number of cations substitute for one another. Magnesium, iron, titanium, aluminum, manganese, nickel, and cobalt are all encountered in identical structural sites. This means that several unlike chemical elements must be counted as one component because they are identical from a mineral–chemical point of view.

The mineralogical phase rule

Mineral assemblages. The general approach to chemical equilibrium among minerals in metamorphic rocks results in an order and regularity that invite natural classifications of such rocks. Contact metamorphic rocks can, for example, be placed in phase diagrams of the type shown in Figure 1.

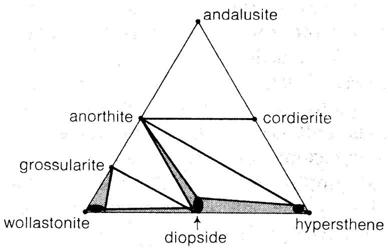

Figure 1: Mineral assemblages of contact metamorphic rocks.

This particular three-component diagram with Al_2SiO_5 (andalusite), $CaSiO_3$ (wollastonite) and $(Mg,Fe)SiO_3$ (hypersthene) at the corners is only applicable to rocks with excess silica metamorphosed in the contact zones around magmas. Any one of the possible mineral assemblages shown in Figure 1 may develop. There are, however, restrictions as to the number as well as types of associated minerals at equilibrium. If chemical analysis of a hornfels places it on a join line between two minerals in Figure 1, then only these two minerals are permitted at stable equilibrium. (Minerals containing elements not shown in the diagram may certainly occur, in addition to those indicated by the phase diagram.) A hornfels falling within one of the three angles in the figure must contain the three minerals at the corners. Only one mineral can be present stably in a hornfels with bulk chemical composition coinciding with that of the mineral itself. Incidentally, such monomineralic rocks are not as rare as one may assume in view of the small chance that bulk composition of sediments should coincide with that of a pure mineral. Pure diopside hornfels and wollastonite hornfels are described from various places.

The Oslo hornfels adjacent to the magmatic intrusives follow very strictly the rules of permitted mineral assemblages. Ten classes of hornfels have been recognized in the field:

Classes of hornfels

Class 1 rocks with andalusite and cordierite (albite);
Class 2 rocks with andalusite, cordierite, and anorthite;

Class 3 rocks with anorthite and cordierite;
Class 4 rocks with anorthite, cordierite, and enstatite;
Class 5 rocks with anorthite and enstatite;
Class *6* rocks with anorthite, enstatite, and diopside;
Class 7 rocks with anorthite and diopside;
Class 8 rocks with anorthite, diopside, and grossularite;
Class 9 rocks with grossularite and diopside;
Class 10 rocks with grossularite (vesuvianite), diopside, and wollastonite.

This sequence of classes of hornfels corresponds to increasing amounts of calcite (calcium) in an argillaceous sediment. Andalusite is the metamorphic product of the typical clay mineral kaolinite, and wollastonite forms at high temperature by calcite and silica interaction.

Metamorphic facies. At grades of metamorphism different from contact metamorphism other minerals and mineral associations occur. These assemblages can be shown in diagrams similar to Figure 1, with calcium, aluminum, and magnesium + iron silicates at the corners. Eight grades, each with its characteristic phase diagram (called ACF diagram), have been recognized and described in studies of areas in Finland and and Norway. The characteristic mineral association of each grade is called mineral facies or metamorphic facies, with the name of each facies chosen from the kind of rock most dominant within that grade. Basic rocks rich in calcium and magnesium are most sensitive to changes of metamorphic grades. The various facies are named after such rocks rather than acidic and alkali-rich ones. This does not mean, however, that acidic and alkaline rocks are not found in the unlike facies or grades; it only emphasizes that it is difficult to distinguish among unlike metamorphic grades in rocks such as granitic gneisses, quartzites, nepheline syenites, and the like. Quartz, potash feldspar, and acidic plagioclase, the chief minerals in such rocks, are stable over the whole pressure-temperature field in which most metamorphism takes place. Thus a granitic gneiss consisting of quartz, potash feldspar, and albite remains a granitic gneiss with the same minerals at all grades of common metamorphism. On the other hand, minerals occurring in basic rocks, being of magmatic or sedimentary origin, such as pyroxenes, hornblendes, chlorites, talc, serpentine, olivine, anorthite, and epidote, have narrow fields of stability. A basic rock of given bulk composition may, for example, yield a gabbro (pyroxene and plagioclase) at high metamorphic grade, an amphibolite (hornblende and plagioclase) at intermediate grade, and a greenschist (chlorite epidote and albite) at low grade.

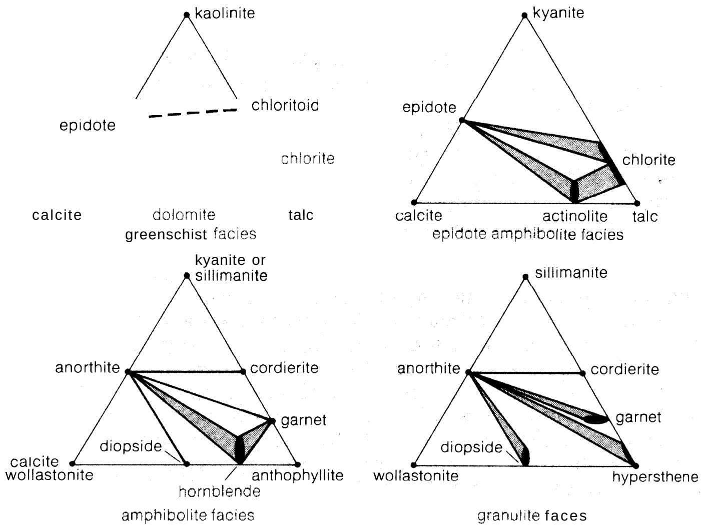

Figure 2: Various grades or facies of regional metamorphism.

The sequence of metamorphic grades from low to high grade of regional metamorphism is greenschist facies, epidote amphibolite facies, amphibolite facies, and granulite facies. Corresponding ACF diagrams are shown in Figure 2. Contact metamorphism belongs to the pyroxene hornfels facies.

Other facies less commonly encountered are eclogite facies, glaucophane schist facies and sanidinite facies. Figure 3 shows the approximate positions of the various facies in a pressure-temperature diagram.

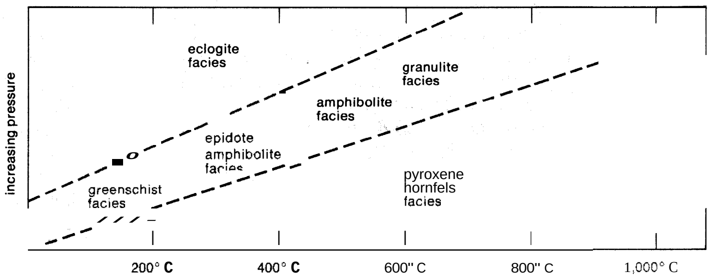

Figure 3: Facies of contact metamorphism.

TEMPERATURE AND PRESSURE OF METAMORPHISM

Knowledge of the temperature and pressure represented by the various metamorphic facies is limited. It seems certain, however, that granulite facies is the highest of regional metamorphic grades and corresponds to about 600"–700" C. Greenschists must have developed at much lower temperatures, perhaps 200" C.

Temperature. Assuming that chemical equilibrium was attained in metamorphic rocks at the time of recrystallization, their mineral assemblages should reveal the correct pressure-temperature conditions of metamorphism. Laboratory studies have given some information on stability relations of mineral assemblages. Such studies indicate that a temperature of 600"–700" C can be assigned to the granulite facies. The two alkali feldspars, microcline and albite, constitute a complete mixed-crystal series above 600" C. At lower temperatures a gradual unmixing takes place, the two coexisting feldspar phases becoming more and more pure. At room temperature only negligible amounts of soda in microcline or potash in albite can exist stably.

Laboratory studies of pressure-temperature conditions of metamorphism

In granulites, albite and microcline are often found as one single phase of solid solution whereas in lower-grade rocks albite with varying amounts of dissolved potash and microcline with varying amounts of dissolved soda are found as two independent minerals (see also FELDSPARS).

A similar situation exists in the calcite-magnesite (calcium carbonate and magnesium carbonate) system. Calcite takes varying amounts of magnesium carbonate in solid solution, depending upon prevailing temperature during recrystallization. It has been determined that magnesian marbles metamorphosed in granulite facies often carry calcite with concentrations of magnesium corresponding to temperatures around 600" C.

Muscovite is a hydrous silicate occurring in many metamorphic rocks. At somewhat elevated temperature the mineral reacts with quartz and loses water, whereby sillimanite and potash feldspar are produced:

$$\underset{\text{muscovite}}{KAl_3Si_3O_{10}(OH)_2} + \underset{\text{silica}}{SiO_2} \rightleftharpoons \underset{\text{feldspar}}{KAlSi_3O_8} + \underset{\text{sillimanite}}{AlSiO_5} + \underset{\text{water}}{H_2O}.$$

Muscovite is never found in true granulites but sillimanite and potash felspar occur frequently together. In lower-grade rocks, muscovite and quartz are commonly found together. Thus the pressure-temperature conditions at which the above reaction takes place should give the lowest boundary of granulite facies—*i.e.*, the boundary line between granulite facies and amphibolite facies. At low pressures this reaction is sensitive to pressure variations because water vapour is involved. At higher pressures, however, laboratory investigations have shown that the reaction temperature at equilibrium is close to 600" C over a wide pressure range. This is then the third mineral system that indicates that the highest temperature in regional metamorphism is not much higher than 600° to 700" C (see MICAS). At higher temperatures silicate rocks begin to melt and magmas are born, a process called anatexis or palingenesis.

A mineral system often applied as a geologic thermometer in metamorphism is calcite + quartz and wollastonite + carbon dioxide.

Pressure. Pressure also varies from one facies to another. In a general way it is known, for example, that pyroxene hornfels facies represent much lower pressures than granulite facies, the latter not only corresponding to the highest temperature in regional metamorphism but also the highest pressure. Reactions among minerals with unlike molal (gram-molecular) volumes are useful geologic barometers. The mineral jadeite, $NaAlSi_2O_6$, which mostly is found in rocks altered or formed at high pressures, is an example. Jadeite has much higher density than albite although the composition of the two minerals is nearly the same, albite having the formula $NaAlSi_3O_8$. Jadeite can form from albite as follows:

$$\underset{\text{albite}}{NAlSi_3O_8} \rightleftharpoons \underset{\text{jadeite}}{NaAlSi_2O_6} + \underset{\text{quartz}}{SiO_2}.$$

The jadeite–quartz combination has considerably less volume than albite so that high pressure favours the jadeite–quartz assemblage. Within the temperature range in which this reaction occurs stably, albite is stable at low pressures and jadeite plus quartz at high pressures. Thus eclogites, which are considered high-pressure rocks by most petrologists, have a high percentage of jadeite molecules (see PYROXENES).

TEXTURE AND STRUCTURE OF METAMORPHIC ROCKS

The mineral assemblages of metamorphic rocks have developed by recrystallization and chemical reactions in the solid state, often under conditions of tectonic stress. Such rocks have therefore texture and structure different from those of igneous and sedimentary rocks.

Mineral grains in metamorphic rocks are mostly without crystal faces and border against their neighbours along irregularly curved surfaces not related to their internal crystalline structure. Such texture is called crystalloblastic. An idioblast is a mineral grain with well-developed crystal faces. During metamorphism certain minerals show greater tendency to form idioblasts than others. Garnet often forms perfect idioblaats in mica schists. whereas quartz never does and feldspar only rarely.

The idioblastic series

Minerals may be placed in the so-called idioblastic series according to their tendency to develop crystal faces during metamorphism. The major members of this series are as follows: sphene, rutile, garnet, kyanite, epidote, pyroxene, hornblende, albite, chlorite, quartz, microcline. Sphene almost invariably forms idioblasts, quartz and microcline very seldom.

Riecke's principle and force of crystallization. A mineral growing in a metamorphic rock has to produce space for itself in a solid environment. Surrounding minerals must then either be pushed aside bodily or disintegrate chemically (for example, dissolve in a pore moisture). The so-called force of crystallization or pressure of growth is of importance in this connection. Any crystal is able to grow against excess pressure if the system is supersaturated with references to that crystal; the more supersaturated the system, the higher the pressure of growth. On the other hand, if a crystal is exposed to excess pressure in a saturated system, it becomes unstable and tends to disintegrate chemically. (Excess pressure here means pressure on the crystal higher than in the rest of the system.) In solid rocks such disintegration does not necessarily mean dissolution in a fluid, because liquid solutions are not always present. It generally means disintegration into individual ions, atoms, or molecules, which are carried away by diffusion along mineral interfaces or even through their crystalline body. This phenomenon of chemical disintegration under excess pressure is referred to as Riecke's principle. It not only explains plastic flow of solid rocks under stress but is also important in explaining recrystallization and neomineralization. A newly stabilized mineral grows in a metamorphic rock because the rock has become somewhat supersaturated with reference to the new mineral owing, for example, to changing pressure-temperature conditions. The growing mineral surrounds itself by a field of pressure in excess of that prevailing elsewhere in the rock. Minerals present in this field of excess pressure disintegrate according to Riecke's principle and thus provide space for the newly stabilized growing mineral. Thermodynamic analysis shows that under otherwise like conditions (same pressure-temperature values, same degree of supersaturation) dense minerals develop higher pressure of growth than less dense minerals. In this connection it may be noted that the above-mentioned idioblastic series of minerals as determined empirically from field studies also is a density sequence, sphene and garnet being dense structures, quartz and feldspar loose, open structures.

Analysis of .structure. The structure of rocks is called isotropic or massive if it is identical in all directions in space. Some contact metamorphic rocks may show such structure, but practically all regional metamorphic rocks have anisotropic structure—*i.e.*, structures with planar and linear features. Planar structure shows up well in most mica schists in which the majority of mica flakes may be parallel to a given plane—the plane of foliation or schistosity. In ideal planar structure all directions in the schistosity plane are identical. Needle-shaped minerals such as siilimanite and hornblende show statistic parallelism to the schistosity plane, but they are oriented at random within that plane. In linear structure needle-shaped minerals show preferred parallelism to a line. This line is called lineation. In most natural rocks linear and planar structures occur together.

The origin of anisotropic structure is twofold:

1. The structure may be relic (a remnant of the original structure) after premetamorphic anisotropic structure of various kinds. Sediments with bedding structure and lavas with flow structure may preserve their anisotropic structure as relic during metamorphic recrystallization even if not exposed to anisotropic stress. Structures formed in this manner are termed mimeoblastic. In polymetamorphic rocks anisotropic structures formed in earlier periods of metamorphism may remain as relic mimeoblastic structure through later recrystallization. In contact metamorphic rocks mimeoblastic structure is common because anisotropic stress is not likely to occur in contact zones around magmas.

2. Anisotropic structure develops in rocks recrystallized under anisotropic stress. The stress causes strain of the rock bodies (cataclastic, with fractures, and plastic, without fractures) and consequent rearrangement of mineral grains into various types of anisotropic structures. The structure of most regional metamorphic rocks is of this kind.

Stress mechanisms in rocks

The mechanism causing such structures to form is little known and probably very complex. It is assumed that the following processes occur in a rock under stress: (1) rotation and relative movement of mineral grains by slip along interfaces; (2) slip along certain crystallographic planes and lines inside mineral grains (so-called glide planes and lines); (3) dissolution (or other kind of chemical disintegration) at points of high compressive stress and redeposition at points of low stress in accordance with Riecke's principle; and (4) fracturing and crushing of mineral grains—so-called cataclasis.

Crushing. Evidence of any one of these processes may be found in metamorphic rocks. If fracturing is dominating the phenomenon is called mylonitization and the produced rock a mylonite. Such mylonites occur usually only in narrow zones in metamorphic terrains, demonstrating intensive shear movements along these zones with corresponding crustal stresses exceeding the crushing strength of minerals. However, many metamorphic rocks show no sign of mineral crushing.

Rotation. Evidence of rotation of mineral grains during metamorphism is not uncommon, the most cited example being the so-called snowball garnet with inclusions arranged in a spiral as a result of rotation during growth.

Slip. Calcite and other carbonates yield readily by slip along certain lattice planes often resulting in polysynthetic twinning and bending of grains. This is observed in many natural marbles in thin sections under the microscope. Laboratory experiments with marble blocks under stress at elevated temperature also show that gliding along crystallographic glide planes is important in rock deformation. It seems, however, that most silicate minerals deform via chemical processes more or less in harmony with Riecke's principle during regional metamorphism. Tectonic stress is generally too weak to produce crushing and lattice slip. Slow creep due to recrystallization seems more important in rock deformation.

Orientation. The statistic parallelism of mineral grains in rocks with anisotropic structure may be dimensional orientation or lattice orientation. Dimensional orientation refers to the external shape of mineral grains, whereas lattice orientation refers to the internal structure of minerals. Quartz grains in schists and gneisses may, for example, have lenticular shapes unrelated to the internal crystal structure. Such quartz lenses are often dimensionally oriented parallel to the schistosity plane. This kind of anisotropic structure is most likely a result of dissolution at points of high compressive stress (*i.e.*, at mineral interfaces that are perpendicular to the highest compressive stress) and redeposition at points of low compressive stress (*i.e.*, at interfaces or surfaces more or less perpendicular to the direction of the least compressive stress or maximum tensile stress).

Minerals with equidimensional outline such as those belonging to the regular crystallographic system may show preferred lattice orientation that can be detected only by accurate microscopic studies.

METAMORPHIC DIFFERENTIATION

During metamorphism, originally homogeneous rock bodies may become heterogeneous in the sense that schlieren (alternating bands of contrasted composition) and veinlets develop. Such phenomena are called metamorphic differentiation. For reasons not clearly understood minerals disintegrate chemically at certain sites in rocks and redevelop at other sites, the transfer probably being in the form of diffusion. Quartz veinlets and clusters commonly form in crystalline schists, "knots" of epidote in green stone, and segregations of diopside or other calc-silicates in crystalline limestone. Such metamorphic differentiation is most prominent in strongly deformed rocks. It is therefore concluded that stress and strain are instrumental in metamorphic differentiation. Minerals that dissolve more readily than others in zones of intensive stress and shearing are leached out from such localities and may be deposited anew where stress is low, thus causing metamorphic differentiation. Interfacial tension, energy of nucleation, and force of crystallization are properties that seem significant in metamorphic differentiation.

Many features in metamorphic terrains caused by metamorphic differentiation are difficult to distinguish from features resulting from magmatic activity. Pegmatite dikes and mineral veins in crystalline schists are commonly products of metamorphic differentiation although similar rocks may also form from magmas. Some workable ore deposits (*q.v.*) in regional metamorphic terrains are probably also products of some sort of metamorphic differentiation.

Rocks, Physical Properties of

The response of rocks to physical forces and conditions is impottant in many practical undertakings as well a5 in scientific study of the Earth's structure and development. Mineral exploration and extraction, groundwater supply, excavation, foundation selection and preparation (for dams, bridges, buildings), earthquake safety, construction of rock fill and concrete, and uses of ornamental and building stone are all dependent on physical properties of rock materials. Scientists deduce the Earth's internal structure and composition from indirect measurements of physical properties of the interior; and the processes of past and present development of the Earth, such as the formation of the continents and cordillera (mountain ranges) and the occurrence of earthquakes and volcanism, depend on physical properties of the rocks of which the Earth is made. This article treats the physical properties important in the above subjects, namely, the volumetric, mechanical, thermal, electrical, magnetic, and optical properties of rocks. The significance of these properties in scientific and engineering fields is explored further in the articles EARTH, STRUCTURE AND COMPOSITION OF; EARTH, MECHANICAL PROPERTIES OF; EARTH, HEAT FLOW IN; ROCK DEFORMATION; EARTHQUAKES; ROCK MAGNETISM; MINERALS; GROUNDWATER; MINING AND QUARRYING; SOIL MECHANICS, APPLICATIONS OF; and ICE SHEETS AND GLACIERS. The mineral and chemical compositions of rocks and the textures and structures that influence their physical properties are dealt with in the articles IGNEOUS ROCKS; METAMORPHIC ROCKS; and SEDIMENTARY ROCKS.

FACTORS THAT AFFECT ROCK PROPERTIES

Rocks are aggregates of mineral grains or crystals, and their physical properties are to a large extent governed by the properties of the individual minerals that compose them. In a rock, the individual mineral properties are averaged in accordance with the relative proportions and orientations of the various mineral crystals present. Because of this averaging, the properties of rocks can usually be considered as isotropic (uniform in all directions), although most minerals individually are in fact anisotropic. Rocks in which the crystals are not oriented at random, such as schist and slate, show a definite anisotropy reflecting that of the individual minerals.

The averaging of mineral properties provides a valid basis for most of the bulk properties of crystalline rocks —that is, rocks composed of a dense, interlocking aggregate of mineral crystals. Most igneous and metamorphic rocks, such as granite, basalt, marble, and gneiss, are of this type. Glassy rocks, such as volcanic glass, are noncrystalline and have properties similar to those of artificial glasses. For clastic rocks, composed of an aggregate of originally loose mineral or rock fragments subsequently cemented together, important additional factors governing the physical properties are the grain packing and contact geometry, the amount and distribution of void space (porosity), and the nature of the cementation.

Clastic rocks

Physical properties of rocks are influenced by pressure and temperature. In addition to effects characteristic of the individual mineral components, there are distinctive phenomena related to the granular and void structure of rocks. In particular, the presence of water or other pore fluids has an important influence on some prop-rties.

Although most of the physical properties described here can be measured with reasonable precision for an individual rock specimen, the measured values vary substantially, often by as much as 50 percent, from specimen to specimen of a given rock type and even from specimen to specimen of rock from a single, apparently homogeneous parent mass or formation. This statistical variability is an inherent attribute of rocks, resulting from their complex constitution and the consequently large number of variable details of chemical composition and granular structure that can influence the physical properties. It contrasts with the better defined properties of individual minerals, although these, too, are subject to some variability resulting from variations in chemical composition and internal structure. Because of variability, precise figures for the physical properties of a particular rock type cannot be stated: instead only representative values that convey the general magnitude to be expected. Whenever precise figures are needed, a thorough statistical study of the rock mass of interest is called for. Some of the aggregate physical properties of large rock masses in situ (in their natural locations) in the Earth are significantly affected by gross inhomogeneities, such as fractures that occur on a scale so coarse that they cannot readily be sampled in specimens appropriate for laboratory tests. Also, the act of sampling itself may disturb the rock so as to alter some of its physical properties, In such cases, the physical properties of interest must be measured in *situ* by field methods.

VOLUMETRIC PROPERTIES

Density. Table 1 gives ranges of observed density for several important rock types. For a pore-free rock, the density p is a volume-weighted average of the densities of the individual mineral components—that is, the sum of the volume fraction of each mineral times its density. Among the plutonic rocks—*i.e.*, crystalline rocks of deep-seated igneous origin—the density increases systematically from granite, composed mostly of the minerals feldspar (density 2.56 grams per cubic centimetre, abbreviated g/cm^3) and quartz (2.65 g/cm^3), to peridotite and eclogite, composed mostly of the minerals pyroxene (3.4 g/cm^3), olivine (3.5 g/cm^3), and garnet (3.8 g/cm^3). This density increase plays an important role in the structure of the Earth: plutonic rocks ranging in composition from granite to diorite form the continental masses and essentially float in a dense substratum of peridotite and eclogite, which lies below depths of 10 to 50 kilometres (six to 30 miles).

The range in densities indicated for the individual crystalline rocks in Table 1 mainly reflects variations in mineral and chemical composition among rocks to which the specific names are applied. The average density of fresh rock samples of the types listed is near the middle of the ranges given. Glasses are generally less dense than crystalline solids of the same composition, as illustrated by obsidian, which is volcanic glass of granitic composition.

Porosity. The bulk densities of clastic rocks and of vesicular lavas (the name given to lavas with frozen-in gas bubbles) are reduced significantly by the void space present. The resulting porosity is important in providing storage space for water or petroleum in the rocks. Porosity η is defined as the ratio of void volume to bulk volume (solid plus voids). Typical values are given in Table 1. If the void-free solid material is of density p,, then the porous solid has bulk density (ρ_b) equal to the void-free density times the quantity one minus porosity—*i.e.*, pa $=$ ρ_s $(1 - \eta)$, or $\rho_b = \rho_s$ $(1 - \eta/100)$, if η is expressed in percent, as in Table 1.

Density range in basalt

The large range of densities for basalt in Table 1 reflects variations in porosity attributable to gas vesicles. The porosity of vesicular lavas increases with the amount of volatile material (such as water) dissolved in the original rock melt. Separation of gas bubbles is inhibited by solidification at depth, under pressure. Thus, Hawaiian basalts solidified on the ocean floor at depths less than 800 metres (2,600 feet) are vesicular and have densities less than 2.8 g/cm^3, whereas those formed deeper than 4,000 metres (13,000 feet) are almost vesicle free and have densities close to 3.0 g/cm^3. The most highly vesicular volcanic rocks, called pumice, have densities so low that they float on water.

Table 1: Densities and Porosities of Important Rock Types

	characteristics	density ρ g/cm^3	porosity η (percentage)
Granite	crystalline, plutonic, sialic	2.5–2.8	0.3–1.5
Diorite	crystalline, plutonic, intermediate	2.7–3.0	0.5 ±
Gabbro	crystalline, plutonic, mafic	2.9–3.1	0.5 ±
Peridotite	crystalline, plutonic, ultramafic	3.1–3.3	0.5 ±
Eclogite	crystalline, plutonic, ultramafic	3.3–3.6	0.5 ±
Gneiss	crystalline, metamorphic	2.6–3.1	0.5 ±
Schist	crystalline, metamorphic	2.7–3.0	0.5 ±
Slate	crystalline, metamorphic	2.7–2.85	4 1
Quartzite	crystalline, metamorphic	2.641	0.5 ±
Marble	crystalline, metamorphic	2.6–2.8	0.4–2
Obsidian	glassy, volcanic	2.3–2.4	low
Basalt glass	glassy, volcanic	2.7–2.85	low
Basalt	crystalline–glassy, volcanic	2.2–3.0	1–30
Scoria	crystalline–glassy, volcanic, vesicular	1.4–2.4	10–50
Pumice	glassy, volcanic, vesicular	0.5–1.1	60–90
Sandstone	clastic, young (Tertiary)	1.9–2.2	10–35
Sandstone	clastic, old (Paleozoic)	2.3–2.5	5–25
Shale	clastic, young, shallow (<0.5 km)	1.8–2.2	15–35
Shale	clastic, young, deep (>2 km)	2.4–2.5	9–11
Shale	clastic, old, deep	2.6–2.7	4–7
Chalk; coquina	clastic, shell aggregates	1.2–2.2	15–55
Limestone	crystalline–clastic, shell fragments	2.5–2.7	0.1–15
Tuff	clastic, volcanic shards	1.4–1.5	35–40

The porosity of clastic rocks is highly variable and depends on the original shape and packing arrangement of the fragments, the amount of subsequent compaction, and the amount of void space filled by cementation. Rounded mineral or rock fragments, such as sand or gravel, pack initially to a porosity of 30–50 percent, which is reduced to 25–35 percent by compaction. Lower porosities are achieved when a wide range of particle sizes is present, so that the finer particles can fill the interstices among the coarser ones. Unconsolidated (*i.e.*, loose) sand and gravel are converted into sandstone and conglomerate by cementation, and the porosity is thereby reduced to 5–30 percent. As the rocks become older, additional cementation accumulates and the porosity decreases further (Table 1).

The packing properties of animal shells and shell fragments give high initial porosities for coquina (limestone composed of coarse shell debris) and chalk (limestone composed of shells of micro-organisms). In ordinary limestones, void spaces among shell fragments tend to be filled with fine calcite or aragonite detritus. Compaction can occur through solution and reprecipitation of these readily soluble minerals, leading in some cases to a rock of very low porosity.

Porous clastic rocks in situ in the Earth are generally saturated with water, the upper limit of saturation being called the water table. If the pores are completely filled with water, the bulk density pa is increased by an amount equal to η, the porosity, over the density of the dry rock, which is the density given in Table 1. The volume fraction of water that is absorbed by an initially dry rock specimen is called the sorption or apparent porosity. In the laboratory, sorption is usually about half the total porosity. Under the pressures at depth in the Earth, however, the water content probably approaches the total porosity.

MECHANICAL PROPERTIES

When an external force acts on a body, such as a rock, and there is a change of volume or shape, called a strain, internal forces will be transmitted throughout its interior. An internal force and its force of reaction acting across an imaginary plane that separates two parts of the body is known as stress, and the magnitude of the stress is measured in force per unit area of the imaginary plane. The unit of stress is the bar, defined as 10^6 dynes per square centimetre; to a good approximation it equals one atmosphere (14.7 pounds force per square inch) or one kilogram weight per square centimetre. Often used is the kilobar (kbar), which is 1,000 bars.

Among types of response to externally applied stress, distinction is made between elastic properties, in which the strain is reversible (recoverable on unloading), and nonelastic properties, in which it is not. In elasticity, strain is usually proportional to stress, and the constant of proportionality is called an elastic constant: specific examples discussed below are the elastic compressibility, bulk modulus, Young's modulus, and shear modulus. The response under the simplest type of stress, hydrostatic pressure, is usually considered separately from the response to directed, nonhydrostatic stress; hydrostatic behaviour is in principle only a special case of nonhydrostatic, but phenomena of different types are important under the two different types of stress.

Elastic properties. Compressibility. The density of rocks under the high pressures at depth in the Earth is increased as a result of compressibility (reduction in volume). Bulk compressibility β is defined in terms of the increase of bulk density ($\Delta\rho_b$) that occurs on raising the pressure by a small amount (ΔP), at constant temperature, and is equal to the fractional bulk density increase

Table 2: Elastic Properties of Rocks at Low and High Confining Pressure*

	compressibility β (10^{-6} bar^{-1})		moduli at low P (10^6 bar)			moduli at high P (10^6 bar)			Poisson's ratio ν	
	low P	high P	K	E	G	K	E	G	low P	high P
Granite	8	2.0	0.1	0.3	0.2	0.5	0.6	0.4	0.05	0.25

'Low pressure—approximately one atmosphere; high pressure—approximately 3,000 atmospheres.

divided by the pressure increase. The density increase considered in this definition is that which results from elastic compression; any loss of volume that is not recovered on releasing the pressure represents compaction (see below).

Compressibility of jacketed rock

When pressure is applied to a rock specimen by means of a fluid that permeates the pores, there is no compaction, and the compressibility observed is an average of the elastic compressibilities of the individual mineral components. On the other hand, when the rock is kept dry by a fluid-impermeable jacket enclosing the specimen, compaction may occur, and, in addition, the elastic compressibility is usually much greater than an average taken of the mineral components. The same behaviour is observed also for jacketed wet specimens vented so that the pore fluid can escape at low pressure. This arrangement simulates the conditions of compression experienced by rocks at depth in the Earth's crust, because rock permeability (discussed later) allows the pore fluids to escape, and the pore fluid pressure is usually only about a third the total overburden pressure.

The high compressibility of jacketed rock specimens is caused by closure of pore space under pressure. This effect is marked even for crystalline rocks of low porosity. As the pressure on a specimen is raised and the pores close, the compressibility decreases markedly. Low- and high-pressure compressibilities measured for rocks of several types are given in Table 2. Above a pressure of about 2,000 atmospheres, the compressibility becomes nearly constant, because substantially all of the pores that can close are already closed. Pores capable of closing over the pressure range zero to 2,000 atmospheres must be narrow cracks; hence the great increase in compressibility at low pressure is said to be due to crack porosity. The cracks probably lie mainly along the boundaries between mineral grains. Pores of roughly equidimensional shape (such as vesicles and interstitial spaces between clastic grains) do not close up rapidly with pressure and contribute only moderately to the compressibility, but the contribution must continue to much higher pressures than that caused by the crack porosity. The drop in compressibility with pressure is much larger in the case of crystalline rocks that formed at depth than it is in those that formed near the surface, suggesting that the cracks opened as a result of the pressure release that followed formation of the deep-seated rocks,.

Once any initial crack porosity has been removed by application of pressure, the compressibility of a rock is an average of the compressibilities of the mineral components. The averaging process is complex, however, because an aggregate of grains having different and generally anisotropic compressibilities cannot compress uniformly but instead develops a complex pattern of stresses and strains varying from grain to grain. An exact method of calculating the compressibility of a rock from the cornpressibilities of its mineral components is not known, but limits on the compressibility can be set by two types of average: (1) the so-called Reuss average (after the German physicist A. Reuss), which is the volumetrically weighted average of the compressibilities of the mineral components; and (2) the Voigt average (after Woldemar Voigt), in which the reciprocal compressibility (called the bulk modulus) is calculated as the volumetrically weighted average of the bulk moduli of the components. The true compressibility must lie between these two averages. The Voigt average can be applied to estimate the compressibility of a rock with quasi-spherical pores by treating the pores as components of zero bulk modulus.

Nonlinear compressibility. Over a pressure range from about 2,000 to 10,000 atmospheres (or zero to 10,000 atmospheres for a rock with no initial crack porosity), the compressibility can be considered to be linear in the sense that the compression increases in direct proportion to the pressure, and the compressibility coefficient β is practically constant. Over a wider pressure range, however, such as the range zero to 2,000,000 atmospheres that occurs within the Earth, deviations from linearity become significant. Theories of finite elastic strain have been developed to deal with compressibility as a function of pressure over this wide pressure range. It is found empirically that for many rocks the bulk modulus K (reciprocal compressibility $1/\beta$) is to a good approximation a linearly increasing function of pressure: K is equal to the bulk modulus at zero pressure (K_0) plus a constant (K') times the pressure P, or $K = K_0 + K'P$. The corresponding rock density (ρ) as a function of pressure is given by the density (ρ_0) at zero pressure times the quantity 1 plus the ratio of pressure to zero-pressure bulk modulus raised to the power $1/K'$, or

$$\rho = \rho_0(1 + P/K_0)^{1/K'}.$$

The dimensionless quantity K' (an arithmetic value without units) has a value in the range four to six for most rocks. It plays an important role in reasoning about the internal density and composition of the Earth.

