American methods had as yet made little impact, but after about 1880 their influence became more noticeable. The evening *Star,* launched in 1888 at a halfpenny under T.P. O'Connor, aimed at a wider public, with bold display, short, lively items, and good racing tips; and another evening paper; the distinguished *Pall Mall Gazette,* adopted American tactics for some of its crusades. Popular journalism in Britain really begins in 1896. however. with the *Daily Mail,* founded by Alfred Harmsworth, later Lord Northcliffe. Harmsworth came into journalism through cheap magazines, which showed him the potential size of the new market and how to exploit it. In 1895, he bought the *Evening News* and by adopting a formula of short, snappy paragraphs quadrupled its circulation within months The *Daily Mail,* designed on the same pattern, was even mole successful; its circulation soon rose to 500,000 and to 1,000,000 at the time of the Boer War (1899–1902). It called itself "A Penny Paper for One Halfpenny" and "The Busy Man's Daily Journal." All its numerous features were broken down to conform to Harmsworth's cardinal precept: "Explain, simplify, clarify." Thus with Narmsworth, the new journalism could be said to have arrived in Britain but in muted form. The *Mail* was not so sensational as its American counterparts; it had no social conscience for crusades, and its public was not the real mass of the people but the aspiring lower middle class, whom it sought to inform quickly and painlessly Commercially, the *Daily Mail* was a portent, for it was the first British paper to be based deliberately on advertising. It cost mole than a halfpenny to produce, but by publishing net sales certificates (the first to do so), it gave advertisers concrete evidence of their possible market and enabled 'the management to charge accordingly—and to make handsome profits for

Popular journalism in Britain

its shareholders. The net sales certificate was a statement of sales based upon the number of copies printed less free and unsold copies as certified by a chartered accountant or professional auditor.

Developments in Europe. Between 1850 and 1900 the rest of Europe also moved toward journalistic independence and a popular press, though by no means uniformly. The continental press as a whole was inclined to remain more solidly middle class in its orientation and to favour the journal of opinion rather than that of information. Important papers founded were ***Le Figaro*** (1854, weekly; 1866, daily) and ***Le Temps*** (1861) in France; the ***Frankfurter Zeitung*** (1856) in Germany; and the ***Corriere della Sera*** (1876) in Italy, all of which marked progress toward modern concepts in journalism, made possible by improved political conditions. The popular press in France may be said to begin with La ***Petite Presse*** and ***Le Petit Journal,*** which had a circulation of 650,000 in 1878, based on a lively approach and an attacking style. Between 1880 and 1900 the number of newspapers in France almost doubled (to 2,400), with several strong provincial journals. Other European papers in a more popular vein were ***Aftenposten*** (1873), in Denmark, and ***Le Peuple,*** in Belgium.

In Spain and Portugal, censorship continued to prevent the development of valid journalistic independence; any periods of comparative freedom would be quickly followed by the reimposition of controls. In Russia, too, censorship remained in force. Alexander II allowed many new papers to be started between 1855 and 1865 but soon brought them under control when radical ideas began to be voiced; as a result, they became predominantly literary in tone. Outside the country, however, revolutionary Russian journals were published in a number of cities, notably ***Kolokol*** ("The Bell"), founded in London in 1857 by Aleksandr Herzen, first as a monthly, then as a fortnightly. These are regarded today as the forerunners of the modem Soviet press.

Newspapers in Russia

Japan. Japanese historians differ as to the first modern Japanese newspaper published by a Japanese. Some choose the ***Batabia shimbun*** (January 1862), 23 volumes of translated abstracts from the ***Javansche Courant,*** a Dutch government organ in Batavia (Djakarta), published by the shogunate "Office for Reviewing Barbarian Papers." This office subsequently published translations of newspapers from the China port cities, Hong Kong, and the United States. The status of these official publications as newspapers is questioned because of their lack of periodicity.

The claim of the ***Kaigai shimbun*** (1865–66; "Overseas Press"), published monthly for about a year, to be the first Japanese newspaper is also questioned because its publisher Joseph Heko, although native-born, had become a naturalized U.S. citizen (he was then an interpreter at the United States embassy).

During 1867–68, when the shogunate collapsed and the Meiji restoration was consolidated, more than a dozen newspapers were started by shogunate sympathizers. Among them was the ***Chugai shimbun,*** published by a group' of Japanese linguistic scholars who had worked on the ***Batabia shimbun.*** Another was the ***Koko shimbun,*** whose publisher, the dramatist and educator Fukuchi Genichiro, had studied Western newspapers while on government missions abroad.

The Meiji government suppressed these publications and promulgated a Newspaper Ordinance, which, in its 1871 version, established the principle that the contents of a newspaper should always be "in the interest of governing the nation." By 1876 the government had begun suspending or suppressing newspapers that displeased it and arresting their staffs. Many of the early Meiji newspapers consequently tended to be closely tied to the political world.

The first Japanese daily

The first Japanese daily newspaper was the ***Yokohama Mainichi shimbun*** (1870); it was among the first to use lead type. Some Japanese historians, however, regard the ***Tokyo Nichi-Nichi shimbun*** (1872), the first daily in the new capital, as being the first truly modem Japanese newspaper. The one-time publisher of the ***Koko shimbun,*** Fukuchi, became its president in 1874 and introduced an editorial column modelled on Western newspapers. The ***Nichi-Nichi,*** however, regarded itself as virtually an official gazette.

Two giants of contemporary Japanese journalism, the ***Asahi shimbun*** and ***Mainichi shimbun,*** were founded in the commercial centre of Osaka and placed more emphasis on general reporting than on political affairs. Murayama Ryuhei, scion of a warrior family who was invited to become president of ***Asahi,*** and the industrialist Motoyama Hikochi, who developed the ***Mainichi,*** are commonly regarded as the fathers of modern Japanese journalism. The ***Asahi*** began as the ***Osaka Asahi*** in 1879; the ***Tokyo Asahi*** was founded in 1888. The ***Osaka Mainichi*** developed from a foundering newspaper venture begun as the ***Osaka Nippo*** in 1876; the name ***Mainichi*** dates from 1888 when the paper became an organ of Osaka business interests. At first an adviser to the venture, Motoyama became president in 1903. In 1906, he added the ***Tokyo Nichi-Nichi*** to his publishing empire.

The third leading national daily of contemporary Japan, the ***Yomiuri shimbun,*** was founded in Tokyo in 1874 and gained a reputation as a "literary" newspaper. In 1924, it was acquired by a former police official, Shōriki Matsutaro, who added such innovations as entertainment sections, colour comics, and Hearst-style promotions.

Developments in other areas. In several other parts of the world, approaches to a modern press developed before the end of the century. Australia, whose first newspaper, ***The Sydney Gazette and New South Wales Advertiser,*** commenced publication as a weekly on March 5, 1803, went through the familiar pattern of censorship (ended 1824) and stamp tax (ended 1830) before being able to produce independent papers; but newspapers grew with the country, notable among them being the ***Sydney Morning Herald*** (1831), the Melbourne ***Argus*** (1846), ***The Age*** (1854), and the more popular ***Sydney Daily Telegraph.*** In South Africa, too, a fight had to be waged for press freedom by the editor of the country's first paper, the ***South African Commercial Advertiser,*** who secured *a* new Press Law in 1828. Later papers, such as the ***Cape Argus*** (1857), were tied to commercial and mining interests; but they gradually acquired some independence through the necessities of their existence.

The Australian press

The first issue of New Zealand's earliest newspaper, the ***New Zealand Gazette,*** was printed in London in 1839 before emigrants left for the island. The second issue did not come out until April 18, 1840, but was printed in Port Nicholson (now Wellington). Two months later, the ***New Zealand Advertiser*** appeared in the Bay of Islands. The oldest newspaper still publishing is the ***Taranaki Herald,*** which began in 1852; more than 20 New Zealand newspapers had celebrated centennials by the early 1970s.

Canada had its first newspapers, French and English, in the 18th century, and these developed regionally as had occurred in the U.S., though on a smaller scale, in Quebec, Montreal, and Toronto. A leader in journalistic standards was the ***Winnipeg Free Press*** (1872). In India, newsletters circulated as early as the 16th century. Under British rule, both English- and vernacular-language newspapers were begun, though the latter were subject to control and suppression. The ***Bombay Times*** (1838, later the ***Times of India)*** is usually considered the chief paper in English, while ***The Hindu*** (1878) was important for the growing national consciousness of Indians. In Argentina, finally, one of the world's greatest newspapers, La ***Prensa,*** was founded in 1869 by Dr. José C. Paz, whose descendants still own and edit it. With the watchwords, "Truth, Honour, Liberty, Progress, Civilization," it has long upheld the highest standards of journalistic independence.

The significance of the 19th-century independent newspaper was, of course, enormous. It provided a great sounding board through which political and social ideas could crystallize and become effective; its advertisements and steady supply of information oiled the wheels of commerce; and at the most popular level it became a medium of education and entertainment in a thousand and one ways. Reference has been made to the political influence of ***The Times*** in Britain and to the muckraking crusades of many American newspapers. In Britain muckraking was inclined to be more sober but nonetheless effective. As an example, one might cite the series of articles "The Maiden Tribute to Modern Babylon" by W.T. Stead in the ***Pall Mall Gazette.*** In these Stead exposed the London trade in young girls by himself procuring one and serving a term in jail. The result was a change in the law, the passing of the Criminal Law Amendment Act (1885). On occasion the press has been at the very centre of national events. Such a case was the Dreyfus Affair in France, in which Émile Zola's famous letter '*J'accuse,'* published in Georges Clemenceau's *L'Aurore* (January 1898), laid bare the political realities in such a way that they demanded debate by the whole nation. Zola was convicted of libel and fled the country. Finally, nothing better illustrates the power of the press, the misuse of that power, and its ultimate limitations than the notorious case of William Randolph Hearst and the Spanish-American War over Cuba in 1898. For months before America declared war, Hearst's ***New York Journal*** stirred the country to a high pitch of hysteria with exaggerations and even complete fabrications. Hearst is reported to have cabled his artist in Cuba, who found no atrocities to illustrate, "Please remain. You furnish the pictures and I'll furnish the war." Yet this he was, in fact, unable to do until events themselves brought it about, especially the blowing up of the American battleship "Maine" in the harbour of Havana with great loss of life. Hearst nevertheless claimed "credit" for the war in a banner headline: "How Do You Like the ***Journal's*** war." It was quite clear by the end of the century that for good and ill the Fourth Estate had arrived.

Hearst and the Spanish-American War

THE PRESS IN THE 20TH CENTURY

Since 1900 the number of newspapers in the world has risen rapidly, and every conceivable stage of press development and type of journal can be found in one country or another, from state-controlled propaganda organs on the one hand to a more or less free press on the other and from small sheets in areas of low literacy to the huge newspapers of a large industrial society. The methods and problems of producing a paper have become correspondingly diverse. Where the methods are most advanced, in the United States, Britain, western Europe, and Japan, the press has become big business and its problems largely financial, centring on advertising revenue and the struggle for circulation.

Technical developments. Technical development has continued to refine and speed the process of production, from the gathering of the news to the printing of the paper. The rotary presses turn even faster, thanks to mechanical improvements, quick-drying inks, and such devices as automatic ink-pumping (1915) and a system of reel joining to provide a continuous flow of paper. High speeds mean, of course, that larger editions can be rushed through the machine rooms in shorter time, and thus copies printed as late as 4:00 AM can still reach breakfast tables many miles away. The city (early) edition of the ***New York Times,*** published in Manhattan, could, until the establishment of a regionally printed national edition in 1980, be purchased in Chicago and on the U.S. West Coast, 3,000 miles (5,000 kilometres) away, on the day of publication.

Economic aspects. ***Labour.*** The increased amount of money in the newspaper industry led to a sharp rise in the pay and status of the journalist, and the growing strength of printing trade unions saw to it that their members were not neglected. Higher wages for those whose skills operated typesetting machines fast and accurately, cast the curved stereoplates without fault, and manned the giant presses at midnight were only to be expected; a much more serious matter was the establishment in succeeding years of systems of restrictive practices, under which precise limits were laid down within which trade union members should work. Any form of extra cooperation or helping out of a workmate was frowned upon and could be the subject of a fine or even a strike. The practice resulted in considerable overstaffing in newspaper printing departments—*i.e.,* the employment of a much larger staff than was necessary to produce the paper efficiently; it inflated costs and was to become a major cause of the financial difficulties that many daily papers found themselves facing in the mid-century. It has been argued that restrictions that were imposed by the unions with the object of creating more jobs for their members in fact had a reverse effect owing to the economic collapse of a number of once-powerful papers in Great Britain and the United States.

Trade unions

Consolidations and chains. As financial interests moved into the press, in place of the old editor-proprietor, the trend was toward consolidations, groups, and the growth of the newspaper chain. Its earliest, but least mercenary, exponent was E.W. Scripps, who began collecting American newspapers in 1878. His main technique was to buy up small, financially insecure papers and set them on their feet by putting in capable young editors, who were given a share of the profits. He always urged them to remember that their first duty was "to serve that class of people and only that class of people from whom you cannot even hope to derive any other income than the one cent a day that they pay for your newspaper." Scripps wanted his papers to be of genuine service to their communities, and though he succeeded in making money from them, his aim was not to extract maximum profits. He did, however, utilize to the full the benefits of large ownership to enable him to buy newsprint and syndicated articles on the most favourable terms. Many of Scripps' methods were adopted by his rivals and by newspaper proprietors in other countries, as the idea of the chain spread with the more commercial approach to newspapers. In the 1920s in the United States there were some 50 chains embracing about 300 papers, which meant that anyone moving about the country was liable to encounter the same news stories and features, all drawn from the same source. William Randolph Hearst, who at one time controlled 42 papers, was among the most acquisitive of the early chain owners; but the purely commercial aspects of proprietorship were epitomized, between 1916 and 1924, by Frank A. Munsey, who bought and merged newspapers, including the New York ***Sun*** and the ***Herald,*** with "the talent of a meat packer, the morals of a money changer and the manners of an undertaker," according to the eminent U.S. editor and author William Allen White.

The Scripps papers

Changes in newspaper content. ***Minority group newspapers.*** The U.S. press had long included a large number of papers for minority groups, especially in foreign languages. The first of these, the ***Philadelphische Zeitung,*** was published by Benjamin Franklin as early as 1732, though only two issues appeared. It was soon followed by others, among them the first foreign-language daily, the ***Courrier Français*** (Philadelphia), which supported the French cause in 1794–98. With successive waves of immigration, especially from Germany in 1830–60, the number of such papers rose phenomenally, until they amounted to 10 percent of all newspapers in 1860. Two-thirds of them were in German, others being in French, Italian, Spanish, Dutch, Swedish, Norwegian, and Welsh. This publishing activity reached its peak between 1900 and 1914, with the addition of papers in many more languages; thereafter, as immigration rates fell and assimilation became more complete, it steadily declined in importance, without by any means vanishing. Another minority press, on the other hand, that of blacks, has grown enormously, especially since World War II. Its origins go back to ***Freedom's Journal*** (New York City, 1827), one of several short-lived anti-slavery papers that sprang up in the period before the Civil War. In the late 1970s, 165 black newspapers were being published, with a total circulation of almost 3,000,000.

Tabloids and their effect. A major innovation that appeared at the beginning of the century was the tabloid—*i.e.,* a newspaper characterized by half the usual page size, abundant pictures, and text correspondingly reduced and condensed. The term was coined by Alfred Harmsworth when he designed and edited an experimental issue of the ***New York World*** for New Year's Day in 1900. The United States, however, ignored the new form for a time, and the first tabloid was Harmsworth's own ***Daily Mirror***

(1903). This was originally founded, in the usual format and style, as a newspaper for "gentiewomen"; when it failed as such, it was quickly revived with the help of a new technique for reproducing photographs as a halfpenny picture paper. Its success was immediate, with circulation running at over 1,000,000 by 1914. A second British tabloid, which proved equally successful, was the *Daily Sketch.* founded by Sir Edward Hulton, in Manchester, in 1909.

The first tabloid in America was the *New York Daily News* (1919), started by Joseph Medill Patterson to a ruthless recipe of sex and sensationalism, which put it in the lead and kept it there against all comers. Its chief rivals were the *Daily Mirror* (1924), siarted by Hearst, and the *Daily Graphic* (1924), begun by Bernarr Macfadden. These three fought a veritable "war of the tabs" in New York City, with the *Graphic* perishing in 1932. The *Mirror* survived until 1963, when it was swallowed by the *Daily News*. The tabloid has long since proved its convenience and popularity acd become a widespread alternative format.

World War I and after. During World War I, the press suffered severe restriction not only through a sharp decline in the quantity and quality of newsprint in Europe but above all through censorship. In Britain, under the Defence of the Realm Act, the British Official Press Bureau was set up within a week of the outbreak of -war, and it continued to function until April 1919. Its nominal purpose was to conceal naval and military intelligence from the enemy, which was naturally accepted by the press: but for want of clear principles, it operated unevenly and was used all too often to suppress opinion and save the face of the politicians. Over the vital matter of the shell (artillery ammunition) shortage, it was boldly defied by Lord Northcliffe, now owner of *The Times* as well as of the *Daily Mail*, who thereby rendered the country a great and necessary service, illustrating afresh the true responsibility of the press. After the United States entered the war, censorship became a little more rational, with some movement toward a self-imposed code. In the United States, more than 75 papers had their mailing privileges withdrawn under the Espionage Act, and the German-language press shrank to half its former size.

Struggle for circulation. After the war, the struggle for circulation became even more intense, especially in the U.S. and Britain. It had now become a matter of life and death; for circulation determined the advertising revenue that made a newspaper financially viable.

Political columnists

In America, readers were constantly wooed with better coverage, more pictures, new features, ever larger papers. New York dailies grew to 40 or even 60 pages, while the Sunday edition of the *New York Herald-Tribune* (merged in 1924) often had 100-140 pages, divided into various sections covering different affairs. The personal impact of the old editors had long since gone, but in its place came that of the new opinion makers, the columnists—*i.e.*, men and women who wrote regular columns of views, comment. and reflection or mere social gossip. The first political columnist was David Lawrence of the *United States News* in the 1920s. Other pioneers were Frank Kent of the *Baltimore Sun* and Mark Sullivan of the *New York Herald-Tribune*. One of the best known was Walter Lippmann, who originally wrote in the New *York World*. Such columns were often syndicated in newspapers all over the country; when this occnrred, the columnist acquired a considerable national following. Syndication of material became a growing practice, either through the news agencies, the picture agencies, and the newspaper chains or through such special feature syndicates as the Newspaper Enterprise Association (NEA), which supplied ready-to-use material of all kinds, from comic strips and crossword puzzles to editorials, book reviews, and medical columns. This service enabled a small-town editor to assemble a respectable paper without a large staff: he needed reporters only for local affairs. Despite the "jazz journalism" of the 1920s, in the tabloids above all, standards of serious news coverage continued to rise, led by the *New York Times*. Such a small-circulation daily as the *Christian Science Monitor* (1908), for instance. gained a high reputation, especially for foreign affairs. A characteristic of the American press, which went back lo the previous century, was the predominance of the afternoon paper, which tended to have the largest circulation. Typical of the time was the. purchase of the New York *Morning*, *Evening*, and *Sunday World* in 1931 by the Scripps-Howard chain: the morning and Sunday editions were. killed, and the *Evening World* was merged with the *New* York *Evening Telegram*. Many such mergers were imposed by economic pressures: the trend toward fewer papers with higher circulations, both individually and collectively, was well under way.

Circulation-boosting stunts

In Britain, a new force appeared after World War I in the person of an iconoclastic Canadian, Max Aitken, created Lord Beaverbrook in 1917 for political services. At about the same time, he acquired the *Daily Express*—which had been limping along since 1900. when it was founded by Arthur Pearson—-and made it Britain's second popular daily through sheer journalistic panache. With his two other papers, the *Sunday Express* (started 1918) and the *Evening Standard* (acquired 1923), he campaigned tirelessly for Empire Free Trade but without great result, showing again the limited influence of the press when it is not in accord with the public will. Among the many circulation-boosting stunts of the 1920s was free insurance for readers, which proved so costly, however, that it had to be abandoned. Another was free gifts, started by the *Daily Herald* in 1930. Despite the condemnation of the Newspaper Proprietors' Association, gift schemes proliferated until the *Herald*, by spending most, achieved a circulation of 2,000,000, the first paper in the world to do so. In this fierce competition, there were casualties, of course; and by 1934, even the popular London tabloid the *Daily Mirror* was failing, with circulation down to 700,000. But it was rescued in striking fashion by Harry Guy Bartholomew, who gained editorial control from a divided board of managers and transformed it into a true working-class paper, the first in Britain, with a radical voice, all the most outré tricks of yellow journaiism. and a compelling strip cartoon about a young lady called Jane. He eventually raised its circulation to.over 4,000,000, the largest in the world. At the same time. Britain's first "popular" paper, the old *Daily Telegraph,* now settled down as a conservative middle class journal (owned by Lord Camrose), absorbed the *Morning Post* in 1937, and rose through solid merit from a circulation of 100,000 in 1927 to 750,000 in 1939. For all the shoddiness of much of the journalism of the 1930s, readership of the popular newspaper.; rose by 1,500,000, and the British press could be said to reflect at last the full social pyramid, including the underprivileged at its base.

Newspaper organization. As the newspaper grew in size and complexity, so too did its organization, which had now assumed its modern form and often required a vast city block or skyscraper to house it. Apart from the business side, which takes care of advertising and circulation, and the mechanical side, which includes composition (*i.e.*, typesetting and correction), engraving, stereotyping (*i.e.*, making duplicate nlates of the printing surface), and the actual printing, the editorial function itself had expanded greatly from its original simplicity. Under the editor in chief and his assistants, responsible for the editorials and overall policy, there are now usually a number of editors in charge of particular departments, such as the news editor, who assigns stories to reporters and rewrite men; the picture editor, with a staff of photographers; the features editor, responsible for the supply of pieces and columns of an entertaining or instructional nature; the sports editor, who usually has his own reporters and photographers; the society editor: the financial editor; the women's editor: the correspondence editor; and many other specialists, covering the arts and such subjects as science and education, with a thoroughness appropriate to the resources of the paper and the interests of its readers. An ever-growing volume of information flows into a newspaper office, from agencies and bureaus, from government departments and foreign embassies, from organizations and individuals of every kind. All has to be assessed, selected, checked, and amplified, if necessary, from the paper's reference library and "morgue" of past material, with a constant watch for possible libels. Finally, before the stereotypes are cast and the paper is "put to bed," each page has to be made up in characteristic style, with the blend of headlines, news, pictures, features, and advertisements that the reader has grown to expect.

Breaking the European news monopoly

News agencies. Since the Agency Treaties of 1870, to which the U.S. Associated Press acceded in 1893 (see above), the international flow of news had remained largely in European hands, dominated by Reuters. During World War I, however, the possibility of national bias became very apparent, though Reuters itself, a private profit-making company, kept a remarkable degree of independence. As a result and as part of the general expansion of American influence after the war, the so-called European news monopoly began to be strongly challenged by the Associated Press, under the inspired leadership of its general manager, Kent Cooper. After a bitter struggle, which came to a head over Japan, a "Reuters territory," a new agreement was signed in 1934 that ended the old exclusiveness. This represented a great advance in international news gathering, for world news could be received from more than one source. The free interchange of news was seen, largely as a result of Kent Cooper's crusade, to be an essential safeguard against governmental control. Reuters eventually became a newspaper-owned trust (1941), with articles guaranteeing its integrity and independence; but despite a renewed campaign for freedom of news after World War II, many national news agencies continued to be state owned or controlled.

Press freedom. In the years leading to World War II, the European press reflected all too faithfully the unhappy state of the Continent. In Germany, Italy, Spain, and Portugal it was subject to censorship and made to serve the ends of the government, as it was also, in a different cause, in the Soviet Union. In France, where the press was more or less open to the highest bidder, articles might be inspired from any quarter prepared to bribe or subsidize; and in Britain it fell far short of its old traditions. ***The Times*** under Geoffrey Dawson became an instrument of government policy, and the ***Express*** maintained a fatuous optimism; apart from the muted tones of the ***Manchester Guardian*** and the ***News Chronicle,*** only the raucous voice of the ***Daily Mirror,*** to its credit, pointed out unpalatable truths. In these circumstances, where the main press was failing in its duty, there was an interesting return to the ancient newsletter. Two in particular, the sober ***News Letter,*** issued by Stephen King-Hall, and the more highly flavoured, somewhat Marxist ***The Week,*** put out by Claud Cockburn, were influential.

Wartime censorship

World War II and after. In World War II the press was handled far more sensibly than in World War I, both in Britain and in the United States. In Britain, apart from censorship in the field and any temporary embargo on items of news, there was no compulsion, nor was comment restricted. Newspapers voluntarily submitted any doubtful material to the censorship department, thus clearing themselves in the event of any proceedings under the Official Secrets Act. A system of Defense Notices issued by the government indicated sensitive areas. In the United States, the Office of Censorship set out a "Code of Wartime Practices for the American Press," which again provided a workable basis for cooperative self-censorship. From the government side, the British Ministry of Information and the American Office of War Information (OWI) both issued a vast amount of official news and propaganda. The level of war reporting and photography, in particular, reached great heights; and many journalists risked, and lost, their lives. The rationing of newsprint, which also affected the United States, though less stringently than Britain, pegged circulations and imposed difficult decisions—*e.g.*, whether to use the limited space more for advertising, and hence income, or for news coverage, and hence the loyalty of readers.

Financial trends. Since World War II the pressure of rising costs of production has accentuated the trend in most of the highly industrialized countries toward monopolistic control—there came to be fewer newspapers and these, in the main, were owned by large, monopolistic corporations. In the United States by the late 1970s almost 60 percent of the daily papers were chain owned, and eight out of 10 of all newspapers were monopolies—*i.e.*, they had no competition in the city in which they were published. New York City, which supported eight major dailies in 1960, had only four in 1980: the ***New York Post,*** an afternoon tabloid; the ***Daily News,*** a morning tabloid; the full-sized ***New York Times;*** and the full-sized ***Wall Street Journal.*** There are about 170 chains in the United States, the largest being Gannett Company, Inc. Lord Thomson, the Canadian and British proprietor, owned 67 U.S. newspapers in 1980. The effect of monopoly is heightened by the all-pervading influence of the two main news agencies, Associated Press (1848, a non-profit-making cooperative) and United Press International (1958, a commercial, profit-making agency, the outcome of a merger between United Press Association, founded by Scripps-Howard in 1907, and International News Service, formed by Hearst in 1909). It has been claimed that monopoly relieves a newspaper from the twin evils of competing for advertising and competing in sensationalism; but lack of competition can also lead to lack of entemrise in exploring subjects and airing opinions.

A serious problem, which has arisen in connection with automation, has been prolonged newspaper strikes. Coupled with the ready availability of news on radio and, especially, on television, it may have led some people to drop the newspaper habit altogether. Though total daily circulation has risen, it has not kept pace with the rise in population. In Canada, an alternative type of publishing group, Free Press Publications, was formed in the early 1960s to provide the financial benefits of a commercial alliance without the drawbacks of uniformity—each of its papers retained its identity and full editorial independence. Although Free Press Publications grew to become one of the largest chains in Canada, in 1980 the Thomson organization purchased the eight papers of the group, selling one, merging two, and terminating the publication of a fourth. Thomson and Southam then owned 48 percent of the total daily circulation, and eight smaller chains held an additional 28 percent.

The trend toward consolidation has also been visible in Britain, but the fact that the principal newspapers are national, available all over the country, has preserved a somewhat greater element of competition and choice for the reader. By 1980 almost two-thirds of Britain's daily newspapers were controlled by six chains: Associated Newspapers Group, Express Newspapers, Mirror Group Newspapers, News Group Newspapers, Thomson Regional Newspapers, and United Newspapers Publications.

Springer group

The same trend toward the large complex has taken place elsewhere in Europe. The Springer group in Germany, built up by Axel Springer after World War II, controlled almost 40 percent of the total daily circulation in West Germany and as much as 70 percent in West Berlin until 1968, when the main press commission *(Günther)* set limits on the proportions of circulation one group would be allowed to control; Axel Springer then reduced his share of the periodical market to 11 percent. The group owns two of the country's most influential national dailies, the quality ***Die Welt*** and the sensational ***Bild Zeitung,*** and two of the most influential national weeklies, ***Welt am Sonntag*** and ***Bild am Sonntag.*** Its influence, essentially conservative, is offset by the national ***Frankfurter Allgemeine*** and the local press (every large city has its daily), as well as by the news magazine ***Der Spiegel.*** In France, where the number of dailies has declined steadily since 1946, the press is controlled mainly by four groups, Hachette, Amaury, Hersant, and Expansion, the biggest being the Hachette Group, which came under the control of Matra, an electronics-defense conglomerate, in 1980. The postwar French press is less open to political pressure and is more informational than in prewar days, with a professional element that asserts itself strongly against the managerial. The editorial staffs of several papers, including ***Le Figaro*** and ***Le Monde,*** a daily of immense integrity, have won complete independence. In Italy, where only 12 percent of adults read a daily paper, the number of papers has fallen sharply, and those that remain have become financially dependent on large industrial groups, political parties, or other organizations with sufficient capital to withstand financial losses. The country's leading daily is ***Corriere della Sera;*** the voice of the Vatican is ***L'Osservatore Romano,*** a weekly; and ***L'Unita,*** the official organ of the Italian Communist Party, has been one of the country's leading newspapers since World War II.

By 1937 there were 1,200 dailies and 600 weeklies in Japan. National mobilization decrees beginning in 1938 led to totalitarian government "guidance" of the press and virtually enforced mergers that reduced the number of dailies to 53 by 1942. The postwar Allied occupation brought another form of "guidance" censorship until 1948. Top management personnel were removed, and for several years radical unions seized virtual control of such papers as the ***Yomiuri.*** After the Korean conflict erupted in 1950, the occupation authorities directed newspaper managements to purge the many Communists who had infiltrated the editorial staffs.

After sovereignty was regained in 1952, the Japanese government passed legislation intended to prevent any new attempts to employ newspapers for the purpose of subversion. By the early 1970s, however, Japanese newspapers had established a vigorous and independent stance, exposing secret government documents before their existence had been publicized in the Diet or elsewhere. Furthermore, because of the popular clamour for news, leading newspapers have increased their standard number of pages and broadened their coverage of global, national, and local affairs. Japanese newspaper circulations have remained among the largest in the world, but the trend has continued away from traditional reliance upon circulation revenues toward an increasing ratio of advertising revenue. The leading newspapers have large magazine and book divisions and are increasingly involved in affiliated television-broadcasting operations.

Though Australian newspapers were originally in the hands of such families as the Fairfax family ***(Sydney Morning Herald)*** or the Davies ***(Hobart Mercury),*** the trend in the 20th century has been toward ownership by joint stock companies, so that, by the early 1970s, no major Australian paper was privately owned. By the early 1980s three principal groups owned the bulk of the print media; the John Fairfax Group, The Herald and Weekly Times Ltd. Group, and News Ltd., and although there has been criticism of the interlocking ownership of the Australian press, no national inquiry into the extent of concentration or cross-ownership has taken place.

Of the 44 daily newspapers in New Zealand in the early 1980s, the largest were the ***New Zealand Herald*** and ***Auckland Star,*** both published in Auckland, the ***Evening Post*** and ***The Dominion*** of Wellington, and ***The Press*** and ***Christchurch Star,*** both of which appear in Christchurch. Although there has been a trend toward amalgamation, papers do prosper on their own.