Nonhydrostatic stress. When a cylindrical specimen is compressed along its length, while laterally unconfined, the compressive stress σ is related to longitudinal elastic strain e_{long} by Young's modulus (after Thomas Young, an English physicist). Young's modulus (E) is equal to the ratio of stress to strain, or $E = \sigma/e_{long}$. The ratio of lateral expansion e_{lat} to longitudinal compression $-e_{long}$ is Poisson's ratio (after a French mathematician, Siméon-Denis Poisson). Poisson's ratio (ν) is thus $\nu = -e_{lat}/e_{long}$. (The longitudinal or lateral strain e is the ratio of change in specimen length, Δl, or width, Δw, to the corresponding initial dimension l or w: el,,, $= \Delta l/l$, $e_{lat} = \Delta w/w$.) When a specimen is loaded in shear—that is, with stress parallel to a particular plane—the ratio of shear stress (τ) to shear strain (y) is the shear modulus, $G = \tau/\gamma$ (see ELASTICITY). Values of the moduli and Poisson's ratio for several rock types are listed in Table 2. Because of the large typical variation of measured moduli from specimen to specimen, the figures in Table 2 are given only to one decimal and convey only the general magnitudes to be expected for the given rock types. The greatest source of variation is crack porosity. As the stress is increased, some of the cracks become closed; hence, Young's modulus increases with compressive stress σ. The cracks that tend to close are aligned transverse to the direction of compression; hence, Poisson's ratio is low (about 0.1) initially, at low σ, and increases with σ, approaching generally a value near 0.25 when the cracks become closed. Similar effects are produced by hydrostatic confining pressure. The high pressure values given in Table 2 represent rocks from which crack porosity has been eliminated.

For isotropic materials, Young's modulus, the shear modulus, and Poisson's ratio are, in principle, related by the condition that Poisson's ratio (ν) is equal to the ratio of Young's modulus (E) to twice the shear modulus (G), less 1, or v $= E/2G - 1$. Similarly, the moduli E and G are related to the bulk modulus K and Poisson's ratio ν by: $E = 3K(1 - 2\nu)$ and $G = 1.5\ K(1 - 2\nu)/(1 + \nu)$. Tabulated values do not always satisfy these relations because the values may have been measured on different specimens, under different conditions, or by different techniques or because the specimens may not have been fully isotropic. For $\nu = 0.25$, it is expected that $E = 1.5$ K and $G = 0.6$ K; these expectations are realized to a rough approximation by the modulus values in Table 2. Limits on the moduli E and G can be estimated from the elastic properties of the mineral components by methods similar to those already discussed for the compressibility.

Cause of elastic anisotropy

Elastic anisotropy occurs when the mineral components have a preferential alignment, as in gneiss (a type of metamorphic or altered rock), schist, and slate. In a schist with highly aligned flakes of mica, Young's modulus measured parallel to the plane of alignment can be as much as three times as large as when it is measured perpendicular to this plane, and an even larger anisotropy in the shear modulus can occur. Actually observed elastic anisotropies of rocks are, however, generally much smaller. Preferential alignment of unclosed microscopic cracks can also cause elastic anisotropy.

Elastic **waves.** When a rock is subjected to oscillatory loading, waves of oscillating displacement and stress, much like sound waves, are propagated through it. These waves are of two types: longitudinal or compressional waves (P waves), in which the displacements occur along a direction parallel to the direction of propagation; and the transverse or shear waves (S waves), in which the displacements occur at right angles to the direction of propagation. P waves propagate with a velocity (v_P) that is equal to the square root of the density (ρ) divided into the sum of the bulk modulus and 4/3 times the shear modulus $v_P = \sqrt{(K + \frac{4}{3}G)/\rho}$ whereas S waves propagate with a velocity (v_S) that is equal to simply the square root of the ratio of the modulus G to the density: us $= \sqrt{G/\rho}$. The velocities can be calculated from static test data such as those in Table 2, but they are often measured directly for comparison with velocities at depth in the Earth as inferred by seismology. At low pressures, crack porosity causes the moduli, and hence the velocities, to be low and erratic, but above a confining pressure of about 2,000 atmospheres the intrinsic velocity, representing an average over the mineral components, is realized. Values for several rock types are listed in Table 3. Higher values are shown by the denser rock types, reflecting the fact that denser minerals generally have elastic moduli that are increased much more than in proportion to their increased density. When, however, the density increase is due primarily to a substitution of iron for magnesium or aluminum in the mineral composition, relatively little increase in elastic moduli occurs, and the elastic wave velocities drop. Empirical observations are summarized by the following approximate formula relating P-wave velocity (in kilometres per second) to rock density p (grams per cubic centimetre) and the average value of the atomic weights of the constituent atoms (symbolized A): or, $v_P \approx 7.3 + 3.1\ (\rho - 3.0) - 0.5(\bar{A} - 21)$. For most igneous rocks A is near 21, except for rocks notably enriched in iron, for which it can approach 30. For mica-rich rocks in which the mica flakes are strongly aligned, such as mica schist, an appreciable velocity anisotropy is expected; for example, the P-wave velocity parallel to the foliation (plane of mica alignment) can be as much as 1.8 times higher than that perpendicular to the foliation of the schist.

Elastic waves are subject to attenuation, a decrease in wave amplitude, which results from imperfections in elasticity, called internal friction, delayed elasticity, or viscoelasticity. The attenuation is measured in terms of the specific damping capacity b, which is the fraction of the elastic energy lost from the wave per cycle of oscillation. (It is often reported in terms of the quality factor [Q], defined as equal to the numerical factor 2π divided by the specific damping capacity, *i.e.*, $Q = 2\pi/b$.) For crystalline rocks, specific damping capacities are typically in the range from 0.5 to 10 percent per cycle under ordinary conditions. Porous clastic rocks such as sandstone and shale often show high attenuation (with a specific damping capacity *[h]*of about 10 to 50 percent per cycle). The attenuation under ordinary conditions is dominated by frictional losses that arise from sliding across microscopic cracks; variability in characteristics of crack porosity is responsible for the wide scatter in observed attenuations. About 5,000 atmospheres of confining pressure inhibits attenuation due to crack sliding and reduces b to less than 2 percent per cycle. The remaining attenuation is due to a variety of mechanisms, which have not yet been thoroughly elucidated, because of the complex composition and structure of rocks. The known individual loss mechanisms have a marked dependence on frequency of the elastic wave, but the aggregate effect caused by superposition of many mechanisms is an observed specific damping capacity that shows no definite dependence on frequency over a wide range of frequencies, from those used in typical laboratory experiments, 10^2 to 10^6 hertz (cycles per second), to those encountered in observed seismic waves, 10^{-1} to 10^{-3} hertz.

Temperature and pressure effects

Increase of temperature generally causes an increase in attenuation, but at depth in the earth's mantle the inhibiting effect of pressure dominates, and b is low (approximately 0.5 percent per cycle). A conspicuous increase in attenuation, by as much as a factor of 2, occurs when a rock begins to melt. Partial melting is probably responsible for the relatively high attenuation (about 5 percent per cycle) for seismic P waves traversing the low-velocity zone in the Earth at a depth of about 200 kilometres (100 miles). In general, attenuation for S waves appears to be larger than for P waves by about 50 percent.

Nonelastic properties. Permanent deformations, nonrecoverable on unloading, become detectable normally at stresses of 10 to 100 bars in mechanical tests on rocks. At the much lower stresses in typical elastic waves, there is some deviation from reversible elastic behaviour, as indicated by attenuation, but permanent deformations are small and generally remain undetected. Except for compaction, the nonelastic properties of rocks appear only under directed stress. **A** representative curve of stress σ

as a function of strain *e* in a mechanical test is shown in Figure 1. In the elastic range of the curve, from *O* to Y, some deviation of the curve from an ideal straight line usually occurs, as shown, because of crack closure. The knee in the curve at Y represents the onset of permanent, nonrecoverable strain and is called the yield point. The permanent strain is evident on unloading, which follows the path from W to *S*. At point R, rupture occurs, and the load that the rock can support (stress) drops abruptly to zero. The amount of permanent strain accumulated between Y and R is a measure of the ductility of the specimen. Under ordinary conditions, most rocks are brittle—*i.e.*, rupture with little or no ductile deformation—and the rupture point R essentially coincides with the yield point Y.

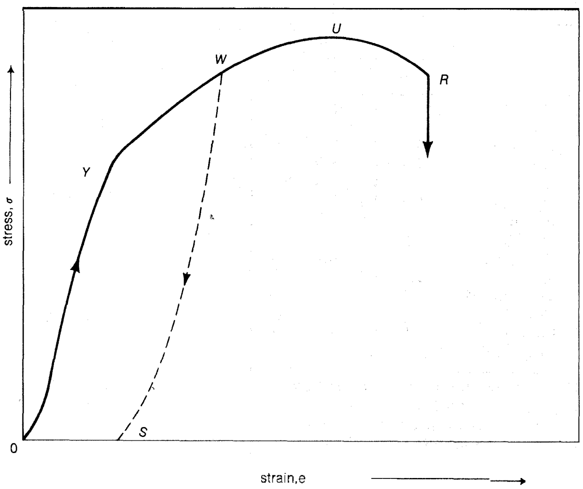

Figure 1: A typical stress-strain curve for rock. *Y* is the yield point (beginning of plastic failure), *U* the point of ultimate strength, and *R* the point of rupture. WS represents unloading before rupture (see text).

Compaction. Porous rocks composed of or cemented by relatively weak minerals, such as clay, undergo significant compaction under pressure, the weak grains deforming inelastically into the pore spaces. Thus the porosity of shale decreases substantially with depth of burial (Table 1). For porous sandstones, compaction is normally minor because the tight packing of strong grains (quartz or feldspar) provides mechanical support for the cementing material, which is itself often a strong mineral (calcite or quartz). Under high pressures (approximately 10,000 atmospheres), however, the strong grains themselves fail and porosity is eliminated. No standard measure of compaction as a physical property is available.

Brittle rupture. In most practical situations in which rocks are used as building or foundation materials, their strength is limited by brittle failure. The sudden release of stored elastic energy that occurs in brittle failure of rocks below the surface of the Earth is the source of the seismic disturbances in earthquakes, and in deep mines it takes place in "rock bursts," causing violent damage. In brittle failure, the rock loses cohesion and splits into two or more pieces along fracture surfaces. Two types of fracture are distinguished (see Figure 2): (1) extension fracture, in which perpendicular separation occurs across a surface oriented at right angles to the direction of greatest tensional (pulling apart) stress; and (2) shear fracture, or faulting, in which there is lateral (shear) displacement across a fracture surface inclined at about 25° to the direction of greatest compressive stress. In extension fracture, the stress supported by the rock always drops abruptly to zero. In shear fracture, an abrupt stress drop usually occurs, but the stress does not drop entirely to zero because of sliding friction across the fracture surface; under some conditions the friction is large enough to prevent any stress drop when the fracture or fault develops. Cylindrical rock specimens fail by extension fracture when loaded in unconfined tension and by shear fracture in unconfined compression, or in compression with superimposed confining pressure. Under intermediate states of stress there is a transition from shear to extension fracture, in which the orientation and nature of the fracture surfaces change progressively.

Crushing strength

The stress required to cause brittle failure in an unconfined compression test is called the compressive strength or crushing strength and, in a tensile test, the tensile strength. Representative values are given in Table 4. The tensile strength of a rock is typically only one-tenth to one-twentieth the compressive strength. Because of effects of internal friction, the strength increases substantially with pressure. In compression tests with superimposed pressure, the strength, measured as the difference between axial compressive stress σ and lateral confining pressure P at failure, increases linearly with the pressure: the strength $(\sigma - P)$ is equal to the unconfined crushing strength (C_0), plus the product of a coefficient (s) times the bulk confining pressure (P); *i.e.*, $(\sigma - P) = C_0 + sP$. The coefficient (s) determines the frictional contribution to the strength and commonly has a value in the range three to 10 (Table 4). At a depth of five kilometres (three miles) in the Earth, where pressure is of the order of 1,500 atmospheres, the frictional contribution (*sP* approximately 9,000 bars) greatly exceeds the contribution from internal cohesion (c, is approximately 2,000 bars).

If a rock contains pore fluid under a pressure *p*, the strength is reduced accordingly: the pressure quantity that is effective in governing the strength according to the formula above is the confining pressure (P) less the pore pressure (*p*), thus $(\sigma - P) =$ C, $+ s(P - p)$. The quantity $(P - p)$ is called the effective confining pressure and plays an important role in the mechanical properties of rocks. It is thought that the pumping of water into the ground under high pressure has, by decreasing the effective confining pressure, been responsible in some instances for reducing the strength of rocks to the point where faulting and earthquakes have occurred. There is evidence that, even in the absence of significant pore pressure, the presence of pore water reduces the strength of sandstones about 50 percent below that of the dry rocks.

Brittle failure of solid rock is controlled by the presence of microscopic flaws that reduce the strength greatly from what is theoretically possible for perfect mineral crystals. These flaws are doubtless closely related to the cracks responsible for anomalies in compressibility and elastic moduli, discussed above. The Griffith theory of failure proposed by the English engineer A.A. Griffith supposes that at the microscopic level the cracks grow by tensile fracture. The theory is applicable to rocks if the additional assumption is made that slippage across the

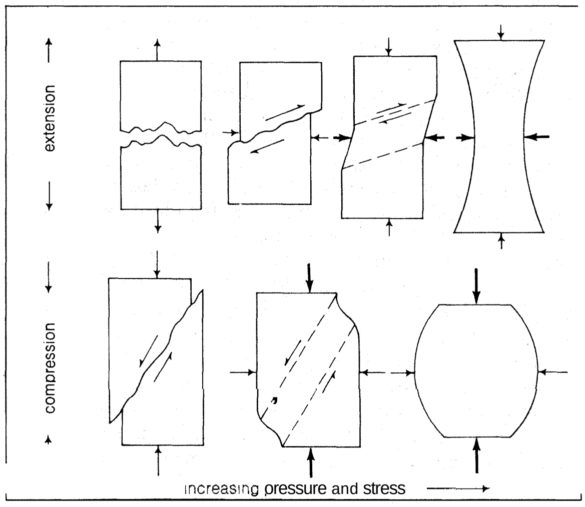

Figure 2: Stages of transition from brittle to ductile failure, as seen in laboratory tests on cylindrical specimens. (Top) The vertical axis is of relative extension, (bottom) of compression. (Left) Extension and shear fracture are illustrated, and (left to right) a progressive increase in confining pressure is shown. Bold arrows indicate directions of greater relative stress.

cracks is restrained by friction. If the coefficient of friction is p, the theory predicts a linear dependence of strength on effective confining pressure, with coefficient $s = 2\mu/(\sqrt{1+\mu^2} - \mu)$. In the Coulomb-Navier-Mohr theory of failure resulting from the work of a French physicist, Charles-Augustin Coulomb, a French engineer, Claude-Louis-Marie Navier, and a German engineer, Otto Mohr, which predicts the same relationship but is conceptually less satisfactory, the quantity μ is called the coefficient of internal friction. (It should not be simply equated with the internal friction that causes elastic wave attenuation.) The theory predicts that the fracture surface should be oriented relative to the compression axis at an angle (θ) that is 45° minus half the angle whose tangent is μ, thus $\theta = 45" - \frac{1}{2} \tan^{-1}\mu$. It also assigns to each rock a quantity called the cohesive strength, which is the shear stress necessary to cause failure across a potential fracture surface in the absence of any frictional constraint; the cohesive strength (τ_0) is related to the crushing strength (C,) as follows: $\tau_0 = \frac{1}{2}C_0(\sqrt{1+\mu^2} - \mu)$. The cohesion τ_0 is of the order 100 bars for clastic rocks and 500 bars for crystalline rocks. The values of μ needed to account for s in the observed pressure dependence of rock strength are reasonable as coefficients of friction, being near unity (Table 4). The predicted fracture orientation angles (Table 4) are in rough agreement with observation, except in the transition from shear to extension fracture. The strength quantities C_0 and τ_0 vary approximately as the inverse square root of the size of mineral grains (the individual crystals or particles of which the rock is made) as is predicted by the Griffith theory: in finer grained rocks microscopic cracks tend to be shorter than in coarser grained rocks; hence the finer grained rocks are stronger.

In rocks with planar anisotropy, such as slate, fractures tend to develop preferentially parallel to the plane of weakness, even when it is misoriented by as much as 30" from the fracture orientation predicted from the theory for isotropic materials. Such fracture, along planes of a definite orientation, is called cleavage. Even apparently isotropic rocks such as granite show a significant tendency in quarrying to split preferentially along certain planes, called the "rift" and "grain" of the rock.

Individual measurements of the crushing and tensile strengths of rocks often show wide fluctuations, typically by as much as 50 percent from the average values for rock from a given source. This wide scatter is probably a result of uncontrollable variations in characteristics of crack porosity from sample to sample. Variations in average values among rocks of the same type from different sources are also large; hence the figures given in Table 4 should be viewed as representative examples only.

Repeated brittle failure. In the Earth, brittle failure commonly occurs in fault zones, in which the rocks have a previous history of failure and are pervaded by pre-existing fractures; this is a situation distinctly different from the failure of virgin rock, described above. If the fractures are not healed by cementation, the rock in bulk has already lost cohesion and has no tensile strength. In compression, in which the rock fails largely by slipping on the pre-existing fractures, however, the friction across these surfaces determines the strength; at depths of several kilometres it is substantial (thousands of bars), unless the effective pressure is reduced by an abnormally high pore pressure. The pre-existing fractures contain comminuted (pulverized) rock debris produced by previous slippage; hence the failure properties are related to those of incoherent granular materials such as sand or soil (see SOIL MECHANICS, APPLICATIONS OF). Of great importance is the distinction between two contrasting types of frictional behaviour: (1) stable sliding, in which the coefficient of friction (a measure of the resistance to sliding) remains essentially constant as slip progresses across the fracture surface; and *(2)* stick-slip friction, in which the initiation of sliding is accompanied by a large and abrupt drop in the coefficient of friction. Stick-slip friction results in sudden stress release, the cause of earthquakes, whereas stable sliding allows a slow creeping motion across the faults, without earthquakes. Increased temperature and decreased pressure promote stable sliding instead of stick-slip friction. The physical conditions controlling the two types of frictional behaviour have important influence on the causes, locations, and hazards caused by earthquakes.

Types of friction

Brittle-duetiletransition. By raising the fracture strength, confining pressure inhibits brittle failure and allows other mechanisms of yielding to occur, which produce a more or less homogeneous permanent deformation and constitute ductile failure (Figure 2). The pressure required to effect the transition from brittle to ductile failure is relatively small (1,000 atmospheres or less) for rock materials of low plastic yield strength, such as limestone, shale, and rock salt. At ordinary temperatures, most igneous and metamorphic rocks and also clastic rocks well cemented by silica begin to show ductile behaviour only at pressures of 10,000 to 30,000 atmospheres, because the directed stress needed to cause plastic deformation in the silicate minerals of these rocks is high. The pressure variable pertinent to the brittle-ductile transition is the effective pressure, as defined above, rather than the total pressure. Intermediate between brittle failure at low pressure and true plasticity at high pressure is a type of deformation behaviour called cataclastic, in which the rock fails in a ductile manner as viewed macroscopically but in which on the microscopic scale there is progressive comminution of the mineral grains by local fracturing distributed microscopically throughout the specimen. Cataclastic deformation occurs under conditions where the internal friction of virgin rock is enough lower than the sliding friction on already formed fracture surfaces that slippage is inhibited on fractures once formed, and brittle failure therefore spreads pervasively through the rock. Increase of temperature promotes true rock plasticity at the expense of cataclastic flow and lowers the brittle-ductile transition pressure. The explanation for this is that temperature has a much greater effect in lowering the plastic yield stresses of minerals than in lowering the cohesions or internal frictions.

Plasticity. In true plastic yielding of rock, intra-crystalline plastic deformation of the individual mineral grains takes place. Crystals, which are composed of uniform layers, or planes, of atoms, deform plastically by two distinct mechanisms: (1) translation gliding, in which individual atomic planes appear to slip past one another, leaving the basic crystal structure unchanged; and (2) mechanical twinning, in which the atomic planes slip through a definite fraction of the crystallographic

Types of crystal deformation

repeat distance, in such a way as to produce a new crystal in twinned orientation relative to the original. The displacements of the atomic planes are actually made possible by the motion of crystal dislocations and are crystallographically controlled: each mineral has certain definite crystallographic planes (called slip planes) across which translation gliding or mechanical twinning can take place by slip in a definite crystallographic direction. Mechanical twinning produces visible twin lamellae (layers) in the individual crystals, which are a common feature of deformed marbles. Translation gliding leaves less obvious traces but can result in a bending of the individual crystals, which is often found in the quartz grains of deformed rocks.

Critical resolved shear stress

For each set of potential slip planes in a given mineral under given conditions, a certain definite shear stress acting across the planes in the direction of slip is necessary to initiate slip; it is called the critical resolved shear stress. For the appropriate planes in calcite this stress is about 80 bars for mechanical twinning and about 1,200 bars for translation gliding at 24° C (75" F) and 3,000 atmospheres confining pressure. With the exception of sheet silicates (clays and micas), silicate minerals generally have high critical shear stresses, in the range 2,000 to 30,000 bars.

Cause of hardening

Once the critical shear stress for a set of slip planes is reached, substantial plastic shear strain can occur by slip across these planes; ideally there is only a modest further increase in stress (called work hardening), so that the stress-strain curve has a sharp knee at the yield point Y (Figure 1), with a low slope above that point. In a rock, the individual crystals cannot yield simultaneously because, with their various orientations, the potential slip planes in different grains have widely different resolved shear stresses for a given stress applied to the rock as a whole. Moreover, the slip systems of adjacent grains in a rock are not generally compatible, and the crystals therefore tend to interfere with one another during plastic flow, disrupting one another and causing increased work hardening. The result of these effects is that the plastic yielding of a rock occurs less sharply and at substantially higher stresses than that of individual crystals of its component minerals. The stress-strain curve has a broad, rounded knee at Y (Figure 1) and a substantial slope above Y. Because of this, a meaningful statement of the plastic yield strength of a rock requires specification of the strain to which the quoted strength refers. Strengths observed for several rock types at 2 percent strain are listed in Table 5. Because of substantial variation in results from one experiment to another, only rough, generalized figures are given. The ultimate strength, which is the maximum stress reached in a loading test (*U* in Figure 1), is often substantially higher than the yield strength because of work hardening. The strain range of ductile behaviour is usually terminated by brittle failure (*R* in Figure 1), which occurs when the deforming stress has risen to the point at which the confining pressure is no longer able to inhibit fracture. Contributing to it is a progressive deterioration of the rock texture caused by structural flaws generated in plastic flow; these flaws reduce the cohesion.

*At strain rate of 2.4 percent per minute. †At strain rate of 0.2 percent per minute.

In conformity with the fact sliding friction is not involved in the plastic yield process, pressure has only a slight effect on the plastic yield strengths of minerals and rocks. The effect is a modest increase in strength, comparable to the increase in elastic bulk modulus with pressure, discussed earlier. Increase of temperature, on the other hand, lowers the yield strength substantially (Table 5). Truly plastic behaviour of igneous and metamorphic rocks containing strong silicate minerals is generally observed only above temperatures of about 600° C (1,100" F). The effect of temperature is even more dramatic when water is present: the yield strength of quartz at 600" C drops from 20,000 to 1,500 bars when water is made available. It is thought that water causes this effect by breaking some of the strong silicon–oxygen bonds in the silicate mineials. The phenomenon of water weakening explains the seeming contradiction between the great rigidity of quartz as observed in most laboratory tests and the abundant evidence of plasticity in the quartz of natural rocks, even in rocks that must have been deformed at only relatively low temperatures.

Time-dependent deformation: creep. When a rock placed under load experiences a strain that does not appear immediately but instead appears gradually as time progresses, the phenomenon is called creep. The slow, drifting motion of the earth's continents and oceanic plates (rigid, slablike regions of the ocean floor) is a surface indication of creep taking place in the rocks at depth. At ordinary temperatures, the creep rate immediately after the initial loading of a specimen may be relatively large, but it decreases with time. Transient creep, as this is called, yields only a limited total strain; it may, however, affect the use of rock as a building material under high loads. Transient creep of this kind is due primarily to a gradual loosening of the granular texture of the rock. At high temperatures (within a few hundred degrees Celsius of the onset of melting) steady-state creep makes its appearance; this is a type of creep in which, after possible initial transients, the creep settles down to a steady rate under fixed stresses. Although the rate may be low, it can lead cumulatively to large deformations when continued over the millions of years of geologic time. The required stress need not exceed the plastic yield stress, and the strain rate may be so low as to be undetectable in laboratory tests on rocks.

Effective viscosity

For creep, the physically significant relationship is not between stress and strain but between stress and strain rate. If the relationship is linear, so that strain rate is directly proportional to stress, the creep behaviour is similar to the flow of a viscous fluid except that the deforming material is a crystalline solid rather than an amorphous liquid. The ratio of shear stress to shear strain rate is called the effective viscosity. Certain creep phenomena in the Earth, such as the slow rise of Scandinavia due to removal of the continental ice-sheet load at the end of the Ice Age (called postglacial rebound), have been interpreted in terms of linear creep and imply an effective viscosity of about 10^{22} poise (dyne sec cm^{-2} unit) for rocks in the outer part of the Earth's mantle. The flow of glacier ice corresponds to an effective viscosity of roughly 10^{14} poise. For comparison, the viscosity of water is 0.01 poise, and the viscosity of molten lava is in the range 104 to 10^5 poise at temperatures of 1,000"–1,100" C (1,800°–2,000°F). With an effective creep viscosity of 10^{22} poise, a rock specimen loaded in compression at 1,000 bar would undergo a total strain of 10^{-6} (one millionth) in a year's time.

Laboratory experiments on limestone, marble, dunite (a kind of igneous rock), rock salt, and ice have shown that over the range of measurable strain rates, the creep behaviour is markedly nonlinear. The same is observed in the high-temperature creep of metals. The type of nonlinearity commonly found in the relation between stress σ and strain rate (*i.e.*, change of strain with time, symbolized $\dot{e}$) has the form, strain rate equals a constant (k) times stress raised to a power n, or $\dot{e} = k\sigma^n$. Values commonly found for the exponent n range from 3 to 7, rather different from a value of 1, which represents linear creep. Linear and nonlinear creep behaviour are compared in Figure 3. Because of the observed creep nonlinearity, strain rates increase much more rapidly than in simple proportionality to stress. The effective creep viscosity decreases as the stress increases. At low stresses, there is hardly any creep, and as the stress rises above a level of order σ_0 in Figure 3, the strain rate increases rapidly, so that the behaviour is somewhat like that of a plastic material with yield stress σ_0. Creep rates in the Earth are probably less, in general, than the experimentally studied range, and it is possible that at the lower stresses the creep behaviour tends toward linearity.

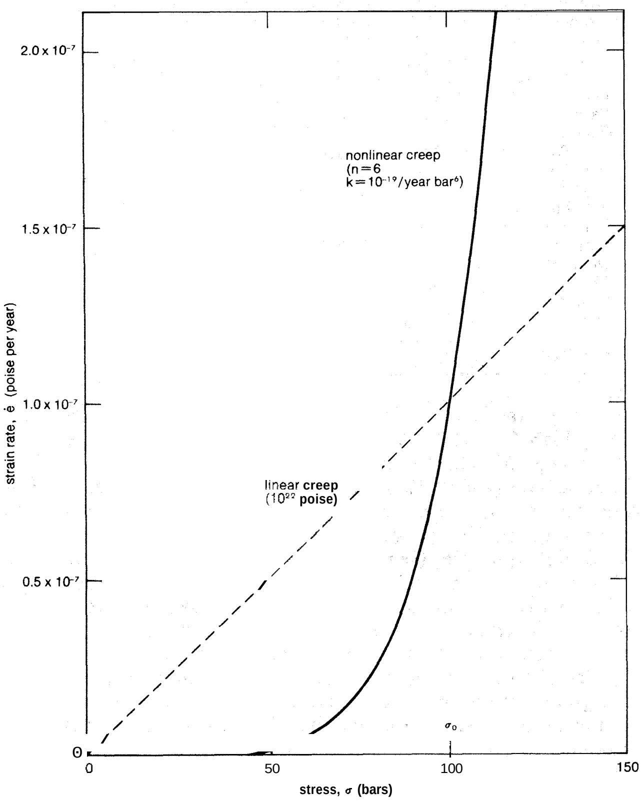

Figure 3: Comparison of stress versus strain-rate curves for linear and nonlinear creep. Linear creep is shown for a rock that deforms to a substantial strain ($e \sim 1$)under a stress of 100 bars applied for 10,000,000 years, a geologically typical period of rock deformation. Nonlinear creep is plotted for a material that behaves approximately as **a** plastic material with yield stress $\sigma_0 \sim 100$ bars.

Rock creep can take place by intra-crystalline deformation of the individual mineral grains, made possible by a motion of crystal dislocations that is similar to what occurs in crystal plasticity, except that the dislocation motion is time dependent, and the dislocations can move out of the plastic slip planes, with the help of atomic diffusion. This type of creep may be called dislocation creep. (In technical practice, distinctions between different types of dislocation creep are made.)

Dislocation creep is usually accompanied by re-crystallization, an important process that modifies the crystalline texture through lateral migration of the grain boundaries and through nucleation and growth of new crystal grains in the rock. By allowing new fresh crystals to grow at the expense of old deformed ones, re-crystallization serves to anneal the disturbances in the crystalline texture generated by intra-crystalline creep or plasticity. As a result of re-crystallization, deformed rocks commonly have a texture much different from the parent rock.

A second creep mechanism, which has been found to be important in the creep of ceramic materials at high temperature, is the diffusion of atoms along the grain boundaries, oı from one grain boundary to another through the intervening crystal grain. This diffusion has an effect much like dissolution of the grains on some sides and growth of the grains by precipitation of dissolved material on other sides. It allows the grains to change their external shape and thus allows the polycrystalline aggregate as a whole to deform, without any intra-crystalline deformation of the grains themselves. The resulting progressive deformation under stress is called diffusion creep. Because the creep rate is limited by the distance that the atoms must diffuse, it is inversely proportional to the grain size; fine-grained materials, with grain sizes in the micron range, are most prone to show diffusion creep.

It is not yet known whether the creep of rocks at depth in the Earth is primarily due to dislocation creep or to diffusion creep. The distinction is important, because diffusion creep is a strictly linear process giving a stress-independent creep viscosity, whereas most types of dislocation creep are markedly nonlinear (exponent n in the range **3** to **7**).

Creep of Earth's mantle

The effects of pressure and temperature on creep have an important influence on the flow of the Earth's mantle at depth, by means of which continental drift and sea-floor spreading take place. Dislocation motion in nonlinear creep is controlled by atomic diffusion around the dislocations, and it therefore follows that regardless of whether the operative mechanism is dislocation creep or diffusion creep, the effects of pressure and temperature on creep rates should be the same as the effects of these variables on the diffusion constant, for which there is experimental information and theoretical reasoning.

The diffusion constant (D) varies with temperature (T) and pressure (P) according to the exponential equation $D = D_o \exp [-(Q, + V_a P)/RT]$, in which Q_a is the activation energy, V_a is the activation volume, and R is the gas constant. For known activation energies and volumes, the diffusion constant increases strongly with temperature and decreases weakly with pressure. On this basis, and from the estimated variation of temperature and pressure with depth in the Earth, it is found that the effect of increasing temperature dominates the creep viscosity down to a depth of about 500 kilometres (300 miles). The predicted viscosity decreases by many orders of magnitude (multiples of 10) down to this depth, at which it has a broad minimum. Below this depth the effect of pressure begins to dominate and the predicted viscosity rises. It is thought that, at depths of 200 to 400 kilometres (100 to 200 miles), the creep viscosity is further reduced by partial melting of the rocks.

Response to shock waves. Impacts of meteoroids on the Earth, Moon, and other planets subject rock to severe stresses on short time scales (fractions of a second). Similar effects are produced by artificially generated shock waves, for which the duration is measured in thousandths of a second; shock pressures as high as 1,000,000 atmospheres have been generated. The point of mechanical failure for a rock is reached early in the shock event. Failure by brittle fracture is abundant both in shock-wave experiments and in cratering impact events: the rock is shattered into many fragments. There is often evidence, however, of plastic deformation (translation gliding, bending, twinning) of the mineral components. A novel and diagnostic type of shock failure is by partial or complete phase change: either by melting or by conversion to glass in the solid state or by transformation to high-pressure mineral phases. As a result of failure, rocks approach a hydrostatic condition at the peak pressure of the shock wave. Hence shock experiments can be used to obtain compressibilities up to very high pressures (see further METEORITE CRATERS).

Hardness and friability. The characteristics of hardness and friability (the resistance of a rock to crumbling into grains) are important in the practical usage of rock materials. Although the hardness of the individual minerals in a rock is a well-defined property, the aggregate, made up of grains of differing hardness, has no single, definite hardness. A rock such as granite, composed mostly of minerals of hardness 6 to 7 on the Mohs scale (in which talc is 1, quartz is 7, and diamond is 10), has a relatively definite, high hardness, whereas a sandy shale has attributes of hardness varying from 1 to 7. The ability of a rock to scratch or abrade other materials is a reflection, by and large, of the hardest abundant mineral component, whereas the extent to which the rock is scratched or abraded by other objects reflects the softest abundant component. Friability, the readiness with which mineral grains are separated from the rock, is also related to the weakest abundant component, usually the cementing mineral in a clastic rock.