Press freedom. Press freedom remains as problematic as ever, even in countries where it might be taken for granted. In France, under the Gaullist Constitution of 1959, seizures of newspapers were made as recently as 1965. A successful case against the state brought them to an end, but government sensitivity remained and press coverage of both Pres. Georges Pompidou's illness in the early 1970s and the war in Chad was minimal. In 1980 the government brought criminal charges against the editor of ***Le Monde,*** alleging that "discredit" had been done to the courts of France in articles criticizing controversial judicial decisions. In West Germany the ***Der Spiegel*** affair of 1962, in which the arrests of several members of the staff in retaliation for personal attacks on Germany's Defense Minister were upheld by the Constitutional Court, illustrated the lack of a strong tradition of press freedom in the country. A later controversy, however, surrounding published reports about the former empress of Iran, was decided in favor of the West German press when an amendment that would have extended protection for foreign heads of state against journalistic intrusion was dropped because of the opposition of German publishers and the journalists' association. Strict control of the press was imposed in Rhodesia (now Zimbabwe) in 1965 and in Greece in 1967. In South Africa, where the press is nominally free, controls and intimidation are applied under a dozen different statutes. As Dr. Hermann Knorr, editor of the ***Rhein-Neckar Zeitung,*** observed: "Press freedom guarantees are only as good as the will of the public to make them good."

Freedom of the press in Communist countries

In Communist countries, of course, press freedom is viewed in a wholly different light. The press is an arm of government, an instrument of social control, and a means to educate and mobilize the masses, with great emphasis on "self-criticism." The state censorship agency in the Soviet Union is known as Glavit, but in any case only leading party members become editors of important papers. To Communists, Western press freedom is illusory because the wealthy few control what is to be printed, whereas in Communist countries all have free access to the press. Certainly, much information is supplied by worker and village correspondents on achievements and shortcomings. One government report elicited 126,000 letters and articles, of which 102,941 were published. To this extent the newspapers are a platform for the people. In the Soviet Union, besides ***Pravda,*** the All-Union daily with a circulation of 11,000,000, and ***Zzvestiya*** (8,600,000), the official voice of the Soviets, both fine productions if perhaps somewhat staid to Western eyes, there are hundreds-of publications representing different interests and many wall newspapers in factories, collectives. and institutions. The press of all Communist countries' is modelled on that of the Soviet Union. Even in Yugoslavia, which is independent of the Soviet bloc and where the 1974 constitution provides certain freedoms, the same strict controls are applied in practice. In China, where the country's many papers take their lead from ***Jen-min Jih-pao,*** the ***People's Daily*** of Peking, the wall newspaper, often mimeographed or hand written, is a strong feature, especially in remote communities. It is maintained by a "keeper," who reads it aloud to illiterates.

Underground presses

Wherever there are strong currents of dissent from prevailing notions, an underground press is likely to develop; clandestine printing is almost as old as the art itself. In Nazi-occupied Europe, there were many such publications, which maintained morale by spreading news of the Resistance and of Allied successes. Since the war the term underground press has been applied to ***samizdat*** ("self-publishing") material in the Soviet Union, where some free literary life continues in spite of official repression. News of this, together with reports of such matters as trials and persecutions for ***samizdat*** activity, religious belief, and demonstrations, is circulated secretly in a publication called "A Chronicle of Current Events," copies of which have reached the West. Nor does the West lack its own vigorous "underground," which is also known more appropriately, since publication does not carry the same risks, as "the alternative press." It consists of a host of small, evanescent productions, chiefly in the United States and Britain but also in western Europe, published by young people as an expression of social dissent. At its most evangelical, it puts forward a radically different, alternative set of values; at the level of entertainment, it leans heavily on pornography and youthful trends. In some cases—*e.g.*, ***The Village Voice*** of New York City and ***Time Out*** of London—the underground becomes virtually overground, with a high, stable circulation.

The press in developing countries. A flourishing press presupposes some degree of literacy, yet approximately three out of every 10 adults in the world are illiterate. During a general conference in 1976, the United Nations Educational, Scientific and Cultural Organization (UNESCO) reported that only about 12 percent of the newsprint consumed worldwide went to the developing countries of South America, Africa, and Asia, representing an average of about 2 pounds (one kilogram) of newsprint per head of population, compared with an average of almost 40 pounds per head of population in the industrially developed countries of Europe and North America. This is one more measure of the disparity between advanced countries and those who are making what has been called the "terrible ascent to modernity." The correlation between economic growth and growth in communications is well established; newspapers are as essential to developing countries as they are elsewhere. Apart from providing a flow of information and acting as a two-way link between leaders and people far more effectively than radio or television can do, newspapers are themselves a vital step in the acquisition of literacy, with all of its benefits. But the problems are immense. Besides the obvious economic ones of equipment and trained staff and the fact that there have to be people who can afford to buy a paper and businesses that can afford to advertise in it, there is the multiplicity of languages in Asia and Africa and the problem of typesetting in local scripts; in some cases a paper is written by calligraphers, reproduced photographically, and printed by lithography. A newspaper in a developing country is also finely balanced in its policy: though it may aspire to be a public watchdog, it is often compelled to mute its bark. In Ghana and Nigeria, for instance, which have a press tradition of more than a century—rooted in colonialism, mission activity, and the national awakening of the 1930s—the press is less free than it was before the countries became independent. There are, of course, fine newspapers in all of the large urban centres in South America, Asia, and Africa; but the rural masses are less easy to reach. For this journalistic techniques have to be adapted to local needs. Basic English is sometimes used, and one newspaper is published in pidgin English, the Nu Gini Toktok (*i.e.*, "New Guinea Talk Talk"). Since 1950 great progress has been made, partly through UNESCO's program of fundamental education. Throughout the underdeveloped world the number of newspapers has risen sharply, and many more national news agencies have been founded, despite a hampering lack of telecommunication facilities.

CONTEMPORARY AND FUTURE TRENDS

New printing techniques

During the past 100 years, technical developments have transformed newspaper production, and they are continuing to do so. A recent innovation has been the application of colour printing to the daily paper. While this may be done partly for its own sake, as a natural evolution, the chief hope is that it will enable the newspaper to compete for advertising on equal terms with colour television and the glossy magazines. More far-reaching is the development of photocomposition and web-offset printing, which eliminate hot-metal typesetting and reduce the amount of skilled labour required. Though capital costs are still high, such new techniques are particularly suited to small-circulation journals and may provide the long-term answer to the needs of emerging nations. Computer typesetting and electronic control systems, despite strong resistance from unions, clearly point the way to future development. So, too, does the increasing use of telecommunication facilities. In 1959 the highly advanced Japanese press led the world in facsimile transmission and teletypesetting by publishing simultaneous editions of newspapers in cities hundreds of miles apart. Such transmission processes, via land line, cable, radio, and space satellite, are bridging ever greater distances at ever greater speeds of operation. The trend points toward multicentre printing of identical material and, hence, stronger national and even supernational newspapers, though regional loyalties—*e.g.*, in the United States—may prove resistant. In 1962 the world news agencies also entered the space age by using the first communications satellite to relay dispatches by telephone and teleprinter.

The trend toward monopoly in advanced countries, owing to the dependence of the modem newspaper on advertising and the high cost of keeping pace with technical development, seems irreversible, for only the big and strong can survive. But although it must be deplored, there are limits to its dangers. Whatever the inhibiting influence of advertisers or the caution of large corporations, the public-service function of a newspaper cannot be denied beyond a certain point without damage to its nature and so, ultimately, to its commercial existence. In addition, there is much evidence of the worldwide strengthening of the professional element in journalism, promoted by the great amount of study it is receiving. Where managements, however monopolistic, uphold the integrity and independence of their editors, the public interest can still be served. Finally, there is always the leaven of the small publication. Though the cost of starting a daily paper has become prohibitive, it has never been easier to issue an alternative paper in some form or other. So easy is it to produce such a newspaper that in Czechoslovakia, where the government has been unable to suppress the strong underground press, anyone who buys a typewriter has to leave his name and address.

Government security

Far more serious for a free press is the trend toward greater government secrecy. In the name of internal stability or external threat or even the projection of a good national image, criticism is all too readily labelled "unpatriotic." As government grows more complex and bureaucratic, important decisions are taken by faceless officials, who are then protected by their ministers. To avoid unwanted disclosures, the press handout has come increasingly to take the place of journalistic investigation. In the United States in 1955, the Moss Sub-committee of Congress reported the development of "An attitude novel to democratic government—an attitude which says that we, the officials, not you, the people, will determine how much you are to be told about your Government." Since then this attitude has become all too widespread and not only in the United States, of course, which at least preserves an unrivalled capacity for self-criticism. There have been many instances of courageous individuals who have set what they judged to be the public interest above their official loyalties and passed on information to newspapers, which, in turn, have risked publication—and both parties have been subsequently justified. This involves the difficult question of obligation to reveal sources; Scandinavian countries are among the few that fully recognize the right of a news source to anonymity. In the last analysis, the answer lies with the public: the health of a free press depends on the expectations and demands of its readers.

As to the future of the newspaper itself, this seems assured; there is nothing on the horizon likely to replace it, though it will doubtless undergo further changes of form. Radio and for similar reasons television, vivid and stimulating though these media are, have proved to be no substitute for newspapers. It is hard to see how the electronic media can ever match the newspaper in its variety of material handled in convenient form for assimilation and reference at will. The most serious effect of television, in countries with a commercial system, has been to draw off advertising revenue. This has added considerably to the financial problems of the press and may eventually lead to higher prices for newspapers. But it seems likely that these will always be paid—for a good product. Even in developing countries, where radio may become the primary means of mass communication, newspapers follow hard on its heels.

III. Magazine publishing

BEGINNINGS IN THE 17TH CENTURY

Though there may have been approaches to a magazine in antiquity, especially perhaps in China, the magazine as it is now known began only after the invention of printing in the West. It had its taproot in the spate of pamphlets, broadsides, ballads, chapbooks, and almanacs that printing made possible. Much of the energy that went into these gradually became channelled into publications that appeared regularly and collected a variety of material designed to appeal to particular groups of interests. The magazine thus came to occupy the large middle ground, incapable of sharp definition, between the book and the newspaper.

The earliest magazine or periodical appears to have been the German Erbauliche Monaths-Unterredungen (1663–68; "Edifying Monthly Discussions"), started by Johann Rist, a theologian and poet of Hamburg. Soon after, there appeared a group of learned periodicals; the Journal des *Sçavans* (later Journal des Savants; 1665), started in France by the author Denis de Sallo; the Philosophical Transactions (1665), of the Royal Society in England; and the Giornale de' *letterati* (1668) published in Italy, issued by the scholar and ecclesiastic Francesco Nazzari. A similar journal was started in Germany a little later, the *Acta eruditorum Lipsiensium* (Leipzig; 1682); and mention may also be made of the exile-French *Nouvelles de la République des Lettres* (1684), published by the philosopher Pierre Bayle mainly in Holland, to escape censorship. All these sprang from the revival of learning, from the need to review its fruits, and the wish to diffuse its spirit as widely as possible. It is notable that England's Royal Society, for instance, embraced the whole field of knowledge and had as one of its aims the improvement of English prose.

While the learned journals might summarize important new books, there were as yet no literary reviews. Book advertisements, by about 1650 a regular feature of the news sheets, sometimes had brief comments added, and regular catalogues began to appear, such as the English quarterly *Mercurius librarius, or A Catalogue of Books* (1668–70). But in the 17th century the only periodicals devoted to books were very short-lived: the *Weekly Memorials for the Ingenious* (1682–83), which offered some critical notes on books, and the *Universal Historical Bibliothèque* (January–March 1686). The latter invited scholarly contributions and could thus be regarded as the true forerunner of the literary review.

The lighter type of magazine, or "periodical of amusement," may be dated from 1672, which saw the first appearance of the *Mercure Galant* (renamed *Mercure de France* in 1714). It was founded by the writer Jean Donneau de Visé and contained court news, anecdotes, and short pieces of verse—a recipe that was to prove endlessly popular and become widely imitated. This was followed in 1688 by a German periodical with an unwieldy title but one that well expressed the intention behind many a subsequent magazine: "Entertaining and Serious, Rational and Unsophisticated Ideas on All Kinds of Agreeable and Useful Books and Subjects." It was issued in Leipzig by the jurist and publicist Christian Thomasius, who made a point of encouraging women readers. England was next in the field, with a penny weekly, the *Athenian Gazette* (better known later as the *Athenian Mercury;* 1690–97), run by a London publisher, John Dunton, to resolve "all the most Nice and Curious Questions." Soon after came the *Gentleman's Journal* (1692–94), started by the French-born Peter Anthony Motteux, with a monthly blend of news, prose, and poetry; and in 1693, after devoting some experimental numbers of the *Athenian Mercury* to "the Fair Sex," Dunton brought out the first magazine specifically for women, the *Ladies' Mercury,* which offered forthright advice on some perennial problems. Finally, another note, taken up time and again later, was struck by *The London Spy* (1698–1700), issued by a tavern keeper, Ned Ward, and containing a sort of running narrative of the sights and sounds of London.

DEVELOPMENTS IN THE 18TH CENTURY

With the gathering momentum of trends at the turn of the century—increasing literacy, especially among women, and a quickening interest in new ideas—the magazine filled out and became better established. In England, three early "essay periodicals" had enormous influence: Daniel Defoe's *Review* (1704–13; thrice weekly), Sir Richard Steele's *Tatler* (1709–11; thrice weekly), to which Joseph Addison soon contributed, and Addison and Steele's *Spectator* (1711–12, briefly revived in 1714; daily). Though they resembled newspapers in the frequency of their appearance, they were more like magazines in content. *The Review* introduced the opinion-forming political article on domestic and foreign affairs; while the cultivated essays of the *Tatler* and *Spectator,* designed "to enliven morality with wit, and to temper wit with morality," did much to shape the manners and taste of an age. The latter had countless imitators, not only in England, where there were in addition a *Female Tatler* (1709–10) and a *Female Spectator* (1744–46), but also on the Continent and later in America. The Stamp Tax of 1712 had a damping effect, as intended (see above), but the magazine proved endlessly resilient, easy to start and easy to fail, then as now.

Addison and Steele's *Spectator*

So far various themes had been tried out; they were first brought together convincingly by the English printer Edward Cave, who began to publish *The Gentleman's Magazine* in 1731, with the motto "*e pluribus unum*." It was originally a monthly collection of essays and articles culled from elsewhere, hence the term magazine—the first use of the word for a periodical. Cave was joined in 1738 by Doctor Johnson, who was later to publish his own *Rambler* (1750–52); thereafter *The Gentleman's Magazine* contained mostly original matter, including parliamentary reports. Rivals and imitators quickly followed, notably the *London Magazine* (1732–85) and the *Scots Magazine* (1739–1817; to 1826 published as the *Edinburgh Magazine);* and, among the increasing number of women's periodicals, there were a *Ladies' Magazine* (1749–53) and a *Lady's Magazine* (1770–1832). Their progenitor, however, outlived them all and perished only in 1907.

The literary and political rivalries of the day produced numerous short-lived periodicals, from which the critical review emerged as an established form. Robert Dodsley, a London publisher, started the *Museum* (1746–47), devoted mainly to books, and a Nonconformist bookseller named Ralph Griffiths founded *The Monthly Review* (1749–1845), which had Oliver Goldsmith as a contributor. To oppose the latter on behalf of the Tories and the Church of England, *The Critical Review* (1756–1817) was started by an Edinburgh printer, Archibald Hamilton, with Tobias Smollett as its first editor. Book reviews tended to be long and fulsome, with copious quotations; a more astringent note came in only with the founding of the *Edinburgh Review* in 1802 (see below).

Europe. In Europe, development was similar but was hampered by censorship. French periodicals containing new ideas had to appear in exile, such as Bayle's (see above); some 30 were published in Holland up to the time of the Revolution. Within France, there were the short-lived *Spectateur français* (1722–23) and *Spectateur suisse* (1723); and *Le Pour et le Contre* (1733–40; "For and Against"), issued by Abbé Prévost. Of more literary interest were the *Gazette littéraire de l'Europe* (1764–84) and *La Décade philosophique, littéraire et politique* (1794–1804). In Germany, the poet and philosopher J.C. Gottsched issued the country's first women's periodical, *Die vernünftigen Tadlerinnen* (1725–26; "The Rational Woman-critics"), and the first literary review, *Beiträge zur kritischen Historie der deutschen Sprache* (1732–44; "Contributions to the History of the German Language"), published in Leipzig. Literary movements were connected more profoundly than in England with the production of new periodicals, the influence of which was often greater than their duration, among them, Schiller's *Horen* (1795–97) and Goethe's *Propylaen* (1798–1800). Of more general and lasting influence was the *Allgemeine Literatur-zeitung* (1785–1849), founded by F.J. Bertuch, "the father of the German periodical."

The first Russian periodical, published by the Academy of Sciences, was a learned journal called "Monthly Works" (1755–64). The first privately published Russian magazine, a critical periodical with essays and translations from England's *Spectator,* was called "Industrious Bee" and began in 1759. Catherine II used her *Olla Podrida* (1769–70), also modelled on the *Spectator,* to attack opponents, among them Nikolay Novikov, whose "Drone" (1769–70) and "Windbag" (1770) were suspended and whose "Painter" (1770–72) escaped only by being dedicated to the Empress.

The United States. In America, magazines got off to a tentative start in 1741. The first was Andrew Bradford's *American Magazine,* beating by a mere three days Benjamin Franklin's *General Magazine;* both appeared in Philadelphia. Neither lasted long, however; Bradford's survived only three months and Franklin's six. Franklin was more widely known for another of his publications, *Poor Richard's Almanack* (1733–58), containing maxims and proverbs. Before the end of the century, some 100 magazines appeared, offering miscellaneous entertainment, uplift, or information, mostly on a very shaky, local, and brief basis. Among the more important were, in Philadelphia, the *Perznsylvania Magazine* (1775–76), edited by Thomas Paine, and the *American Museum* (1787–92) of the bookseller Mathew Carey; the *Massachusetts Magazine* (1789–96); and the *New-York Magazine* (1790–97).

THE 19TH CENTURY AND THE START OF MASS CIRCULATION

General periodicals. Most of the early periodicals, designed for the few who could afford them, reflected the tastes of the leisured classes; they were largely "quality" magazines. In the 1830s, however, cheap magazines began to appear amed at a wider public. At first they were strong on improvement, enlightenment, and family entertainment, but, toward the end of the century, they evolved into a popular version of the old "periodical of amusement."

The pioneers in England were Charles Knight, publisher for the Society for the Diffusion of Useful Knowledge, with his weekly *Penny Magazine* (1832–46) and *Penny Cyclopaedia* (1833); the Chambers brothers, William and Robert, with *Chambers's (Edinburgh) Journal* (1832–1956), which reached a circulation of 90,000 in 1845; and teetotaler John Cassell, with his *Working Man's Friend and Family Instructor* (1850) and the *Quiver* (1861). Besides popular magazines, many standard works appeared in parts, often with illustrations. Typical of the family type of entertainment were Charles Dickens' *Household Words* (1850), followed in 1859 by *All the Year Round;* several similar periodicals such as *Good Words* (1860); and, for young people, the *Boy's Own Paper* (1879) and the *Girl's Own Paper* (1880). Germany, too, had its *Pfennigmagazin* (1833), edited by J.J. Weber, and a *Familienblatt* ("Family Magazine") modelled on that of Dickens, such as the *Gartenlaube* (1853–1937; "Arbour"), which enjoyed great popular influence, with a circulation of 400,000, in the 1870s. The United States had no national magazines before about 1850, but two of its most well-known early periodicals were the *Saturday Evening Post* (1821–1969) and *Youth's Companion* (1827–1929). The latter, published in Boston, was typically wholesome in content, intended to "warn against the ways of transgression" and to encourage "virtue and piety."

German popular magazines

By the last quarter of the century, largely as a result of compulsory education, the potential public for magazines had greatly increased and was avid for miscellaneous information and light entertainment. The first man to discover this in Britain was George Newnes, who liked snipping out any paragraph that appealed to him. In 1881, he turned his hobby to advantage by publishing a penny magazine, *Tit-Bits from all the Most Interesting Books, Periodicals and Contributors in the World,* soon shortened to *Tit-Bits* (still in publication). It was a great success and the beginning of an empire that was to include *Country Life* (1897–), *Wide World Magazine* (1898), and, above all, the *Strand* (1891–1950), one of the first monthly magazines of light literature with plenty of illustration; it became enormously popular for its Sherlock Holmes stories by Arthur Conan Doyle. Among the early contributors to *Tit-Bits* was Alfred Harmsworth (later Lord Northcliffe), who had a similar appetite for odd bits of information. In 1888, after editing *Youtlz* and *Bicycling News,* he launched a rival to *Tit-Bits* called *Answers to Correspondents,* or *Answers,* which he successfully promoted by contests. Within five years he had a string of cheap magazines for the same popular market, including *Comic Cuts* and *Home Chat.* A similar empire was built up by Arthur Pearson, another former *Tit-Bits* man, with *Pearson's Weekly* and *Home Notes,* among others.

Early popular monthly magazines in the U.S.

In the United States, magazine publishing boomed after the Civil War, as part of the general expansion, and it was also helped by favourable postal rates for periodicals (1879). But a gulf remained between expensive magazines geared to the genteel, such as *Harper's* and *Scribner's* (see below), and the cheap weeklies and miscellanies. The first man to aim at a popular monthly in between and thus spark off a revolution in the industry was S.S. McClure, who began publishing *McClure's Magazine* in 1893, at 15 cents instead of the usual 25 or 35 cents. John Brisben Walker, who was building up *Cosmopolitan* (1886–) after acquiring it in 1889, cut his price to 12% cents, and, in October 1893, Frank A. Munsey reduced the price of *Munsey's Magazine* (1889–1929) to 10 cents. All three saw that, by keeping down the price and gearing contents to the interests and problems of the average reader, high circulations would become possible. Frank Munsey estimated that, between 1893 and 1899, "the ten-cent magazine increased the magazine-buying public from 250,000 to 750,000 persons." This in turn led to high advertising revenue, making it possible to sell a magazine, like a newspaper, for less than its cost of production, a trend that was to become increasingly pronounced in the next century. The role of technical development was also important; mass-production methods and the use of photoengraving processes for illustration enabled attractive magazines to be produced at ever lower unit costs.

The first periodical published in Australia was the *Austıalian Magazine,* which began in 1821 and lasted for 13 monthly issues. The *South Asian Register* began quarterly in 1827 but published only four issues. The *Hobari Town Magazine* (1833–34) survived longer and contained stories, poems, and essays by Australian writers; the *Sydney Literary News* (1837) was first to contain serial fiction and advertisements. Illustrations were introduced in the 1840s; the *Australian Gold Digger's Monthly Magazine and Colonial Family Visitor* (1852–53) was followed by the *Melbourne Punch* (1855–1925; incorporated in *Table Talk,* 1885–1937). In India, the first published magazine was the *Oriental Magazine; or, Calcutta Amusement* (1785–86); it was followed by a number of short-lived missionary publications. The first periodical founded and edited by an Indian was the *Hindustan Review,* which commenced in 1900.

Magazines in China

Missionaries founded the first periodical in China; printed in Malacca, the *Chinese Monthly Magazine* lasted from 1815 to 1822. It was followed by the *East-West Monthly Magazine,* printed in Canton from 1833 to 1837 and in Singapore from 1837 until its end in 1847. Although learned journals were founded in the 19th century, only in the 1900s, with the literary revolution, did they circulate widely.

Illustrated magazines. Woodcuts had been used to illustrate newspapers from the beginning, but the early ones were inclined to be decorative and imaginative rather than accurate and topical. The first reliable pictures to portray events shortly after their occurrence date from 1806, when *The Times* (London) published a picture of Nelson's funeral car. Thereafter, news illustration became more common, especially in the case of great public occasions such as coronations. The first man to notice their effect on sales and grasp their possibilities was a British newsagent in Nottingham, Herbert Ingram, who moved to London in 1842 and began publishing the *Illustrated London News,* a weekly consisting of 16 pages of letterpress and 32 woodcuts. It was successful from the start, winning approval from the Archbishop of Canterbury and hence the support of the "rectory" public. Though it suffered at first from the old defect—its pictures were by well-known artists but were not taken from life—it later sent artists all over the world. Drawings made on the spot during the South African War, sometimes at considerable risk, were a great popular feature. Among its competitors was the monthly *English Illustrated Magazine* (1883–1913).

News in pictures

The idea of presenting the news largely in pictures was quickly taken up on the Continent, in France by *L'lllustration* (1843–1944) and in Germany by the *Leipziger illustrierte Zeitung* (1843) and *Die Woche* (1899–1940).

In the United States, the main early forerunners of the genre were *Leslie's Weekly* (1855–1922) and *Harper's Weekly* (1857). Soon after its founding, *Leslie's* had a circulation of 100,000, which doubled or trebled whenever there was something sensational to portray. During the Civil War, of which it gave a good pictorial record, it had as many as 12 correspondents at the front.

The invention of photography and the development of the halftone block began to transform this type of magazine in the last decade of the century; from then on the artist was gradually replaced by the camera.

Women's magazines. Women's magazines are barometers of fashion in more ways than one; they reflect the changing view of women's role in society. In the 18th century, when women were expected to participate fully in social and political life, they were robust and stimulating in content; in the 19th, when domesticity became the ideal, they were inclined to be insipid and humourless. After about 1880, they began to widen their horizons again.

Typical of the Georgian and Regency magazines in Britain were The Lady's Magazine (1770), a sixpenny monthly that, along with its literary contributions and fashion notes, gave away embroidery patterns and sheet music; The Lady's Monthly Museum (1798), which had a half-yearly "Cabinet of Fashion" illustrated by coloured engravings, the first to appear in a women's periodical; and La Belle *Assemblée* (1806), which encouraged its readers to unburden themselves in its correspondence columns. These three merged in 1832, the first instance of what was to become a common occurrence, but ceased publication in 1847. The Victorian type of magazine included The Ladies' Pocket Magazine (1824–40), The Ladies' Cabinet (1832–52), The New Monthly Belle *Assemblée* (1847–70), and The Ladies' Treasury (1857–95). All contained verse, fiction, and articles of high moral tone but low intellectual content. There were attempts to swim against the tide, such as The *Female's* Friend (1846), which was one of the first periodicals to espouse women's rights, but they seldom lasted long.

In 1852, a wider market began to be tapped by The Englishwoman's Domestic Magazine, a monthly issued by Samuel Beeton at twopence instead of the usual one shilling; it was also the first women's periodical to concentrate on home management, to offer service to women rather than upper class entertainment. Beeton's wife (author of the classic Book of Household *Management*, 1861) visited Paris regularly and acquired the use of the fashion plates from Adolphe Goubaud's Moniteur de la Mode. A feature of the magazine was the "Practical Dress Instructor," a forerunner of the paper dressmaking pattern. In 1861, Samuel Beeton followed up his success with The Queen, a weekly newspaper of more topical character.

The great expansion of women's magazines into a major industry may be dated in Britain from Myra's *Journal* of Dress and Fashion (1875–1912) and *Weldon's* Ladies' Journal (1875–1954), both of which supplied dressmaking patterns and met the needs of a mass public. There were several new quality magazines, such as *The* Lady (1885–) and The Gentlewoman (1890–1926), one of the first to acknowledge the financial necessity of advertisements, but many more cheap weeklies, such as Home Notes (1894–1957), Home Chat (1895–1958), and Home Companion (1897–1956), which were of great help to the average woman in meeting new standards of hygiene, nutrition, and child care.

Among the earliest women's magazines in the United States was a monthly published in Philadelphia called Godey's Lady's Book (1830–98), which employed up to 150 women to hand-tint its famous fashion plates. Of the early national magazines, one of the best and hardiest was Harper's Bazar (1867; Harper's Bazaar after 1929), modelled on the Berlin women's periodical Der Bazar, Srom which it obtained its fashion material. The practical trend was begun in 1863 by Ebenezer Butterick, who devised the tissue-paper clothing pattern and, to popularize it, brought out the Ladies' Quarterly Review of Broadway Fashions and, later, Metropolitan. These merged in 1873 into the Delineator, which had a highly successful career down to 1937. The field of women's magazines was finally transformed, however, by Cyrus Curtis with his Ladies' Home Journal (1883–), edited by his wife. This soon reached a circulation of 400,000, and, under the editorship of Edward W. Bok, after 1889, it broke with sentimentality and piety and became a stimulating journal of real service to women. Other popular magazines were Ladies' Home Companion (1886; called Woman's Home Companion 1897–1957), *McCall's* Magazine (1897–), and Pictorial Review (1899–1939). Two requiring special mention were Good Housekeeping (1885–), which established a testing station for consumer goods early in the 1900s, and *Vogue* (1892–), a fashion weekly (originally) dedicated to "the ceremonial side of life," which was designed for the elite of New York and had Cornelius Vanderbilt among its backers.

Literary and scientific magazines. The critical review, often as an adjunct to a book-publishing business, developed strongly in the 19th century. It became a forum for the questions of the day, political, literary, and artistic, to which all the great figures contributed. There were also many magazines with a literary flavour, which serialized some of the best fiction of the period, and a few that marked the beginning of specialization—*e.g.*, in science.

The Edinburgh Review

Britain was particularly rich in reviews, beginning with the Edinburgh Review (1802–1929), founded by a trio of brilliant young men, none over 30, but all gifted critics, Francis Jeffrey, Henry Brougham, and Sydney Smith. The higher and more independent tone they adopted was said by Coleridge to mark an "epoch in periodical criticism." Though Tories, including at first Sir Walter Scott, wrote for it, it gradually became Whig in attitude. When it did, Scott transferred his allegiance to the Quarterly Review (1809–), its Tory rival, founded by the London publisher John Murray and first edited by William Gifford, who had previously edited Canning's review The *Anti-Jacobin* (1797–98). In opposition to these and more political than either of them was the *Westminster* Review (1824–1914), started by Jeremy Bentham and James Mill as an organ of the philosophical radicals. Two other early reviews were the *Athenaeum* (1828–1921), an independent literary weekly, and the Spectator (1828–), a nonpolitical weekly that nevertheless supported Reform and the cause of the North in the American Civil War. Later reviews included the Saturday Review (1855–1938), which had George Bernard Shaw and Max Beerbohm as drama critics (1895–1910); the Fortnightly Review (1865–1954), which had John Morley as editor (1867–83); the *Contemporary* Review (1866–); the Nineteenth Century (1877; now quarterly as Twentieth Century); and W.T. Stead's Review of Reviews (1890–1936), a limited kind of *Reader's* Digest.

Of the closely related literary magazines, one of the earliest and best was Blackwood's Edinburgh Magazine (1817–), founded by a book publisher, William Blackwood, as a rival to the Edinburgh Review, but a less ponderous one than the Quarterly. It provoked in turn the founding of the London Magazine (1820–29), in which Lamb's Essays first appeared. The rivalry between these two led to a duel in which John Scott, the first editor of the London Magazine, was mortally wounded. Other literary periodicals included the Examiner (1808–80), edited by Leigh Hunt, who introduced Shelley and Keats through its columns; the New Monthly Magazine (1814–84); Bentley's Miscellany (1837), which had Dickens as its first editor and "Oliver Twist" as one of its serials; and the *Cornhill* (1860–), first edited by William Thackeray and the first magazine to reach a circulation of 100,000. Finally, two rather different periodicals must be mentioned: Nature (1869–), which began to make scientific ideas more widely known and to which Darwin and Huxley contributed; and *Punch* (1841–), which provided a weekly humorous comment on British life illustrated by many distinguished draftsmen.