THERMAL PROPERTIES

Specific heat. The heat capacity of a rock is a mass-weighted average of the heat capacities of its mineral constituents (*i.e.*, sum of the heat capacity of each mineral times its mass fraction). Figure 4 shows heat capacity as a function of temperature for important rock-forming silicate minerals and thus outlines the range of possible variation of the heat capacities of common silicate rocks. Because the mean atomic weight $\bar{A}$ of most rock-forming minerals is near 21, the high-temperature specific heat (Dulong-Petit value) is near 0.3 calorie per gram degree Celsius. This value is reached only above temperatures of about 1,000" C (1,800" F), because the strong interatomic bonds, especially silicon–oxygen, inhibit excitation of some of the thermal vibrations at lower temperatures. The heat capacity is roughly half the limiting Dulong-Petit value at room temperature. The presence of water, either mechanically included (in pores) or in chemical combination (hydrous minerals), adds appreciably to the heat capacity; anomalously high apparent heat capacities are shown over ranges of temperature in which water is driven off on heating, either by volatilization or by thermal breakdown of hydrous minerals.

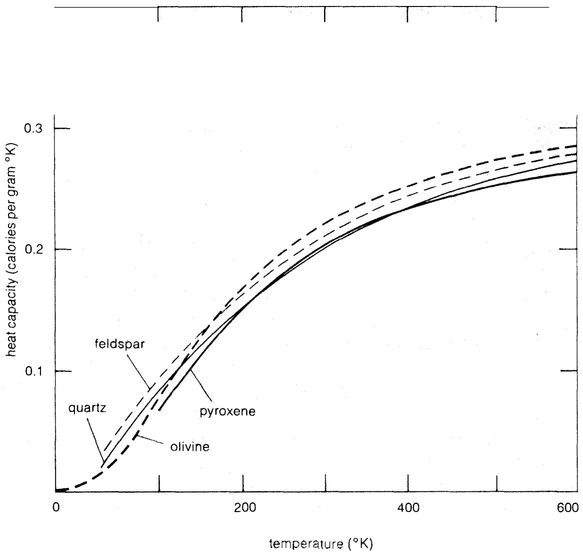

Figure 4: Specific heats (at constant pressure) of rock-forming minerals, as a function of temperature. Weighted averages of these curves give the specific heats of common rocks.

Thermal conductivity. The rate at which heat escapes from the Earth's interior to the surface is controlled by thermal conductivity, and this property affects the suitability of rock as a building material, for which its insulating capability is important. The conductivity of a rock is a somewhat complex average over the conductivities (generally anisotropic) of its component minerals modified by effects of porosity. As shown in Table 6, crystalline silicate rocks have conductivities generally in the range from about 0.004 to about 0.008 calorie per centimetre degree Celsius second (abbreviated cal/cm°C sec), the lower values being typical of silicate rocks relatively rich in magnesium and iron, such as basalt and gabbro, whereas the higher values are typical of rocks rich in silica and alumina, such as granite and granodiorite. The variations reflect the fact that the conductivities of quartz are relatively high (—0.020 cal/cm°C sec), those of feldspar are low (~0.005), and those of chain and sheet silicates are intermediate (—0.007). Porosity reduces the thermal conductivity by interfering with the thermal contact between mineral grains; thus porous sandstones have conductivities lower than quartzite (see Table *6*), and the conductivities of dry soils are especially low (—0.0004). Conductivities of individual specimens vary by as much as 20 percent from the average values in Table 6, probably to a large extent because of variations in the effects of crack porosity. By eliminating crack porosity of rocks and bringing the grains into more intimate contact, confining pressure causes an increase in conductivity, which for most rocks amounts to 10 to 20 percent for a pressure of 1,000 atmospheres. Beyond this effect, pressure has little effect on conductivity. Saturation of the pores with water causes an increase in conductivity similar to that obtained by closing the pores under pressure. The conductivity of mica is about six times greater parallel to the micaceous sheets (mica layers) than perpendicular to them; hence, rocks with abundant, well-aligned mica flakes have anisotropic conductivity; this is illustrated by gneiss and phyllite in Table 6.

Porosity and thermal conductivity

Table 6: Thermal Conductivities of Rocks

*At 100° C.

Glassy rocks, like glasses generally, have a low thermal conductivity (—0.002 cal/cm° C), which increases with temperature. In contrast, increasing temperature reduces the conductivities of most crystalline materials, as shown by the data for rocks in Table 6. The decrease in conductivity is large for quartz, but for feldspars it is small, and, in fact, calcium-rich feldspar shows a small increase, indicated by the data for anorthosite in Table *6.* These differences in behaviour account for the fact that sialic rocks show a larger drop in conductivity with temperature than do mafic rocks. The drop in conductivity tends to cause the geothermal gradient to increase with depth in the Earth, for a constant flux of heat escaping outward. Above temperatures of about 1,600" C (2,900" F), however, conductivities begin to increase with temperature, because transport of heat by thermal radiation through the solid becomes significant; radiative transfer probably makes an important contribution to heat conduction in the Earth's mantle.

Thermal expansion. The increase in volume of a rock specimen with temperature is expressed in terms of the coefficient of volumetric thermal expansion. The coefficient α is equal to the reciprocal of the specimen volume (V) times the ratio of the increase in specimen volume (ΔV) that occurs for a small temperature increase (AT) to that temperature increase, or $\alpha = (1/V)\ (\Delta V/\Delta T)$. Similarly the increase AL in linear dimension (L) of the specimen is expressed in terms of the coefficient of linear thermal expansion $\Delta L/L\Delta T$. It is equal to $\alpha/3$, for isotropic specimens. The volumetric expansion is of particular importance in estimating the density of rocks at the high temperatures within the Earth and in assessing the possibility that temperature gradients in the Earth will cause convective motion analogous to the convection of a viscous liquid. The linear expansion is important where rock must remain fitted to other structural materials over wide variations in ambient temperature. Most rocks have a volumetric expansion coefficient in the range 1.5–3.3 × 10^{-5} per degree Celsius under ordinary conditions. Quartz-rich rocks, especially sandstone and quartzite, have the highest values, indicating a relatively high thermal expansion of quartz itself. Thermal expansion coefficients increase substantially with temperature. At the microscopic level, the thermal expansion of a rock is a complex affair, because of the generally anisotropic character of the expansion of the individual minerals and the differences in expansion from grain to grain. A complex pattern of stresses is set up in the grains, controlled by the thermal expansions and the various elastic properties. To some extent the stresses are relieved by opening up of microscopic cracks, and a part of the measured expansion, probably about 10–20 percent, thus represents increase in crack porosity. Crack opening is not entirely reversible, so that the contraction on cooling generally is less than the expansion during the previous heating, and the expansions on successive heatings may differ. Because of the cracking, piolonged thermal cycling causes mechanical disintegration of rocks into their granular components. These effects are inhibited by confining pressures sufficient to keep the cracks closed.

Thermal cycling

Radioactive heat productivity. Of importance in determining the temperature and thermal evolution of the Earth's interior is the heat produced by absorption of radiation that is emitted from radioactive elements in the rocks. Significant contributions come from the nuclear decay of potassium-40, thorium-232, uranium-235, and uranium-238. In Table 7, average rates of heat production are given for several major rock types, including chondritic meteorites (meteorites imbedded with nodules of certain materials), which are considered to represent a possible composition for the Earth's mantle. The great enrichment of the radioactive heat producing elements in the more sialic rock types of the Earth's crust is evident in Table 7 and has important consequences in the thermal history of the Earth, the generation of magmas, and volcanism. The average geothermal heat flow at the Earth's surface (1.2 × 10^{-6} calorie per square centimetre per second) could be generated by a layer of granite only 16 kilometres (ten miles) thick, somewhat thinner than the typical thickness of the continental crust, whereas some 300 kilometres of chondritic material would be required.

Table 7: Radioactive Heat Generation by Rocks

	heat production (10^{-6} cal g^{-1} $year^{-1}$)			
	from U	from Th	from K	total

*Shows very wide variation.

Melting. Rocks begin to melt at temperatures somewhat lower than the melting points of any of their constituent minerals, and melting occurs over a range of temperatures, from the first appearance of liquid to the final disappearance of the last crystals. Melting points of the common anhydrous (non-water-bearing) rock-forming silicates lie between 1,100" and 1,800" C (2,000" and 3,300" F). The lowest melting mixture of these has the composition of granite (mainly quartz and potassium-sodium feldspar) and begins to melt at 950" C (1,750" F). The temperature of first melting does not depend on the relative proportions of the different minerals present and hence is the same for granitic rocks of diverse compositions, representing different proportions of quartz, potassium feldspar, and sodium feldspar. The temperature of first melting does depend, however, on which minerals are present and on their individual compositions. Thus the more mafic igneous rocks such as diorite and basalt, which lack quartz and potassium feldspar and which contain a calcium-rich sodium feldspar, begin to melt at higher temperatures, approaching 1,100" *C* (2,000" F). Ultramafic rocks such as peridotite, containing only pyroxene and olivine, begin to melt at 1,350"–1,550" C (2,450"–2,800" F). The completion of melting is sensitive to the mineral proportions in the rock. Most granites have a narrow melting range, because their bulk compositions are close to that of the first-formed melt. Increasing the proportion of a mineral conrtituent of high melting point widens the melting range by raising the completion of melting. Thus mafic rocks, containing substantial amounts of high-melting iron-magnesium silicates, have melting ranges 200"–300" C (400"–500" F) wide.

Melting of rocks is greatly affected by the presence of water vapour under pressure, because water can dissolve in silicate melts. Increasing the water-vapour pressure to a few thousand bars lowers the first melting of granite from 950" to 650" C (1,750" to 1,200" F) and causes water to dissolve in the melt to the extent of several percent. The effect of water-vapour pressure in lowering the melting range of basalt and the first melting temperature of granite is shown in Figure 5. Similar considerations apply to the melting of metamorphic and sedimentary rocks of similar compositions.

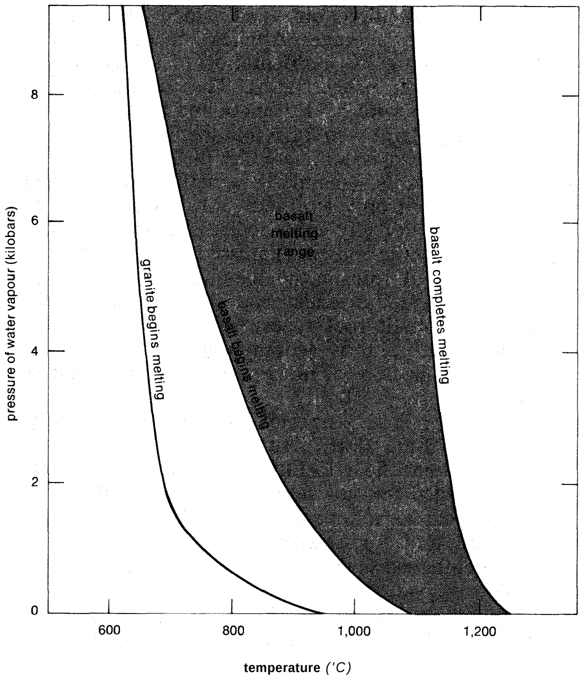

Figure 5: Melting range for basalt (shaded) and temperature of beginning of melting for granite, as a function of water-vapour pressure.

Importance of water vapour under pressure

Another important effect of water vapour under pressure is to increase the stability of hydrous minerals, such as mica and amphibole. When heated at atmospheric pressure, these minerals break down to anhydrous minerals (with release of water) at temperatures of only 500"–700" C (900"–1,300" F), well below the start of melting. Raising the water-vapour pressure both lowers the onset of melting and raises the stability of the hydrous minerals against breakdown, so that it becomes possible for them to melt or, on cooling, to crystallize from a rock melt. The fact that these minerals actually formed in many igneous rocks at the time of initial crystallization shows that substantial pressures of water vapour must have operated on the parent magmas.

ELECTRIC AND MAGNETIC PROPERTIES

In deciphering the history of the Earth's magnetic field and the wandering motions of the continents and in estimating temperatures in the Earth's interior, electric and magnetic properties of rocks play an important role. They are also utilized in methods of geophysical exploration.

Magnetic susceptibility. Application of a magnetic field (H) to a rock specimen induces a magnetization (M) that is generally proportional to the field; the proportionality constant (symbolized by χ, the Greek letter chi) in the equation $M = \chi H$ is the magnetic susceptibility (see MAGNETISM). Substances are classified as paramagnetic or diamagnetic accordingly as χ is positive or negative. In a paramagnetic material, the directions of the inducing magnetic field and the induced magnetization are the same, whereas in a diamagnetic material they are opposite. Most minerals are weakly diamagnetic, with magnetic susceptibilities of about —10-6. Minerals containing iron, manganese, and related elements (transition elements in the periodic table), whose atoms act as individual little magnets, are paramagnetic and typically have magnetic susceptibilities of about $+10^{-4}$. Certain paramagnetic materials typified by iron and the common magnetic mineral magnetite have abnormally large susceptibilities (χ is approximately 1 to 10^{+3}) and are called ferromagnetic. In these materials, the individual atomic magnets (*e.g.*, iron atoms) align themselves spontaneously to produce a magnetization even in the absence of an inducing field. A ferromagnetic mineral normally shows little or no net magnetization in bulk because the spontaneous magnetization occurs in microscopic regions, called domains, the magnetic orientations of which point in diverse directions, and which therefore cancel out on the average. Application of a magnetic field causes progressive reorientation of the domains, inducing a net bulk magnetization. The corresponding susceptibility varies with field strength and magnetic history, but it is always large—so large that the bulk magnetic susceptibility of rocks is dominated by their content of ferromagnetic minerals (mainly magnetite), even though these are present only as minor constituents. The magnetic susceptibility χ of most rocks is approximately 0.3 times the magnetite content expressed as volume fraction. Because of regularities in the chemical processes of rock formation, magnetite tends generally to be more abundant in more mafic rock types; hence the susceptibilities of basalts and gabbros (commonly $\chi \sim 10^{-3}$) are as a rule larger than those of most granites, granitic gneisses, and sandstones $(\chi < 10^{-4})$.

Rocks of higher than normal magnetic susceptibility at depth beneath the Earth's surface tend to enhance the Earth's magnetic field locally in the same way that an iron core enhances the field of an electromagnet. The resulting local variations in the Earth's field provide a geophysical tool for assessing the distribution of rock types at depth, especially ore bodies containing magnetic minerals.

Remanent magnetization. The variety of magnetite called lodestone is the oldest known example of a ferromagnetic material in which remanent magnetization is retained in the absence of an inducing magnetic field, forming a permanent magnet. Remanent magnetization results from some non-randomness in the orientations of magnetic domains. Rocks containing ferromagnetic minerals can acquire a remanent magnetization that results from the magnetizations of the individual grains (see ROCK MAGNETISM).

Significant remanent magnetism in igneous rocks is acquired by a process called thermoremanent magnetization, which develops as the rock cools from high temperature. Above a critical temperature, called the Curie temperature (578° C [1,072° F] for magnetite), thermal agitation disrupts the orderly alignment of atomic magnets in a ferromagnetic mineral, so that the ferromagnetism is destroyed and χ decreases abruptly to values of about $+10^{-4}$, typical of paramagnetic minerals. At the Curie temperature, a remanent magnetization develops parallel to and proportional to the ambient magnetic field. Because the bulk magnetism of rocks is contributed by several different minerals and because grain size and shape also influence magnetic behaviour, the thermoremanence is actually acquired over a wide temperature range from 600" C (1,100" F) down to about 300" C (600° F). An important empirical principle is that the partial thermoremanent magnetization acquired over any particular cooling interval is independent of that from other intervals and is destroyed by heating over the original cooling interval. Thermoremanent magnetizations of basalts are typically about 1 percent of the ambient magnetic field. For the same composition, coarser grained rock should have lower remanence.

Depositional magnetism

Sedimentary rocks can acquire magnetization during their original deposition, by the settling of magnetized particles from water suspension, the particle orientation being controlled by the Earth's field. This is called depositional magnetization. The particles are commonly elongated grains of magnetite, magnetized parallel to their long dimension. Because the particles tend to settle with their long axes horizontal, depositional magnetization tends to ignore the dip of the magnetic field, but it records the direction of the field in the horizontal plane at the time of deposition.

Rock magnetization provides a record of the Earth's magnetic field as it existed at the time of rock formation. This record tends to be obscured by magnetization components impressed later, under changed magnetic fields. Fortunately, however, these later components can often be removed by suitable heat and alternating-field demagnetization treatments without destroying the original magnetization. The permanence of a given magnetization is measured in terms of the corresponding coercive field, which is the strength of the reversed magnetic field required to reduce the bulk magnetization to nil. For the thermoremanent magnetization in bulk samples of magnetite, the coercive field is about 20 oersted units, which, although substantially larger than the Earth's present field (about 0.5 oersted), is considered not stable by comparison with what is achieved in other materials. It appears nevertheless that the magnetite in rocks contributes to the stable thermoremanent magnetization, probably because much of the magnetite is present as grains smaller than the domain size; if elongated in shape, these one-domain grains have a high coercive field (about 500 oersted).

The thermoremanent magnetization acquired by large masses of basalt in the oceanic crust is strong enough to modify measurably the Earth's magnetic field in their vicinity. In certain strip-shaped areas of the ocean floor, the basalts of the oceanic crust are magnetized essentially parallel to the Earth's present field direction, whereas in intervening strips they have the reversed direction of magnetization because they formed at times when the Earth's field was reversed. The magnetic fields from these oppositely magnetized rock masses set up local variations amounting to about 1 percent of the total field. These variations, readily detected by sensitive ship- or air-borne magnetometers, provide a basis for mapping the magnetized strips and inferring the history of formation of the oceanic crust.

Electrical conductivity and dielectric behaviour. The common rock-forming minerals (silicates, oxides, carbonates, sulfates) are electrical insulators, having resistivities higher than about 10^8 ohm metres (units of ohm times metre) at ordinary temperatures. Many ore minerals (sulfides and sulfosalts) and some oxides (notably magnetite and ilmenite, which are common accessory minerals in rocks) are electronic semiconductors, with resistivities in the range of 10^{-4} to 10^4 ohm metres. Metallic conductors are rare in nature, with the exception of graphite. The electrical conductivity of rocks depends on mineral content, texture, and porosity in a way similar in most respects to the thermal conductivity. Crack porosity increases the resistivity of dry rocks. A conductive minor mineral component such as graphite, magnetite, or pyrite gives only a modest increase in bulk conductivity if present as isolated grains but gives a large increase if distributed in interconnected networks, such as interstitial cementation in a clastic texture, intersecting fracture fillings, or dendritic (branching) growth structures. Resistivities of slates, for example, are normally several thousand ohm metres but can be reduced to less than one ohm metre by a content of graphite and pyrite amounting to only a few percent.

Resistivities of dry igneous rocks approximate 10^{10} ohm metres at room temperature. Above about 500" C (900" F), the resistivity begins to drop rapidly with temperature. Atoms displaced by thermal agitation out of their stable sites in mineral structures can diffuse through the structures under the force of the electric field, and at high temperatures this type of ionic or electrolytic conduction dominates the electrical behaviour of insulating minerals. Its temperature dependence follows the exponential form for thermally activated processes: $1/\rho =$ A $\exp(-Q/RT)$, in which $1/\rho$ is conductivity [reciprocal resistivity, expressed as $\text{ohm}^{-1}\ \text{m}^{-1}$—that is, 1/(ohm metre)], A is a constant, Q is the activation energy for the conduction process, and R is the gas constant (2 calories per mole per degree Kelvin). For olivine, which is thought to be a major constituent of the outer part of the Earth's mantle (in the rock peridotite), the constant A is 5 $\text{ohm}^{-1}\text{m}^{-1}$ and the activation energy is 16 kilocalories per mole; the resistivity falls from about 10^6 ohm metres at 200" C (400" F) to about 10^2 ohm metres at 1,000" C (1,800" F). The resistivities of rocks in the Earth's interior can be calculated from the magnetic effects of currents induced in the interior by current flow in the ionosphere. Resistivities so determined decrease from about 103 ohm metres in the lower part of the crust to one ohm metre in the upper mantle, at a depth of about 600 kilometres (400 miles), and to the order of 10^{-2} ohm metres in the lower mantle. This is doubtless the effect of temperature increase inward. Because ionic conductivity, like diffusion, has a substantial activation volume, it is inhibited by the high pressures in the mantle, and it therefore seems likely that the high conductivities of rocks in the deep mantle are due to appreciable electronic semiconduction at the high temperatures prevailing there.

Resistivity in the Earth's interior

In the shallower parts of the crust, at depths less than about six kilometres, where because of the relatively low confining pressure (less than 2,000 atmospheres) the rocks retain some crack porosity, their electrical properties are dominated by the presence of water. Pure water is a reasonably good insulator (its resistivity is 2×10^5 ohm metres), but the water present in rocks (groundwater, connate water [water trapped during rock formation]), is moderately conductive due to the presence of dissolved salts; resistivities are commonly in the range one to ten ohm metres and less commonly as low as that of seawater (0.2 ohm metre) or even lower. Except for rare rock types containing substantial amounts of conductive minerals, the resistivities of water-saturated rocks do not depend on the mineral resistivities but are instead proportional to the resistivities of the contained water and depend sensitively on the amount and nature of the pore space. It is found empirically that for a given type of porosity, the resistivity p varies approximately as the inverse square of the porosity η: p $=$ a $\rho_w\eta^{-2}$. Here a is a constant and ρ_w is the resistivity of the contained water. The empirical constant a depends on the type of porosity: for clastic rocks (interstitial porosity) it is about 0.7, whereas for volcanic rocks it is larger ($\sim$1.5), indicating the relatively poor connectivity of the vesicular pore space. Crack porosity is the most effective source of rock conductivity, the value of the constant a for crystalline rocks being about 0.3. It has been found that the increase in crack porosity that occurs in stressed rocks just before brittle failure can be detected by a corresponding decrease in resistivity, thus providing a possible method for anticipating the occurrence of fracture in the Earth, and hence the resultant earthquakes and earth tremors.

Earthquakes predicted by resistivity

For rocks only partially saturated with water, which occur above the water table, the resistivity increases as expected for a reduced porosity corresponding to that portion of the pore space actually occupied by water. Beyond a certain reduction in water content, corresponding to about half of the total porosity, the resistivity increases more rapidly, probably because the connectivity of thin films of water between the mineral grains becomes severed as the water content becomes increasingly lower.

Information about the average resistivities of rocks down to depths of about 100 metres (300 feet) in the Earth is obtained by electromagnetic measurements at radio frequencies. It is found that younger sedimentary rocks generally show resistivities less than 40 ohm metres, older sedimentary rocks and volcanic rocks are intermediate (40–100 ohm metres), and crystalline rocks of low porosity show resistivities greater than 100 ohm metres.

In addition to setting up current flow, an electric field (E) causes the displacement of bound charges in a material medium, creating a state of electric charge unbalance called the polarization (P). It is analogous to the magnetization produced by a magnetic field and obeys a similar linear relation between polarization and the electric field producing it: P $= \alpha E$, in which α is the polarizability of the medium, analogous to the magnetic susceptibility χ. The constant a may be calculated directly from a measured quantity, the dielectric constant, E $= 1 + 4\pi\alpha$. The dielectric constant is highest in a static (steady state) electric field and generally decreases in alternating fields of progressively higher frequency. At the frequencies of visible light, the dielectric constant equals the square of the refractive index and ranges from 2.3 to 3 for the common rock-forming minerals; at radio frequencies, E is generally two to three times larger. The corresponding bulk dielectric constants for rocks are given to a reasonable approximation by a volume-weighted average over the mineral components. The effect of porosity can be included by treating the pore space as a component with dielectric constant 1. Water-saturated pore space can also be included, provided account is taken of the great dielectric dispersion (change of ε with frequency) of water near 10^{11} hertz, the dielectric constant dropping from a value of about 85 at lower frequencies to about 5 at higher frequencies.

Rocks containing appreciable amounts of moisture, even absorbed moisture, begin to show departures from the above type of behaviour at frequencies less than about 10^6 hertz. Below about 10^4 hertz, the apparent dielectric constant measured by standard techniques begins to increase rapidly with decreasing frequency; the values reported at low frequencies, below one hertz, are prodigious (10^5 to 10^8), higher by many orders of magnitude than the static (zero hertz) dielectric constants of any of the mineral components or water. The high apparent values are probably caused by the flow of electric currents that are unable to pass freely through the rock, owing to internal obstructions along the conductive water films in the rock and to electrochemical blocking either internally or at the measuring electrodes. When the currents are blocked in this way, they result in what appear to be displacements of bound charge and give a large apparent contribution to the dielectric constant E. The product $\varepsilon\rho\omega$ (in which ρ is the bulk resistivity and ω is the frequency), is found to be nearly frequency-independent over a wide frequency range, from 10^3 hertz to as low as 10-3 hertz. Because the resistivity appears frequency-independent, the apparent dielectric constant at low frequencies thus varies inversely as the frequency. The reciprocal product $1/\varepsilon\rho\omega$ is known as the loss tangent and is the fractional power dissipated per cycle of oscillation of the electric field; it is thus analogous to the specific damping capacity b for elastic waves, which for rocks shows a similar frequency independence. Loss tangents are more useful than dielectric constants for characterizing rocks electrically at frequencies below 1,000 hertz.

HYDRAULIC CONDUCTIVITY

Although porosity indicates the capacity of a rock to store fluids such as water or petroleum, the usefulness of this storage capacity depends on the readiness of extraction or recharge, which is controlled by the permeability

Darcy's law

(hydraulic conductivity). This is defined in terms of the volume of fluid that will flow per unit time through a rock cross-sectional area under a specified pressure gradient driving the fluid forward. The driving pressure is the excess over the simple hydrostatic pressure that would be present in the fluid at rest and is expressed in terms of the excess fluid head (h). Darcy's law (after Henri Darcy, a French engineer) states a linear relationship between the volume of fluid and the pressure gradient (the decrease in pressure with distance x in the direction of flow, —*dh*/*dx*) along the fluid flow path: the volume (Q) of fluid flowing through a rock per unit time is equal to the cross-sectional area (A) times the permeability (K) times the driving pressure gradient—*i.e.*, Q — — AK *dh*/*dx*. In engineering practice, ***Q*** is expressed in gallons per day and ***A*** in square feet; so that, if h and x are taken in the same units, the permeability K has dimensions gallons per day per square foot, a unit also called the Meinzer (after Oscar Meinzer, an American hydrologist). The values of K in these units vary from less than 10^{-5} for crystalline rocks to 10^{6} for gravel; some intermediate values for the permeability of various rock materials to water at *25"* C (77" F) are sandstone 10^{-2}–102, shale 10^{-6}–10^{-4}, limestone 10^{-4}–10, and sand 10 2–104. Permeabilities for other fluids, or for water at other temperatures, can be obtained from the fact that the permeability is inversely proportional to the fluid viscosity.

Although the more porous rocks generally have higher permeability, the relationship is greatly affected by the type of porosity: interstitial porosity in a clastic texture, where the pore spaces interconnect, gives a much greater permeability than does vesicular porosity. For porosities of a given geometrical type, the permeability varies directly as the square of the pore dimensions, hence coarse detritus and coarse-grained clastic rocks have much higher permeabilities than their finer-grained counterparts. The strong dependence on pore size distinguishes hydraulic conductivity sharply from electrical conductivity. The wide range of observed permeability values for rock materials of a given type (*e.g.*, 10^{-2} — 10^{4} for sand) indicates the influence on pore sizes of various factors in addition to clast size: size sorting, compaction, clast shapes, cementation, etc. Thus clean sands have much higher permeabilities than clay-rich sands, whose interstices tend to be blocked by clay. Crystalline rocks have not only small total porosity, but also thin pores (cracks), and the permeability of sound specimens is for practical purposes nil. Masses of crystalline rock undergound, however, usually show some bulk permeability because of the presence of macroscopic fractures (joints, faults) on a coarse scale; this type of fracture permeability cannot be assessed primarily from laboratory tests on small rock samples.

OPTICAL PROPERTIES

Colour effects

The effects of rocks on visible light are best considered in terms of the optical properties of the individual component minerals, and are best observed in slices of rock about 30 microns (3 × 10^{-5} metre) thick. To the naked eye, the striking optical feature of many rocks is their colour, which derives from the colour of one or more mineral constituents. Striking colours are often caused by minor and petrologically insignificant mineral components, as, for example, in the pink colour of some granites. In most common rocks the colour effects are dominated by iron-containing minerals. Reds, browns, and ochre yellows are caused by oxides or hydrous oxides of ferric iron, and greens by silicates of ferrous iron or by finely divided silicates or hydrous silicates of both ferrous and ferric iron. Less commonly, other metal ions with distinctive absorption spectra in the visible range are responsible for striking rock colourations, when there is local enrichment of the comparatively rare minerals containing these ions: thus blue from copper, pink from manganese or cobalt, green from chromium or nickel, yellow from cadmium, orange from chromium or molybdenum, red from mercury, etc.

The lustre of rock surfaces depends on the lustres of the component minerals, modified by the effects of grain size: coarse-grained minerals display their inherent lustre, whereas fine-grained aggregates generally have a dull lustre. Rock weathering produces a dull lustre because it involves chemical alteration of the original coarse-grained minerals to aggregates of clay and other fine particles.

BIBLIOGRAPHY. S.P. CLARK, JR. (ed.), *Handbook of Physical Constants* (1966), is a basic reference that contains an exhaustive compilation of measured data on physical properties of rocks and minerals, with a brief introductory discussion of each of the properties treated. J.C. JAEGER, *Elasticity, Fracture and Flow, with Engineering and Geological Applications,* 3rd ed. (1969), gives a general discussion of mechanical properties and their application to the calculation of stresses and deformations in the Earth. **A** more detailed treatment of mechanical properties, with emphasis on current experimental studies and theoretical concepts of brittle failure, is contained in C. FAIRHURST (ed.), *Failure and Breakage of Rock* (1967); and in K.G. STAGG and O.C. ZIENKIEWICZ (eds.), *Rock Mechanics in Engineering Practice* (1968). These works also discuss engineering applications of the mechanical properties, and methods of testing, particularly of rock masses *in situ.* Experimental studies of rock plasticity and creep pertinent to geological phenomena are collected in *Rock Deformation,* ed. by D.T. GRIGGS and J. HANDIN (1960). A recent survey of creep properties of rocks in relation to the flow of the Earth's mantle is given by J. WEERTMAN, "The Creep Strength of the Earth's Mantle," *Rev. Geophys. Space Physics,* 8:145–168 (1970); the approach is primarily theoretical, but contains references to recent experimental studies. The behaviour of rocks under shock loading and the structural changes produced in rocks by shock waves are treated by B.M. FRENCH and N.M. SHORT (eds.), *Shock Metamorphism of Natural Materials* (1968). Magnetic properties of rocks and some of their applications are discussed by D.W. STRANGWAY, *History of the Earth's Magnetic Field* (1970). Electrical properties, particularly in relation to their use in exploration geophysics, are discussed by G.V. KELLER, "Electrical Characteristics of the Earth's Crust," in J.R. WAIT (ed.), *Electrontagnetic Probing in Geophysics* (1971).

(W.B.K.)

Rocky Mountains

The major section of the great upland system that dominates the western North American continent, the Rocky Mountains stretch from northern Alberta and British Columbia southward through the western United States to Mexico, a distance of some 3,000 miles. In places the system is several hundred miles wide. Limits are mostly arbitrary, especially on the western side, where other mountain systems, generally excluded, exist (see Figure 1). The explorations of Silvestre Vélez de Escalante, Lewis and Clark, and John Wesley Powell caught the imagination of the world, and through their reports the knowledge of the Rockies began to unfold. The snow-capped peaks, the conifer forests, the wide intermountain valleys, the crystal-clear streams, the big sky, and a vast mineral resource provide homes and work for about 5,000,000 people, and millions more come each year to tour and play. The Rockies comprise one of the country's most popular tourist attractions.

The basic divisions

To the west, especially in Nevada, western Utah, and Arizona, lies the Great Basin, or the Basin and Range Province (*q.v.*). Here, the earth's crust has been broken by numerous faults, with the blocks between faults uplifted, depressed, and tilted. This manner of deformation, geologically speaking, has been a rather recent affair, and has produced a kind of relief and drainage entirely different from that of the more typical Rocky Mountains to the east. As a result, it is necessary to recognize that there are two basic divisions of the Rocky Mountains. The first is that of the map area (see Figure **2**), in which the ranges retain characteristics of their original structure and shape, and the second, that west of the map area, where the original structures and forms have been broken and much defaced by block faults. In fact, there is much controversy about what the original structures of the western division were like.

This article deals with fundamental themes in the geological evolution of the Rockies, with particular emphasis on the basic structural elements from which the mountains of today have been formed. The article NORTH AMERICA treats the development of the Rockies as a factor in continental evolution, and the articles BASIN AND RANGE PROVINCE; SIERRA NEVADA RANGE; PACIFIC COAST RANGE; and ALASKAN MOUNTAINS describe other component ranges of the western mountain system. Articles on the GRAND CANYON and the major rivers of the area provide more detailed information regarding individual physical features of the Rockies. The article NORTH AMERICAN DESERT contains descriptions of the plant and animal life of the region. Full treatment of the contemporary landscapes of the region will be found in the article UNITED STATES: *Landscape* and in the articles on individual states.

Ranges and basins of the Eastern division

Eastern division. A study of Figure 2 gives an indication of the number of ranges in the eastern division. Each one is a large uplifted mass; many have high peaks and dramatic scenery. The uplifts or ranges are named on the map (Figure 2), as are the better known basins. The Front Range of Colorado and the central Arizona uplift are the two most massive uplifts, but most of the rest have a somewhat uniform area, about 62 miles (100 kilometres) long and 15 miles (25 kilometres) wide. The Front Range supports peaks over 14,000 feet high. including Mt. Elbert, which at 14,431 feet is the highest point in the Rockies. Wyoming has peaks in the Wind River and Teton Ranges well over 13,000 feet high, as does Utah in the Uinta Mountains. Some of the high mountain areas have remained virtually untouched by man and have been set aside as national wildernesses. All have national forests.