European reviews tended to be more literary than political, perhaps because of the persistence of censorship. The most notable in France were the Revue des Deux Mondes (1829–), with such contributors as Sainte-Beuve and Victor Hugo, and its rival the (Nouvelle) Revue de Paris (1829–), which published authors disapproved by the other, notably Flaubert. In Germany, F.A. Brockhaus, the book publisher, tried to emulate the Edinburgh Review with Hermes (1819–31) but had more success with Literarisches Wochenblatt (1820–98). Later reviews were the conservative *Deutsche Rundschau* (1874–) and the liberal Freie *Bühne* (1890). Two influential Italian reviews were the ***Nuova Antologia*** (1866–) and ***La Cultura*** (1881–1935).

Early U.S. literary magazines

The early literary magazines in the United States included, among many others often of more local interest, the ***Philadelphia Literary Magazine*** (1803–08); the ***Monthly Anthology*** (Boston, 1803–11), which became the quarterly ***North American Review*** (1815–1940), with a host of famous contributors; the ***New York Monthly Magazine*** (1824); ***Dial*** (1840–44), the organ of Emerson's Transcendental Club (there was a second, literary ***Dial,*** 1880–1929); and ***De Bow's Review*** (New Orleans, 1846–80). The cultured weekly ***Home Journal*** (1846–1901; then as ***Town and Country)*** introduced Swinburne and Balzac to Americans, while ***Harper's New Monthly Magazine*** (New York, 1850–) founded by the book-publishing Harper brothers, serialized many of the great English novels and became one of America's finest quality magazines. It was rivalled only by the ***Atlantic*** (Boston, 1857–), which had a long line of distinguished editors, beginning with James Russell Lowell, and published most of the great American writers, from Emerson, Longfellow, and Holmes onward: it seemed to enjoy “a perpetual state of literary grace. Not far below in excellence was ***Scribner's Monthly*** (1870), which became the ***Century*** (1881–1930) but was restarted as ***Scribner's Magazine*** (1887–1939); and a fine magazine in the Far West was ***Overland Monthly*** (San Francisco, 1868–1935), first edited by Bret Harte. Of more specialized magazines, three require mention: ***Scientific American*** (1845–), founded by Alfred Ely Beach, a talented inventor whose magazine encouraged inventors; ***Popular Science Monthly*** (1872–), for the spreading of scientific knowledge, which had William James and John Dewey among its contributors; and the ever-popular ***National Geographic Magazine*** (1888–), published by the National Geographic Society, which used some of the proceeds to sponsor scientific expenditions.

Scholarly journals. The publishing of scholarly journals, begun in the 17th century, expanded greatly in the 19th as fresh fields of inquiry opened up or old ones narrowed into specialties. Numerous learned societies were formed, dealing with such fields as classical studies, biblical studies, archaeology, philology, Egyptology, the Orient, and all the branches into which science was dividing, each with its regular bulletin, proceedings, or "transactions," which enabled scholars to keep in touch with what others were doing. In the sober pages of these journals, seldom read by the general public, some of the most far-reaching discoveries were first made known and then filtered through into the world at large, to change man's view of himself and the universe. Notable at random were ***Annali del Institutio di Corrispondenza Archaeologica*** (1829–), the ***Revue Archéologique*** (1844–), ***Philologus*** (1846–), ***Mind*** (1876–), the ***Journal of Hellenic Studies*** (1880–), the ***American Journal of Philology*** (1880–), the ***Asiatic Quarterly*** (1886–), the ***Geographical Journal*** (1893–), or an interesting informal aid to scholars, ***Notes and Queries*** (1849), with the motto: "When found, make a note of." In every advanced country the professions too began to have their journals, such as medicine's ***Lancet*** (1823–), in Britain, originally started to attack abuses in hospital administration, the ***Mining Journal*** (1835–), the ***British Medical Journal*** (1840–), the ***Engineer*** (1856–), and the ***Solicitors' Journal*** (1857–), to cite only a few examples. In the course of time, these developed endless technical ramifications. The economics of all such journals are based on necessity. Though their circulation is small, anyone working in a particular field must subscribe to them or at least have access to them in appropriate libraries. They can be described as reference books in installments; for further description see INFORMATION PROCESSING.

THE 20TH CENTURY

The advertising revolution. There is a tradition of resistance to advertising in magazines, in keeping with their literary affinities. When the advertisement tax in Britain was repealed in 1853 and more advertising began to appear, the ***Athenaeum*** thought fit to say: "It is the duty of an independent journal to protect as far as possible the credulous, confiding and unwary from the wily arts of the insidious advertiser." In the United States many magazines, such as ***Harper's,*** took a high line with would-be advertisers until the 1880s; and ***Reader's Digest,*** with its mammoth circulation, only admitted advertisements to its American edition in 1955. Yet today some sectors of the magazine industry are dominated by advertising, and few are wholly free from its influence.

This revolution grew out of the social and economic conditions of the late 1880s, when industrialization was producing a swelling flood of goods to advertise; when education, income, and leisure were rising among an increasing number of potential consumers; and when technical innovations, such as cheap paper from wood pulp, the rotary press, and the halftone block, were opening up fresh possibilities in magazine production. Its pioneers, as has been noted, were McClure, Walker, and Munsey in the United States and Harmsworth in Britain, who discovered the possibility of mass circulation by reducing prices below costs of production and recouping themselves through advertising revenue. This technique was developed with growing vigour during the next decades.

Magazine advertising economics. Among its most vivid exponents in the United States was Cyrus Curtis with the ***Saturday Evening Post.*** He bought the magazine for $1,000 in 1897, when it was on its last legs, and sank into it $1,250,000 of his profits from the ***Ladies' Home Journal*** before it finally caught on. But when it did, through an appeal based on well-founded stories and articles about the business world, a prime interest at the time, its success was enormous; by 1922 it had a circulation of more than 2,000,000 and an advertising revenue in excess of $28,000,000. It was a classic demonstration of modern magazine economics: as circulation rose in the initial phase of low advertising rates, money had to be poured in to meet the cost of producing more copies; but, as soon as high advertising rates could be justified by a high circulation, profitability was assured. Conversely, when high rates are maintained on a falling circulation, it is the advertisers who lose, until they withdraw their support.

Verifying circulation

Once circulation figures became all-important, advertisers naturally asserted their right to verify them. The first attempt, made in 1899 by the Association of American Advertisers, only lasted until 1913, but fresh initiatives in 1914 created the Audit Bureau of Circulation. Though resented at first by publishers, it was eventually seen as an asset to them, as a guarantee of their claims. From the publishers' side, interest in circulation led them into market research. The first organization for this purpose was set up by the Curtis Publishing Company in 1911; but such research did not become general until the 1930s. When it was purely promotional—*i.e.*, designed to convince advertisers of the value of a particular medium—it came to be viewed with a certain skepticism. Reader research, to ascertain what readers wanted, was also developed in the 1930s and proved to be a useful tool, though no substitute for editorial flair. As was once observed by the features editor of ***Vogue:*** "If we find out what people want, it's already too late."

Thus the popular magazine in the United States, expanding with the economy, became a part of the marketing system. By 1900 advertisements might form up to 50 percent of its contents; by 1947, the figure was more often 65 percent. A proprietor was no longer just selling a bundle of attractive editorial matter to a segment of the public; he was also selling a well-charted segment of the public to the advertiser. Though the process was most pronounced in the United States, a vast country where, in the absence of national newspapers, national magazines had a special function, the same principles came to apply, in varying degrees, in Britain and the rest of Europe.

The effects of advertising on the appearance of the magazine have been, on the whole, stimulating. At the turn of the century, advertisements began to move forward from the back pages into greater prominence among the editorial matter, and this was often regretted by readers. At the same time, advertising agencies were developing from mere space sellers into copywriters and designers; their efforts to produce work of high visual appeal forced editors to make their own editorial typography and layout more attractive. The use of colour, in particular, was greatly fostered by advertisers, as they discovered its effectiveness. In the 1880s, it was rare, but, after the development of the multicolour rotary press in the 1890s, it steadily became more common; by 1948, nearly half the advertising pages of the leading American magazines were in two or more colours.

Advertising and editorial content

The effect of advertising on editorial content is more open to question. There is no doubt that advertisers have not been slow to exercise their financial pressure and have often succeeded in suppressing material or modifying policy. In 1940, for instance, Esquire lost its piano advertisements after publishing an article recommending the guitar for musical accompaniment; six months later it tried to win them back with a rueful editorial apology. Yet many magazines, notably the Saturday Evening Post, Time, and the New Yorker, insisted on editorial independence. Something like a balance of power has come into being, which can tip either way. What can safely be said is that advertising pressure as a whole has been a socially conservative force, playing on conformity, inclining magazines to work on the principle of "minimum offense," and holding them back from radical editorial departures until they are clearly indicated by changes in public taste. This has tended to make the large-circulation magazine an exploiter rather than a discoverer of fresh talent or new ideas. Yet in the last analysis, advertisers have been forced to recognize that magazines, like newspapers, cannot forgo too much of their independence without forfeiting the loyalty of their readers and hence their value as an advertising medium.

Women's magazines. The bond with advertising is probably most evident in magazines for women, since they are the greatest buyers of consumer goods. In the United States, up to the mid-1930s, such magazines were largely "trade-papers for home-makers." There were exceptions, such as True Story (1919–), which concentrated on entertainment, and Vogue, which had windows onto a wider world, but more typical was Better Homes and Gardens (1922–), which gave fresh impetus to the trend toward "service" by helping women and their husbands in the running of their homes. In this area, of course, advertising pressure can be considerable—*e.g.*, for editorial support of a new product—but editors have usually contained it within some limits. An innovation in the 1930s was the store-distributed magazine. One of the first and most successful was Family Circle (1932–), given away in Piggly Wiggly supermarkets until 1946, when it was sold as a family monthly for five cents, increasing to 69 cents in the early 1980s. Equally successful were Woman's Day (1937–), published by a subsidiary of the Great Atlantic and Pacific Tea Company, and Better Living (1951–), sponsored by the Super Market Institute. During the 1930s, to combat falling circulations and to meet changes in taste, women's magazines broadened their base, as they did again in the 1950s, in a similar crisis. Among the casualties in 1957, however, was the long-running Woman's Home Companion; and in 1956 even *McCall's* came under "outside" commercial control. By 1980 more than 65 feminist-oriented political and literary magazines had been established, the best known being Ms. (1972–), a nonprofit magazine with a circulation of 500,000. Another general trend, in keeping with the growing youth of the United States, has been to direct appeal toward younger women, not only in the old magazines but also in such new ones as Seventeen (1944–), Ingenue (1959–), and 'Teen (1957–).

The muckraking era

Before they entered their most commercial phase, general magazines in the United States went through a muckraking period, in which they were responsible for some major social reforms. This began when *McClure's* Magazine for January 1903 contained three articles on social problems, including one by Ida M. Tarbell on the Standard Oil trust. They were in accord with the public's interest at the time and prompted a spate of others, in Arena, Collier's, Cosmopolitan, Everybody's, *Hampton's*, and, for a brief time, American Magazine (1876–1956). The movement ended in 1912, helped by the pressure of financial interests. Thereafter, magazines grew and survived largely on their formula—*i.e.*, their particular blend of material and style of presentation. Collier's, for instance, became known for its brevity, and American for its success stories, until 1929, when it adopted a family formula. Competition for market leadership led to promotion schemes, such as cut-price subscriptions canvassed through the post, and also to casualties, including *McClure's* in 1933. When Collier's died in 1957 with a circulation of 3,750,000, it was due to falling income through cut-price promotion, rising costs through bigger printing bills, and insufficient advertising revenue to bridge the widening gap. Before the veteran Saturday Evening Post ceased publication in 1969, it tried to save itself, ironically, by cutting its circulation to a third. Since the 1930s the ranks of the general magazine have been thinned steadily, partly by the effects of paperbacks and television and partly by the advent of specialized publications—news, picture, and digest magazines.

Advertising in Britain and Europe. Though the advertising revolution began in Britain at much the same time as in the United States, its course has been less explosive. By 1898, The Gentlewoman was pointing out in its first issue that every copy cost "nearly double the price for which it is sold." Yet Britain's Audit Bureau of Circulations was not set up until 1931, and membership remained small until the 1960s; for it was only then that consumer spending in Britain and hence advertising really began to soar, to be reflected characteristically in a boom in women's magazines. In the early part of the century, the old general magazines continued to flourish, with such additions as the *Windsor* Magazine (1895–1939), Pearson's Magazine (1896–1909), Argosy (1926–), which published only fiction, and the popular weekly John Bull (1906–64), which thrived on "revelations." Several American magazines, especially women's, began to come out in British editions, such as Vogue (1916–), Good Housekeeping (1922–), and Harper's Bazaar (1929–). Society periodicals lost ground after World War I to those catering to the so-called new poor and new rich created by the social upheaval. The fortnightly Queen (1861–1970), Woman's Weekly (1911–), and the monthly Woman and Home (1926–) and Woman's Journal (1927–) were joined by such popular weeklies as Woman's Own (1932–), Woman's Illustrated (1936–61), and, above all, Woman (1937–), the first to be printed by colourgravure. After reaching a circulation of 750,000 before the war, it climbed to 3,500,000 in the late 1950s and has remained Britain's leading advertising medium in the women's market. During World War II some of these magazines achieved a high degree of reader identification with their advice on how to make fruit flans from carrots and brassieres from old lace curtains. Following the arrival of mass affluence in the late 1950s, Britain had its first store-distributed magazines with Family Circle (1964–), a service-only Anglo-American production, and its sister publication, Living (1967–); while the trend toward youthful markets was indicated by She (1955–), broad and robust in outlook, Honey (1960–), *Annabel* (1966–), for newlyweds, and Petticoat (1966–), for 14–19 year olds, and 19 (1968–), a market leader with a circulation of more than 184,000 in the early 1980s. The death of many of the old general magazines, under the pressure of paperbacks and television, and the dearth of weekly illustrated~(see below) left room for a new advertising vehicle. The first to perceive this was Lord Thomson, who in 1962 brought out a colour magazine as supplement to the Sunday Times. Though it lost £900,000 in its first 18 months and was derided as a failure, it went on to make money and obliged the Observer and the Daily Telegraph to compete with their own colour supplements.

Youth magazines

In the rest of Europe the impact of advertising on magazines has been more delayed and less pronounced, partly because market prices of Continental magazines tend to be closer to the production cost. General magazines were fairly limited before World War II, but since then, as part of the economic expansion, there has been a rich crop, most of the Time and Life type (see below) but also of magazines for women. France has several with large circulations, including *Nous Deux*, *Elle*, and *Intimité*, while those in Germany include entries for all age groups, such as *Jasmin* for newlyweds and *Eltern* for parents. Though Scandinavia has fewer periodicals, it is worth noting that the top-circulation magazine in Finland, *Pirkka,* is a giveaway distributed through grocery stores.

Publications outside Europe and the United States. *Japan.* The outstanding early 20th-century personality in Japanese magazine publication was Noma Seiji, who published nine magazines, nearly all with six-figure circulations. World War II did not seriously affect periodicals; and, at the end of occupation in 1952, there were more than 2,000 of all kinds, including *Shufu No Tomo* (1917–56; "Woman's Friend"), *Yoiko No Tomo* (1924–1957; "Child's Friend"), and Le-no-Hikari (1925– ; "Light of Home").

Africa. Important publications in Africa have included the quarterly East Africa *Africana* (Nairobi, 1962–); the Zimbabwean *Africa Calls* (1960–), published every two months; the quarterly *Nigeria Magazine* (1933–); the quarterly *Pan African Journal* (Nairobi, 1967–); and, in South Africa, journals in Afrikaans. Elsewhere, magazines in African languages have increased, as have those in English and French—*e.g.*, *Black Orpheus* (Ibadan, Nigeria, 1957–), containing creative writing by Africans and West Indians.

India, Bangladesh, and Pakistan. Important 20th-century magazines in India, Bangladesh, and Pakistan include the *Illustrated Weekly of India* (Bombay, 1880–), a topical review for educated readers; the *Statesman Weekly* (Calcutta, 1924–), an illustrated digest of Indian news and views; the monthly general review *Current Events* (Dehra Dun, 1955–); *Thought* (New Delhi, 1949–), a political and economic weekly; the monthly *Akhand Anand* (1947–); and the weekly *Akashvani* (New Delhi, 1936–), *Dharmayug* (Bombay, 1950–), and *Mukhabir-I-Alam* (Morādābād, India, 1903–). *Sport and Pastime* (1947–), with offices in nine cities, is well illustrated. *Eve's Weekly* (Bombay, 1947–), in English, Urdu, and Hindustani, is a popular women's magazine. Bangladesh weeklies include *Bangladesh Sangbad* (1972–). Pakistani periodicals include the monthly *Subrang Digest* (1970–) and the weekly *Muslim World* (1961–).

South America. Argentina had a greater magazine circulation than any other nation in South America until the mid-1970s, when total circulation decreased by almost one-half (it has been slowly rising since then). The weekly rotogravure *Maribel* (1932–56) long had the highest periodical circulation in that area, closely followed by that of the women's weekly *Para ti* (1922–). Mexico's leading magazine in the early 1980s was the weekly *Selecciones del Reader's Digest;* others included the weeklies *El Libro Semanal* (1954–) and *Alarma* (1963–). Venezuelan periodicals include the weekly *Resumen* (1973–) and *Elite* (1925–).

News and photo magazines. The accelerated tempo of life in the 20th century, coupled with the bewildering amount of information appearing in print, suggested the need for more concise ways of presenting it. The first to show how it could be done and so give rise to a whole new class of periodical was the U.S. news magazine *Time* (1923–), founded by Briton Hadden and Henry Luce.

The Luce magazines

Time magazine. There had, of course, been news magazines before, both in Europe and the United States. *Time* magazine's immediate forerunner was the folksy *Pathfinder* (1894–1954), a weekly rewriting of the news for rural audiences. There had also been attempts at compression of the digest type (see below). But *Time* was the first to aim at a brief and systematic presentation of the whole of the world's news. It was based on the proposition that "People are uninformed because no publication has adapted itself to the time which busy men are able to spend simply keeping informed." Its beginning was amateurish and precarious; neither Hadden nor Luce had much experience when they started summarizing the news from bundles of daily papers (being perishable, news was not protected by copyright). But after 1928 it grew steadily, finding its market chiefly among the rising number of college graduates. What came to be known as the *Time* style was characterized, in the words of a later critic, by two great democratic ideals, disrespect for authority and reverence for success. It presented the news in narrative form, well researched and checked, in tightly packed sentences, with a general air of omniscience. In the 1930s, to ensure adequate sources of information, Time Inc. built up a large news-gathering organization of its own. It also branched out into other publications, including *Fortune* (1930–), summarizing business news, and *Life* (see below). In the early 1980s *Time* had a circulation of about 4,300,000.

Among the direct followers of *Time* in the United States were *Business Week* (1929–), *United States News* (1933–), and *Newsweek* (1933–), its nearest rival. Simiiar magazines appeared in Shanghai, *East* (1933), and in Britain, the *News Review* (1936), though the latter did not have a comparable success, partly because Britiain was so well supplied with national dailies. After World War II the United States had several news magazines of a regional nature, such as *Fortnight* (1946) in California and *Texas Week* (1946). *Time* has had its greatest influence, however, in postwar Europe, where such magazines as *L'Express* (1953–) in France, *Der Spiegel* (1947–) in West Germany, and *Panorama* (1962–) in Italy derive directly from it. J.-J. Servan-Schreiber, the owner of *L'Express*, remodelled it following a visit to Time-Life in America; he also started two business weeklies, *L'Expansion* and *Le Management. Der Spiegel* ("The Mirror") became famous for its aggressive, anti-authoritarian exposures of scandal and malpractice, while *Panorama* achieved a high standing in Italy and is often cited as a reliable source. The influence of *Time* can probably be traced in most of the news magazines, as in *Tiempo* (1942–) in Mexico or *Primera Plana* (1962–) in Argentina.

Picture magazines. Conciseness can also be achieved through pictures, which obviate the need for description. Illustrated news magazines began in the last century (see above), but they took an altogether new form as photography developed. The most influential, though by no means the first of the modern type, was undoubtedly the United States weekly *Life* (1936–72), started by Henry Luce and the staff of Time Inc.

Pictorial journalism grew up alongside advertising techniques, the tabloid, and the documentary film and was spurred on by the new miniature camera of the Leica type, with wide-aperture lens and high-speed shutter, which enabled top-grade photographs to be taken quickly under almost any conditions. Its pioneers were particularly active in Germany, until many had to flee the Nazis. One of them was the Hungarian Stefan Lorant, who developed the story in pictures with *Bilder Courier* in Berlin in 1926 and with the *Munchener illustrierte Presse* in the period 1927–33. He then went to Britain, where he started a pocket picture magazine, *Lilliput* (1937–60), and was the first editor of *Picture Post* (1938–57). Another pioneer and one of the originators of candid camera shots was a German, Erich Salomon, whose pictures in the London *Tatler* in 1928 prompted *Fortune* to invite him to America, where he inspired *Life* photographer Thomas McAvoy.

In November 1936, therefore, when *Life* first appeared, picture magazines were very much in the air. Only a month before, *Mid-Week Pictorial* (1914–37), an American weekly of news pictures, was restyled along the lines *Life* was to take but was quickly overwhelmed by it. Though expected to have a circulation of well under 500,000 copies, *Life* was running at 1,000,000 within weeks. Its first issue, 96 large pages of pictures on glossy paper for 10 cents, was a sellout, the opening picture brilliant: an obstetrician slapping a baby into consciousness, with the caption "Life begins." Over the years, it kept the promise of its prospectus: "To see life; to see the world; to witness great events; to watch the faces of the poor and the gestures of the proud; to see strange things. . . ." During World War II, which it covered with great accomplishment, it enlarged its operations with a fortnightly international edition, and in 1952 a Spanish-language edition was added for Latin America, *Life en Español.* In 1971 *Life* magazine's circulation was about

7,000,000, but its high costs were no longer being met by advertising income, and it ceased publication in December 1972; it was revived as a monthly in October 1978.

Imitators of *Life* magazine

Of the countless imitators of *Life*, many were American, such as *Focus, Peek, Foto,* and two of longer duration, *Pic* (1937–48) and *Click* (1938–44). Best known was *Look* (1937–71; revived 1979), a popular biweekly. It was founded by Gardner Cowles, Jr., who also started *Quick* (1949–53), a miniature magazine. Britain had two news picture magazines, *Picture Post* (1938–57), which acquired much prestige through its social conscience, and *Illustrated* (1939–58); their place was taken to some extent by the Sunday colour supplements (see above). Preeminent in the rest of Europe is the French *Paris-Match* (1949–), exceptionally well produced and well supplied with photographers; while West Germany has *Stern* (1948–), a glossy blend of light and serious material, and Italy, where magazines are read more than newspapers, has *Oggi* (1945–), which thrives on not-too-sensational disclosures, and the elegant *Epoca* (1950–). There are magazines similar to *Life* in a number of other countries, such as *Cruzeiro (c.* 1908–) in Brazil and *Perspectywy* (1969–) in Poland, and still more that follow the cheaper style of *Look,* such as *Manchete* (1952–) in Brazil, *Caretas* in Peru, or the Australian *Pix–People.*

Digests and pocket magazines. The need for concise reading matter that gave rise to *Time* and *Life* was met even more successfully, in terms of circulation, by a U.S. magazine that reprinted in condensed form articles from other periodicals. This was the pocket-size *Reader's Digest* (1922–), founded by DeWitt Wallace.

Reader's Digest

Reader's Digest magazine. Its forerunners in the United States (apart from those in Europe) were the *Literary Digest* (1890–1938), "a repository of contemporaneous thought and research as presented in the periodical literature of the world," started by two former Lutheran ministers, Isaac K. Funk and Adam W. Wagnalls; the *Review of Reviews* (1890–1937), founded by Albert Shaw to condense material about world affairs; and Frank Munsey's *Scrap Book* (1906–12), "a granary for the gleanings of literature." The *Literary Digest,* in particular, with a circulation of more than 1,000,000 in the early 1920s, was something of a U.S. institution. Its famous straw votes successfully predicted the result of presidential elections after 1920, and its highly publicized wrong prediction of the outcome in 1936 played a decisive part in its collapse. *Reader's Digest,* however, was more specific in content and more universal in appeal. It aimed to supply "An article a day from leading magazines in condensed, permanent, booklet form." Each article, moreover, had to satisfy three criteria: "applicability" (it had to be of concern to the average reader); "lasting interest" (it had to be readable a year later); and "constructiveness" (it had to be on the side of optimism and good works).

The story of *Reader's Digest* is a classic of ingenuity and enterprise, The idea for it occurred to DeWitt Wallace, the son of a Presbyterian minister, when he was recuperating from war wounds in 1919. He prepared a sample, but no publisher was interested. So in 1921 he raised $5,000, and, with the help of his wife-to-be, Lila Bell Acheson, whose father was also a Presbyterian minister, he began to produce the magazine himself (first issue February 1922) from a basement office in Greenwich Village in New York City. After a year, with subscriptions running at about 7,000, the Wallaces moved to a garage and pony shed in Pleasantville, 40 miles north of New York City. Three years later, they were able to build their own house there, and in 1939, when circulation had reached 3,000,000, *Reader's Digest* moved into large premises at nearby Chappaqua. Until 1930 it was produced entirely by amateurs. Condensed books began to be added at the end of the magazine in 1934, and from this grew the Reader's Digest Condensed Book Club, with 2,500,000 members four years later. Overseas editions were started in 1939 (British), and foreign-language editions in 1940 (Spanish), others being steadily added over the following 10 years. In the early 1980s, *Reader's Digest* had one of the largest circulations of any magazine in the world: about 18,000,000 in 13 languages.

Problems of condensing articles

This success was not achieved entirely without setbacks and criticism. At first, permission to reprint was easy to obtain and without charge; but after a while, and especially after competitors entered the field and sometimes reprinted without permission, magazines began to regard the digests as parasitic. Charges were made, which rose steadily, and the major proprietors withheld their permission at various times. To guard against this and because articles of the sort he wanted were in short supply, Wallace began to print original material in the *Digest* in 1933. To keep up the appearance of a digest, articles were commissioned and then offered to other magazines in exchange for the right to "condense" and reprint them. Such articles, "cooperatively planned" accoiding to the *Digest,* "planted" according to critics, were naturally welcome to many magazines with slender budgets, but they did lead to controversy. In 1944, the *New Yorker,* fearing that *Reader's Digest* was generating too big a fraction of magazine articles in the United States, attacked the system as "a threat to the free flow of ideas and to the independent spirit"; but, in the more general view, the matter was regarded as a private one for the parties concerned. Internationally, too, the *Digest* has been attacked since World War II for its part in "American cultural imperialism"; even a U.S. senator has called it a "world cartel." But it has continued to find favour with the magazine public. Its formula, consistently applied from the beginning, has revealed the common denominator in men and women all over the world.

The digest idea was soon taken up by others, often in direct competition but also in more limited areas, such as *Science Digest, Catholic Digest, Negro Digest,* and *Children's Digest.* There was also a *Cartoon Digest* (1939), an *Editorial Digest* (1947), and a *Column Digest* (1949). Most of the general digests were forced to use original articles, since competition for the limited amount of highly popular material became too keen, and *Reader's Digest,* as first in the field, was always able to outbid everyone else. One of the more successful was *Magazine Digest* (founded 1930), based in Canada, with a good deal of scientific and technical matter. One that tried a new formula, based on timeliness and a liberal slant, was *Reader's Scope* (1943–48). The most successful book digest was probably *Omnibook* (1938–57), each issue of which contained abridgments of several popular books, fiction and nonfiction. The digests originally carried no advertising, but, since World War II, they have gradually been driven to it by rising costs. One of the last to capitulate was *Reader's Digest* in 1955 (though some of its foreign editions had always carried advertising), to avoid raising its price (25 cents until 1961); the proportion of advertising was restricted, however, to 20 percent. In general, competitors of *Reader's Digest* have tended to be short-lived and utterly dwarfed by it.

Types of pocket magazines. The success of *Reader's Digest* also had an influence through its format; it popularized the pocket magazine as a type. Several of the self-improving variety, such as *Your Life* (founded 1937) and *Success Today* (1946–50), were started by.Wilfred J. Funk on the proceeds from his father's *Literary Digest* (sold to *Time* in 1938). Of those more directly inspired by *Reader's Digest, Coronet* (1936–61), an offshoot of Esquire Inc., built up a large circulation during World War II, and when it closed, a victim of the promotion race, it was still running at more than 3,000,000. Somewhat livelier and glossier was·*Pageant*, first published in 1944. Britain had several pocket magazines, such as *London Opinion, Men Only,* and *Lilliput,* but these owed rather less to *Reader's Digest.* Finally, there have been a few "superdigests," miniature news magazines with pictures and a minimum of text, such as *Tempo* (1950), *People Today* (founded 1950), and *Jet* (1951–).

Specialized magazines. Though general magazines take the limelight, by far the largest number of periodicals are of the type that cater to specialist interests or pursuits. They vary greatly in circulation, but, even where it is small, it is usually stable over the short term and has the advantage, for an advertiser, of offering a well-defined market. Such magazines may be broadly classified into professional (including trade and technical journals) and nonprofessional.

Professional types. The professional magazine, often the organ of an association, keeps members informed of the latest developments, helps them to maintain standards, and defends their interests. Many were started in the last century, but since then, with the growth of specialization or with the need for a different viewpoint, they have greatly increased in number. Instead of two or three medical journals, for instance, there are now likely to be as many as a dozen, besides those in specialized areas such as dentistry, ophthalmology, and psychiatry. The same can be said of accounting, law, engineering, or any other profession. Though most of these magazines are of little interest to the general public, a few have authoritative articles of broader scope.

Controlled circulation magazines

Trade and technical journals serve those working in industry and commerce. During this century they too have grown enormously in numbers. Apart from all the traditional occupations, every major discovery in science, in manufacturing methods, or in business practice has led to a fresh subdivision of technology, with its own practitioners and, more often than not, its own magazine. The *Standard Periodical Directory* lists more than 65,000 magazines in 230 different categories, in the United States with subjects ranging from accounting and advertising through funeral service and hypnosis to sewage and zoology. Benn's Press Directory lists almost 5,600 periodicais in the United Kingdom, covering more than 340 topics. Such papers tend to be highly factual and accurately written, by people deeply immersed in their subjects. Most are well produced, often on art paper for the sake of the illustrations, and heavily dependent on advertising. Indeed, many are issued for a controlled circulation; *i.e.*, a publisher undertakes to distribute a magazine free of charge to a given number of specialist concerns, who can be relied upon to want a certain range of products. The manufacturers of these products, for their part, are naturally glad to have an advertising medium guaranteed to reach their particular market. The business papers may lack glamour, but they play a vital and highly influential part in economic life.