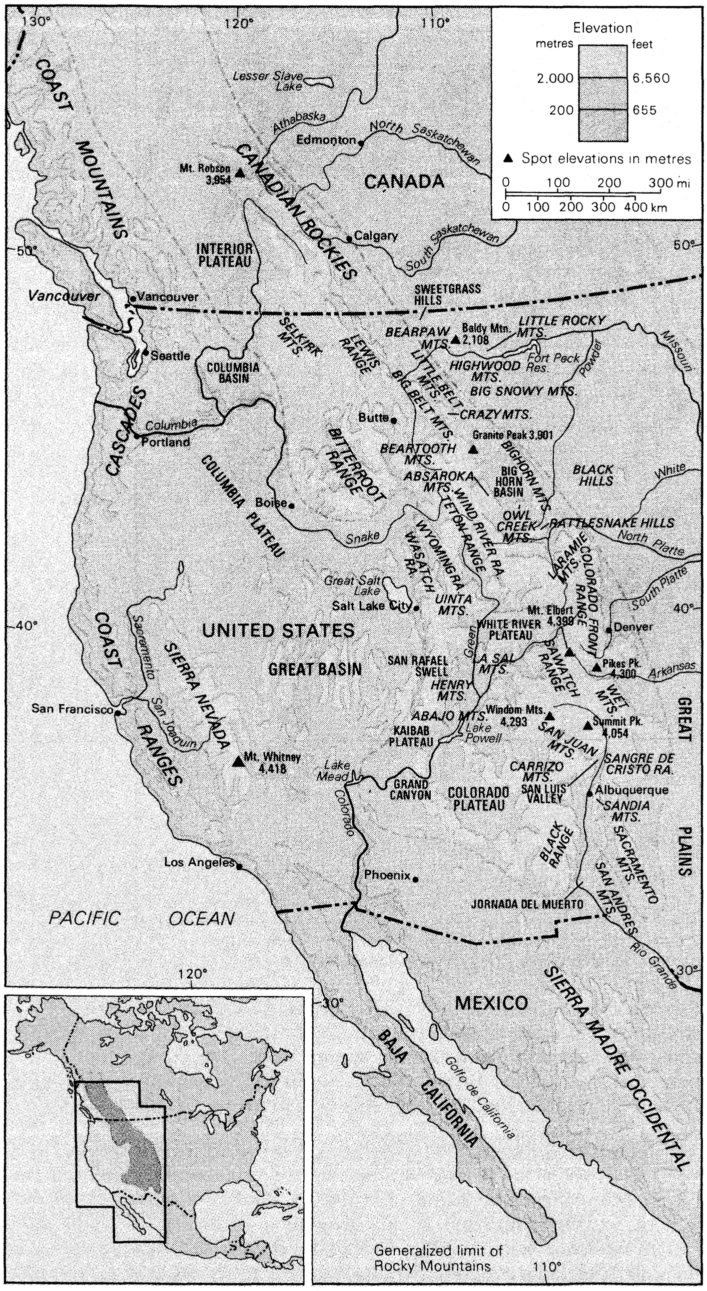

Figure 1: The Rocky Mountain ranges in the United States and Canada.

The basins of the eastern division are broad and generally from 4,000 to 7,000 feet high. During the period of the uplift of the ranges and for some time afterward the basins were the receptacles of the rock debris eroded from the uplifts. Later, as drainage became well established to the Missouri and Colorado rivers, the basin sediments were cut into by water action and were in some spots deeply eroded.

Western division. The Canadian and northwestern Montana Rockies, including the mountains of Glacier National Park and the Lewis Range of northwestern Montana, are a subdivision of the western division. They are characterized by a series of parallel ridges, which resulted generally when thick sections of sedimentary rocks were thrust on top of each other. The same tyye of linear mountain ridges is noted in western Wyoming and southeastern Idaho (see Figure 2), but from the southwestern corner of Wyoming to the southwestern corner of Utah and southern Nevada the western division is masked by the later Basin and Range block faulting. How far west in western Utah and Nevada the true Rocky Mountains once extended is still regarded as controversial.

In summary, therefore, the eastern division of the Rockies is marked by blister-like uplifts and large intermontane basins and the western division by thrust faults and folds.

HISTORY OF SCIENTIFIC STUDY

Early explorers

Catholic missionaries had worked their way northward from Mexico into New Mexico by the middle of the 18th century, and in 1776 Padre Escalante and his party explored and documented their travels into what is now Utah, reaching almost to the Great Salt Lake. The Lewis and Clark expedition in 1803–06 explored and charted a route up the Missouri River into Montana and thence across Idaho and Oregon to the Pacific. Following the Missouri River into east-central Montana, Jedediah Smith worked his way southward into the Big Horn Basin and thence into southeastern Idaho, northern and southwestern Utah, southern Nevada, around the Sierra Nevada, and back to the Great Salt Lake across the Great Basin. His journeys occurred in the years 1822 to 1831 and were possibly the most remarkable of all western explorations, but unfortunately Smith wrote very little. John Frtmont's explorations occurred in 1846–48: he followed the North Platte River into Wyoming, up the Sweetwater River to the south end of the Wind River Range (South Pass), and thence southwestward into Utah. He then explored northward into Idaho and around the broad north end of the Great Basin into Oregon and down into California. This was an important scientific survey because he charted distances, determined latitudes, longitudes, and elevations and recorded objectively in some detail what he saw.

Fdur great western surveys were then organized by the federal government, namely that of Clarence King (the 40th Parallel Survey of 1867–78), that of Ferdinand V. Hayden (geological survey of Nebraska and Wyoming 1867–78), that of George M. Wheeler (100th meridian, 1872–79), and that of John Wesley Powell (exploration of the Colorado River and of Utah, Arizona, and southern Nevada, 1869–78). The maps and preliminary observations of these important surveys laid the groundwork for a great mass of research that followed. The Rocky Mountains, with their abundant coalfields, numerous oil, gas and uranium prospects, and a wealth of metal prospects have provided the U.S. Geological Survey with much work over the past century. Many of the prospects have turned into large and small mines, making a substantial contribution to the regional and national economies. The mountains yield lumber and; by the second half of the 20th century, were offering summer and winter recreation facilities of increasing importance. They also yield water, of paramount importance in this semi-arid and arid land.

GEOLOGICAL EVOLUTION

Sedimentary provinces. The eastern division as defined above is one in which the layers of sedimentary rocks deposited in seas of the Paleozoic and Early Mesozoic Era (from about 550,000,000 to 225,000,000 years ago) are relatively thin, while those of the western division are thick. The western division is characterized as geosynclinal (resulting from a vast downwarping in the earth's surface), whereas the thinner eastern deposits are of a peripheral (shelf) type. The sedimentary layers of the uplifted ranges of the shelf vary in thickness from a few feet to 6,000–7,000 feet, whereas those of the western geosyncline exceed 40,000 feet in places.

Age and thickness of deposits

As the beds of the downwarp began to be uplifted, folded, and thrust faulted under the pressure of earth movements in Late Mesozoic time (during the Jurassic and Cretaceous periods of 136,000,000 to 190,000,000 years ago), their waste products, formed by the erosive action of wind and water, were carried eastward and deposited on the adjacent shelf in considerable volume. In fact, a foredeep basin (*i.e.*, one in proximity to the great downwarp) in western Wyoming and central Utah subsided and received over 10,000 feet (3,080 metres) of the sediments, which consequently spread eastward in diminishing amounts.

Structures of the western divisions. The sediments of the geosyncline were first deformed by vast earth movements in Jurassic time; with the deformation, a broad upland was created where marine waters had once existed. As has been noted, the sediments eroded from the upland were deposited in the foredeep basin to the east, where marine seas advanced and retreated and in which marine animals lived. It is the fossils of these animals, trapped in the sediments, that indicate to geologists the age of the foredeep beds and thus, by inference, of the uplift to the west.

The exposed rocks of the ranges of the Great Basin reveal that the chief structures formed at this time of massive changes in the earth's crust were great folds and sheets of rock, with some beds thrust and folded over each other. The thrust sheets of this type in southeastern Idaho and western Wyoming appear to be large slices of the sedimentary rocks that started on the Cache uplift (Figure 2) and slid by gravity eastward 20 to 30 miles to their present position. The Canadian and northwestern Montana Rockies consist of a similar succession of thrust sheets, and the base of this enormous assembly is visible at the surface for a number of miles. Its width and near flatness attest to the long-distance transport of the thrust sheets and strengthen the theory that gravity caused the sheets to slide at a low angle down the east slope of a west-lying uplift. The Lewis Thrust along the east front of Glacier National Park is the best known of the thrust sheets. One has only to view these sheets on the ground to become aware of their vast magnitude. They are several thousand feet thick, probably ten to 20 miles wide, and 50 to 150 miles long and can be visualized as gigantic landslides moving down a slope of only 2° to 5°. The Charleston–Strawberry–Neb Thrust (see Figure 2) is interesting inasmuch as a sequence of rocks from its geosyncline, 25,000 feet in depth, has been moved eastward against, and probably over, a rock sequence of the shelf, itself more than 3,000 feet thick. There is no doubt as to the size and importance of these huge sheets of rock in the formation of the Rockies. In Canada and Montana, as in southeastern Idaho and western Wyoming, their mechanical aspects can be fairly well analyzed, but in the Great Basin of Utah and southern Nevada their sizes, extent, and connections remain controversial.

One school of thought suggests that the thrust sheets arose from an uplift in eastern Nevada and that the sheets then rode eastward 120 miles to central Utah. Another hypothesis posits an uplift like the Cache only 25 or so miles to the west and has the sheets coming from this nearby source. Still a third hypothesis submits that stresses occasioned by the weight of sea-floor deposits, and associated earth movements, at and under the continental margin of the Pacific 500 miles to the west, may have been transmitted to the western division of the Rocky Mountains thrusting the sheets eastward.

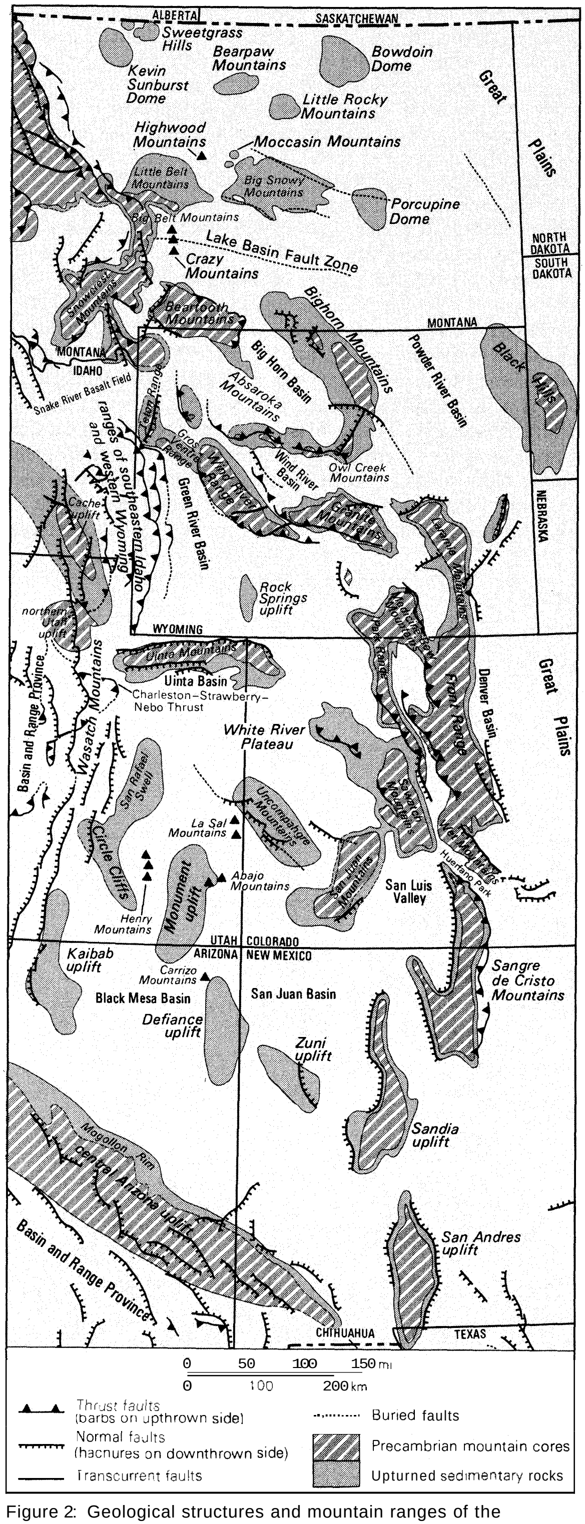

Figure 2: Geological structures and mountain ranges of the eastern division of the Rocky Mountains within the U.S.

Structures of the shelf. The uplifts of the Eastern, or shelf, division of the Rocky Mountains may conveniently be considered state by state, although state boundaries are, of course, in no sense geologically significant.

In Montana a belt of uplifts extends eastward through the centre of the state and is composed principally of the Little Belt and Big Snowy Mountains. Figure 2 indicates the oldest rocks exposed, which are the cores of the

Ages of the rocks in the shelf area

uplifts. The oldest rocks are those of Precambrian age, which have been dated by radioisotope samples from various locations as being from 1,100,000,000 to 2,700,000,000 years old. Cambrian time began about 570,000,000 years ago, and all Precambrian rocks lie below the Cambrian strata. As one of these great uplifts (known technically as a dome or anticline) is elevated, the highest part is attacked by erosion first, and thus, as the strata, or beds of rock, are eroded away by wind, rain, and ice, the oldest rock in the core ultimately is exposed. The Little Belt Mountains are asymmetrical, that is, with the core of Precambrian rocks exposed near the southern margin rather than at the centre. The Big Belt Mountains uplift extends southward from the Little Belt and must be partly involved in the multiple thrust faulting of the geosyncline to the west. The Porcupine Dome is a gentle but broad uplift along the easterly trend.

North of the east–west belt of uplifts are a number of scattered uplifts, the Bearpaw and Little Rocky supporting the highest peaks. In the Bearpaw Mountains is Baldy Mountain at 6,956 feet. The Sweetgrass, Kevin–Sunburst, and Bowdoin uplifts are gentle domes. There are a number of volcanic fields in Montana, but the Highwood and Crazy mountains are the areas that stand conspicuously apart by virtue of their Alpine relief. In this area, the dike swarms — networks of rock figures filled with solidified lava — are classical examples of the type.

In Wyoming the Big Horn Basin is surrounded by the Bighorn Mountains, the Owl Creek Mountains, the volcanic Absaroka Mountains, and the Beartooth Mountains. The Laramie, Sweetwater, and Wind River uplifts form a barrier across central Wyoming. The Sweetwater uplift was originally as high and imposing as the Wind River. After much erosion it foundered until almost all the peaks were covered with sediments, some of volcanic origin. In the current cycle of erosion these ancient peaks are now being exhumed.

The Black Hills uplift is large but was not raised to the same height as some of its neighbours. The Precambrian granites are, nevertheless, exposed, and it was from these that the gigantic Rushmore Memorial was carved. The newest and most rewarding oil field area of the Rockies is located in the Powder River Basin, close to the northwest extremity of the Black Hills.

Special features of the Uintas

The Uinta Mountains uplift in northeastern Utah and northwestern Colorado follows an easterly bend and is structurally linked to the White River Plateau, which is a projection of the Sawatch uplift. The Uintas are interesting for several reasons. They seem to have inherited their position from a Late Precambrian basin that extended eastward from the main north–south basin. The broad anticlinal, or upward, bending nature of the rock strata of the Uintas gives strong support to the theory that they are a vast blister-like upwarp. The upwarp is also bordered by upthrust faults, which accentuate the anticlinal structure and confirm that the uplift was caused by vertical, upward-directed forces. It may be contended that the Uintas are typical of the mode of formation of all the uplifts of the eastern division of the Rockies, although it must be noted that some uplifts are asymmetrical with a border upthrust fault only on one side, as in the case of the Wind River mentioned above.

The large Front Range uplift is terminated on the south by Huerfano Park, with the Wet Mountains making up an arm linked to the north end of the Sangre de Cristo uplift. The Front Range passes into the Laramie uplift on the north by way of narrowing and a lower relief area. On the west it is crowded against the Sawatch uplift, and in this zone the sediments are compressed together, with marked folding and thrust faulting.

Part of the San Juan uplift and part of the San Luis Valley, or depression region, are covered by a large volcanic field. Some of the highest peaks in the San Juans are volcanic rocks. These include Windom Mountain 14,166 feet (4,293 metres) and Summit Peak 13,377 feet (4,054 metres).

In New Mexico the most significant geological aspect is that a post-Rocky Mountain rift, or fault-bounded, valley system developed in Late Cenozoic time (about 30,000,000 years ago), proceeding in a northerly direction through the central part of the state. This rift valley complex now conducts the Rio Grande (*q.v.*) down to west Texas and Mexico. A major block of the valley flow, dropped down between the great faults on either side, has, in fact, cut the San Andres uplift into two opposite facing escarpments, or rock outcrops, the Sacramento Mountains on the east and the San Andres Mountains on the west. The Jornado del Muerto Valley west of the San Andres is another downfaulted block. Farther north the hypothetically reconstructed Sandia uplift has been shortened by the earth movements associated with the rifting process. The rifting is regarded as a north-extending arm of the Basin and Range Province (*q.v.*).

Rift valley of New Mexico

The physiographic province called the Colorado Plateau in southeastern Utah, western Colorado, northern Arizona, and northwestern New Mexico is also basically part of the Rocky Mountains. The several uplifts shown on the map in the Colorado Plateau are comparable in size (but not in height) to the other uplifts of the eastern division. They have not been domed up as much as in the uplifts to the north, and consequently less erosion has occurred, for in none of them are Precambrian rocks exposed. The beauties of the wilderness of the Colorado Plateau area had, by the 1970s. become more accessible to tourists. The Canyonlands National Park over part of the Monument uplift was being opened up by roads, and a new interstate highway had been completed across the San Rafael Swell.

Volcanic activity in the south

The Grand Canyon of the Colorado (*q.v.*) cuts across the southern end of the Kaibab uplift in this region. In addition to the uplifts, four mountain groups — the La Sal, the Henry, the Abajo, and Carrizo mountains — are notable. These are noted examples of laccolith-type mountains, in which, from a central pipelike intrusion reaching deep down into the earth's crust, molten magma has been injected between the layers of sedimentary rocks, causing the overlying beds to bulge up in small domes about one mile across. The domes are called laccoliths, and each mountain group is made up of a cluster or group of laccoliths.

In summarizing overall trends in the complex formation of the Rocky Mountain uplifts, it may be postulated that, in those uplifts in which erosion has exposed Precambrian rocks in the core, border upthrusts have developed on one side or both. In other words, when the uplift, from which mass the present-day mountains have been formed, has developed to a height greater than 20,000 feet above the adjacent basin, a border upthrust has also developed. Authoritative opinion would now suggest that the border thrust dips into the uplifted mass, steepens in depth, and eventually becomes vertical. This aspect of the uplifts results in a further postulate, that the force and mechanism responsible for each uplift is a blister-like magma injection rather deep in the Precambrian crust. The magma is supposedly of basaltic composition and comes from the upper mantle of the Earth's molten interior.

Relation to Sierra Nevada. The Basin and Range Province extends from central Utah to the Sierra Nevada, and although the geological relations in this wide region are not unknown, about three-fourths of the bedrock geology is covered and concealed by volcanic fields and alluvium (erosion waste material). In consequence, there is scope for various interpretations.

It is well established that a belt of deformation and mountain building extended northward through central Nevada. It evolved from Late Devonian time to Permian time (about 345,000,000 to 280,000,000 years ago) and thus preceded the growth of the Sierra Nevada and Rocky Mountains. In the Sierra Nevada (*q.v.*) the earliest intrusions occurred in Triassic time (some 225,000,000 years ago) and seem to have been a continuation of the earlier central Nevada mountain-building activity.

Commencing in Jurassic time (190,000,000 years ago), crustal unrest occurred to the east of the central Nevada belt of deformation. There is controversy as to its nature and extent. It appears that eastern Nevada and western Utah became land, mostly mountainous, in Jurassic time, and this region probably attained its highest elevations in the mid-Cretaceous period (100,000,000 years ago). This was the time of folding and thrusting in west central Utah and in western Wyoming, when, as has been already noted, the western segment of the Rocky Mountains was formed.

Relation to Basin and Range Province. Since part of the western division of the Rocky Mountains now has the Basin and Range faulting superimposed on it and thus has had its bedrock geology partly obscured, the western limit of the Rocky Mountain system is not readily defined or clear. Some aspects of eastern Nevada seem to suggest a different structure from that in western and central Utah, and thus the western limit may lie just east of the Nevada line.

Igneous rocks. Large volcanic fields occur in many parts of the Rocky Mountains. Some of these have already been mentioned, as have the laccolithic mountains of the Colorado Plateau, a further manifestation of volcanic activity. The chemical nature of most of the volcanic rocks is such that silica is abundant in them. Another rock type, in contrast, has abundant iron and magnesium and a lesser amount of silica and potassium. This would seem to indicate that the molten magmas of the high-silica volcanic rocks originated, at least in part, in the melting of the Precambrian rocks of the crust, rather than from basalt magma originating in the mantle of the Earth's interior.

Mineral origins

The western division of the Rockies, especially where the Basin and Range faulting occurs, is noted for numerous crosscutting intrusions of solidified magma known as stocks. These are generally one to five miles across where exposed and, like the volcanics are silicic. The magma of the stocks likewise appears to have been mobilized from the silicic rocks of the Precambrian crust. Virtually every stock is the focus of numerous mineral deposits, both large and small. Hot solutions were given off by the crystallizing magma in the stocks, and these carried metal compounds, such as the sulfides of copper, lead, zinc, silver, and iron. These sulfides commonly contained a little gold. The hot solutions worked upward through the existing pore spaces in the rocks, and as the temperatures dropped, various metaliferous sulfide minerals were precipitated. Where the intrusive stocks have penetrated limestones, chemical reactions may have occurred between the solutions and the limestones, and in places massive sulfide deposits have resulted. Mining districts such as Bingham, Park City, and Ely have sprung up as a result of the mineralization in and around such stocks.

ENVIRONMENTAL AND ECONOMIC RESOURCES

Water supply. Water for irrigation, industry, and culinary needs is generally in short supply in the Rocky Mountains. To the south, as the climate becomes drier, the water supply factor becomes more critical. New Mexico and Arizona are the states most affected. The U.S. Bureau of Reclamation is the federal agency that has been most concerned in the construction of water-storage reservoirs all over the western United States, and certainly the Rocky Mountains has its share of these projects. Not many more favourable unused dam sites remain, so that within a short time—certainly not more than 50 years—all the annual precipitation in the Rocky Mountains will have been stored and used. It may then be necessary to import water from the Columbia River (*q.v.*) and from western Canada. This process would be fraught with numerous technical, financial, and political difficulties.

National parks, forests, and recreational areas. Many of the nations finest national parks, national monuments, and wilderness areas are in the ranges of the Rocky Mountains and in the Colorado Plateau. To these areas of natural beauty have been added such large recreation facilities as the Glen Canyon National Recreation Area, located on either side of Lake Powell in Utah and Arizona. The parks, monuments, and recreational areas have been withdrawn from mining, oil, and gas drilling and in general from stock grazing and are under federal control and carefully regulated to maintain the natural conditions.

Most of the ranges and mountain groups have been designated as U.S. national forests. As such the principle of multiple use obtains, with lumbering, mining, oil and gas drilling, and grazing permitted under well-regulated federal laws. In the marginal and, as yet, unclaimed basin and arid lands, the federal government still has control of the public domain. In effect, the Rocky Mountain states control less than half of the land; more than half is controlled and regulated by the federal government. Serious problems have arisen as a result of grazing, mining, and oil exploration, although by the start of the 1970s the federal government, with the cooperation of the several states, was attempting to preserve the natural heritage of the Rockies from misuse and pollution. By this time the disturbance of primitive habitats in some areas of the Rockies had generated concern among experts and laymen alike, although the floral and faunal associations had been hurt badly only in limited sections.

Metallic and nonmetallic resources. Copper is easily the most valuable of the many metallic resources of the Rocky Mountains. Great mines in Montana, Utah, and Arizona produce nearly all of the nation's red metal. Iron ore in Wyoming and Utah support a steelmaking industry. Perhaps the Rockies, however, are most noted for many underground mines for silver, gold, lead, and zinc. Such mines occur in Colorado, Montana, Idaho, Nevada, Utah, New Mexico, and Arizona. The Rockies produce all of the nation's molybdenum and nearly all of the beryllium and uranium.

Great reserves of nonmetallic substances occur in various places in the Rocky Mountains. These are rock phosphate, potash, trona, magnesium and lithium salts, glaubers salt, gypsum, limestone, and dolomite. If necessary, the nation's needs could be supplied for a long time with the stoles already known in the Rockies.

Oil and gas production. The large basins between the uplifts of the Rocky Mountains contain many oil and gas fields. Wyoming, New Mexico, Montana, Colorado, and Utah are all substantial producers, with the Powder River Basin proving one of the leading regions. The western division of the Rockies has yielded very little oil, perhaps because of the extensive folding and faulting.

The Rockies also hold extensive shale deposits containing a solid hydrocarbon material that can be driven off as oil by heat treatment. They occur principally around the Uinta Mountains in Wyoming, Colorado, and Utah. The amounts of potential oil are vast, and, as viewed by certain economists, if the exploitation of the oil shale is not carefully planned and regulated, a national calamity could result. As yet, the extraction of the oil has not been made profitable.

Immobile oil is located in certain sandstones in various places. These deposits are called bituminous, oil, or tar sands. In amounts, they compare to giant oil fields. Like the oil shales, the bituminous sandstones have not yet yielded their oil economically except in Alberta, where a major enterprise costing $300,000,000 remains marginal.

Coal. The Rocky Mountains and the adjacent Great Plains on the east contain the Western Hemisphere's most abundant and usable coal reserves. These are bituminous, subbituminous, and lignitic in character. Although not readily usable for metallurgical purposes, they constitute a tremendous energy source, and it is predicted that in the near future these coals will be used much more extensively for electrical-power generation than at present.

BIBLIOGRAPHY. A.J. EARDLEY, Structural Geology of North America, 2nd ed., ch. 19–27 (1962), a discussion of the divisions of the Rocky Mountains and a summary of the geological characteristics of each, and "Major Structures of Colorado and Utah," UMR Journal, series 1, no. 1, pp. 79–99 (1968), an article presenting the theory that most mountain ranges are blister-like uplifts and not due to horizontal compression of the crust; R.J. ROBERTS, "Tectonic Framework of the Great Basin," ibid., pp. 101–119, an article presenting a review and theory of evolution of the western geosyncline that is concerned in part with the western division of the Rocky Mountains; R.L. ARMSTRONG, "Sevier Orogenic Belt in Nevada and Utah," Bull. *Geol. Soc. Am.*, 79:429–458 (1968), an article similar in theory to Roberts with a map connecting the exposed thrust faults. These three articles represent the most recent thinking of the evolution of the western division of the Rocky Mountains.

Rodentia

The rodents, or Rodentia, are the most abundant order of mammals. At present, over a quarter of the families, 35 percent of the genera, and 50 percent of the species of living mammals are rodents. Probably an even higher percentage of individuals are rodents, for they tend to be small animals with dense populations. They are one of the few groups of animals that flourish in close association with men. Some, such as squirrels, live independently but fairly successfully near humans. Others, such as the house mouse (Mus musculus) and black and Norway rats (Rattus *rattus* and R. norvegicus), have adapted themselves to human civilization, and live everywhere that man does. These two rats (and the Polynesian rat, Rattus *exulans*, of Australia and Oceania) have travelled in ships and boats of all sizes, and have populated the entire habitable world, especially near human habitations.

For entries on particular rodent families and species, see also RELATED ENTRIES under RODENTIA in the Ready ***Ref***erence *and* Index.

GENERAL FEATURES

All rodents possess one pair of upper and one of lower incisors, growing throughout life, with the enamel restricted to a band on the front side of the teeth. Behind this is a large gap (diastema) followed by two to five cheek teeth. The jaw articulation is so arranged that when the cheek teeth are in use, the incisors do not meet, and vice versa. The incisors grow continuously, and must be worn off equally fast, or the whole gnawing mechanism is ruined. Because of the necessity to abrade these incisors, rodents spend a considerable amount of time gnawing hard objects.

Generally rodents are small. Some mice and dormice are among the smallest of living mammals, adults being as small as 75 millimetres (three inches) long, including the tail, and weighing as little as 20 grams (0.7 ounce). The largest living rodent is the South American capybara (Hydrochoerus hydrochoeris), reaching over 1.3 metres (four feet) in length and as much as 50 kilograms (about 110 pounds) in weight. A fossil rodent recently described from Uruguay is reported to have had a skull as large as that of a bull and a body bulk as large as that of a wild boar.

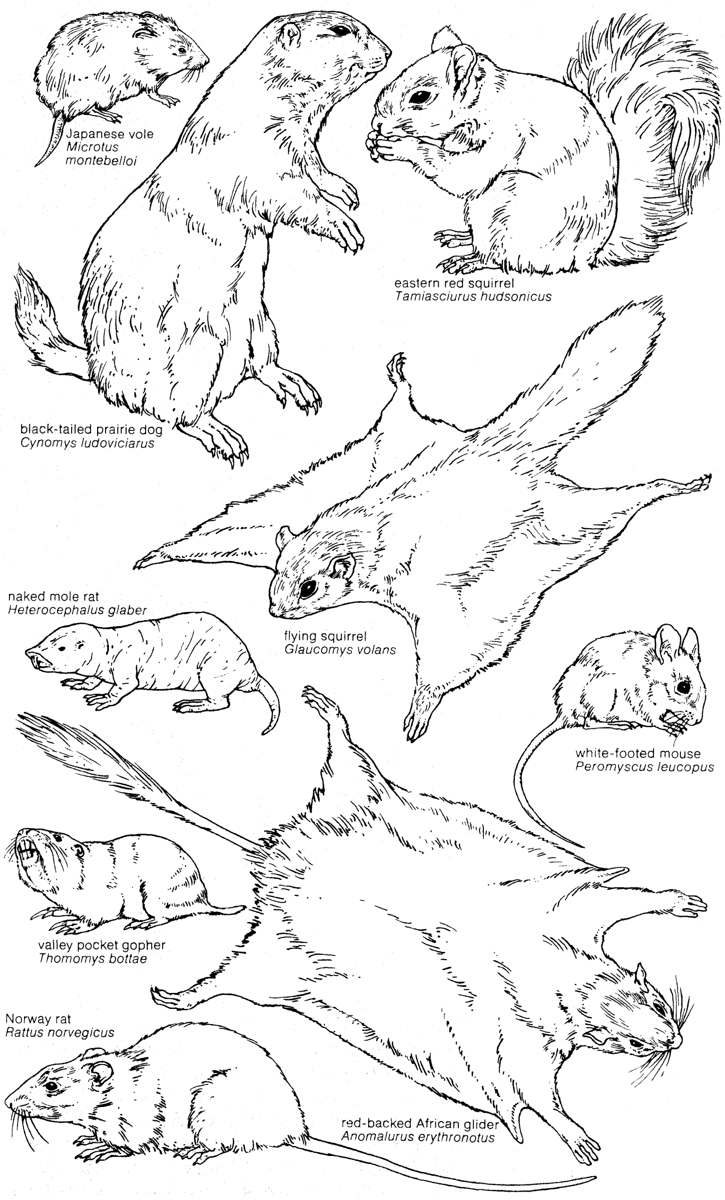

Figure 1: Range of body-plan variation of Rodentia.

Rodents are of major economic importance, primarily as consumers of the grains that are the basic foodstuff for man. It has been estimated that rats and mice destroy up to one-third of grain crops under conditions of heavy infestation. Burrowing rodents may damage root crops. The muskrat (Ondatra *zibethica*) and nutria (Myocastor coypus), introduced into Europe as fur sources, have escaped and spread over much of Europe between the Baltic and the Alps. Their burrows, particularly in canal banks, have been a major source of damage to the drainage system, most especially in The Netherlands. A number of rodents serve as reservoirs for human diseases, such as bubonic plague, tularemia, scrub typhus, and others. The plague that ravaged Europe during the mid-14th century was transmitted by fleas from rats to humans.

Several rodents (beaver, muskrat, chinchilla, nutria, squirrel) produce fur useful to man. All but beaver and squirrel have been domesticated for this purpose. Albino mice and rats, hamsters, and guinea pigs are widely used as laboratory animals for biological and medical pur-

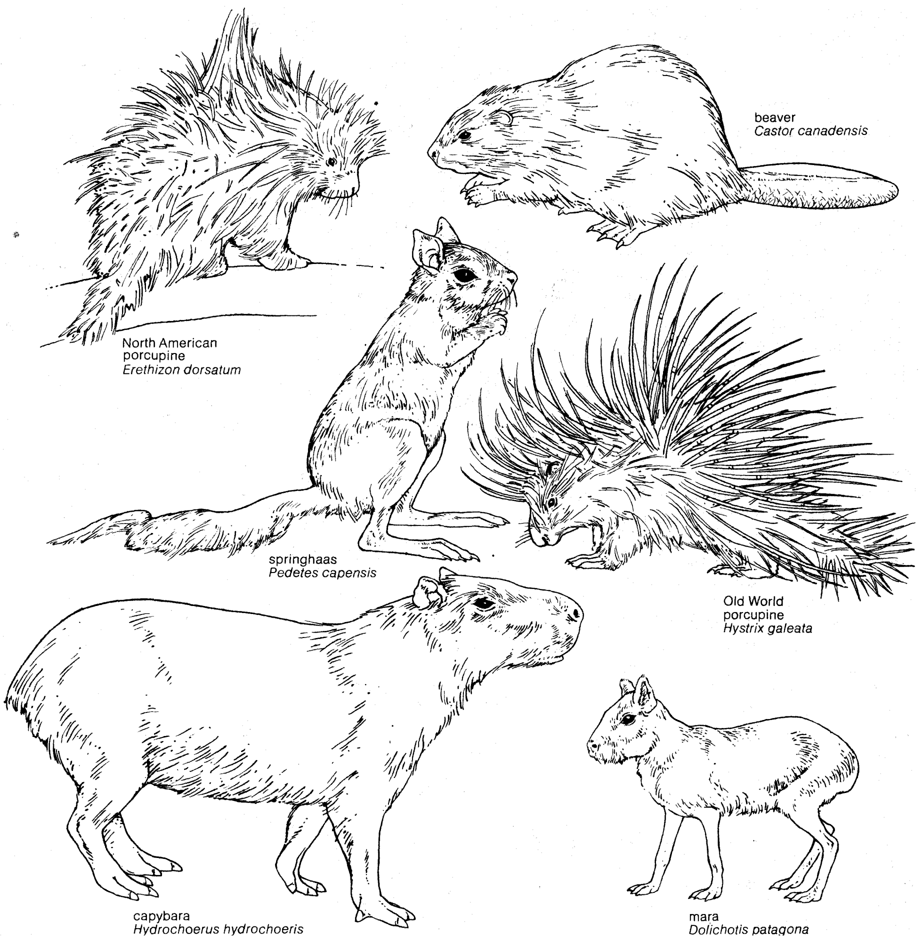

Figure 2: Range of body-plan variation of larger Rodentia.

poses. Guinea pigs were domesticated by the Incas for food; a few kinds of rodent have been raised as pets.

Distribution of rodents

Rodents occur naturally in all parts of the land where there is an adequate food supply and are found in essentially all terrestrial habitats. They range from well above the Arctic Circle to the southern tips of Africa and South America, and were the only terrestrial placental mammals, other than bats, to reach Australia before the arrival of man. Many rodents have successfully adapted to difficult environments such as deserts. Many rodents have broad climatic tolerances, an example being the North American porcupine, which is found from the Arctic Circle to central Mexico and from the Atlantic to the Pacific. Most are quadrupedal scamperers, but they generally have much freedom of use of their forefeet in manipulating food; many are burrowers, spending most of their life underground; some are ricochetal, leaping on their hind legs; flying squirrels use skin membranes to glide from one tree to another; a few (beaver, muskrat, water vole, nutria) have become amphibious in habits, living in freshwater streams and ponds; and a number of South American rodents are cursorial (running) animals.

IMPORTANCE TO MAN

Destruction **of crops and** foodstuffs. The most important rodents, from the point of view of economic damage, are the Norway and black rats, with the house mouse close behind them. It has been frequently estimated that the rat population of the United States is approximately equal to the human population. **A** population of over 1,000 rats per acre on an Iowa farm has been reported. Population explosions of house mice occurred in the Central Valley of California in 1926–27 and 1941–42. During the former, the mouse population was estimated to have reached over 80,000 per acre.

Remarkable population explosions of voles ***(Microtus)*** and wood mice ***(Apodeinus)*** are well known in western Europe, recurring every few years. In France, from 1790 to 1935, there were at least 20 mouse plagues, some lasting several years. Estimates of abundance are highly inaccurate, but there are reports of 8,000 voles per acre and 15 to 20 vole burrows per square metre, in peak conditions. There was a population explosion of voles and wood mice over much of Germany beginning in late summer of 1917 and lasting through 1918. Damage to crops was serious; clover was the favourite food; winter rye and wheat, sugar beets, and potatoes also were destroyed in many areas. During the winter the voles invaded barns and farm buildings, destroying all kinds of stored food. In 1932–35 voles and lemmings were in epidemic proportions in over 40,000 square miles of the southern U.S.S.R. This plague resulted in extensive damage to wheat and other field crops and to orchards.

Rats will eat almost anything that humans eat. Perhaps the most serious damage is to the seeds of grain plants, both before and after harvesting. Grain stored on farms is often not only eaten by rats but also rendered unsuitable for human consumption by being mixed with rat droppings. Food that has reached warehouses in cities is also eaten by rats, and here the excess of damage over the amount actually consumed is even greater. It is estimated that rats damage about twice as much grain as they eat. About 50 pounds of grain are required to support a rat for a year, so the total cost is about 150 pounds per rat per year. Rats sometimes demonstrate a fondness for animal food and have been known to kill several hundred baby chickens in a single night. Eggs are frequently eaten, and even full grown hens, baby pigs, and lambs may be killed. Rats will also follow a farmer in the planting season and dig up newly planted seeds.

Depredation by rats

Rats also do extensive damage in searching for food or in making nests. They gnaw holes to gain entrance to barns, warehouses, or houses, or through walls once they are inside. Clothing, upholstered furniture, and other textiles are gnawed to provide nest-building materials. In areas of cities where extensive quantities of garbage and other refuse are available, the rat populations may exceed the human populations, and rat infestation is one of the commonest complaints of slum dwellers. Such rats are very apt to bite sleeping humans, especially children, and fatal attacks on babies have been known to occur.

The house mouse has food preferences similar to those of the Norway rat but is not as abundant nor as large. Other rodents are much less likely to attack stored supplies of human food, but they do eat considerable quantities before harvesting. This is true of such forms as voles, field mice, and squirrels. The seeds of both wild and domesticated grasses are a major food source for large numbers of wild rodents. Because of the quantities of these that are eaten, such animals are often considered a major threat by grazing interests, but the benefit that rodents give by collecting seeds into underground storehouses, where they may later sprout and grow into new plants, certainly comes close to balancing any damage they cause to man's interest.

Transmission of diseases. Plague. Rodents serve as reservoirs for a number of diseases that may be transmitted to humans by arthropod agents. The most devastating of these is bubonic plague. This disease is fundamentally a disease of rodents, especially rats, transmitted from one rodent to another by an intermediate host, the flea, which also serves to transmit the disease to humans. An epidemic (called a "pandemic" because of the totality of infection in the human population) that seems to have been plague spread over Europe in the 6th century AD. If this epidemic was indeed plague, it must have involved an unusual rodent host because it antedated the arrival of Rattus in Europe. The epidemic known as the Black Death originated in Mesopotamia about the middle of the 11th century, and spread to Europe, particularly in the 14th century, being accompanied by the spread of rats throughout the Continent. It has been estimated that 25,000,000 people died of that pandemic of the plague in Europe. The latest pandemic originated in southwestern China in the late 19th century and was spread all over the world by the rat populations of oceangoing ships. Plague is controlled by controlling rat populations, particularly those on ships, and preventing shipborne rats from reaching land. Although plague epidemics have been brought under control, there still remain numerous foci of infection.

The role of rats in the "Black Death"

The plague bacillus (Pasteurella *pestis*) can infest a variety of other rodents, and foci have been established among native rodents other than Rattus in many parts of the world. This disease is referred to as "sylvatic plague" to distinguish it from the basically urban occurrence of ratborne plague. Over 80 species of ground-living and burrowing rodents are known to be involved in sylvatic plague, including ground squirrels, some cricetids (*e.g.*, voles, lemmings, muskrats), several murids (*e.g.*, Old World mice), and a few others, including guinea pigs.

Tularemia. Tularemia is primarily a disease of lagomorphs (rabbits and hares) and secondarily of rodents. It has been reported from all parts of the United States, and seems to have spread from there to many other parts of the world. Among rodents, it is carried by ground squirrels, tree squirrels, prairie dogs, chipmunks, muskrats, and beavers, and is transmitted largely by ticks.

Rickettsia1 diseases. Three rickettsia1 diseases—murine typhus, Rocky Mountain spotted fever, and tsutsugamushi disease—involve rodents as reservoirs. Murine typhus, which is much less severe than epidemic typhus, is transmitted to man by fleas, primarily from Rattus. It is probably almost universal in tropical and subtropical areas. Rocky Mountain spotted fever, which apparently originated in the northwestern United States, has spread over much of that country, and very similar if not identical diseases are found in Mexico, South America, and Africa. It is transmitted to humans by tick bites, and is presumably endemic in a considerable number of rodents as well as other animals. The cottontail rabbit is believed to be a major reservoir animal. Tsutsugamushi disease, or scrub typhus, is transmitted to humans by the bite of a rat mite. It is found in the East Indies and Southeast Asia. The reservoir seems to be primarily rodents of the genus Rattus. A variety of other diseases of lesser importance are transmitted to humans from a reservoir in rodents, largely Rattus, by rat bites, ticks, or in other ways.

Damage by burrowing and gnawing. Rodents have been accused, in many parts of the world, of damage to agricultural interests because of their burrows. Cattlemen in the western United States supported campaigns to poison prairie dogs (*Cynomys*) because horses or cattle might (and occasionally did) break their legs in prairie-dog holes. But perhaps the most striking case of damage from rodent burrows has been caused by the American muskrat, introduced into European fur farms, from which it escaped as early as 1905, spreading widely over much of Europe, from Great Britain and Brittany to the Ukraine. It burrows in the banks of streams, and has caused damage especially by making burrows in the banks of drainage ditches, canals, and in dikes.

The ever-growing incisors of rodents need to be used regularly on hard substances to wear them off. This need results in the gnawing of lead pipes or telephone transmission cables, or the making of holes in boxes, walls, and stored inedible items.

Rodents as valuable furbearers

Benefits derived from rodents. Trapping for furs. The beaver (Castor canadensis) was extremely important in the development of the western United States and Canada, the trappers of the first two-thirds of the 19th century being primarily interested in beaver skins. Most of the initial exploration of the West was performed by beaver trappers. The beaver skin became the basic unit of currency over much of the western United States. The trapping was so extensive and effective that beavers were exterminated over much of the area, but they are making a slow recovery under current conditions of protection. The fur of the chinchilla (*Chinchilla* laniger) was of such value that these rodents were almost exterminated in Argentina. Muskrat and nutria have also been extensively hunted for their fur.

Rats in the laboratory. Among the best laboratory mammals, for all types of biological, medical, and psychological investigation and for testing of new drugs, are the laboratory rats and mice, normally albino strains of wild species of the Norway rat and the house mouse. Guinea pigs (Cavia cobaya) are also widely used. There are a number of other laboratory rodents of lesser importance, of which the Syrian or golden hamster (*Mesocricetus* auratus) is the most widely used. Some strains of rats are nearly unique among nonhuman animals in being susceptible to dental caries, and most of the experimental work on tooth decay has been performed on them.

ECOLOGY AND NICHE RELATIONSHIPS

The basic scampering rodent

Habitat and locomotion. The most typical members of the order are the small, ground-living rodents, of the type generally called rats or mice, similar to what was probably the ancestral condition for the order. While these generally stay on the ground, most can climb shrubs and bushes with ease and many climb trees; among the smallest rodents, harvest mice climb stalks of wheat to reach the seeds on which they feed. This central generalized adaptive type of rodent, the scamperer with limited burrowing or arboreal adaptations, includes the family Muridae (Old World rats and mice, now worldwide), the family Cricetidae (field mice, wood rats, voles, lemmings, muskrats, to name a few; found in most parts of the world other than Australia), some Sciuridae (the ground squirrels and chipmunks), the nonleaping members of the New World family Heteromyidae (pocket mice); some South American rodents (degus, spiny rats, and chinchilla rats), and the South African rock rats (Petromyidae). Although there are many adaptive variants among the scampering rodents, there is a strong tendency for them to inhabit either open country or limited areas of woodland. Rodents of this type are found over essentially the entire land surface of the world. In most cases individual or family territories are set up, and intruders are successfully kept at bay by a variety of threatening and defiant postures. Normally there is no actual combat. The territories are, of course, of varying size, related to the available food supplies and the size of the animals. Individual ground squirrels have been observed over a territory of 2,500 square metres (about 0.6 acre).

Changes with time in the territories of chipmunks (*Eutamias*) indicate rather striking seasonal changes, with an increase in the area toward the end of the foraging season (perhaps to allow greater accumulation of food), and very little shift of the territory from one year to another. With few exceptions, these terrestrial rodents make burrows near the centre of the territory where they may spend as much as half of the time, where the young are born, and where the adults hibernate, in forms where hibernation occurs. Normally more young are produced than there is room for and as a result there is extensive migration of subadult or young adult individuals. For most rodents, the lengths of these migrations are unknown, but it has been shown that muskrats will migrate as much as 20 miles (over 30 kilometers), including several miles cross-country, over a period of one to two weeks, looking for suitable new stream or swamp sites.

From occasional tree climbing it is a relatively short evolutionary step to an arboreal habitat, such as that occupied by the tree squirrels, or, with an increase in size and decrease in rapidity of movement, by the New World porcupines. Tree squirrels are, essentially, scamperers that have developed the capability of holding onto bark with their claws. They are as much at home on the ground as in trees, and show no special anatomical modifications for tree life. Their nests may be either in hollow trees or other sheltered places (*e.g.*, barns) or built of twigs and leaves among the smaller branches of trees. In Europe and adjacent parts of North Africa and Asia, the dormice (Gliridae) have similar habitat but spend an even larger part of their lives in the trees. Many murids and cricetids (rats and mice, in the broad sense) are about as fully arboreal in their habits as are the tree squirrels.

Gliding rodents

Scampering arboreal animals are faced with the necessity, from time to time, of moving rapidly from one tree to another, and do so by leaping. It is generally agreed that gliding forms have evolved their skin fold (patagium), which assists them in gliding, as a direct adaptation to this type of habitat. Patagia have evolved, probably several times independently, among the sciuridae (squirrels) of both the Old World (*Pteromys* and others) and North America (*Glaucomys*) and in the quite distinct and unrelated African family of scaly-tailed squirrels (Anomaluridae). The patagium of the anomalurids is supported at the anterior end by a long, slender cartilage, which has apparently evolved from the olecranon process of the ulna (the posterior bone of the forearm) at the elbow.

Larger, heavier arboreal forms such as the New World porcupines move slowly along the trunks and main branches of trees. One of these, in South and Central America, has developed a prehensile (grasping) tail that assists in climbing.

A large proportion of the small, ground-living rodents construct underground nests, where the young are born and reared. Often there are adjacent chambers for food storage. In many cases two or more exits provide an opportunity for escape from predators. From ancestors such as this, many lines of rodents have evolved into habitual burrowers that make extensive subterranean tunnels and rarely or never come to the surface, foraging, feeding, mating, and raising their families underground. Among the numerous varieties of burrowing rodents are the prairie dogs, colonies of which were formerly abundant in the western United States. The mouth of the burrow is surrounded by a volcano-shaped mound of dirt, on which a prairie dog frequently sits upright, alert for potential enemies. The animal forages on the ground surface, returning to the mound or to the burrow to eat. Voles (Microtus) may make lengthy runways, two or three inches below the surface, arching up the ground surface over them. The pocket gophers (*Geomys* and Thomomys) are even more effective burrowers, throwing up mounds a foot or more across and spending most of their life beneath the ground. They use the incisors as well as the front legs in digging. During times of heavy snow, they may burrow through snow, feeding on plants above ground. Similar types of burrowing occur in the Old World mole rats (Spalacidae). An extreme form of burrowing is found in the African mole rats or blesmols (Bathyergidae), in which the incisors extend forward, with a fold of skin closing the mouth behind them, permitting their use as the primary digging tools, having replaced the forelimbs in this respect. The burrows of a single blesmol form a crisscross of tunnels, at several levels below ground surface, that may occupy an area a thousand or more square metres. All of these burrowing forms have short, heavy limbs used in digging, short tails, and small eyes. In one genus of blesmol, Heliophobius, the eyelids have grown together so that the eyes do not form images. These animals remain permanently below ground. Many burrowing rodents are solitary, but a number of them live in colonies, unlike other members of the order.

Giant rodents

Relatively few rodents have become large animals. Several of the South American caviomorphs have done so, however, and have evolved as quadrupedal terrestrial cursorial animals. Usually these have the claws modified into or toward hooves, reducing the number of toes on each foot to four or occasionally three, and tending to make each foot symmetrical about the median plane. Among these are the capybara (the largest living rodent), nutria, paca (*Cumiculus* paca), and agouti. The guinea pig is a smaller relative with the same adaptations. Such animals normally escape predators by running away, although both capybara and nutria will take to the water. The Old World porcupines are slow-moving terrestrial quadrupeds that are protected, as are the New World porcupines, by the quills, which are elongate, pointed hairs.

Many rodents have become bipedal jumpers, escaping their enemies with long leaps. These forms include the kangaroo rats (*Dipodomys* and Microdipodops) of western North America, the jumping mice (*Zapus* and *Na*paeozapus) of eastern North America and eastern Asia, the jerboas (Dipodidae) and gerbils (Gerbillus) of North Africa and Southeast Asia, the saltatorial dormouse (*Selevinia*) of Kazakstan, U.S.S.R., the chinchilla of the southern Andes, and the springhaas or Cape jumping hare (Pedetes) of South Africa. All of these are small, except Pedetes, which stands 30 centimetres (12 inches) tall. Most of the saltatorial rodents have very highly enlarged tympanic bullae—the bony covering of the middle ear—which is not true of other rodents. It is probable that this is an adaptation to life in a desert, where an amplification of the noise made by approaching predators may be of great importance. Certainly the large middle-ear cavity greatly increases the amplification of sounds. The fact that the bullae are particularly large in leaping forms suggests further that there may be some relationship between the size of the bulla and the balancing and stabilizing activities of the ears.

Although a number of rodents are at least partially aquatic, special adaptations are rare, being found only in the beavers. Beavers have large hind legs, with strong webs between the toes and an enlarged first digit, as long as the other toes, making very efficient paddles. Swimming is carried out primarily by the feet, but the broad flat tail may be used on occasion for sculling. A number of other rodents that are semiaquatic have webbed feet and soft, dense underfur but few other aquatic adaptations. These semiaquatic forms include muskrats, water voles, capybaras, nutrias, South American fish-eating rats, and the water rats of Australia and New Guinea.

Vegetable foods

Food habits. As a whole rodents are herbivorous, although most of them will eat animal food on occasion. The diet includes a wide variety of plant foods, although seeds are the favourite item. Many are particularly fond of the seeds of the various grasses, both wild and domestic. These may be eaten on the spot, but large quantities are usually carried home in the cheek pouches that are common among rodents. Seeds carried home may be eaten in the safety of the burrow or stored for later use. Such storage is an important item to the plants concerned, as it places the seeds in a favourable location for sprouting, if the rodent either forgets about them or himself becomes food for a predator. Many rodents, such as squirrels, are fond of nuts and can open even the hardest black walnuts to get at the seed within. Acorns, seeds, fruits, berries, young leaves, buds and shoots, green leaves, tubers, and bulbs are eaten by a wide variety of rodents. Burrowing rodents tend to concentrate on the roots, tubers, and bulbs that they encounter in making their tunnels, although some burrowers forage on the surface as well. The larger caviomorphs, such as the capybara, paca, mara (Dolichotis *patagona*), and agouti (Dasyprocta aguti), are essentially grazing animals, eating all kinds of green vegetation, young stems, and fruits. Marmots (Maimota) have rather similar food habits. Old World porcupines are essentially omnivorous, including carrion in their food. New World porcupines eat leaves, twigs, buds, and bark. Beavers cut aspens, willows, and poplars, using leaves, buds, and bark for food; they also eat a variety of aquatic plants. Many desert-living rodents have a diet that, in the dry season, may be almost exclusively seeds, from which they are able to obtain enough water for survival, using the water produced by metabolism. African cane rats eat coarse grasses and shrubs, one of their favourite foods being sugarcane. A number of rodents, especially during hard winters, strip the bark from trees. Because of their large numbers, rodents can seriously damage the natural plant cover.

On the other hand, many rodents will, on occasion, eat animal food. Muskrats eat freshwater mussels and crayfish, as well as a wide variety of dead or dying water animals. Many rodents, will, at least occasionally, eat birds' eggs, nestlings, or insects. Several genera of South American cricetids live mostly on aquatic animals, of which fish make up the largest part. The grasshopper mice (Onychomys) of western United States and adjacent parts of Mexico and Canada are almost exclusively carnivores. Their food consists primarily of insects and earthworms, but may include birds and even other rodents that they kill. In the Arctic portion of their range, ground squirrels eat any carrion available, including their own dead relatives or even walrus or whale meat. They particularly like meat with a high fat content, presumably for the energy value.

Longevity. Rodents are generally considered to have a very short life span. This is certainly true in nature, where rodents are one of the primary food sources of carnivorous birds and mammals. Particularly among the small, mouselike rodents, the average life expectation at birth must be only a few weeks or months; relatively few individuals live much more than a year; and an animal two years old has reached a ripe old age. It is clear that this limitation is largely imposed on the animals by the activities of predators. Cricetids, for example, which normally live less than two years in the wild, have been kept up to 5½ years in captivity, chipmunks and ground squirrels up to seven or eight years, gerbils and dormice over five years, guinea pigs about eight years, chinchillas, and North American porcupines about ten years, and woodchucks, pacas, and the Old World porcupine even longer.

Limits of
life span

Predation on rodents. Because rodents are one of the most important items in their food supply, carnivorous birds (especially hawks and owls) and mammals provide a very strong selective force acting on small rodents. Many raptorial birds use their eyes for hunting and are able to detect any rodent slightly less well concealed than the average. It has been shown experimentally that owls selectively capture light-coloured mice over dark ones on a dark background and dark over light on a light background down to a light level of 10^{-7} of a footcandle. As a result of such selective pressure, rodents have evolved fur colours that closely match the environmental background where they live. For example, a late Pleistocene flow of dark lava in New Mexico is now inhabited by melanistic (dark) rats and mice, in strong contrast to the normally coloured rodents surrounding it and to the almost white rodents found in the nearby White Sands area.

Among mammalian carnivores, all but the very largest normally eat rodents, at least as an important part of their diet, and many will start teaching their young how to hunt at the expense of small rodents. The abundance of rodents, moreover, affects the numbers of their predators in at least some instances. The English ecologist Charles Elton has shown that there are striking parallels between cyclic abundance of lemmings and snowy owls and foxes in northern Labrador, the lemming maxima and minima preceding those of the predators by about six months to a year.

BEHAVIOUR

Gnawing. One of the most general habits of rodents is gnawing, much of which serves merely to wear down the incisors. These teeth grow continuously, at rates that have been found to range upward from two millimetres per week in the few species in which rates have been measured. Gnawing is performed by all rodents at frequent intervals. It involves the fore-and-aft movement of the lower jaw, the upper incisors holding a hard object and the lower incisors cutting against it. The same movements may be used with nothing held in the teeth, the lower incisors merely alternating between cutting against the rear side of the upper incisors and shifting forward so that the uppers cut against the rear of the lowers. Because the hard enamel is limited to the anterior side of the teeth, such use wears away the softer dentine at a faster rate, leaving the enamel to form a sharp chisel edge. Rodents prefer to use their incisors on hard objects, which provide part of the abrasion. These may be nuts, bark, tree trunks (as in beavers), often bones (which may also be gnawed for a supply of calcium), or even human possessions such as boards in houses and barns or even metal telephone cables.

Function
of gnawing

Nesting and denning. Food storage. A large proportion of rodents build underground homes, with a central nest chamber, in which they sleep, raise their young, and, often, hibernate. Many others have similar nests in grass or trees. Special food storage areas often are associated with such living quarters; for burrowing forms, these food areas are special chambers off the main passageways. Ground squirrels, kangaroo rats, and other rodents bring grass seeds back to such chambers in their cheek pouches (on the inside of the mouth of ground squirrels; outside the mouth and fur lined in the Heteromyidae and Geomyidae), and will often store several times as many seeds as they will eat during the season when they rely on their stores. Excavation of one kangaroo rat den, from which a single rat weighing 149 grams (about five ounces) was removed, showed nine underground storage chambers, containing from one to over eight quarts of seeds, with a total of almost 35 quarts. Kangaroo rats, in addition, dig storage pits, about an inch in diameter and an inch deep, near their burrows, which they fill with seeds. In one case, 875 such caches were located in an area of 5.1 square metres (55 square feet) adjacent to a single den. It has been estimated that seed collection in this manner may result in the loss of as much as a quarter of the grain crop in some parts of the world, and at times of rodent plagues, the destruction locally may approach totality. On the other hand, such underground stores are an important source of germinating seeds for wild grasses in steppe regions such as western North America and Central Asia.

The habit of squirrels of carrying acorns and nuts to hollow trees or barns, or digging holes in the ground in which the nuts are placed, is well known. The animal's memory of the location of these stores is poor, but if enough nuts or acorns are hidden, the animal will be able to find a sufficient number to keep him alive during the winter.

The North American pack rat or trade rat (*Neotoma* cinerea) is attracted by bright and shining objects, which it picks up to carry home to its nest, a jumble of sticks, twigs, grass, and assorted collectors items. A popular superstition is that this animal is a fair businessman, who, on seeing something he wants, always leaves a replacement that is, in his opinion at least, of equal value. The fact is that, while carrying one trophy, the rat may see another that is more attractive and so puts down the first to pick up the second, leading the human who has lost a possession to believe that the rat was carrying out a "business deal."

Beaver dams and lodges. Among the best known activities of rodents are those of beavers, which go to great lengths to store food, cutting alder and other food trees into 0.5 to 2.5 metre (two to eight foot) lengths and floating the logs in their ponds or embedding one end of these sticks in the mud of the ponds formed by their dams.

Constructions by
beavers

These sticks make an available food supply during the winter when the ponds are frozen. In order to provide an aquatic habitat, safe from their normal predators, beavers build dams that often run several hundred feet in length, and as much as two metres (more than six feet) high on the downstream side. The largest dam reported, from near Three Forks, Montana, was 622 metres (2,140 feet) long, 4.3 metres (14 feet) high at the highest point, and seven metres (23 feet) thick at the base. The dams are made of twigs, branches, and logs from which the bark has been eaten, piled on the ground with alternating layers of gravel or mud. When finished, the upper surface is plastered with mud, usually dug from the bottom of the pond above the dam, to make it watertight. The pond behind the dam serves as the refuge and first defense of the beaver. Consequently, beavers work continually to maintain the dams, by repairing, raising, and lengthening them, a process that may extend over several generations. Abandoned beaver ponds gradually silt up, forming very characteristic meadows.

Beavers also build lodges in the ponds behind their dams or burrows in the banks. Lodges are built up in the same manner as dams, and they are enlarged along with the rising water level of the ponds as the dam is raised. For ventilation, however, the upper part of the lodge is much more loosely constructed than the dam. The floor is kept above the water level, and there may be two levels, the lower for feeding, the upper for sleeping. The entrance to the lodge is through a tunnel, the outer end of which is below water level. Bank lodges are burrows in the bank, with the inside arranged like that of lodges. Again, access is gained through a tunnel with the mouth below water level. Burrows may extend more than nine metres into the bank.

Beaver canals are less well known but highly remarkable. They are dug to permit the transport of birch or aspen logs for food supplies from the sources where they are cut to the ponds. The logs are floated in the water, where the beaver is much safer than on land. Such canals are dug whenever they can be made with little or no damming. They vary from 0.3 to 1.2 metres (one to four feet) in width, up to 0.6 metres (two feet) deep, and canals as long as 223 metres (732 feet) have been reported.

Beavers live on the bark of trees, that of aspen being their favourite, but birch, cottonwood, willow, and alder also are used. When these are in short supply other plants are eaten, but conifers are rarely cut except for building materials. In one night a single adult beaver can fell a seven- to ten-centimetre (three- to four-inch) poplar, cut it into sections one to three metres long, and drag the logs to the water. Normally, beavers do not cut up logs over 15 centimetres in diameter, although they will fell trees considerably larger. The largest tree on record cut by beavers was 115 centimetres (46 inches) in diameter. The cutting of trees is apparently done at random, with all gnawing likely to be on one side, unless the tree has a large diameter, in which case it may be gnawed all the way around. Because trees normally fall downhill, hence toward a pond, this is probably the origin of the legend that beavers can make trees fall as they wish.

Types of dormancy

Hibernation. Many rodents use their nests or burrows for shelter during unfavourable seasons, especially winter. There is considerable variation, even among closely related animals, in the amount of activity that occurs at such times and how often animals wake and eat some of the stored food. In a considerable number, including chipmunks, pocket mice (Perognathus), some jerboas, and some field mice, there is extensive torpor in wintertime, the animals sleeping extensively, but waking two or three times a day to eat. Hamsters (Cricetus and *Meso*cricetus) are deep hibernators, going into a sound sleep from which they awaken only periodically to eat. The most pronounced type of hibernation involves the accumulation of extensive amounts of body fat during the late summer and early fall, and deep hibernation with few or no awakenings during the winter. This condition occurs in marmots, some ground squirrels, a large proportion of dormice (whose English name is derived from the French *dormir* meaning "to sleep"), the jerboa (Allactaga), and most or all zapodids (jumping mice and birch mice). Estivation, or summer sleep, is rare in rodents but occurs in woodchucks and some ground squirrels. No suggestions of hibernation occur in murids, caviomorphs, or phiomorphs, any other tropical rodents, or rodents with a recent tropical or subtropical ancestry.

Population **movements.** Several types of rodents, subject to periodic fluctuations in numbers, reduce the amount of overpopulation by migration. Generally, the migration is simply the movement of juveniles away from a home area that has become fully populated. Migration of such animals may be quite extensive, but, because it is usually an individual phenomenon, it is often not noticed. Such animals are subject to very high mortality from predators because they are moving in unaccustomed territory and without the shelter of a permanent home. Muskrats and beavers are examples that are more readily noted, because they move from one suitable stream to another and may travel as much as several miles across country looking for a suitable home. There are many reports of major migrations. In August 1946, gray and fox squirrels migrated out of an area in northwest Wisconsin, apparently due to a shortage of acorns. When they reached streams and rivers, they crossed them by swimming, many drowning in the wider rivers. In 1935 a mass movement of gray squirrels was noted from the area east of the Hudson River, to the west. Hundreds (one report says 2,000) of drowned squirrels were found along the west bank of the Hudson River.

Lemming migrations

The most famous migrations of rodents, however, are those of lemmings, especially in Scandinavia. There tend to be two migrations per year, one in spring and one in autumn. The exact causes of the movement are not known, but a change of habitat with season seems to be the most important single factor. It has been believed that the migrations are caused by overpopulation and a shortage of food, or by claustrophobia (a feeling of mental anguish from the crowded conditions), but these probably are not valid causes.

The lemming migrations are individual activities rather than unified movements, as is popularly supposed. Careful observations of migrations show that each individual acts alone, but that there may be groups of several individuals within a few minutes, followed by a gap of ten minutes or more. In autumn, at least, the migrations normally occur at night. Individual lemmings generally move fairly rapidly in a generally constant direction, although they will occasionally stop to feed or groom. Rates of migration have been calculated as about one metre per second (2.25 miles per hour), but such speeds are not sustained, and it is probable that distances of eight–ten kilometres (five–six miles) per day are normal. The migrations tend to be oriented by roads or paths made by humans, trails made by reindeer, or other similar routes, although the general direction seems to be outward in all directions from the general source area and to be determined before the movement begins. Contrary to the older reports and popular belief, lemmings do not rush forward without hesitation into water when reaching a shoreline. They apparently try to avoid swimming, if possible, running up and down the shore looking for a narrow crossing or an area where they can cross on ice. Apparently, they enter water willingly only if they can see the silhouette of the far shore. This is in marked contrast to activities of their relative, the water vole (Arvicola), which always heads for the water when threatened. When swimming lemmings use their hind legs almost exclusively but swim very high out of the water. Lemmings become exhausted and drown after swimming 15 to 25 minutes in water with waves about 15 centimetres (six inches) high. Observations along the Swedish-Finnish border show that the lemmings had no problem crossing a strait 200 metres (650 feet) wide on a calm night, but that considerable numbers drowned on a windy night. A lemming was observed swimming at approximately the middle of a lake two kilometres (1.2 miles) wide. Reports of lemmings swimming out into the North Sea and being found alive 16 kilometres (ten miles) or more from shore must be viewed skeptically. Recent studies in Scandinavia indicate that the migrations are a normal part of the activity of the lemmings, serving not only as a means of dispersal of the species but also to permit the animals to occupy different habitats at different seasons.

Rodents are often thought of as defenseless animals, but the incisors are very sharp and powerful, are activated by powerful jaw muscles, and can inflict a deep wound. Among themselves, rodents fight for territories, the possessor of a territory usually being able to drive interlopers away. They also fight very effectively in self-defense, as indicated by the popular expression, "fighting like a cornered rat." A full-grown wharf rat is capable of defending itself against a determined tomcat. Even animals as small as lemmings are able to discourage attack by weasels.

REPRODUCTION

Flexibility in breeding habits

The reproductive habits of rodents are exceedingly varied in nature and are capable of being even further modified in domesticated or partially domesticated forms. Many, especially the larger types, reproduce once a year. Others produce several litters during a single season. Some have only one or two young at a time; others, large numbers. Some are capable of reproduction at very early ages, others (particularly members of the Caviomorpha) not until after a considerable period of growth. Most are born naked and helpless, and are cared for in nests; a few are able to run and keep up with their mothers almost at once. Most rodents are polygamous; some mate for the duration of a single breeding season; and a few (beavers, for example) have permanent mates.

Beavers do not breed until the second January or February after birth, producing a litter of two or four young after about **12** weeks of gestation. The capybara has a litter that is, on the average, slightly larger, after **15** to **18** weeks gestation; the viscacha, a smaller animal, has two young in the spring about **22** weeks after breeding. Nutrias breed twice a year after reaching an age of one year, if the winter temperature does not fall below **60**" **F** for lengthy periods, and produce litters averaging about five young. The European porcupine (Hystrix cristata) breeds in the spring, with one to four young being born about **16** weeks later, and some of its tropical relatives (other members of the Hystricidae) produce two litters a year. The North American porcupine (Erethizon dorsatum) of the caviomorph family Erethizontidae, has a single young after **30** weeks gestation. Most of the smaller members of the order, however, have considerably higher reproductive rates. In many cases there may be more than one litter per year, with high numbers per litter, examples being shown in the Table.