Nonprofessional types. Of the nonprofessional magazines, quite a number serve broad interest groups, religious, political, or social. Most churches have their journals and often more than one to meet the needs of ministers or sustain faith among the laity. As examples in Britain, one might mention the Catholic *Tablet,* the Anglican *Church Times,* and the Jewish *Chronicle* and, in the United States, the Catholic *Commonweal,* the Protestant *Christian Century,* and the Jewish *Commentary.* Though some of these magazines are subsidized as part of a drive to spread their message, most of them merely aim to foster corporate feeling among co-religionists. Much the same applies to political magazines in the narrow sense—*i.e.*, where they are issued by political organizations: they discuss doctrine, give news of activities, and forge links among members. More general political discussion tends to take place in the literary magazines (see below). Certain periodicals spring from the needs of particular social groups, examples being student magazines, magazines for blacks, or "underground" magazines, all of which see life from some shared point of view, which they encourage and clarify.

By far the largest number of specialized magazines for the layman fall into the hobby category. Very often a professional magazine has its amateur counterpart, as, for instance, in electronics, where the amateur has a wide range of technical magazines on radio, television, hi-fi, and tape recording. Other popular subjects are photography (the British *Amateur Photographer* dates from 1884) and motoring (Hearst's *Motor* was founded, as *Motor Cycling and Motoring,* in 1902); specialization even extends to types of camera and makes of car. No hobby or sport, indoor or outdoor, is without its magazine: boating, fishing, skin diving, philately, model railways, golf and tennis, ballroom dancing, chess, and many others. As soon as any activity becomes sufficiently popular, a magazine appears to cater to its adherents and to provide an advertising medium, not only for manufacturers and suppliers of special goods and services but also for readers, to help them buy and sell secondhand equipment.

"Pulp" and "comic" magazines

Some special tastes in entertainment are met by the "pulp" and "comic" magazines. In 1896, Frank Munsey turned his *Argosy* into an all-fiction magazine using rough wood-pulp paper. The "dime novel" did not qualify for cheap postal rates in the United States, but the pulp magazine did, and so an industry was born. Pulps began as adventure magazines but soon split up into further categories: love, detective, and western. Such magazines sold in millions up to the mid-1930s, when they gradually lost ground to the comics. These began as collections reprinted from the comic strips in newspapers; the first to appear regularly was *Famous Funnies* (1934). After 1937, however, with *Detective Comics,* they came into their own as original publications, and, like the pulps, they grew into a major industry, dividing up into much the same types. They may be seen, in effect, as pictorial condensations of the pulps. Though mainly for children, they were widely read by adults. "Comic" rapidly became a misnomer, as they played increasingly on horror and violence. While some defended them as harmless and cathartic, others condemned them as incitements to imitation. Attempts at control were made through legislation in the United States and elsewhere, and the industry itself tried to regulate standards. Television has since drawn off much of the criticism onto itself and aiso reduced the demand for comics; but they remain big business. One type of magazine, originally classed as pulp but growing to a significant stature, is the science-fiction magazine, which was pioneered by Hugo Gernsback's *Amazing Stories* in 1926.

The "fan" magazines offer glimpses of life behind the scenes in the world of entertainment and sport. In the heyday of motion pictures, numerous magazines appeared about films and their stars, beginning with *Photoplay* (1911) and *Picture Play* (1915) and a succession of others, such as *Movie Mirror* (1930) and *Movieland* (1942). When radio and TV became popular, similar magazines sprang up centring on broadcast programs and their personalities. One of their main functions was to provide a weekly timetable of programs. Today most countries have them, such as the *Radio Times* and *T.V. Times* in Britain, the *TV Guide* in America, *Télé 7 Jours* in France, and *Hor Zu!* in Germany, all with seven-figure circulations.

Finally, there are a number of what might be called "special service" magazines—*e.g.*, financial magazines to help the private investor, magazines of advice issued by consumer associations, magazines specifically for house hunters, racegoers, or for trading in secondhand goods, and so on. It is safe to say that no recognizable group of any size lacks its periodical.

Scholarly and literary magazines. Under the changed social circumstances of the 20th century and with many alternative forums for public debate, the old critical review lost some of its former glory, but it continued to have an influence quite out of proportion to its circulation. One may distinguish broadly between the scholarly type of review, the more widely read politico-cultural periodical, and the purely literary magazine.

Britain. Many of the British reviews founded in the 19th century (see above) have continued to flourish. Among additions of the scholarly type were the *Hibbert Journal* (1902–70), a nonsectarian quarterly for the discussion of religion, philosophy, sociology, and the arts; the *Times Literary Supplement* (1902–), important for the completeness of its coverage of all aspects of books and bibliographical matters; *International Affairs* (1922–), the journal of Chatham House, the Royal Institute of International Affairs, containing serious, long-term articles; and the *Political Quarterly* (1930–), for the discussion of international social and political questions from a progressive but nonparty point of view. Of the weekly political reviews, the long-established *Spectator* (1828–) represents the right and the *New Statesman* (1913–), founded by Sidney and Beatrice Webb, the left, though both in a broad context; while *Time and Tide* (1920–79), originally founded by Lady Rhondda as an independent

Political reviews

journal, was an influential news magazine. Several other periodicals meet the need for serious articles on current questions; among them are the *Economist* (1843–), which carries more general material than its name implies; *The Listener* (1929–), published by the British Broadcasting Corporation and consisting mainly of radio talks in printed form; the *New Scientist* (1956–), drawing attention to current scientific work; and *New Society* (1962–), which does the same for sociology. Among the literary magazines that came and went, but not without leaving their mark, were the *Egoist* (1914–19), associated with Ezra Pound and the Imagists; the *London Mercury* (1919–39), started by J.C. Squire, one of the Georgian poets; the *Criterion* (1922–39), founded and edited by T.S. Eliot; the *Adelphi* (1923–55), of John Middleton Murry, friend of D.H. Lawrence; *New Writing* (1936–46), edited by John Lehmann, who also later revived the old *London Magazine* (1954–); and *Horizon* (1940–50; 1958–), which Cyril Connolly started as a medium for literature during the war years. Since then, *Encounter* (1953–), an international review originally sponsored by the Congress for Cultural Freedom, has proved an intellectual magazine of value and distinction. In addition, many "little magazines" have struggled along, as always, providing essential seedbeds for new writers.

The United States. U.S. counterparts to British scholarly journals would include the *Political Science Quarterly,* edited by the political science faculty of Columbia University; the *American Scholar* (1932–), "a quarterly for the independent thinker" edited by the united chapters of Phi Beta Kappa; *Foreign Affairs* (1922–), a quarterly dealing with the international aspects of America's political and economic problems; and *Arts in Society* (1958–), a forum for the discussion of the role of art, which also publishes poetry and reviews. Of general political journals, the oldest still in publication in the early 1980s was *The Nation* (1865–), founded by E.L. Godkin and edited in the period 1918–34 by Oswald Garrison Villard. By tradition it adopted a critical stand on most matters, disdaining approval by the majority; it was notable for the "casual brilliance" of its literary reviews. When the muckraking phase in the popular magazines died down, zeal for reform was left to a succession of little magazines that led precarious lives, often needing extra support from loyal readers or rich individuals. Such were the *Progressive* (1909), of the La Follette family; *The Masses* (1911–17), run by the Greenwich Village Socialists; and the *New Republic* (1914–), which was started by Herbert Croly with the backing of the Straight family as "frankly an experiment" and "a journal of opinion to meet the challenge of the new time" and which survived as a liberal organ, after many triumphs and vicissitudes. Between the wars came the Marxist *Liberator* (1918–24); the *Freeman* (1920–24 and 1950–54), founded to recommend the single-tax principle of Henry George and later revived as a Republican journal; the *New Leader* (1927), for 10 years the organ of the American Socialist Party; and the extreme left *New Masses* (1926–48). Postwar foundations included the anti-Communist *Plain Talk* (1946–50); the fortnightly *Reporter* (1949–68), strong on "facts and ideas"; and the conservative *National Review* (1955–). Of the literary magazines, the *Atlantic* and *Harper's* were joined by the *American Mercury* (1924–), which had a brilliant initial period under Henry L. Mencken and George Jean Nathan, when it published work by most of the distinguished writers of the time; and the *Saturday Review* (1924–), which began as a purely literary magazine but broadened its scope in the 1940s. In 1972 a new ownership brought additional changes. A powerful influence on American writing has been exerted by the *New Yorker* (1925–), mainly through its founder Harold Ross, a perfectionist among editors. It became famous for its cartoons and probing biographical studies. Finally, there has been no lack of "little magazines" to foster talent; in the early 1980s there were more than 2,000 such magazines.

Europe. Among the numerous literary magazines in Europe, several in France and Germany in particular may be mentioned. The *Mercure de France* was revived in 1890 as an organ of the Symbolists; the influential *Nouvelle Revue française* (1909–) aimed at a fresh examination of literary and intellectual values; and the *Nouvelles Littéraires* (1922–) was founded by Andre Gillon as a weekly of information, criticism, and bibliography. Since World War II there have been Jean-Paul Sartre's left-wing monthly *Les Temps modernes* (1945–); *La Table ronde* (1948–); and *Les Lettres nouvelles* (1953–). In Germany, political magazines at the beginning of the century included the radical *Die Fackel* (1899; "The Torch") and *Die neue Gesellschaft* (1903–07; "The New Society") of the Social Democrats. An important literary influence was *Blatter fur die Kunst,* associated with the Neoromantic movement of Stefan George. The Nazi period imposed an artificial break in development, but since the war there have been the liberal weekly *Die Zeit* and a number of literary journals such as *Westermanns Monatshefte, Neue deutsche Hefte,* and *Akzente.*

Reviews in Communist countries

The political involvement of the literary review has been especially marked in the Soviet Union and iron curtain countries. The *Literaturnaya Gazeta* (1929–) and the influential *Novy Mir* (1925– ; "New World") have often been the centre of controversy in the Soviet Union when writers have been condemned for their views or denied the opportunity to publish. This has led to a strong underground press. In Czecholovakia the *Literárne Listy* played a prominent part in the freedom movement of 1968 and was later suppressed at Soviet insistence, along with the *Reportér* and *Student,* leading again to the starting of several underground magazines. Even *Sinn und Form* (1949–), a Marxist critical journal in East Germany, has been subject to temporary suspensions by the government for publishing such banned authors as Sartre, Kafka, and Hemingway.

CURRENT PROBLEMS AND TRENDS

Magazines in the second half of the 20th century are faced with rising production costs, falling advertising revenue, and competition from paperbacks and television. Their most expansive phase is almost certainly over, and there is a marked trend away from the general-interest magazine toward specialization. Yet the industry as a whole is far from declining; it is merely changing, as it always has done, in response to social change and technical development.

Production costs. Rising costs of production are a fairly universal phenomenon that can only be offset by increased efficiency. Some help in stabilizing costs in the magazine industry may come eventually through electronic techniques, but these are still in their infancy, and the cost of installing equipment is itself an inhibiting factor. It has been suggested that greater gains in economy might be obtained by rationalizing the process of manufacture. Traditionally, a magazine is set up, printed, and bound under one roof, but successful experiments have been made in separating these operations. Such specialization has obvious organizational advantages, and overheads are generally confined to each specific operation without penalizing any other. Closer collaboration between publisher and printer is also currently recommended, to avoid false lines of development, leading to either bottlenecks or idle capacity.

Competition with television

Increased costs have naturally been reflected in higher charges for advertising, which have weakened the competitive position of magazines with respect in particular to television advertising. It seems that in the early days of the television boom any advertising through that medium was extra and did not cut into magazine advertising, but this is no longer true. Television's share of advertising has been rising, and that of magazines has been falling. Yet there are signs that this trend is past its maximum. The cost of advertising, per message per 1,000 of audience, is higher in magazines than in the daily press or on television, but it has a much greater "recall value," which gives it a strong fundamental position.

Circulation. High circulations are, of course, the *sine qua non* of high advertising rates, but there are levels at which returns begin to diminish, and this has led to the anomaly of deliberate reductions in circulation. In 1970, *Life* magazine, with a circulation of 8,500,000 and a charge of $67,000 for a full-page colour advertisement, found it was losing 14 percent of its advertising revenue. It therefore restricted circulation to 7,000,000 and dropped its charge to the more viable rate of $54,000, but even this reduction could not prevent the magazine's demise. Similarly in Britain, when its circulation of 3,500,000 was proving an embarrassment to *Woman* in 1957, *Woman's Realm* (1958–) was launched to absorb the excess. A solution adopted in America is "regionalization." For the sake of the advertising, *Time,* for instance, has split up into 200 different area editions. It seems likely that much can be done through flexibility of makeup to enable a magazine to catch national, regional, and local advertising.

Playboy magazine

While some magazines, as always, are on the way down, numbers of periodicals continue to rise in almost every country, and there is no indication of any decline in the total amount of money that is spent on them. It is true that magazines relying heavily on entertainment have been affected by television, just as those relying on fiction have been hit by paperbacks. But categories of magazines have become somewhat blurred; *Life,* for instance, was "illustrated," "information," and "entertainment." In general, the "all or none" principle applies—*i.e.*, the media tend to reinforce each other; keen television viewers, for instance, are also keen magazine readers. Moon shots are exciting on television but are more permanent in a magazine; news is fresher in a daily paper, but interpretation is less transient in a magazine. The mortality rate among periodicals is traditionally high, as are the odds against success for a new one. Yet a clear editorial intent, backed by adequate capital, can still succeed on the scale of *Playboy* (1953–) in the United States, for instance, with a circulation of about 5,200,000, or, more modestly, of the woman's magazine *Nova* (1965–75) in Britain. *Nova* got off to a magnificent start as "The New Magazine for a New Kind of Woman," but it lost ground, significantly, when it began to waver editorially between features and femininity. As society grows more complex, the need is not so much for a comparatively small number of mass-circulation magazines, as in the past, as it is for a large number of periodicals to serve the many subgroups that are continually forming. As leisure time has increased, so too has the number of magazines of the hobby or special-interest type; and as educational standards have risen, so too has the broadly educational content of many magazines. Every new area of interest, such as ecology and conservation, quickly produces a spate of new magazines. These trends seem likely to continue and become more pronounced.