Reproductive Rates of Certain Rodents

animals	litters/year	young/litter
North American gray squirrel (*Sciurus carolinensis*)	*2*	*2–3*
Eurasian gray squirrel (*S. vulgaris*)	*2*	*5–7*
Red squirrels (*Tamiasciurus*)	2	*4–6*
Pocket gophers (*Geomys*)	*1–2*	1–4
Pocket mice (*Perognathus*)	1–2	*2–8*
Kangaroo rats (*Dipodomys*)	1–3	*2 4*
Deer mice (*Peromyscus*)	**up to** *4*	*2–7*
Hamsters (*Cricetus*)	**several**	*6–12*
Lemmings (*Lemmus*)	**several**	*3–9*
Muskrats (*Ondatra*)	*2–5*	*5–7*
Voles (*Microtus*)	**up to** *13*	*4–8*

Source: E.P. **Walker,** ***Mammals of the World (1964)*** **and** S.A. Asdell, ***Patterns of Mammalian Reproduction (1964).***

This rather high rate of breeding is intensified by the fact that, in many of the smaller rodents, sexual maturity is reached at an early age, normally earlier in the females than in the males. The females breed when less than a year old in many squirrels, some pocket gophers, and the pack rat. In most of the Cricetidae, however, the young appear to reach sexual maturity considerably earlier—harvest mice (*Reithrodontomys*) in five weeks; the hamster (Cricetus) in six weeks; and voles (Microtus) in six to seven weeks.

Reproductive potential

In the United States, wild populations of the house mouse reproduce throughout the year, with an average of **5.5** litters and **31** young per female per year in buildings, and **10.2** litters and **57** young per year on farms. In the laboratory mouse, the mean litter size has been reported as ranging from **4.5** to **7.4,** depending on the strain. The second litter is the largest, after which there is a steady decrease. Litter size has been reported to have a range of two to **12,** and as many as **19** healthy embryos have been removed just before term from a single female. There may be five or more litters per year. The gestation period is about **20** days, and the first mating usually occurs at seven to ten weeks of age, though it has been reported that, in one strain of albino mice, the first estrus occurs, on the average, at **39** days and results in about **50** percent pregnancies. The breeding span of most mice in the laboratory is **12** to **18** months. Lactating females may become pregnant, but the gestation will be lengthened by one to two weeks.

Wild Norway rats breed throughout the year, taking advantage of the sheltered environment available from living in association with humans. The size of the litter is correlated with the size of the mother. In the laboratory female rats reach sexual maturity in **33** to **120** days. The number of young varies with the strain, two typical ones having litters averaging **6.5** and **8.9.** Normally, a female's second or third litter is the largest, and the litter size decreases rapidly after the tenth. Over a number of generations of laboratory life in a colony of gray rats, however, the total number of young per female grew from an average of **23** to an average of **63.**

The laboratory guinea pig has a gestation period of about **68** days, a very long period for such a small animal but characteristic of caviomorphs. There are usually three or four young per litter. The age of puberty varies from **55** to **70** days.

Although most rodents seem to increase their reproductive potential under domestication, this is not true of chinchillas. In the wild, they produce litters one to six after about **15** weeks pregnancy; domesticated ones seem normally to have only one offspring at a time.

FORM AND FUNCTION

In most aspects rodents are relatively primitive, not highly specialized mammals. The skeleton is usually that of a quadrupedal, scampering mammal, not far from the basic placental stock. The digits are clawed and usually five in number, with little or no opposability of the first digit. The limbs are not far from the same length, although the hind legs are always somewhat longer. The animals are adapted to a broadly herbivorous diet. The main specialization of the digestive system is the possession of a large cecum (a blind pouch) at the junction of the large and small intestines.

Specializations for gnawing. As opposed to this basic primitiveness, the rodents have developed, as their basic innovation, a gnawing mechanism of an efficiency that is not approached by that of any other mammals. The gle-

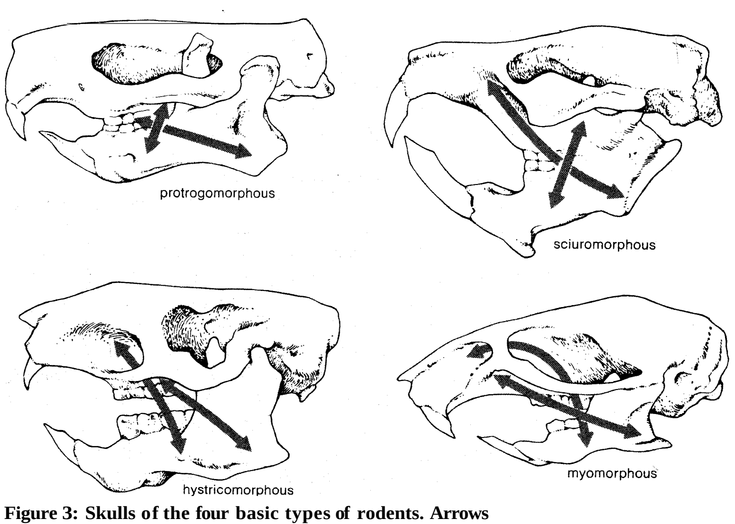

Figure 3: Skulls of the four basic types of rodents. Arrows show positions of branches of the masseter muscle.

noid fossa, the concavity where the lower jaw articulates with the skull, slopes downward, from rear to front, and there are no processes (as there are in all other mammals) at the anterior and posterior limits of the fossa that restrict the anteroposterior movement of the jaw. The jaw, therefore, is capable of functioning when pulled to the rear, separating the incisors from each other, and permitting chewing or grinding by the cheek teeth. The jaw can also be pulled forward and downward, separating the cheek teeth and bringing the tips of the incisors together for gnawing.

Evolutionary shifts in jaw muscle attachments

These shifts in the position of the jaw, as well as the functioning of the jaw in either position, are brought about by a combination of the actions of the various jaw muscles, of which the temporal, pterygoid, and masseter are the most important. The forward and backward (anteroposterior) movements, including those of gnawing, were caused, primitively, by all three muscles, all of which have a slight anteroposterior component. But a shift of the anterior muscle, the masseter, began to occur during the Eocene Epoch (about 50,000,000 years ago). Originally, in a condition called protrogomorphous, the masseter ran from the zygomatic arch (cheekbone) to the lower jaw. Parts of the muscle, retaining the original points of insertion on the lower jaw, shifted their origins forward onto the snout, doubling the length of the muscle and greatly changing its direction of pull. In some rodents it was the lateral portion of the masseter that shifted forward onto the face, compressing the infraorbital foramen (an opening in the bone), through which pass nerves and blood vessels, between the muscle and the snout (the sciuromorphous condition); in others it was the deeper portion of the masseter that shifted forward, through the infraorbital foramen (presumably following an initial enlargement of the foramen), onto the face, resulting in further enlargement of the foramen until it may now be larger than the eye socket (the hystricomorphous condition); and in still others, a combination of the two shifts has occurred (the myomorphous condition). Although these changes are of importance in determining rodent taxonomic relationships, they are probably not as controlling as was once thought, as each structural condition may have originated more than once.

Continuous growth of incisors

But the main structural change from the primitive mammalian condition has occurred in the incisors. In all known rodents, beginning with the very earliest, the incisors are reduced to a single pair in each of the upper and lower jaws. These teeth grow throughout life, the enamel cap being restricted to the anterior 30 to 60 percent of the perimeter of the tooth. The rate of incisor growth has been measured in several rodents, and varies from about two to three millimetres per week in nonburrowing forms to five millimetres per week in pocket gophers, in which the incisors are used for digging as well as for gnawing. In hibernating rodents, the incisors continue to grow, but at a greatly reduced rate. If the incisors do not meet, due to deformity or breakage, the teeth will continue to grow indefinitely. Since the lower teeth are arcs of large circles, the lower incisors simply curve forward and upward, becoming completely nonfunctional. But the upper incisors are large arcs of much smaller circles. With growth, they may spiral outward, like the spirals on a handle-bar moustache, or they may grow around and upward through the throat between the lower jaws, growing through the snout and eventually locking the jaws closed. Either condition is fatal, but rodents have survived in nature for a long time with such malformed incisors.

Because of the continual growth of their incisors, rodents have an unusually heavy need for calcium, which, together with a need for abrasion of the incisors, explains the frequency with which rodents gnaw bones.

Adaptations for specialized locomotion. Many rodents have shifted their locomotion from the characteristic scampering type. In burrowing rodents, the limbs are short and massive, and the hands, particularly, are widened and strengthened with heavy claws. Many, but not all, burrowing rodents use their incisors to help in digging. In such cases, a fold of skin is likely to close the mouth behind the incisors, and the radius of curvature of both upper and lower incisors is increased, so that they extend forward from the mouth, cutting the soil an appreciable distance in front of the animal. Eyes and ears are generally reduced in size in these forms.

There is little difference, structurally, between the terrestrial scampering rodents and the arboreal scamperers, such as squirrels. The claws of the latter are sharper, but locomotion is basically the same. A few rodents, such as the New World porcupine, actually climb (as would a human) rather than running up and down the bark, as does a squirrel. Only one rodent, the tree porcupine (Coendou) of Central America and northern South America, has a truly prehensile tail (although several rodents have semiprehensile tails that they can wrap around branches for extra support). A number of gliding rodents, "flying squirrels" of one sort or another, some of which are not closely related to the true squirrels (Sciuridae), are supported in the air by a fur-covered membrane (patagium) extending between the fore and hind limbs and usually between the hind limbs and the tail.

A rather common development among rodents has been the reduction of the forelimbs and an increase in the size of the hind limbs and tail for locomotion by means of a series of kangaroo-like leaps, which in several forms can exceed 15 feet.

Adaptations for water conservation. With their wide geographic distribution, rodents have invaded desert regions in all parts of the world. Many of these have developed the ability to function on limited supplies of water. This has been achieved in several ways. Some are nocturnal, remaining asleep during the heat of the day in burrows deep enough to reach ground moisture, thus reducing evaporation. Others seek out succulent desert plants for food. But it has been shown that a number of desert rodents (kangaroo rats and jerboas, for example) have the ability to live exclusively on seeds, with no external water source, and to obtain all of their needed water from their metabolism. Such forms also produce a greatly reduced quantity of extremely concentrated urine and a small amount of feces. Two species of spiny mouse *(Acomys)* were investigated in Israel. Both inhabit the same desert areas, but one is diurnal and the other is nocturnal. Both produce urine the urea content of which is extremely high. Neither species can survive on a diet of barley without water to drink, although gerbils and jerboas from the same area showed no ill effects after four weeks without water. The diurnal spiny rats, however, were able to survive and grow with no water except seawater, whereas the nocturnal ones could not tolerate such a salt concentration.

EVOLUTION AND PALEONTOLOGY

Rodents are relatively poorly represented in collections of fossils, in spite of their great abundance at the present time. They have often been overlooked because of their small size, but modern intensive exploration for fossils usually results in a much more abundant representation of small mammals, especially rodents.

Paleocene. The earliest known rodents come from the late Paleocene (about 57,000,000 years ago) of North America, by which time they had already acquired all of the diagnostic features of the order. The ancestral family, the Paramyidae, was also present in Europe, where it first appeared in the earliest Eocene. There was very rapid diversification of the order during the Eocene, initially involving the Paramyidae, but with other families soon appearing. Most of the Eocene rodents were protrogomorphous, the masseter muscle restricted to its primitive origin on the cheekbone. By the middle Eocene of Europe, rodents with advanced types of masseters were present, and others occurred in the late Eocene of North America. The skeleton of the paramyids was basically that of a generalized scampering animal, approximating a rat in its method of locomotion. Before the end of the Eocene it is probable that both leaping and burrowing variations had arisen, although there is some uncertainty on this point.

Paramyidae, the earliest rodents

Oligocene. A major gap in the knowledge of rodent evolution occurs at the Eocene-Oligocene boundary (about 38,000,000 years ago). A number of modem families with advanced types of jaw muscles appeared at about the same time in North America, Europe, or Asia, including the Cricetidae, Heteromyidae, Geomyidae, Castoridae, and Ctenodactylidae, with no good indications at present as to their geographic or ancestral sources. At about the same time, rodent groups appeared suddenly in South America and Africa (Caviomorpha and Phiomorpha, respectively). Both groups are hystricomorphous and hystricognathous and have often been considered to have been related, though others consider them to have acquired their similarities independently.

Miocene. The majority of the living families of rodents had appeared by the Oligocene, and most of the remaining ones occur in the Miocene (around 26,000,000 years ago), so that the later part of the evolution of the rodents was largely a diversification of the various groups. The ancestors of a wide variety of specialized modem forms can be recognized from teeth, but most of them are not known from skeletons, and the evolutionary status of the modern locomotor conditions is not well known. Highly evolved burrowing rodents were certainly present in the Oligocene in Mongolia, however, and less specialized ones occurred in North America. Ancestral kangaroo rats had attained a leaping ability by the Miocene of North America. Gliding and burrowing forms are known from the Miocene of Africa. In South America, the differentiation of the descendants of the invaders present in the early Oligocene proceeded rapidly, and the Miocene forms occupied nearly all potential rodent niches on that continent.

Richard Keane

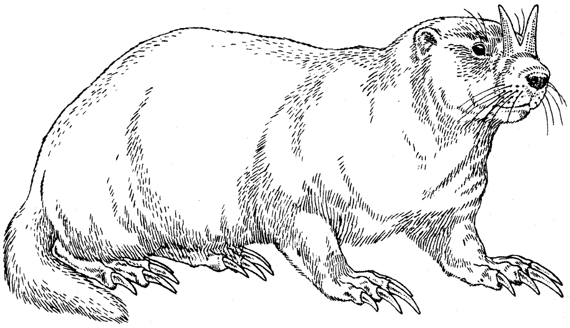

Figure 4: Reconstruction of *Epigaulus*, a primitive Pliocene rodent.

Later evolution of rodents. The latest rodents to differentiate apparently were the members of the family Muridae. This group appears suddenly in early Pliocene deposits of Europe, probably having invaded that continent from Asia, the southeastern part of which, together with the adjacent East Indies, is now considered the evolutionary centre of the family. The Muridae expanded rapidly all over the Old World. An isolated incisor is known from the Pliocene (approximately 7,000,000 years ago) of New Guinea, where considerable local evolution has occurred. The murids reached Australia late in the Cenozoic Era (they are unknown there before the Pleistocene), and underwent a rapid evolution, developing arboreal, burrowing, and leaping forms, paralleling the evolution of the entire order in the rest of the world.

Appearance of Muridae

When North and South America were united in the beginning of the Pleistocene (about 2,500,000 years ago), there was a major invasion of South America by cricetids, which expanded rapidly and became highly diverse in that area.

An interesting aspect of rodent evolution are the very rapid diversifications (evolutionary explosions) that occurred whenever highly specialized members of the order reached areas previously uninhabited by gnawing mammals (South America and Africa in the Oligocene, New Guinea in the Pliocene, Australia in the Pleistocene). These, apparently, resulted in a rapid spread into most of the major available ecologic niches in a matter of, at most, 2,000,000 or 3,000,000 years. The differentiation of the South American cricetines since the beginning of the Pleistocene has not been quite as fast, though still explosive, presumably because there already were numerous rodents on that continent. The initial diversification of the rodents during the Eocene seems to have been considerably slower, probably because they had not yet become as thoroughly adapted for gnawing as was the case later.

Because of their small size and great abundance, rodent fossils are becoming progressively more important as guide fossils that enable accurate separation of successive geologic horizons.

CLASSIFICATION

Distinguishing taxonomic features. Many features have been used to determine the relationships of the subgroups of the rodents. The most generally used are the differentiations of the jaw muscles or the modifications of the skull and jaws resulting from muscular changes. The masseter muscle may have its primitive position, arising from the cheekbone (protrogomorphous); its lateral division may have shifted forward onto the snout, compressing the infraorbital foramen against the snout (sciuromorphous); the medial division may have moved forward through the infraorbital foramen, onto the snout, greatly enlarging the foramen (hystricomorphous); or both branches of the masseter may have shifted (myomorphous). In most rodents the angular process at the rear of the lower jaw extends downward from the ventral side of the alveolus of the incisor (sciurognathous); in some, all of which are also hystricomorphous, the angle arises from the side of the alveolus (hystricognathous). Other features that have been given important weight in delimiting the major subgroups include crown patterns of the cheek teeth (premolars and molars); histologic structure of incisor enamel, which may have one layer (uniserial), a few (pauciserial), or many (multiserial); structure of the penis or of the baculum (os penis); structure of the male genital tract, including particularly the presence or absence of an outgrowth, the sacculus urethralis; fusion or lack thereof of two of the ear ossicles, the malleus and incus; and the pattern of development of the extra-embryonic fetal membranes.

ANNOTATED CLASSIFICATION

The classification presented here is based upon that of American paleontologist A.E. Wood. The rodents are one of the outstanding examples of a group in which closely similar structures have evolved numerous times independently, a phenomenon known as parallelism, with the result that there is very strong disagreement among taxonomists working with the group as to how the order should be subdivided.

Groups indicated by a dagger (†) are known only from fossil remains. Dental formulas indicate the number of pairs of teeth present in the upper jaw (above the line) and lower jaw (below), the figures representing, respectively, pairs of incisors, canines, premolars, and molars. When a partial formula is given the type of teeth is indicated by I, C, P, or M.

ORDER RODENTIA

Gnawing mammals with ever-growing incisors, reduced to a single pair in both upper and lower jaws and with the enamel limited to the anterior face of the incisors, so that wear maintains a sharp chisel edge; glenoid fossa slanted, with neither preglenoid nor postglenoid process, masseter the principal jaw muscle; dental formula reduced, never exceeding $\frac{1.0.2.3}{1.0.1.3} = 22$. About 350 living genera and 2,400 living species; over 400 extinct genera have been described.

Suborder Sciuromorpha

Masseter primitively either limited to zygoma, or rarely with only a slight forward displacement, but in the squirrels shifted forward onto face (sciuromorphous). Always sciurognathous. No sacculus urethralis. Malleus and incus bones of ear separate. Incisor enamel pauciserial or uniserial. Paleocene to Recent.

†Family Paramyidae

Paleocene to early Miocene; Northern Hemisphere. Cheek teeth cuspidate, clearly derived from basic mammalian tribosphenic type. Tympanic bullae became co-ossified with the skull several times independently, within the family. Incisor enamel pauciserial, with one possible exception. Presumably ancestral to the rest of the order. One genus incipiently hystricognathous. From size of a mouse to as large as a beaver. Locomotion, when known, scampering, with possible incipient leaping in one form.

†Family Sciuravidae

Eocene of North America; one genus from Eocene of Central Asia. Cheek teeth formed of 4 transverse crests rather than of separate cusps; locomotion probably scampering; mouse-size to rat-size. Incisor enamel pauciserial. Perhaps ancestral to several mouse- or ratlike groups.

†Family Ischyromyidae

Oligocene of North America. Masseter muscle has begun to move forward onto the snout in some forms, in primitive position in others. Cheek teeth 4-crested. Incisor enamel uniserial. Locomotion scampering. Size of a gray squirrel or somewhat larger.

†Family Cylindrodontidae

Middle Eocene to Oligocene of North America, Oligocene of Central Asia. Burrowing rodents with high-crowned to evergrowing cheek teeth, based on a pattern of 4 transverse crests. The most specialized forms used the incisors for digging, as shown by forward extension of these teeth. Incisor enamel uniserial. Size from that of a chipmunk to that of a marmot. Presumably derived from North American Sciuravidae.

†Family Protoptychidae

Late Eocene of North America. Skull with highly inflated auditory bullae, suggesting, by analogy with other rodents, that these were leaping animals. Cheek teeth high crowned, with pattern of 4 crests. Size of a gray squirrel.

Family Aplodontidae (mountain beaver, or sewelled, and fossil relatives)

Late Eocene to Recent of North America, Oligocene and Miocene of Europe, Pliocene of Asia. Single living species restricted to wet areas from British Columbia south to San Francisco Bay. Extreme hypsodont cheek teeth, based on cuspidate rather than crested pattern. Incisor enamel uniserial. Burrowers. Head and body length of living species (***Aplodontia rufa***) 300 to 460 mm, with a short tail; weight 900 to 1,800 g.

†Family Mylagaulidae

Miocene to Pliocene of North America. Strongly hypsodont cheek teeth, with greatly enlarged premolars, whose continual growth forced 1 or more of the anterior molars out of the jaws. Incisor enamel uniserial. Some individuals had paired horns on the snout. Whether these are taxonomic or sexual characters has not yet been demonstrated. Powerful burrowers. About the same size as ***Aplodontia.***

Family Sciuridae (squirrels, chipmunks, and marmots)

Oligocene to Recent of Northern Hemisphere, Miocene to Recent of Africa, Recent of South America. Highly developed sciuromorphous pattern, with masseter muscle extending forward along the side of the snout and compressing the infraorbital foramen. Postorbital process of frontal separates the eye from the temporal muscle. Cheek teeth typically very similar to those of the Paramyidae, but some forms have rather complicated tooth patterns. Incisor enamel uniserial. About **70** living genera.

Suborder Myomorpha

Lateral branch of masseter muscle usually displaced forward alongside of snout, forcing infraorbital foramen against side of snout; in most forms, deep masseter penetrates a variable distance through upper part of infraorbital foramen. Sciurognathous. Incisor enamel uniserial. Locomotion scampering, jumping, arboreal scampering, or fossorial. A few forms are partially adapted to an aquatic life. Malleus and incus never fused. No sacculus urethralis. Cheek teeth usually reduced in number, with only a single fossil genus known that retains the primitive rodent dental formula; except for the Geomyoidea, the premolars are either lost or greatly reduced; the last molars are occasionally lost as well. Most members of the group are small, from the size of a mouse to that of a rat (head and body length ranges from 50 to 300 mm, except in the Rhizomyidae, which may be somewhat larger).

Family Cricetidae (field mice, deer mice, voles, lemmings, muskrats)

Early Oligocene to Recent of Europe and North America, middle Oligocene to Recent of Asia, late Pliocene to Recent of South America, Pleistocene of Madagascar, Recent of Africa. Deep masseter expanded through upper part of infraorbital foramen to face; no premolars, molars $\frac{3}{3}$; cheek tooth pattern based on cusps arranged into 5 transverse crests in both upper and lower teeth; teeth low crowned to very high crowned. Scampering, fossorial, arboreal scampering, jumping, or partly aquatic.

Family Muridae (Old World rats and mice)

Early Pliocene to Recent of Europe and Asia. late Pliocene to Recent of East Indies, Pleistocene to Recent of Africa and Australia. Introduced throughout the world by man. Deep masseter as in Cricetidae; cheek teeth normally the 3 molars, but one subfamily, the Hydromurinae of Australia and New Guinea, has lost the third molars, reducing the cheek teeth to $M\frac{2}{2}$, tooth pattern based on rounded cusps, arranged in transverse rows, but derivable by modification of a pattern like that of primitive cricetids; low to medium high crowned teeth. Scampering, arboreal scampering, occasionally fossorial or semiaquatic.

Famiy Heteromyidae (pocket mice, kangaroo rats and mice)

Oligocene to Recent of North America, Recent of northern South America. These and the next two families are sciuromorphous, with no penetration of the infraorbital foramen by the masseter, and seem to be closely related. Fur-lined cheek pouches, opening beside the mouth and reaching back to the shoulders, are used for the transportation of food to underground storage areas near the nests. Central stock of family scampering; specialized ones leap with their hind legs. Generally small, mouselike; length of head and body from 55 to 180 mm. Cheek teeth, which include P) $\mathbf{M\frac{3}{3}}$, are low crowned to very high crowned. Pattern of teeth based on **2** transverse rows of 3 cusps each. Derivable from late Eocene members of the Eomyidae.

Family Geomyidae (pocket gophers)

Early Miocene to Recent of North America. Like heteromyids in jaw muscles, dental formula, and tooth pattern, and in possession of fur-lined cheek pouches. Highly adapted burrowing animals. Cheek teeth have already become high crowned in the Miocene, and those of the living forms grow throughout the animal's life, with the enamel reduced to a plate on the anterior side of the upper teeth and the posterior side of the lowers.

†Family Eomyidae

Late Eocene to late Pliocene of North America; late Eocene to Pleistocene of Europe. Sciuromorphous jaw muscles; cranial anatomy and jaw structure very similar to heteromyids. Cheek teeth usually low crowned, with pattern of 5 crests, rather similar to that of the cricetids, although some members of the family developed teeth suggesting that they might be ancestral to heteromyids. Cheek teeth usually P) $\mathbf{M\frac{3}{3}}$, but **1** genus had $\mathbf{P\frac{2}{1}}$. Skeleton and habits unknown.

Family Zapodidae (birch and jumping mice)

Late Oligocene to Recent of Eurasia, early Miocene to Recent of North America. **A** late Eocene genus from California is often (perhaps incorrectly) placed here. The Old World birch mice are arboreal scampering forms, as were probably all the earlier fossil members of the family. The jumping mice are as saltatorial as the kangaroo rats. lnfraorbital foramen of medium size, with the deep masseter passing through it but with the superficial masseter remaining on the zygomatic arch. Cheek teeth $\mathbf{P\frac{1}{0}\,M\frac{3}{3}}$, with pattern very similar to that of cricetids, with which the fossils have frequently been confused.

Family Dipodidae (jerboas)

Late Oligocene to Recent of Asia, late Miocene to Recent of Europe, Pleistocene to Recent of North Africa. Masseter muscle like that of zapodids but with larger deep division. Highly saltatorial rodents of the steppes and deserts of the Old World, with extremely inflated auditory bullae. Cheek teeth $\mathbf{P\frac{1-0}{0}\ M\frac{3}{3}}$, high crowned in all living and most fossil forms. Tooth pattern suggestive of that of zapodids, from which the family is probably descended. General tendency to elongate the hind foot and to fuse the 3 median metatarsals to form a cannon bone, as part of the leaping adaptation.

Family Spalacidae (mole rats)

Early Pliocene to Recent of Europe, Pleistocene to Recent of Western Asia and North Africa. Highly specialized burrowing rodents with short, powerful legs and no external tail. Eyelids permanently closed. Masseter muscle a short distance forward on face. Cheek teeth reduced to $\mathbf{M\frac{3}{3}}$ (or possibly $\mathbf{P\frac{1}{1}\ M\frac{2}{2}}$). Ancestry unknown.

Family Rhizomyidae (African mole rats, bamboo rats)

Oligocene of Europe, early Miocene to Recent of Asia, and Pleistocene to Recent of Africa. Myomorphous, with considerable forward extension of the masseter. Burrowing animals with powerful legs and short tails, superficially resembling pocket gophers (Geomyidae). Cheek teeth high crowned to ever-growing, consisting of $\mathbf{P}\frac{1-0}{1-0}$ $\mathbf{M}\frac{3}{3}$. The European Oligocene *Rhizospalax* has features suggesting that this family and the Spalacidae are related. Otherwise, relationships unknown.

Suborder Caviomorpha

Deep branch of masseter has shifted its origin forward onto the face, passing through the very large infraorbital foramen. Angle of jaw hystricognathous. Malleus and incus fused; usually a sacculus urethalis in male genital tract. Incisor enamel multiserial. Cheek teeth usually P) $\mathbf{M}\frac{3}{3}$, but occasionally the milk premolar is retained throughout life, the formula being $\mathbf{dP}\frac{1}{1}$, $\mathbf{M}\frac{3}{3}$. Early Oligocene to Recent of South America, Pleistocene to Recent of North America and West Indies.

Familv Octodontidae (octodonts, degus)

Early Oligocene to Recent of South America, Pleistocene to Recent of the West Indies. Small for caviomorphs, generally somewhat ratlike in appearance. Scampering to fossorial in habits. Occur from sea level to over 3,000 m elevation in the southern half of South America. The teeth range from low crowned to ever-growing, the enamel of the grinding surface arranged in the shape of a kidney or figure 8. The burrowing forms use the incisors in digging. The genus Platypittamys from the early Oligocene of Patagonia is very close to being a common ancestor of all the Caviomorpha.

Familv Echimvidae (spiny rats)

Oligocene to Recent of South America. Pleistocene to Recent of West Indies and Central America. Ratlike in appearance. Usually with spiny fur, although there are a few exceptions. Cheek teeth rooted, with a pattern formed by transverse folds of enamel. In all but the earliest known member of the family, the milk or deciduous premolars are retained throughout life, and permanent premolars never make an appearance. Inhabit moist forested regions; climbing or scampering; one genus is burrowing.

Familv *Ctenomvidae* (tuco-tucos)

Pliocene to Recent of South America. The single living genus inhabits all of the southern half of South America, from sea level to elevations over 4,000 m. They are fossorial and presumably derived from octodontids. Body form and size are very similar to those of the North American pocket gophers, with powerful digging muscles in the forelimbs and long, powerful claws.

Family Abrocomidae (chinchilla rats or abrocomes)

The common name comes from the soft underfur and ratlike appearance. Pliocene to Recent of South America. The living species inhabit mountainous areas of Peru, Bolivia, Argentina, and Chile. Presumably evolved from octodontids. The cheek teeth grow throughout life.

Family Chinchillidae (chinchillas and viscachas)

Eary Oligocene to Recent of South America. One living genus (Lagostomus) lives in lowlands of Argentina; the other two (Lagidium and Chinchilla) live at elevations of about 800 to 6,500 m in the southern half of the Andes. The fur of Chinchilla is very soft and dense—that of the other genera less so. All gregarious, but especially the lowland viscachas (*La*gostomus), which occupy colonies resembling those of prairie dogs. The lowland viscachas are large, head and body length being 470 to 660 mm; the mountain genera are 230 to 320 mm (Lagidium) and 225 to 380 mm (Chinchilla). Cheek teeth ever-growing, but details of pattern lost early in life.

*Family Caprom*yidae (hutias, coypus)

Middle Pliocene to Recent of South America, Pleistocene to Recent of West Indies, introduced in southern United States and parts of Europe. Differ from the Chinchillidae, from which they are probably derived, in having high-crowned to ever-growing cheek teeth, but with the details of the pattern persistent. The hutias of the West Indies resemble large rats. The coypus of South America are considerably larger, looking rather like a large muskrat. The fur is excellent, and the flesh is widely eaten in South America.

Family Dasyproctidae (pacas and agoutis)

Early Oligocene to Recent of South America, Pleistocene to Recent of West Indies, Recent of Central America. Large rodents (head and body length 320 to 800 mm), with weight up to 10 kg. Limbs modified for cursorial locomotion, with the lateral toes, especially on the hind foot, reduced in size. Flesh is very palatable. Pacas in moist forested areas from Mexico to southern Brazil; agoutis in the same regions (plus the Lesser Antilles), but not restricted to forested areas.

Family Dinomyidae (pacaranas)

Early Miocene to Recent of South America; Pleistocene of West Indies. There is only a single living genus inhabiting the lower elevations of the northern half of the Andes The animal is among the largest of living rodents. A considerable number of fossil forms, once thought to represent a separate family (Heptaxodontidae) probably belong here.

†*Family Elasmodontomyidae*

Pleistocene to Recent of Puerto Rico and northern Lesser Antilles. These forms are all extinct, but survived until about the time the area was colonized by the Spaniards. Medium-sired ground-living rodents, with ever-growing cheek teeth formed of a series of enamel plates inclined at about 45° to the long axis of the jaws.

†*Family* Eocardiidae

Early Oligocene to middle Miocene of South America. Cheek teeth medium to high crowned. Size about that of a guinea pig.

Family Caviidae (guinea pigs, cavies, and maras)

Late Miocene to Recent of South America. Cheek teeth ever-growing, with a simplified crown pattern of alternating V's. Digits reduced to 4 on the front and 3 on the hind foot. Cavies with short legs, ears and tails; maras superficially resembling hares.

Family Hydrochoeridae (capybaras)

Early Pliocene to Recent of South America, Pleistocene to Recent of Central America, Pleistocene of West Indies and southern United States. Most members of this family are extinct, there being but a single living genus, with 1 species in eastern Panama and the other in South America east of the Andes and north of the Rio Paraná. Forest dwellers, capable of escape by running, but tend to retreat to water when closely pursued. Derived from Caviidae and have the same reduction of digits. Largest living rodents, head and body length reaching 1.2 m; they may weigh over 45 kg.

Family Erethizontidae (New World porcupines)

Early Oligocene to Recent of South America, Pleistocene to Recent of North America, recent of Central America. Large, slow-moving, heavy-bodied rodents, with some hairs modified into sharp, barbed spines that are easily detached when they make contact with an enemy. Cheek teeth rooted, with a simple pattern of reentrant folds, essentially unchanged since the Oligocene. One South American genus has a prehensile tail.

Suborder Phiomorpha

A group of families of African rodents the ancestry of which can be traced back to the early Oligocene of Egypt. Most of them are hystricomorphous and hystricognathous, and they are often considered very closely related to the Caviomorpha. Multiserial incisor enamel; malleus and incus fused and sacculus urethralis present in living forms. Cheek teeth), consisting (in all but a few of the earliest types) of the last deciduous premolar, retained throughout life, and $\mathbf{M}\frac{3}{3}$.

†*Family* Phiomyidae

Oligocene to Miocene of Africa. These rodents reached Africa when it was isolated from the rest of the world and differentiated to become highly diverse, including scampering, burrowing, and perhaps arboreal and leaping forms. In the Miocene other rodents reached Africa, and only a few lines of phiomyids were able to survive the resulting competition. Several Oligocene genera retained permanent premolars, although in 1, at least, they apparently never were functional.

Family Petromuridae (rock rats or dassie rats)

Pleistocene to Recent of southern South Africa. Ratlike in body form, the single species inhabits rocky hills, living in narrow crevices in rocks.

Family Thryonomyidae (cane rats)

Miocene to Recent of Africa and early Pliocene of India. Body form and habitat generally similar to a muskrat, inhabiting marshes and the borders of streams and lakes. There is only a single living genus, spread over Africa south of the Sahara. Head and body 350 to 610 mm.

Family Bathyergidae (blesmols or African mole rats)

Miocene to Recent of Africa. The most completely fossorial of all rodents, with short, powerful limbs and heavy claws. The incisors are highly procumbent, and in some forms are used in burrowing. In some genera the growing base of the upper incisors has shifted backward to a level behind the rear of the upper cheek teeth. Only slight penetration of infraorbital foramen by masseter (probably secondary reduction); angle hystricognathous but peculiar. One genus (Heterocephalus) has the pelage reduced to scattered short hairs. External ears are greatly reduced; eyes are reduced and the eyelids usually kept closed. The number of cheek teeth reaches $\frac{6}{6}$; it is by no means clear which teeth are involved. These animals spend essentially all their lives in their burrows; some are colonial.

Families of uncertain relationships

The remaining 10 families of rodents are of completely uncertain relationships, and are best treated as individual families.

Family Hystricidae (Old World porcupines)

Pliocene to Recent of Asia, Africa, and Europe, Pleistocene to Recent of East Indies. Spined forms, resembling the New World porcupines in appearance, but less arboreal in habits; quills without barbs. The ease with which even a slight touch loosens the quills, leaving them inserted in the attacker, is the origin of the belief that these animals are capable of shooting their quills like arrows, as reported, for example, by Marco Polo. Hystricognathous and hystricomorphous; malleus and incus fused; incisor enamel multiserial; sacculus urethalis present; cheek teeth consist of P+, $\mathbf{M}\frac{3}{3}$, all exhibiting a crown pattern broken up into numerous small cuspules. The origin and relationships of the group are not clear, but they may have originated in southern Asia.

Family Castoridae (beavers)

Early Oligocene to Recent of Europe and North America, late Oligocene to Recent of Asia. Sciuromorphous and sciurognathous rodents, with cheek teeth ($P\frac{(2-1)}{1}$, $\mathbf{M}\frac{3}{3}$) progressively becoming high crowned and ever-growing. Restricted at present to a single genus ***(Castor)***,formerly widespread in Eurasia and North America, but greatly reduced as a result of very intensive trappping for the very fine, soft fur. Aquatic animals, with webbed feet and broad, flattened tail. Numerous fossils from the Tertiary do not seem to have been aquatic but rather to have been fossorial. In western Nebraska an early Miocene beaver seems to have constructed spiral burrows ("Devils' corkscrews").

†***Family Eutypomyidae***

Rodents from the Oligocene of North America sometimes (but probably erroneously thought to have been related to the beavers, but with very complexly folded enamel on the cheek teeth, and with a peculiar foot structure of uncertain function (very slender inner digits and heavy outer ones).

Family Anomaluridae (scaly-tailed "squirrels")

Miocene to Recent of Africa. Sciurognathous but hystricomorphous rodents; arboreal, and most living forms with a membrane extending from front to hind legs to tail, used in gliding from one tree to another. A long cartilaginous support, derived from the ulna in the region of the elbow, supports the anterior end of the membrane. Head and body length about 60 to 430 mm.

Family Ctenodactylidae (gundis)

Oligocene of Mongolia, Miocene of India, and Miocene to Recent of Africa. Hystricomorphous and sciurognathous rodents; malleus and incus fused; perhaps a sacculus urethalis; incisor enamel multiserial. Quite diverse in Oligocene of Mongolia, but the fossils do not suggest close relationship to any possible ancestors. Scamperers, with body form similar to that of a guinea pig; 4 toes on each foot. Head and body length 160 to 240 mm.

Family Pedetidae (springhaas or Cape jumping hare)

Miocene to Recent of Africa. Hystricomorphous and sciurognathous; malleus and incus not fused; incisor enamel multiserial. The single living genus lives in eastern and southern Africa. **A** large rodent, with elongate hind limbs, jumping like a kangaroo. The cheek teeth ($P\frac{1}{1}$, $\mathbf{M}\frac{3}{3}$) are ever-growing, with the pattern preserved only in completely unworn teeth. Head and body length about 350 to 430 mm.

Family Gliridae (dormice)

Middle Eocene to Recent of Europe, Recent of Asia, Miocene to Recent of northern Africa. Sciuromorphous and sciurognathous; uniserial incisor enamel. Small arboreal rodents, similar in appearance to the smaller squirrels. Generally have partial hibernation. It has recently been demonstrated that they can be traced back to an ancestry among small European paramyids of early to middle Eocene; as a result, although they are similar to sciurids in being sciuromorphous, they are clearly of independent origin. Head and body length about 60 to 190 mm.

Family Seleveniidae (Selevin's mice)

Probably related to dormice; a single genus recently discovered in the deserts of Central Asia. Elongate hind legs and a long tail. Head and body length 72 to 96 mm.

†***Family Pseudosciuridae***

European, middle Eocene to Oligocene. Hystricomorphous and sciurognathous; incisor enamel pauciserial. Cheek teeth low crowned. They can be derived from European early Eocene paramyids, and gave rise to the Theridomyidae. The gradual development of the hystricomorphous condition can be traced in this group.

†***Family Theridomyidae***

Abundant European late Eocene and Oligocene rodents, with low-crowned to ever-growing cheek teeth. Incisor enamel pauciserial or uniserial. They have had a central position in many theories of the origin and relationships of the various hystricomorphous groups (Caviomorpha, Phiomorpha, Hystricidae, Anomaluridae, Ctenodactylidae, and Pedetidae), but there is no evidence to show that they were actually related to any of these.

Critical appraisal. The rodents are one of the most clearly demarcated of all mammalian orders. No animals are known, either living or fossil, where there is question as to whether or not they belong to this order. Within the order, however, there is great disagreement as to the interrelationships of various families or groups of families. There is no question that the Caviomorpha, as listed above, are related, and there seems to be little question that the Phiomorpha are a natural group. There is disagreement as to whether the two suborders should be united with each other, or with the Hystricidae. If the three are united, the combination should be called the suborder Hystricomorpha (the oldest name for such a group). The Anomaluridae, Ctenodactylidae, Pedetidae, Pseudosciuridae, and Theridomyidae are included in the Hystricomorpha by some authors. The relationships of all five families are very uncertain (except that pseudosciurids clearly gave rise to theridomyids). Much uncertainty exists as to whether the families here included in the Myomorpha are a natural unit. There is considerable diversity within the group. Many authors unite the Muridae and Cricetidae into a single family; still others separate the microtines from the cricetids as a third family. The two families are recognized here largely as a matter of convenience — about 100 genera each of murids and cricetids are known; combining them makes an unwieldy family including over half the order. The microtines were quite obviously derived in late Pliocene times from cricetids; if they are recognized as a distinct family, it is the only family of either animals or plants known to have originated so recently.

Currently, attempts are still being made to find satisfactory bases on which to subdivide the order. The incompleteness of knowledge of fossil rodents is a major handicap that will certainly be overcome in the future. The classification presented here is an attempt to give what seems to be a reasonable interpretation of the present knowledge of the subject.

Rodeo

A rodeo is a series of contests and exhibitions derived from riding, roping, and related skills developed by cowboys during the era of the range cattle industry in northern Mexico and the western United States.

Five standard rodeo events

Rodeo events. The five standard rodeo events are calf roping, bull riding, steer wrestling (bulldogging), saddle bronc riding and bareback bronc riding (a bronc [bronco, broncho, or bucking bronco] is an unbroken range horse picked for its resistence to training and its tendency to buck, or throw, its rider). Two other events are recognized for championships: single-steer roping and team roping. There is no ban on additional contests, and there are usually contract acts—professional specialty performances such as trick riding, fancy roping, and other exhibitions. The barrel race, a saddle horse race around a series of barrels, is a popular contest for cowgirls. Steer decorating is seen in junior contests. The chuck-wagon race is featured at the Calgary (Canada) Stampede. Prize money may be offered in a wild horse race, wild cow milking, trick and fancy riding, or a contest for cutting horses (horses trained to separate cattle from a herd).

Participants pay entry fees, and the prize money won is their only compensation. More than half of all rodeos are independent of state and county fairs, livestock shows, or other attractions, and many, large and small, are held in arenas devoted to the purpose. The equipment, however, is simple and may be improvised. Most rodeos are sponsored locally by chambers of commerce or other civic organizations, which offer prize money and employ contract acts. Among necessary employees are the clowns who, in addition to their entertainment value, have the duty of distracting animals that might injure contestants.

Origins and early shows. Rodeo events are much older than the North American cattle industry and may go back to the beginnings of the domestication of cattle and horses. Rodeo, however, developed as a peculiarly American sport and is confined mainly to Mexico, the United States, and Canada. The South American gaucho, often featured in Wild West shows, left little impress on rodeo. Australia has made only minor contributions, despite the long popularity of rodeo there, where it is often known as Bushmen's carnival. One notable importation from overseas is the Brahman bull, used in most bull-riding contests.

In the days of open range, when cattle were grazed on unfenced public lands, it was customary to round up and separate the cattle of various owners twice yearly: in spring to brand calves and in fall to select cattle for sale. The roundup brought together cowboys from many ranches. During off hours they found time for horse racing and for betting on experts in such essential skills as calf roping and bronco riding. There is record of such contests as early as 1847.

"Cowtowns" often celebrated the 4th of July with similar events. In 1869 at Deer Trail, Colorado, Emilne Gardenshire was declared champion bronco buster. Wild steer riding was staged at Cheyenne in 1872. An "Old Glory Blow-Out," sponsored by William F. ("Buffalo Bill") Cody at North Platte, Nebraska, in 1882, attracted 1,000 contestants. Its success inspired Buffalo Bill's Wild West show, which opened in Omaha in 1883. Its feature, called "Cowboy Fun," was essentially rodeo. Between 1883 and 1938, some 120 travelling Wild West shows popularized the cowboy and his skills over the United States and throughout the world.

Denver had a cowboy tournament in 1887, followed by several Mountain and Plains festivals. The Pendleton (Oregon) Round-Up started in 1910, and the Calgary (Alberta) Stampede in 1912. The latter has been an annual event since 1919. But the oldest annual show of all is Cheyenne Frontier Days, which has been presented each year since 1897.

Outstanding performers. In 1903 Bill Pickett, a Negro cowboy from Texas, leaped for the horns of a steer to save his horse from being gored and wrestled the steer to the ground, biting its upper lip in a bulldog grip. He found he could repeat the act, which became known as bulldogging—or, more politely, steer wrestling, after rodeo rules eliminated the lip biting. Pickett was hired by Joseph C., Zack T., and George L. Miller for their 101 Ranch near Ponca, Oklahoma. In 1907 they organized the Miller Bros. 101 Ranch Real Wild West show, which also employed such notables as Lucille Mulhall, called the first cowgirl and world's lady champion in roping and tying wild steers; Tom Mix, silent movie cowboy actor; and Guy Weadick, who organized the first Calgary Stampede.

Organization of the sport. In 1929 the Rodeo Association of America, an organization of rodeo managers and producers, was formed to regularize the sport. Contestants took a hand in 1936 after a strike in Boston Garden and organized the Cowboy Turtles Association—"turtles" because they had been slow to act. This group was renamed the Rodeo Cowboys Association (RCA) in 1945, and its rules now are accepted by most rodeos. Amateur rodeo has continued to grow in popularity, and the National Intercollegiate Rodeo Association, formed in 1948, has 80 member schools. Some 500 secondary school, 4-H Club, Future Farmers of America, and other junior rodeos are held annually.

Judging of events. The calf for roping and the steer for wrestling are released from chutes, an innovation since early rodeos. These are timed events. The calf must be roped and thrown, and three feet tied together. In the steer wrestling contest, a hazer helps to keep the steer moving straight forward. The wrestler must throw the steer with head and all feet in line. In calf roping, championships have been won in 16 seconds, but it has been done in well under 15 seconds. In steer wrestling, 11 seconds is championship time, but less than 10 seconds is of record.

In riding events the contestant is mounted before the chute gates are opened. The rider must stay on the animal for eight seconds. Judging, on a point system, is based on the performance of the animal as well as that of the contestant. Broncos are not trained to buck, and RCA rules ban cruelty. In all riding events the contestant is disqualified if he touches the animal or its rigging with his free hand.

All-around championships and championships in each of the five standard events are determined each year on the basis of a point-award system established by the RCA.

Rodin, Auguste

At the beginning of the 20th century, the French sculptor Auguste Rodin was famous throughout the world and long had been revered as a modern-day Michelangelo, a titan of sculpture, an incarnation of the power of inspired genius. Even his prodigious sensuality was excused as a symbol of his Olympian stature. Three-quarters of a century later, however, criticism has become less uniform, pointing to the elements in his work that belie his early life as a decorative sculptor and the concomitant lack of formal discipline. Nonetheless, he exerted an immense influence on sculpture, and his numerous students from many countries helped to spread his style. His example was particularly fruitful for such later French sculptors as Charles Despiau, Aristide Maillol, and Émile Bourdelle. Most major museums own copies of his works, and museums in Paris, Philadelphia, and Tokyo are dedicated to him. Rodin's prime contribution was in bringing Western sculpture back to what always had been its essential strength, a knowledge and sumptuous rendering of the human body. He is often considered the greatest portraitist in the history of sculpture, as if he required these commissions to harness his fertile imagination and unleash his genius. His evocations of great men, such as his "Balzac," are uniformly brilliant.

Rodin with his sculptures "Victor Hugo" and "The Thinker," gum print by Edward Steichen, 1902. In the Art Institute of Chicago.

Early life and work. Rodin was born in Paris on November 12, 1840, into a poor family. In 1854 he entered a drawing school, where he learned drawing and modelling. At 17 he attempted to enter the École des Beaux-Arts, but he failed the competitive examinations three times. The following year (1858) he was earning his living by doing decorative stonework. Traumatized by the death of his sister Marie in 1862, he considered entering the church; but in 1864 the young sculptor met Rose Beuret, a seamstress, who became his life companion, although he did not marry her until a few weeks before her death in February 1917.

Rodin had begun to work with the sculptor A.-E. Carrier-Belleuse when, in 1864, his first submission to the official Salon exhibition, “L’Homme au nez casst" ("The Man with the Broken Nose"), was rejected. His early independent work included also several portrait studies of Rose. In 1871 he went with Carrier-Belleuse to work on decorations for public monuments in Brussels. Dismissed by Carrier-Belleuse, he collaborated on the execution of decorative bronzes, and Rose joined him in Brussels.

Italian influences

In 1875, at the age of 35, Rodin had yet to develop a personally expressive style because of the pressures of the decorative work. Italy gave him the shock that stimulated his genius. He visited Genoa, Florence, Rome, Naples, and Venice before returning to Brussels. The inspiration of Michelangelo and Donatello rescued him from the academicism of his working experience. Under those influences, he molded the bronze "Le Vaincu" (“The Vanquished"), his first original work, the painful expression of a vanquished energy aspiring to rebirth. It provoked scandals in the artistic circles of Brussels and again at the Paris Salon, where it was exhibited in 1877 as “L’Âge d’ Airain" ("The Age of Bronze"). The realism of the work contrasted so greatly with the statues of Rodin’s contemporaries that he was accused of having formed its mold upon a living person.

In 1877, Rodin returned to Paris, and in 1879 his former master Carrier-Belleuse, now director of the Sèvres porcelain factory, asked him for designs. He was rejected in various competitions for monuments to be erected in London and Paris, but finally he received a commission to execute a statue for the Hôtel de Ville (City Hall) in Paris. Meanwhile, he explored his personal style in "St. Jean-Baptiste prêchant" (1878; "St. John the Baptist Preaching"). Its success and that of "The Age of Bronze" at the salons of Paris and Brussels in 1880 established his reputation as a sculptor at the age of 40.

Toward the achievement of his art. At an age when most artists already had completed a large body of work, Rodin was just beginning to affirm his personal art. He received a state commission to create a bronze door for the future Musée des Art Décoratifs, a grant that provided him with two workshops and whose advance payments made him financially secure.

That bronze door was to be the great effort of Rodin’s life. Although it was commissioned for delivery in 1884, it was left unfinished at his death in 1917. The theme of its scenes was borrowed from Dante's Divine *Comedy,* and eventually it came to be called "La Porte de l’Enfer” ("The Gates of Hell"). His original conception was similar to that of the 15th-century Italian sculptor Lorenzo Ghiberti in his "Gates of Paradise" door for the Baptistery in Florence. His plans were profoundly altered, however, by his visit to London in 1881 at the invitation of the painter Alphonse Legros. There Rodin saw the many Pre-Raphaelite paintings and drawings inspired by Dante, above all the hallucinatory works of William Blake. He transformed his plans for "The Gates" to ones that would reveal a universe of convulsed forms tormented by love, pain, and death. This unachieved monument was the framework out of which he created independent sculptural figures and groups, among them his famous "Le Penseur" (1880; "The Thinker"), originally conceived as a seated portait of Dante for the upper part of the door.

Monument at Calais

In 1884, Rodin was commissioned to create a monument for the town of Calais to commemorate the sacrifice of the burghers who gave themselves as hostages to King Edward III of England in 1347 to raise the year-long siege of the famine-ravaged city. Rodin completed work on “Les Bourgeois de Calais" (“The Burghers of Calais") within two years, but the monument was not dedicated until 1895. In 1913 a bronze casting of the Calais group was installed in the gardens of Parliament in London to commemorate the intervention of the English queen who had compelled her husband, King Edward, to show clemency to the heroes.

While the artist's glory continued to increase, his private life was troubled by the numerous liaisons into which his unbridled sensuality plunged him. In about 1885 he became the lover of one of his students, Camille Claudel, the gifted sister of the poet Paul Claudel. It proved a stormy romance beset by numerous quarrels, but it persisted until Camille's madness brought it to a finish in 1898. Their attachment was deep and was pursued throughout the country. During the years of passion Rodin executed sculptures of numerous couples in the throes of desire. The most sensuous of these groups was "Le Baiser" (1886; "The Kiss"), sometimes considered his masterpiece. Originally conceived as the figures of Paolo and Francesca for "The Gates of Hell," it exposed him to numerous scandals.

Discords and triumphs. In spite of his success, Rodin was often in conflict with L’Institut de France, the national art academy, with the public, and even with the parliament. He devoted a decade to executing four monuments honouring the landscape painter Claude Lorrain, Pres. Dorningo Sarmiento of Argentina, and the writers Victor Hugo and Honor6 de Balzac; and each of the four monuments was challenged. In Nancy, France, the Claude statue and, in Buenos Aires, the "President Sarmiento” caused riots. The conflicts over the "Victor Hugo" and the "Balzac" were even more serious.

Bronze of Victor Hugo

In 1886 he received the order for the monument to Hugo for the Panthéon, France's hall of its great men. The nudity depicted in the work caused such shock that he had to abandon the project. It was 1909 before another "Victor Hugo," also nude but seated, was installed at the gallery of the Palais-Royal, although it had been intended for the Luxembourg Gardens. In 1891, Rodin was commissioned to portray Balzac for the Société des Gens de Lettres (Society of Men of Letters). He gave himself over completely to massive research designed to translate the several Balzac portraits into sculpture. He obtained the exact measurements of the novelist's body by finding his former tailor. After much conjecture and experimentation to find an appropriate posture for the statue, he finally conceived of the writer as partly draped. The concisely designed model resembled a menhir, or upright prehistoric altar stone, foreshadowing the simplicity of modern art. The artist's delays and his design for the statue brought on a legal dispute with the Société; and, when the model was shown at the Salon de la Société Nationale des Beaux-Arts in 1898, it generated a violent debate in which the sculptor was defended by Georges Clemenceau, the future premier of France. Finally Rodin reimbursed the Société and took back the model. The statue, cast in bronze, was not erected until 1939, in the crossroads of the Montmartre section of Paris.

The Exposition Universelle of 1900 in Paris featured a pavilion in which 150 of Rodin's sculptures and numerous drawings were displayed, testifying to the international scope of his fame. After it closed, he had his works transported to a property that he had bought at Meudon in 1896. His residence there became a vast workshop where he employed a legion of assistants amid an endless stream of "favourites" who passed as his students. He was by then less a sculptor than an entrepreneur of sculpture. He himself executed only models, of which he made many, while searching for the form that suited him. Casting in bronze was the domain of specialists; but he also delegated the hewing of marble to others, to be executed under his direction but not by him. He was assisted in this "industrial" enterprise by a series of secretaries, including for a brief period the Austrian poet Rainer Maria Rilke.

International success and honors

After 1900, Rodin's worldwide success attracted abundant orders for portrait busts from the United States, Germany, Austria, England, and France. He enjoyed great renown in England, where he had numerous friends and which he often visited. In 1902 he was carried in triumph by students at a banquet in his honour in London. In 1907 he went to London for the inauguration of his monument to the poet William Henley at Westminster Abbey, and he—along with the French composer Camille Saint-Saens and the U.S. writer Mark Twain—was made a doctor *honoris causa* at Oxford University. In May 1908, King Edward VII of England visited him at his workshop in Meudon.

In the same month Rodin also rented a floor in one of the most beautiful 18th-century Parisian hotels, the Hôtel Biron, which was surrounded by an immense garden. Eventually he occupied the entire premises under an agreement by which the French state agreed to acquire and preserve the hotel as a Rodin museum in return for his donation to the state of all his works. These negotiations were endangered, however, by the self-serving intrigues of the last of his great favourites, an American who became duchess of Choiseul. They were furthered by Judith Cladel, who became his chronicler and who worked to see that the negotiations were successful, and by his last secretary, Marcelle Tirel, who defended him from the covetousness of women who tried to coax away his legacy. The purchase of the hotel and the donation of Rodin's goods was finally completed in 1916. The museum is constituted as an autonomous organization maintained by sales of castings from plaster casts that he left. Rodin died at Meudon on November 17,1917, and on the day of his burial a solemn service was celebrated in his honour at Westminster Abbey in London.

To his sculpture, Rodin added, during his lifetime, book illustrations, dry-point etchings, and innumerable drawings of nudes, principally female. He also had literary pretensions and produced several writings with the help of friends. He was enamoured of the art of the Middle Ages, and among his major efforts was the book *Les Cathédrales de France* (1914; *Cathedrals of France,* 1965).

MAJOR WORKS

SCULPTURE: All bronzes (in multiple editions) unless otherwise noted. "L'Homme au nez cassé" ("The Man with the Broken Nose"; 1864; Muste Rodin, Paris); "Young Girl with Flowers in Her Hair" (plaster, 1865–70; Musée Rodin); "Young Mother and Child" (1865–70; Muste Rodin); "The Age of Bronze" ("L'Âge d'Airain"; 1876; Minneapolis Institute of Arts, Minnesota); "St. John the Baptist Preaching" ("St. Jean-Baptiste prêchant"; 1878; Museum of Modern Art, New York); "The Gates of Hell" ("La Porte de l'Enfer"; 1880-1917; Rodin Museum, Philadelphia); "Le Penseur" ("The Thinker"; 1880; Musée Rodin); "Adam" (1880; Rodin Museum, Philadelphia); "Eve" (1881; Toledo Museum of Art, Ohio); "Le Petit Homme au nez cassé" ("The Little Man with the Broken Nose"; 1882 Muste Rodin); "The Earth" (1884; MusCe Rodin); "The Burghers of Calais" ("Les Bourgeois de Calais"; 1884–86; Joseph H. Hirshhorn Collection, New York); "The Martyr" (1885; Rodin Museum, Philadelphia); "The Kiss" ("Le Baiser"; 1886; Tate Gallery, London); "Balzac, Nude" (1893; Musée Rodin); "Balzac" (1897; Rodin Museum, Philadelphia); "Victor Hugo" (1897; Muste Rodin); "Fugit amor" (1897; Musée Rodin); "The Bather" or "Beside the Sea" (marble, 1905; Metropolitan Museum of Art, New York); "The Walking Man" (1905; MusCe Rodin); "George Bernard Shaw" (1906; Rodin Museum, Philadelphia); "Nijinsky" (1912; MusCe Rodin).

WRITINGS: A *la Vénus de Milo* (1910; *To the Venus de Milo,* 1912); *L'Art* (1911 and 1946; *On Art and Artists,* 1957), conversations collected by Paul Gsell; *Les Cathédrales de France* (1914; *Cathedrals of France,* 1965).

BIBLIOGRAPHY. ROBERT DESCHARNES and J.F. CHABRUN, *Auguste Rodin* (1967), is the most complete monograph on the life and work of the artist. Other important works are: C.J. BURCKHARDT, *Rodin und das plastische problem* (1921), a morphological study; JUDITH CLADEL, *Auguste Rodin: l'oeuvre et l'homme* (1908; Eng. trans., *Rodin: The Man and His Art,* 1917); *Rodin sa vie glorieuse, sa vie inconnue* (1936; Eng. trans., *Rodin*, 1938), studies by a direct witness; H. CHARLES-ESTIENNE DUJARDIN-BEAUMETZ, *Entretiens avec Rodin* (1913); E. HERRIOT, A *la gloire de Rodin* (1927), an expression of admiration from a great man of politics; G. GRAPPE, *Rodin* (1955), by the conservator of the MusCe Rodin in Paris; R. MARIA RILKE, who was the artist's secretary for a short time, *Auguste Rodin* (1902; 2nd ed., 1913; Eng. trans., 1945); and *Lettres à Rodin* (1928–34); DENYS SUTTON, *Triumphant Satyr: The World of Auguste Rodin* (1966), an aesthetic and biographical study; MARCELLE TIREL, *Rodin intime* (1923; Eng. trans., *The Last Years of Rodin*, 1925), by Rodin's secretary; and L. WEINBERG, *The Art of Rodin* (1918).

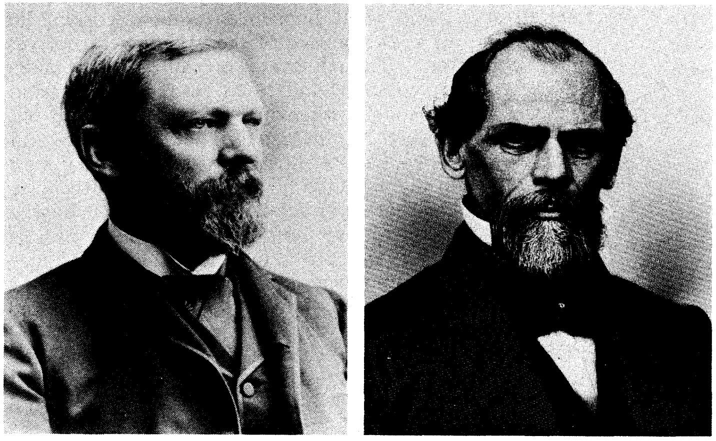
Roebling, John Augustus and Washington Augustus

John Augustus Roebling, a pioneer in the design of steel suspension bridges, whose best known work is the Brooklyn Bridge, was among the first to recognize the resilience of steel wire and to weave it into massive cables of great strength and flexibility.

By courtesy of (left) Rutgers University Library, Nevi Brunswick, New Jersey, (right) the Smithsonian institution. Washington. D.C.



(Left) Washington Roebling, 1870. (Right) John Roebling, engraving by William Murray.

He was born on June 12, 1806, in Miihlhausen, Prussia. After graduating from the polytechnic school in Berlin, he worked for the Prussian government for three years and at the age of 25 emigrated to America. He settled with others from his hometown in a small colony that was later called Saxonburg, near Pittsburgh, in the hills of western Pennsylvania. He married the daughter of another Miihlhausen emigrant, and they had nine children—the eldest of whom, born on May 26, 1837, was Washington Augustus Roebling. After a few years of unsuccessful farming, John Roebling went to the state capital in Harrisburg and applied for employment as a civil engineer.

Development of method of stranding cables

He had often watched canalboats being hauled over hills from one watershed to another, and he persuaded the canal commissioners to let him replace the hempen hawsers with wire cables. He developed his own method for stranding and weaving wire cables, which proved to be as strong and durable as he had predicted. The demand for such cable soon became so great that he established a factory to manufacture it in Trenton, New Jersey. This was the beginning of an industrial complex that finally was capable of producing everything from chicken wire to enormous 36-inch cables. It remained a family-owned business, carried on by three generations of Roeblings.

Roebling was less a businessman than an engineer, and with the growth of his reputation as a designer and builder of long-span suspension bridges he spent less and less time at the Trenton factory. His eldest son Washington, after graduating from Rensselaer Polytechnic Institute, joined him in his work. In the 1850s and 1860s the Roeblings built four suspension bridges: two at Pittsburgh, one at Niagara Falls, and another across the Ohio between Cincinnati and Covington, Kentucky, with a main span of 1,051 feet (320 metres). New York state accepted Roebling's design for a bridge connecting Brooklyn and Manhattan with a span of 1,595 feet (486 metres) and appointed him chief engineer. He sent his son Washington, who had been in charge of the construction of the enormous masonry towers that supported the Cincinnati–Covington cables, to Europe to study new methods for the sinking of the foundations on which the granite towers of the Brooklyn Bridge were to stand.

The building of Brooklyn Bridge

According to legend, "every bridge demands a life." In this instance the life was that of the designer himself. Roebling was taking final compass readings while standing on some pilings at a ferry slip and did not notice that a boat was docking. As it banged into the slip, one of his feet was caught between the pilings. He was rushed to his son's house in Brooklyn Heights, where the doctors amputated his injured toes. Three weeks later, he died of tetanus at the age of 63.

Washington Augustus Roebling had been a colonel in the Union Army, and the title remained with him the rest of his life. On his father's death he was asked to serve as chief engineer and immediately began work on the foundations for the two towers. The use of pneumatic caissons (watertight chambers) was still in a somewhat experimental stage, and what happened to men working in compressed air at the bottom of the caisson was not yet fully understood. Though every precaution was taken there were more than a hundred cases of decompression sickness (the "bends") when men were brought up too rapidly. There were also the usual difficulties of fires and breakdowns, as well as so-called blow-outs that shot mud and water into the air. Like his father, Colonel Roebling felt he had to inspect every detail of the work. One day he remained 12 consecutive hours in the compressed-air chamber, finally being carried out unconscious. In those days they did not understand the amount of time needed for slow decompression. The nitrogen bubbles in the bloodstream could paralyze a man for life.

His health was permanently affected, and though he lived to be almost 89, the Brooklyn Bridge was his last undertaking. From his bedroom window he watched the cables being spun, and his wife carried orders to the engineers and foremen. The bridge took 13 years to complete. On a spring day in May 1883, Pres. Chester A. Arthur and his Cabinet, along with the Governor of New York and a host of distinguished visitors, marched across the East River from Manhattan to Brooklyn. The design of the bridge has been an inspiration to painters and poets, and after 90 years it is still one of New York's important traffic arteries, carrying thousands of vehicles a day.

(H.H.B.)

Roger II of Sicily

Creator of the Norman Kingdom of Sicily, Roger II ruled one of the best-governed states in 12th century Europe, where Italians, Greeks, Muslims, and Jews lived together in a cosmopolitan society. He was the son of the Great Count Roger I of Sicily and his third wife, Adelaide of Savona. Born on December 22, 1095, he succeeded his elder brother Simon on September 28, 1105, at the age of nine. Little is known of his childhood; the tradition that he was baptized by St. Bruno, founder of the Carthusian Order, is undocumented. These years, during which his mother acted as regent, he probably spent between Mileto in Calabria, the family castle in northeast Sicily, and Messina; but it was at Palermo in 1112 that he was knighted and assumed the reins of government, and there his Sicilian capital was henceforth established.

Alinari

Roger II, mosaic depicting his coronation by Christ, 12th century. In the Church of Martorana, Palerrno, Sicily.

Character and personality

Though the island that Roger I and his brother Robert Guiscard had conquered was populated predominantly by Arabs—with a strong admixture of Greeks—the Great Count had always remained essentially a Norman knight. His son, by contrast, was a man of the Mediterranean. Deprived of paternal influence from the age of five, brought up in a cosmopolitan, multiconfessional world of Greek and Muslim tutors and secretaries, of studies pursued and state affairs conducted in four languages, Roger soon revealed an exotic strain in his nature that cannot wholly be ascribed to his mother's Italian blood. The latter was obvious enough in his complexion and in the darkness of his eyes and hair, but his contemporaries soon learned to their cost that he was not only a southerner—he was also an Oriental. He was a ruler for whom diplomacy, however tortuous, was a more natural weapon than the sword, and gold, however corrupting, a more effective currency than blood.

Two qualities, however, he had inherited from his Norman forebears: his energy and his ambition. It was these, combined with a gift for imaginative statesmanship all his own, that enabled him to profit from the fecklessness of his cousins—the son and grandson of Robert Guiscard—and to acquire, in return for military aid against a rebellious baronage, more and more of their mainland territories. By 1122 all Calabria was his; and in 1127, when

Duke William of Apulia died without issue, Roger laid claim to the duchy as his rightful heir. Opposition was considerable; the barons had always resented the domination of the Hautevilles, whom they looked upon as upstarts no better than themselves, and the papacy had no wish to see too powerful a state established on its southem frontier. But they were no match for Roger's particular technique of armed diplomacy, and in 1128 Pope Honorius II invested Roger as duke of Apulia, Calabria, and Sicily.

Thus, at 32, the young duke found himself one of the most influential princes in Europe. Only one thing more was necessary before he could weld his triple duchy into a single nation and treat with his fellow rulers on equal terms: a royal crown. Two years later he got it. Honorius' death early in 1130 led to a dispute over the papal succession. One of the two candidates, Innocent II, thanks to the energetic advocacy of St. Bernard of Clairvaux, soon had almost the whole continent behind him. His rival, the antipope Anacletus II, turned to Roger, who promised full support in return for coronation.

Enthronement as King of Sicily

The first king of Sicily was crowned on Christmas Day 1130 in the cathedral at Palermo. The antipope Anacletus died in 1138 and in the following year, after routing a papal army at Galluccio and taking the Pope captive, Roger forced Innocent to confirm him in the kingdom of Sicily, with the overlordship of all Italy south of the Garigliano. After this he was quickly able to pacify his mainland realm, where his vassals—abetted by the German emperor Lothair II who led a large, though unsuccessful, expedition to South Italy in 1136–37—had kept up an almost permanent insurrection. In Sicily itself, where the ban on large fiefs had left little opposition to Roger's rule, the new kingdom steadily grew more prosperous. The King himself, more than any other ruler of his day, was an intellectual who had thought deeply about the science of government, and although he cherished no love for the empire of the East—which, like that of the West, maintained its claim to its former South Italian possessions—his whole upbringing inclined him toward the Byzantine concept of monarchy: a mystically tinged absolutism in which the sovereign, as God's viceroy, lived remote and elevated from his subjects in a magnificence that reflected his intermediate position between Earth and heaven. It is no coincidence that in one of the only two portraits of Roger with any claim to authenticity—the mosaic in the Church of the Martorana at Palermo—he is depicted in Byzantine robes being symbolically crowned by Christ.

But splendour did not mean empty extravagance. A contemporary chronicler notes that Roger would personally go through his exchequer accounts, recording even the smallest expenditure, and that he was as scrupulous in the payment of debts as in their collection. Still less did it mean idleness. In the words of his court geographer, the King "accomplished more in his sleep than others did in their waking day." Building on the foundations his father had laid, he created a civil service, based eclectically on Norman, Greek, and Arabic models, that was the wonder and envy of Europe. He entrusted finance to his Arab subjects, who also supplied him with the spearhead of his army. The navy, by contrast, was predominantly Greek; its chief, known by the Arabic title emir of emirs—from which the word admiral derives—served also as head of the government, ranking second after the king himself.

Roger's navy

It was on this navy above all that Sicily's security and prosperity depended, and Roger's use of it was not overscrupulous. Under the greatest of its admirals, George of Antioch, it subdued much of what is now Tunisia to form a profitable, if short-lived, North African empire; it captured Corfu; it harassed the Greek coast, abducting the best of the Theban silk workers to found the court workshop at Palermo; and in 1149 it sailed up the Bosporus to fire a few impudent arrows into the gardens of the imperial palace. Significantly, however, it played no part in the Second Crusade of 1147. Roger had hated the Frankish rulers of Jerusalem ever since his mother's disastrous remamage to King Baldwin I of Jerusalem 34 years earlier. Besides, most of his Sicilian subjects were Muslims, and toleration was the cornerstone of his kingdom.

This policy even showed itself in his church buildings. Roger's first great building, the cathedral at Cefalu, shows little Saracenic influence; but the Palatine Chapel in Palermo, conceived on a Latin plan and aglow with Byzantine mosaics, is topped by a stalactite roof of pure Arab workmanship. Oriental inspiration is equally evident in the five vermilion cupolas of the Church of S. Giovanni degli Eremiti, built in 1142 for the Benedictines.

The Assizes of Ariano

After the pacification of South Italy, the King promulgated in 1140 at the so-called Assizes of Ariano a corpus of law covering every aspect of his rule. He then returned to Palermo, which he seldom left again. There he spent his last 15 years in the most intellectual court of Europe, surrounded by the leading thinkers of the time. Sicily was already the only land where scholars could study both Greek and Arabic—then the scientific language par *excellence.* Through Roger's enthusiasm, Sicily became a cultural clearinghouse where, for the first time, Western and Oriental scholars could meet on an equal footing.

Roger II was mamed three times. He outlived his first wife, Elvira, daughter of Alfonso VI of Castile, and his second, Sibyl of Burgundy. His third wife, Beatrice of Rethel, whom he mamed in his last year, bore him a daughter, Constance, after his death. Constance married the future emperor Henry VI, bringing Sicily under the control of the Hohenstaufens. Roger died, aged 58, on February 26, 1154, and was succeeded by his fourth but oldest surviving son, William. Despite his repeatedly expressed wish to rest in Cefalu, the King was buried in the cathedral at Palermo, having created, in a Europe rent by schism and exhausted by the Crusades, not just a kingdom but a political and religious climate in which all races, creeds, and cultures were equally encouraged and equally favoured.

BIBLIOGRAPHY. A full biography of Roger II in English is JOHN JULIUS NORWICH, *The Normans in the South* (U.S. title, *The Other Conquest,* 1967), which takes the story of the Norman conquest of South Italy and Sicily up to Roger's coronation in 1130; and its sequel, *The Kingdom in the Sun 1130–1194* (1970). Both volumes contain comprehensive bibliographies. E. CURTIS, *Roger of Sicily and the Normans in Lower Italy, 1106–1154* (1912), is inaccurate in several important respects. See also F. CHALANWN, *Histoire de la Domination normande en Italie et en Sicile,* 2 vol. (1907, reprinted 1960); and E.L.E. CASPAR, *Roger II. (1101–1154) und die Gründung der normannisch-sicilischen Monarchie* (1904).

Roman Catholicism

Roman Catholicism, a Christian church characterized by its uniform, highly developed doctrinal and organizational structure, traces its history to the college of Apostles in the 1st century AD. As with Eastern Orthodoxy and Protestantism, it is a major branch of Christianity.

This article is divided into the following sections:

VI. Practices
Missions, education, and eleemosynary activities
Sociopolitical views and practices
VII. Roman Catholicism following the second Vatican Council

Other articles that deal with the nature and history of Roman Catholicism are CHRISTIANITY; CHRISTIANITY BEFORE THE SCHISM OF 1054; ROMAN CATHOLICISM, HISTORY OF; EASTERN CHRISTIANITY, INDEPENDENT CHURCHES OF; PROTESTANTISM, HISTORY OF; EASTERN RITE CHURCHES; PAPACY; PROTESTANTISM; EASTERN ORTHODOXY; and ECUMENISM.

I. Nature and significance

The name Roman Catholicism designates that Christian church that has the largest number of communicants and the oldest single identity. "Catholicism" is from the Greek word *katholikos,* meaning "universal," and can be traced to the early period of Christianity, when there was only one Christian church. This early unity concealed various diversities that led to ecclesiastical schisms from the 4th century on, but the largest church retained the designation *katholikos.* Although the word Roman appears to make the name self-contradictory, Roman Catholics believe that this contradiction is only apparent and not real; they continue the identification of the *katholikē* with the church that acknowledges the primacy of the bishop of Rome, the pope.

HISTORICAL AND CULTURAL IMPORTANCE

Influence on the development of Europe

Roman Catholicism has been one of the major factors in the historical and cultural development of western Europe and in the extension of European culture to other continents beginning in the 15th century. This statement is quite independent of any evaluation of the influence of Roman Catholicism, an evaluation that has long been hotly disputed between apologists of Roman Catholicism and its critics and that has to be a mixed judgment if it is to be at all fair. The effects of Roman Catholicism, not always evident on the surface in modern times, can be seen in the political theory and structure of Europe, the mind-set of European thought (as opposed to Muslim, Indian, and Chinese, for example), European education, the Roman Catholic patronage of literature and the arts, and the very theory of the universality of European culture. For many historians, the worldwide expansion of European culture as the one culture for all is a secular reflection of the Roman Catholic belief in one church for all.

On the other hand, Roman Catholicism has received—and taken—very little from any other history and culture. Its Romanism has in modern times taken away something from its Europeanism; but it is the single most "European" religious and cultural phenomenon in the world today, even if much of its Europeanism is archaic. The history of Roman Catholicism since the colonial expansion of Europe has been normally a refusal to adapt itself to new cultures, which were evaluated by the churchmen at much the same level as pagan religions.

Although the Roman Catholic Church by its original documents and traditions is not a political body or agent, in fact it has been deeply involved in the politics of Europe. When the Papal States existed (754–1870), these were as genuinely political as the kingdoms of France and Spain. Theoretically, this should not have involved the Roman Catholic Church, for, even though it was the church of all Europe for most of this period, its members were not subject to the sovereignty of the Roman pontiff as head of the Papal States. Practically, however, the popes were unable to draw a real distinction between their spiritual sovereignty and their temporal sovereignty, and without scruple, it often seemed, they used the Papal States to support the authority of the church or—more frequently—the church to support the power of the Papal States. Many of the manoeuvres can now be seen to have been abuses of power, and many churchmen saw them as abuses of power when they happened.

This has meant that the structure of Roman Catholic power over the centuries took on the features of the political sovereignty normal in the Middle Ages and in early modern times. It also meant that the political sovereignties of Europe assumed some of the features of the spiritual authority of the church. The divine right of kings is the most obvious example of this; it survives to this day in the idea of absolute sovereignty of the nation, which is accountable neither to God nor its citizens nor another nation.

CHARACTERISTICS AND MEMBERSHIP FIGURES

Centralization and uniformity

Among the Christian churches Roman Catholicism has been characterized by its rigorously centralized structure; its uniformity of doctrine; its uniformity of ritual; its dependence on tradition and precedent, indeed a tendency to create or to fortify tradition when there is a weak connection between existing belief or practice and the past; a complex gradation of hierarchy and clergy; and a clear division between clerics and laymen. These characteristics are truly Roman, both in the sense that they developed within the genius of the historic Roman Catholic Church and were not borrowed from other religious bodies and also in the sense that they distinguish the Roman Catholic Church from other Christian churches. It is, for example, opposed to the Eastern Orthodox churches in its centralization (and its understanding and use) of authority, its uniformity of doctrine and ritual, and its esteem of tradition and precedent. The Orthodox and Protestant churches find Rome rigid and authoritarian; Rome finds these churches too loosely structured and vacillating.

Exact figures for the number of Roman Catholics in the world are not available. Estimates of 1980 are listed in the table.

Roman Catholic Populations	
Europe	251,256,000
United States, Canada	78,647,000
Latin America	328,896,000
Asia, Australia, Oceania	73,569,000
Africa	76,789,000
World total	809,157,000

These figures show that the strength of the Roman Catholic Church lies in Europe; being merely for continents, they do not show that the church's strength outside Europe lies in those countries that are most Europeanized, especially in the Americas. Roman Catholicism was not strong in Russia under the tsars, and it has lost no ground under Soviet Socialism. Its success in the "missionary continents" of Asia, Africa, and the Americas results largely from the fact that the earliest colonization of these continents was carried on by the Catholic powers: Spain, Portugal, and France. It must also be said in all candour that Roman Catholicism traditionally exhibited a missionary zeal that the Protestant churches had to learn from the Roman Church.

II. History

THE EARLY CHURCH (TO AD 313)

Roman Catholicism claims continuity with the church of the New Testament. What church historians call "early Catholicism" appears in some of the later books of the New Testament; these include the Pastoral Letters (I and II Timothy and Titus) and the letters of Peter. Early Catholicism means the first appearance of characteristic church structures and a normative scheme of belief. The major elements of what appeared later as Catholic structure and Catholic belief cannot be clearly perceived before the 2nd century. Historical sources up to AD 200 are not extensive. The Christian Church of the early period was an underground movement, whatever its numbers may have been, in the sense that by far the majority of its membership was drawn from the lower classes, including slaves. It attracted very few of the ruling classes, the wealthy, or the intellectuals. The government of the Roman Empire tolerated Christianity more frequently than not, although it did not have legal standing (such as Judaism possessed). The traditional "persecutions" of the Christians were isolated local incidents, except for the persecutions by the emperors Decius, Valerian, and Diocletian in the 3rd century. It appears that the numbers of Christians had by this time grown sufficiently to alarm the government, and these three emperors and their officers seemed to recognize that Christianity would destroy the Roman Empire if it destroyed paganism. They were correct in their evaluation of the Christian ethos, but they did not foresee that Christianity would reach a compromise with the empire, that it would become "Roman."

During this period the collection of the New Testament was formed. Theological literature made its appearance in the apologists, who intended to present Christianity as a belief acceptable within the Roman policy and society, and in the writings of the first theologians, most of whom were bishops; these writings were elicited by doctrinal controversies. Doctrine became sufficiently stabilized for a canon of belief to arise that was accepted throughout the entire Christian world; communications between the churches of different regions were remarkably close and frequent. Questions of doctrine and discipline were often dealt with by meetings of the bishops of a particular region. The most important theological event of the period was the establishment of the school of Alexandria, illuminated by Clement and Origen, which initiated a celebrated school of Platonists.

THE MIDDLE AGES (313–1517)

Christianity as the state religion

The Edict of Milan, a cluster of documents issued by Constantine the Great in 313, made Christianity a lawful religion; by the end of the 4th century it had become the state religion. Historians call the church of this period the Constantinian church, designating the privileged position of the church within the state. This position is characteristic of the entire Middle Ages. It did not mean that there were no quarrels between church and state; the privileged position appears in the fact that the church could contend with the state on equal terms and sometimes win the conflict.

During this period Roman Catholicism developed the hierarchical structure that endured largely unchallenged until the Reformation. The fall of the Roman Empire and the barbarian conquests meant that the Roman Church was the cultural link between the old and the new; and the Europe that arose out of the barbarian conquests was a community identified with Roman Catholicism. This identity was sharpened by the Muslim conquests after the 7th century, which forced Christian Europe to affirm its identity against the Muslim peril; and it was sharpened further by the schism of the Greek churches, which became permanent in 1054. By the 10th century the religious and cultural community that is called Christendom had come into being. In every European state the religion of the state was Roman Catholicism. Christendom fought back against Islām in the Crusades, which failed to repossess the lost territories but strengthened the unity of Christendom and rendered it conscious of its power.

The Middle Ages saw the rise of the universities and of a "Catholic" learning, sparked, oddly enough, by the transmission of Aristotle through Arab scholars. Scholasticism, the highly formalized philosophical and theological systems developed by the medieval masters, dominated Roman Catholic thought into the 20th century and contributed to the formation of the European mind-set. With the rise of the universities, the threefold level of the ruling classes of Christendom was established: *imperium* (political authority), *sacerdotium* (ecclesiastical authority), and ***studium*** (intellectual authority). The principle that each of these three was independent of the other two within its sphere of authority had enduring consequences in Europe.

Rise of monasticism

The same period saw the growth of monasticism. One may see in this withdrawal from the world a response to the essential conflict between Christianity and Roman civilization; those who refused to accept the prevailing compromise between the religious and secular spheres could find no place in the world of the early Middle Ages. Perhaps the most remarkable feature of monasticism was that this withdrawal did not take the form of heresy or schism. Monasticism found a way of refusing the compromise without departing from the church that had made the compromise.

The early Middle Ages, especially from the 4th to the 7th century, were the ages of the great ecumenical, or general, councils. It was no doubt the new "Roman" character of the Constantinian church that led Christians to look for an expression of the voice of the whole church, the *katholikē*, that would be the voice of the whole world, the *oikoumenē*, just as the emperor was the voice of secular authority for the whole world.

This period also revealed the possibilities of corruption within the Roman Catholic Church. The moral collapse of the papacy in the 10th and 15th centuries, a similar collapse of much of the episcopacy during the 13th to the 16th century, and even the collapse of religious orders during the 15th century demonstrated the effects of the compromise between the church and the world. By seeking wealth and power the church lost much of its moral authority to proclaim even a diluted version of the gospel. This, more than anything else, led to the religious revolution that concluded the Middle Ages of the Roman Catholic Church and initiated modern times.

THE REFORMATION TO THE FIRST VATICAN COUNCIL (1517–1870)

The Protestant Reformation is conventionally dated from Martin Luther's publishing of his Ninety-five Theses in Wittenberg on October 31, 1517. By the time Luther died in 1546, much of Europe had renounced allegiance to the Roman pontiff; France had been internally rent by religious strife; and the seeds had been planted that came to maturity in the horrible religious struggle of the Thirty Years' War (1618–48). The Reformation must still be viewed as the greatest revolution within the Christian world community. It attacked just those institutions of Christendom that have been mentioned as established during the Middle Ages and destroyed or profoundly altered them, even in countries that remained Roman Catholic. Although there were doctrinal issues that separated Rome and the Reformers, these differences became greatly exaggerated. More importantly, there was no longer a unified Christendom, and Europe was no longer identified with the Roman Catholic Church. The political power of the papacy shrank to minimal dimensions with the loss of religious power. Moreover, the Roman Catholic Church lost its cultural leadership: the new learning—in particular, the beginnings of modern science—proceeded largely without the blessing of the Roman Catholic Church. The educational system of Europe was often Protestantized or secularized. The old Catholic world view gave way before new systems in philosophy and science. The rise of the nation states was both helped by Protestantism and a help to Protestantism; the result was a theory and practice of politics that was secular in the sense that religion, and in particular the Roman Catholic Church, was a negligible factor.

The Council of Trent

The Roman Catholic Church rallied to meet what appeared to some observers to be a fatal threat by the movement called the Counter-Reformation, which took form in the Council of Trent (1545–63). The council set firm lines of doctrine against Reformed theology and took firm action against the more notable forms of moral corruption that had lent credibility to the charges of the Reformers. It closed the ranks of discipline by centralizing more responsibility in the papacy. Unfortunately, the Council of Trent occurred during a period of deep and rapid change. It responded to this change by doing the best it could to crystallize the past; and, although there is no doubt that it was the major factor in preserving Roman Catholicism from disintegration, it did this by making the Catholic Church almost impervious to change in the centuries that followed.

Although the Roman Catholic Church lost many members in Europe during the 16th century, the discoveries of new lands, mostly under the leadership of stoutly Catholic Spain and Portugal, gave the church new members to offset these losses; and Roman Catholicism became a force in colonialism. The 17th and 18th centuries, however, were a period of decline in Roman Catholicism in almost every area of activity. In spite of this growing archaism, the Roman Catholic Church survived the French Revolution, which again many observers thought would be its death blow. But survival is the best word; the 19th century was another period of decline, one in which the church adopted a firm position against almost every intellectual, social, and political development that is called modern. Pius IX, whose long pontificate (1846–78) enabled him to dominate Roman Catholicism during the 19th century, saw the strength of the Roman Catholic Church in the supremacy of the Roman pontiff. In line with the Pope's view, the first Vatican Council (1869–70) defined both the primacy and the infallibility (assurance against error when teaching the whole church on matters of faith or morals) of the Roman pontiff only three months before Victor Emmanuel II destroyed the Papal States and rendered the papacy politically impotent.

FROM THE FIRST VATICAN COUNCIL TO THE PRESENT

The 100 years following the first Vatican Council was a period of frequent attacks on the Roman Catholic Church by anticlerical governments in Europe, which attempted to reduce Roman Catholicism to utter impotence. The losses in Europe were balanced by the fantastic growth of Roman Catholicism in the United States (the result of European immigration), and North America became the most prosperous area of the Catholic Church. Much of the first half of the 20th century witnessed the struggles of Roman Catholicism against Fascism in Italy and National Socialism in Germany and the adoption of a firm position against Communism, based not so much on the Socialism of Communism as on its explicit atheism. Within the church the struggle against Modernist theology seemed to be ended with its condemnation by Pius X (1907). In fact, the Modernist attempt to update Roman Catholic theological thought did not end and reached fruition in the sessions of the second Vatican Council (1962–65). This council reversed the Council of Trent to the extent that it abandoned the attempt to crystallize the past; but in opening Roman Catholicism to the present the council created much uncertainty among Roman Catholic communicants. In the early 1970s it was.asserted by many that the second Vatican Council had initiated a revolution within Roman Catholicism perhaps as profound as the Protestant Reformation, yet without the same shattering effect.

The second Vatican Council

III. Nature and structure of the church in Roman Catholic teaching

DOCTRINAL BASIS OF THE CHURCH STRUCTURE

The nature of the church. In 1965 M.-J. le Guillou, a Roman Catholic theologian, defined the church in these terms: "The Church is recognized as a society of fellowship with God, the sacrament of salvation, the people of God established as the body of Christ and the temple of the Holy Spirit." The progress of Roman Catholic theology can be seen in the contrast between this statement and the definition still current as late as 1960, substantially the definition formulated by Robert Bellarmine, a Jesuit controversialist, in 1621: "the society of Christian believers united in the profession of the one Christian faith and the participation in the one sacramental system under the government of the Roman Pontiff." The older definition, created in response to the Protestant claims, defines the church in external and juridical terms. The more recent definition is an attempt to describe the church in terms of its inner and spiritual reality.

From the earliest heresies, the church has thought of itself as the one and only worshipping group that traced itself back to the group established by Jesus Christ. Those who withdrew from this group were religiously no different from those who had never belonged to it. The ancient adage, "There is no salvation outside the church," was understood as applying to membership in this group. When this adage was combined with the notions contained in Bellarmine's definition of the church, lines were clearly drawn. These lines were maintained in the breakup of Western Christendom in the Reformation.

NC Photos/KNA

There were, however, other factors determining the idea of the one true church. The Roman Catholic Church had never excluded the Orthodox Church, which had seceded from the Roman Church in 1054, from the community of Christian believers. Furthermore, the juridical definition of the church did not include such traditional themes as the communion of the saints and the body of Christ. Both of these themes look beyond the visible, juridically constituted church. The communion of saints views the church as a whole that includes both the living (the church militant) and the dead (the church suffering in purgatory—a state for those who must be cleansed from lesser sins—and the church triumphant in heaven). The idea of "communion" appears in early church literature to indicate the mutual recognition of union in the one church and the notion of mutual services.

The mystical body of Christ

The theme of the body of Christ appears in the letters of Paul (Rom. 12; I Cor. 12; Eph. 4 and 5; Col. 1). In modern Roman Catholic theology the term mystical has been added to "body," doubtless with the intention of distinguishing the church as body from the juridical society. Pius XII, in the encyclical *Mystici Corporis* (1943; "The Mystical Body"), identified the mystical body with the Roman Catholic Church. Most Roman Catholic theologians and the second Vatican Council have taken a less rigorous view, trying to find some way of affirming membership in the body for those who are not members of the Roman Catholic Church. The documents of the council described the church as the "People of God" and as a "Pilgrim Church," but no generally accepted statement of membership in this church has yet emerged. The second Vatican Council also departed from established Roman Catholic theology since the Reformation by using the word church in connection with the Protestant churches. This use has caused some confusion, but the trend is now rather to think of one church divided than of one true church and other false churches.

Apostolic succession. The claim of the Roman Catholic Church to be the one legitimate continuation of the community established by Jesus Christ is based on apostolic succession. This does not mean that there are apostles, nor does it mean that individual Apostles transmitted some or all of their commission to others. The officers of the church, the bishops, are a college that continues the college of the Apostles, and the individual bishop is a successor of the Apostles only through his membership in the college.

The idea of apostolic succession appears in the writings of Irenaeus, a Church Father who died about 202. Against the Gnostics (dualistic sects that maintained that salvation is not from faith but from some esoteric knowledge) Irenaeus urged that the Catholic teaching was verified because a continuous succession of teachers, beginning with the Apostles, could be demonstrated. In the 3rd and 4th centuries, problems of schism within churches were resolved by appealing to the power of orders (*i.e.*, the powers a person has by reason of his ordination either as deacon, priest, or bishop) transmitted by the imposition of hands through a chain from the Apostles. Orders in turn empowered the subject to receive the power of jurisdiction (*i.e.*, the powers an ordained person has by reason of his office). In disputes between Rome and the Eastern churches, the idea of apostolic succession was centred in the Roman pontiff, the successor of Peter; it will be observed that this goes beyond the idea of collegial succession. Apostolic authority is defined as the power to teach, to administer the sacraments, and to rule the church. Apostolic succession in the Roman Catholic understanding is validated only by the recognition of the Roman pontiff; and the Roman Catholic Church understands the designation "apostolic" in the creed as referring to this threefold power under the primacy of the Roman pontiff.

Apostolic succession in other churches

The Roman Catholic Church has not entirely denied apostolic succession to non-Roman churches. Rome recognizes the validity of orders in the Orthodox churches; this means that it recognizes the sacramental power of the priesthood but does not recognize the government of these churches as legitimate. The orders of the Anglican and the Swedish Lutheran churches, on the contrary, are not recognized by Rome, and the entire threefold quality of apostolic succession is denied them. Oriental churches in union with Rome (Eastern Catholics) are recognized as in full apostolic succession. Luther and Calvin saw clearly that their position could not be maintained if apostolic succession were necessary; they therefore affirmed that apostolic succession had been lost in the Roman Church by doctrinal and moral corruption and that the true church was found only where the gospel was rightly preached and the sacraments were rightly administered. Thus, Protestant churches generally have not accepted the necessity of apostolic succession.

STRUCTURE OF THE CHURCH

The papacy. In Roman Catholic belief the Roman pontiff is the successor of Peter, upon whom Jesus conferred the primacy of the college of the Apostles. This belief is based on some rather involved biblical arguments (for details see PAPACY). There is no clear assertion of this belief before the conversion of Constantine in 312. The fullness of Roman Catholic teaching on the papacy was defined as dogma in the first Vatican Council; it was stated that the pope enjoys absolute supreme jurisdiction (meaning legislative and judicial power) within the church. He has the same absolute supreme power to declare Catholic doctrine, and he enjoys, even when he speaks alone as the head of the church, the same infallibility that the church as a whole enjoys. Most of these claims did not depart radically from the traditional teaching of the Roman Catholic Church, although many at the time thought they were excessive or that the statement was imprudent. The declaration, however, did not include a statement on the jurisdiction and teaching power of the bishops, and this meant that for almost 100 years Roman Catholicism lived with what was recognized as a one-sided statement of papal power, completed only in the second Vatican Council.

The papacy is an institution as well as a person, and the term Holy See officially includes the Roman offices (the Roman Curia) through which the pope governs the Roman Catholic Church.

The College of Cardinals. Cardinals are designated as cardinal bishops, cardinal priests, or cardinal deacons; these designations have nothing to do with the orders they possess, and since John XXIII all cardinals are ordained bishops. The cardinal bishops represent the early seven suburban sees, or dioceses, of Rome and, since 1965, the Eastern Catholic patriarchal sees. The cardinal priests and deacons represent the clergy of the diocese of Rome, and each of them is attached to a Roman church, his "titular" church.

Electors and advisers of the pope

Election of the pope has been the prerogative of the cardinal bishops since Nicholas II (1059) and of the entire College of Cardinals since Alexander III (1159–81). As the college became the electoral body, it also became the chief advisory body of the pope, and these two functions continue to the present day. In neither of these functions is the college a representative body because it has always had a majority of Italian members. Since the Reformation there have been demands for a wider representation, but these have never been fully met. The number of cardinals was set by Sixtus V (1586) at 70; this was not changed until John XXIII and Paul VI began increasing the number.

Cardinals are selected by the personal choice of the pope, in consultation with the cardinals in Rome at the time, in a consistory, or solemn meeting, which is secret. The pope's choice is limited somewhat by the fact that certain sees in large (or once large) cities are traditionally held by cardinals. Cardinals are either residential bishops, who live in their own sees, or resident members of the Roman Curia, who form the highest rank of papal advisers and officers of the Curia. Insofar as they are the personal staff of the pope, it is no more than proper that he should select them. Insofar as they are representatives of the whole church and electors of the pope, this method is not apt. The Roman Catholic Church is aware of this problem but seems unable to depart enough from its traditions to solve it. One solution that has been proposed is not to find a different way of selecting cardinals but to divorce the staff from the electors and representatives.

The college of bishops. It has been noted that in Roman Catholicism the college of bishops is the successor to the college of the Apostles. This is said in spite of certain differences between the two offices. The Apostles in the New Testament were a college (except for Paul, not one of the Twelve); the bishops are individual officers, and their collegial function has not been operative in recent centuries. The Apostles had a power that was not defined locally; every Roman Catholic bishop is a bishop of a place, either a proper area, a jurisdiction, of which he is the ordinary (as he is called in church law), or a fictitious place, a see no longer existing, of which he is named titular bishop. Such a monarchical officer does not appear in the New Testament. Nevertheless, Ignatius of Antioch, whose letters (written about 107) provide an early description of the Christian community, was clearly a monarchical bishop, and he did not think himself the only one of his kind; thus, the institution must have arisen in apostolic or early post-apostolic times.

Monarchical officers

The bishops in Roman Catholic belief succeed to the apostolic power, which is understood as the power to teach Catholic doctrine, to sanctify the church through the administration of the sacraments, and to govern the church. The residential bishop is supreme in his territory in this threefold function, having no superior other than the Roman pontiff. An archbishop governs a metropolitan see, usually the largest or oldest see in a region of several dioceses called a province. The metropolitan archbishop convokes and presides at provincial synods, or meetings, and has certain rights of visitation; but he has no jurisdiction in the suffragan, or subordinate, sees. The power of the bishop in governing is only over his own diocese; even there, however, it is not absolute, because church law provides the bishop with certain advisory bodies.

Until the second Vatican Council, the Roman Catholic Church had not dealt with the ambiguity of two concurrent jurisdictions, pontifical and episcopal. The pope cannot define or limit the powers of a bishop; the powers are "ordinary," inhering in the office itself. The second Vatican Council accepted the emphasis that recent theologians have laid on the collegial character of episcopacy, and the supremacy of the pope is understood as supremacy in the college; the pope needs the college of which he is head, although the first Vatican Council declared that he needs neither its consultation nor its approval. It is now understood that such solitary action should be the emergency rather than the rule; and the synod of bishops, established after the second Vatican Council, was a step toward involving the body of bishops in the policy of the entire church, hitherto formulated exclusively by the Roman see.

The qualifications for a bishop as defined in church law, which is known as canon law, are so general as to suit candidates for any office in the church, major or minor. Because bishops have been chosen by the pope since the 11th century, the qualifications are not made public and depend on a number of factors that are difficult to assess. In modern practice most bishops have been career administrators in the church, rarely pastors or scholars. Election is a much older tradition, and there have been many calls for a restoration of election of bishops, but, because the selection of bishops is a basis of Rome's power over the whole Catholic Church, Rome has been generally unsympathetic to these calls.

Modern duties of a bishop

Bishops in modern times are more visible as managers of the business of the diocese than as pastors and teachers. The responsibilities of the office are great and demand leadership and the ability to delegate business to a competent staff. A common criticism from certain quarters within the Catholic Church in the mid-20th century was that the episcopacy has been conceived more in terms of power than in terms of leadership. One of the reasons that episcopal conferences of nations and regions were set up following the second Vatican Council was to promote leadership by giving bishops the strength that lies in community. No authentic "Catholic" activity is conducted in a diocese without at least the tacit approval of the bishop; his disposal of funds and persons makes it evident that the activity will flourish much more vigorously if it enjoys his active support and encouragement. His power to discourage or forbid activities, which he is free to use according to his own sole judgment, is both a strength and a weakness of the Roman Catholic structure.

The bishop is assisted in governing the diocese by a staff called, like the staff of the pope, a curia. The structure of the staff is to some extent determined by canon law—*e.g.*, vicar general, chancellor, and official, or head, of the diocesan tribunals. Otherwise, the bishop at his discretion may appoint a staff according to the needs of the diocese. In modern times a great amount of diocesan business has settled upon the bishop. This has become a constant strain on the structure of the Roman Catholic episcopacy, and it cannot be a strength when so much of the time of the supreme officer must be consumed by purely routine business.

The power of the bishop over his clergy has been absolute, with almost no effective restraint except the human kindness of the bishop. This appeared to be changing, following the second Vatican Council, with the institution of senates of priests. The council strongly recommended that bishops introduce priests into the decisions of the diocese, but this was left to the discretion of the bishop.

Ecumenical councils. Regional councils of bishops to settle doctrinal and disciplinary questions appeared in the 2nd century. The first general council representing the bishops of the whole world (the Greek *oikumenē* referred to the inhabited world) occurred at Nicaea in Asia Minor in 325. The council was convoked not by an ecclesiastical authority but by Constantine, who wished to have a final decision on the Arian controversy. (According to Arius, the Son of God was a creature of like but not the same substance as God the Father.) The representatives of Constantine's bishop, the bishop of Rome, presided over the council. The Roman Catholic Church has held 21 such assemblies. The chronological distribution of the last three (Trent, 1545–63; first Vatican, 1869–70; second Vatican, 1962–65) shows that in modern times the ecumenical council has been convened less frequently.

The settling of doctrinal and disciplinary questions

Canon law defines an ecumenical council and its procedure; actually, the law represents the procedure followed in the convocation of the first Vatican Council. There is no real criterion for an ecumenical council, and one can say only that those councils are ecumenical that the Roman Catholic Church regards as ecumenical. The Orthodox churches recognize the first eight only.

The ecumenical council is recognized by the Roman Catholic Church as the supreme authority. With the pope this makes two supreme authorities; the Roman Church reconciles this logical dilemma by asserting that the ecumenical council, acting with the pope, is supreme. Only the pope can convoke an ecumenical council, and he or his legates must preside. There are no limits to the competence of an ecumenical council, but its decrees must be approved by the pope for validity.

The scandals of the Great Western Schism (1378–1417), which at its worst saw three men claiming the papacy, and the corruption of the papal court during the 15th century led to the movement of "conciliarism," according to which the ecumenical council was the means of saving the church from scandal and corruption. Much of the policy of the Roman see since that time has been devoted to the suppression of any feeling like conciliarism. This has naturally led to questions about the value of ecumenical councils, which are cumbersome and expensive, when an omnicompetent office such as the papacy is prepared to handle the business of the Roman Catholic Church. Both the first and second Vatican councils illustrated the values of the ecumenical council. Apart from the public and psychological impact produced by a consensus so broad, the council not only makes available for the church a fund of worldwide wisdom and experience not available to the Roman Curia but also seems to generate a state of mind that raises the members of the council above their normal level of thought and action.

The priesthood. The title of priest (Greek *hiereus*) is given to no church officer in the New Testament. Nevertheless, the office appears in the 2nd century, no doubt with the development of the monarchical episcopate; the bishop needed assistance in his threefold task of teaching, sanctifying, and governing, and the priest exercises this power as an officer of the bishop. A priest is either a member of a diocese or of a religious community; but in the exercise of the threefold ministry every priest is subject to the bishop of the diocese where the ministry is conducted.

Assistant to the bishop and cultic officer