BIBLIOGRAPHY. O.H. CHENEY, *Economic Survey of the Book Industry,* 1930–31 (1931, reprinted 1960), a massive work covering all aspects of U.S. publishing and bookselling that still has relevance to present-day problems; COLIN CLAIR, *A History of Printing in Britain* (1965), a detailed account of individuals and their contributions, particularly useful for the early period in England; EUGENE EXMAN, *The House of Harper* (1967), a full-scale account of a famous American publishing firm, from its founding down to the present—especially useful for the 19th century and early U.S. copyright complications; GINN AND COMPANY, *Seventy Years of Text Book Publishing: A History of Ginn and Company,* 1867–1937 (1937), outlines the state of U.S. illiteracy after the Civil War and the opportunities for educational publishing that were ably exploited; HENRY HOLT, *Sixty Years As a Publisher* (1924), personal memories of a famous American publisher, valuable for details of trade practices and early copyright arrangements (or lack of them): ALLEN KENT and HAROLD LANCOUR (eds.), *Copyright: Current Viewpoints on History, Laws, Legislation* (1972), a useful collection of essays on copyright from varied professional viewpoints; R.J.L. KINGSFORD, *The Publishers Association* 1896–1946 (1970), a detailed and fully documented history of the first 50 years of the association that covers all the main problems of book trade organization and attempts at their solution in Britain; W.J. LEAPER, *Copyright and Performing Rights* (1957), a legal handbook covering the history of copyright in England and the implications of the Berne Convention and the Universal Copyright Convention; H. LEHMANN-HAUPT, *Das Amerikanische Buchwesen* (1937; Eng. trans., *The Book in America,* 2nd ed., 1951), one of the few general books on the subject, especially good in relating American publishing to its historical background; LENOX LOHR, *Magazine Publishing* (1932), a detailed account, department by department, of the work involved in the editing and management of a weekly or monthly magazine; RUARI MacLEAN, *Magazine Design* (1969), a handsomely produced royal octavo volume containing reproductions of the covers of famous magazines of the United States and of Britain and other European countries; JOHN C. MERRILL, CARTER R. BRYAN, and MARVIN ALISKY, *The Foreign Press* (1970), a very complete and concise survey of the current state of newspaper publishing throughout the world, taking the American press as its point of departure and also containing some data on magazines; F.A. MUMBY, and IAN NORRIE, *Publishing and Bookselling,* 5th ed. (1974), traces the history of the trade from classical and medieval times to the beginnings of the modern approach in the 17th century and then deals most fully with the 19th and 20th centuries in Britain; THEODORE PETERSON, *Magazines in the Twentieth Century,* 2nd ed. (1964), a scholarly survey describing not only the course of the development of some principal U.S. magazines but also the social and economic factors that affected their fortunes; G.H. PUTNAM, *Memoirs of a Publisher,* 1865–1915 (1915), useful background material on post-Civil War social economics and the effects on book buying, also on Japanese literary piracy following the Perry expedition; E. LLOYD SOMMERLAD, *The Press in Developing Countries* (1966), a discussion from every angle of the many problems involved in bringing out a newspaper in countries just beginning to have a regular press; S.H. STEINBERG, *Five Hundred Years of Printing,* 2nd ed. rev. (1962). a most complete and readable account for the general reader, covering all its aspects of printing and its impact on civilization; GRAHAM STOREY, *Reuters' Century,* 1851–1951 (1951), a thorough account of the history of news gathering, told primarily from Reuters' point of view, which does full justice to much else, including the great U.S. agencies; JOHN TEBBEL, *A History of Book Publishing in the United States,* 4 vol. (1972–81), a detailed and interesting account of book publishing in the United States from 1930 to 1980; UNESCO, *World Communications,* 5th ed. (1975), a worldwide survey, including statistics on the press, news agencies, radio, television, and films; CYNTHIA WHITE, *Women's Magazines,* 1693–1968 (1971), a history of women's magazines in Britain, with a chapter on American equivalents, by a social historian; FRANCIS WILLIAMS, *The Right to Know* (1969), a detailed account of the world press, with emphasis on Britain, the United States, and leading European countries, by a former editor of the London *Daily Herald* and a governor of the BBC, who regards newspapers as unique barometers of their times that indicate the climate of the societies from which they spring; RICHARD WINCOR and IRVING MANDELL, *Copyright, Patents and Trademarks* (1980), a legal handbook covering the history of copyright in the United States, including the copyright act of 1976; JAMES P. WOOD, *Of Lasting Interest: The Story of the Reader's Digest* (1958), outlines the early life of DeWitt Wallace and describes in vivid detail the conception, launching, and brilliant development of the most famous and successfui of the digests.

(P.U./G.U.)

Puccini, Giacomo

Almost exclusively a composer of opera, Giacomo Puccini virtually brought the history of Italian opera to an end. He wrote what are perhaps the only Impressionistic Italian operas, at least, to the extent that they avail themselves of Impressionistic musical technique.

Puccini's approach to dramatic composition is expressed in his own words: "The basis of an opera is its subject and its treatment." The fashioning of a story into a moving drama for the stage claimed his attention in the first place, and he devoted to this part of his work as much labour as to the musical composition itself. The action of his operas is uncomplicated and self-evident, so that the spectator, even if he does not understand the words, readily comprehends what is taking place on the stage.

Giacomo Antonio Domenico Michele Secondo Maria Puccini was born on December 22, 1858, in Lucca, Italy. He was the last descendant of a family that for two centuries had provided the musical directors of the Cathedral of S. Martino in Lucca. Puccini initially dedicated himself to music, therefore, not as a personal vocation but as a family profession. He was orphaned at the age of five by the death of his father, and the municipality of Lucca supported the family with a small pension and kept the position of cathedral organist open for Giacomo until he became of age. He first studied music with two of his father's former pupils and he played the organ in small local churches. A performance of Verdi's *Aida*, which he saw in Pisa in 1876, convinced him that his true vocation was opera. In the autumn of 1880 he went to study at the Milan Conservatory, where his principal teachers were Antonio Bazzini, a famous violinist and composer of chamber music, and Amilcare Ponchielli, the composer of the opera *La gioconda*. On July 16, 1883, he received his diploma and presented as his graduation composition *Capriccio sinfonico*, an instrumental work that attracted the attention of influential musical circles in Milan. In the same year, he entered *Le villi* in a competition for one-act operas. The judges did not think *Le villi* worthy of consideration, but a group of friends, led by composer-librettist Arrigo Boito, subsidized its production, and its premiere took place with immense success at Milan's Teatro dal Verme on May 31, 1884. *Le villi* was remarkable for its dramatic power, its operatic melody, and, revealing the influence of Wagner's works, the important role played by the orchestra. The music publisher Giulio Ricordi immediately acquired the copyright, with the stipulation that the opera should be expanded to two acts. He also commissioned Puccini to write a new opera for La Scala and gave him a monthly stipend: thus began Puccini's lifelong association with Giulio Ricordi, who was to become a staunch friend and counsellor.

Alinari—Mansell

Puccini.

Elopement with Elvira

After the death of his mother, Puccini fled from Lucca with a married woman, Elvira Gemignani. Finding in their passion the courage to defy the truly enormous scandal generated by their illegal union, they lived at first in Monza, near Milan, where a son, Antonio, was born. In 1890 they moved to Milan, and in 1891 to Torre del Lago, a fishing village on Lake Massaciuccoli in Tuscany. This home was to become Puccini's refuge from life, and he remained here until three years before his death, when he moved to Viareggio. But living with Elvira proved difficult. Tempestuous rather than compliant, she was justifiably jealous and was not an ideal companion. The two were finally able to marry in 1904, after the death of Elvira's husband. Puccini's second opera, *Edgar*, based on a verse drama by the French writer Alfred de Musset, was performed at La Scala in 1889 and it was a failure. Nevertheless, Ricordi continued to have faith in his protégé and sent him to Bayreuth in Germany to hear Wagner's *Die Meistersinger*.

Puccini returned from Bayreuth with the plan for *Manon Lescaut* based, like the *Manon* of the French composer Massenet, on the celebrated 18th-century novel by the Abbé Prévost. Beginning with this opera, Puccini carefully selected the subjects for his operas and spent considerable time on the preparation of the libretti. The psychology of the heroine in *Manon Lescaut*, as in succeeding works, dominates the dramatic nature of Puccini's operas. Puccini, in sympathy with his public, was writing to move them so as to assure his success. The score of *Manon Lescaut*, dramatically alive, prefigures the operatic refinements achieved in his mature operas: *La Bohème* (1896), *Tosca* (1900), *Madarna Butterfly* (1904), and *La fanciulla del west* (1910, *The Girl of the Golden West*). These four mature works also tell a moving love story, one that centres entirely on the feminine protagonist and ends in a tragic resolution. All four speak the same refined and limpid musical language of the orchestra that creates the subtle play of thematic reminiscences. The music always emerges from the words, indissolubly bound to their meaning and to the images they evoke. In *Bohème*, *Tosca*, and *Butterfly*, he collaborated enthusiastically with the writers Giuseppe Giacosa and Luigi Illica. The first performance (February 17, 1904) of *Madama Butterfly* was a fiasco, probably because the audience found the work too much like Puccini's preceding operas.

Characteristics of mature work

In 1908, having spent the summer in Cairo, the Puccinis returned to Torre del Lago and Giacomo devoted himself to *Fanciulla*. Elvira unexpectedly became jealous of Doria Manfredi, a young servant from the village who had been employed for several years by the Puccinis. She drove Doria from the house threatening to kill her. Subsequently, the servant girl poisoned herself, and her parents had the body examined by a physician, who declared her a virgin. The Manfredis brought charges against Mrs. Puccini for persecution and calumny, creating one of the most famous scandals of the time. Elvira was found guilty, but through the negotiations of the lawyers was not sentenced, and Puccini paid damages to the Manfredis, who withdrew their accusations. Eventually the Puccinis adjusted themselves to a coexistence, but the composer from then on demanded absolute freedom of action.

The premiere of *La fanciulla del west* took place at the Metropolitan in New York on December 10, 1910, with Arturo Toscanini conducting. It was a great triumph, and with it Puccini reached the end of his mature period. He admitted "writing an opera is difficult." For one who had been the typical operatic representative of the turn of the century, he felt the new century advancing ruthlessly with problems no longer his own. He did not understand contemporary events, such as World War I.

In 1917 at Monte-Carlo in Monaco, Puccini's opera *La rondine* was first performed, and then was very quickly forgotten.

Always interested in contemporary operatic compositions, Puccini studied the works of Claude Debussy, Richard Strauss, Arnold Schoenberg, and Igor Stravinsky. From this study emerged the *Il trittico* (*The Triptych;* New York, 1918), three stylistically individual one-act operas—the melodramatic *Il tabarro (The Cloak)*, the sentimental *Suor Angelica*, and the comic *Gianni Schicchi*. His last opera, based on the fable of *Turandot* as told in the play *Turandot* by the 18th-century Italian dramatist Carlo Gozzi, is the only Italian opera in the Impressionistic style. Puccini did not complete *Turandot*, unable to write a final grand duet on the triumphant love between Turandot and Calaf. Suffering from cancer of the throat, he was ordered to Brussels for surgery, and a few days afterward, on November 29, 1924, he died with the incomplete score of *Turandot* in his hands.

Turandot was performed posthumously at La Scala on April 25, 1926, and Arturo Toscanini, who conducted the performance, concluded the opera at the point Puccini had reached before dying. Two final scenes were completed by Franco Alfano from Puccini's sketches.

Solemn funeral services were held for Puccini at La Scala in Milan, and his body was taken to Torre Del Lago, which became the Puccini Pantheon. Shortly afterward, Elvira and Antonio were also buried there. The Puccini house became a museum and an archive.

The themes of the operas

The majority of Puccini's operas illustrate a theme defined in *Il tabarro:* "Chi ha vissuto per amore, per amore si mori" ("He who has lived for love, has died for love"). This theme is played out in the fate of his heroines—women who are devoted body and soul to their lovers, are tormented by feelings of guilt, and are punished by the infliction of pain until in the end they are destroyed. In his treatment of this theme, Puccini combines compassion and pity for his heroines with a strong streak of sadism: hence the strong emotional appeal but also the restricted scope of the Puccinian type of opera.

The main feature of Puccini's musicodramatic style is his ability to identify himself with his subject; each opera has its distinctive ambience. With an unfailing instinct for balanced dramatic structure, Puccini knew that an opera is not all action, movement, and conflict; it must also contain moments of repose, contemplation, and lyricism. For such moments he invented an original type of melody, passionate and radiant, yet marked by an underlying morbidity; examples are the "farewell" and "death" arias that also reflect the persistent melancholy from which he suffered in his personal life.

Puccini's conception of diatonic melody is rooted in the tradition of 19th-century Italian opera, but his harmonic and orchestral style indicate that he was also aware of contemporary developments, notably the work of the Impressionists and of Stravinsky. Though he allowed the orchestra a more active role, he upheld the traditional vocal style of Italian opera, in which the singers carry the burden of the music. In many ways a typical *fin-de-siècle* artist, Puccini nevertheless can be ranked as the greatest exponent of operatic realism.

MAJOR WORKS

OPERAS: *Le villi* (first performed 1884); *Edgar* (1889); *Manon Lescaut* (1893); *La Bohème* (1896); *Tosca* (1900); *Madama Butterfly* (1904); *La fanciulla del west* (1910, *The Girl of the Golden West); La rondine* (1917); *Il trittico: Il tabarro, Suor Angelica, Gianni Schicchi* (1918); *Turandot* (1926).

BIBLIOGRAPHY. Complete catalogs of Puccini's compositions may be found in MOSCO CARNER, *Puccini: A Critical Biography,* 2nd ed. (1977); and CLAUDIO SARTORI, *Puccini,* 2nd ed. (1963), in Italian; a complete catalog of recordings in EUGENIO GARA, *Carteggi Pucciniani* (1958). The principal collections of autographed compositions and letters are at the Puccini Villa in Torre del Lago; the archives of the Ricordi House in Milan; and the library of the Boccherini Musical Institute in Lucca. Puccini's letters have been published in *Carteggi Pucciniani* (cited above); and in GIUSEPPE ADAMI (ed.), *Letters of Giacomo Puccini,* new ed. (1974). English translations of the letters to Sybil Seligman have been published in VINCENT J. SELIGMAN, *Puccini Among Friends* (1938, reprinted 1971). Other works on the life and music of Puccini include: GEORGE R. MAREK, *Puccini* (1951), an exhaustive biography; DANTE DEL FIORENTINO, *Immortal Bohemian* (1952); RICHARD SPECHT, *Giacomo Puccini; das Leben, der Mensch, das Werk* (1931; Eng. trans., *Giacomo Puccini, the Man, His Life, His Work,* 1933, reprinted 1970); WILLIAM ASHBROOK, *The Operas of Puccini* (1968); and HOWARD GREENFELD, *Puccini* (1980).

(C.Sa.)

Puerto Rico

An autonomous political entity in voluntary association with the United States according to a 1953 UN resolution, the Commonwealth of Puerto Rico occupies a central position among the West Indian islands. Its land rises sharply from the tropical sea, and its coastal plain quickly ascends to meet the steep mountain ranges that give the island the appearance of a nearly rectangular pyramid. By air it is about 1,600 miles (2,600 kilometres) from New York City, 1,050 miles from Miami, and 550 miles from Caracas. To the west lie the other, larger islands of the Greater Antilles—Hispaniola (containing the Dominican Republic and Haiti), Jamaica, and Cuba—while to the east is St. Thomas, of the Virgin Islands group, the closest of the myriad islands of the Lesser Antilles.

Impact of Spanish tradition

San Juan was the name given the island when it was discovered by Columbus in 1493; its capital city was known as Puerto Rico (Spanish: "rich harbour"). In the course of centuries, during which it played an integral role in Spain's empire in the Americas, the names for island and city were interchanged. At the same time its people developed traditions and a way of life that remain deeply rooted in Spanish culture. This factor, even more than the island location, helps to isolate the Puerto Rican from the northern European culture that shaped most of the institutions of other U.S. citizens. Pride in this unique heritage has been a major emotional component in the continuing internal debate among proponents of U.S. statehood, independence, and the maintenance of a commonwealth status.

Despite their heritage, Puerto Ricans began a massive exodus to mainland cities in the 1950s, largely because of an exploding population, which by 1980 was more than 3,100,000. Many persons lacking the skills to participate in the island's industrial development found themselves crushed into a hilly land whose area, counting several small adjacent islands, totals only 3,435 square miles (8,897 square kilometrcs). By the early 1970s the exodus to the mainland had been slowed but not completely stopped, and escape from crushing poverty in some areas remained a definite factor of life in Puerto Rico, along with a critical shortage of adequate housing and an unemployment rate more than twice the national average of the United States. In spite of these continuing problems, Puerto Ricans in general enjoy the highest per capita personal income and the highest standard of living in Latin America. They have come to represent a unique social and political community within both the United States and the Spanish-speaking nations of the Americas. (For information on related topics, see the articles CARIBBEAN SEA; UNITED STATES, HISTORY OF THE; and SPAIN, HISTORY OF.)

THE HISTORY OF PUERTO RICO

Pre-Columbian habitation. The early inhabitants of Puerto Rico were Indians from either the Florida peninsula or the Orinoco River Basin in South America. The Indians whom Christopher Columbus met, when he discovered Puerto Rico on November 19, 1493, belonged to the South American Arawak stock, a peaceful, sedentary people, given to fishing and agriculture. They numbered from 30,000 to 50,000, but their hold on the island was already being challenged by the bellicose Caribs from the Lesser Antilles.

Exploration and early development. Puerto Rico became one of the earliest Spanish settlements in the New World. The Spanish explorer Juan Ponce de Leon landed from Hispaniola in 1508, and he founded the first town, Caparra, and initiated the first mining and agricultural efforts. Gold mining was briefly profitable, but production declined with dwindling Indian labour. Sugarcane became the leading agricultural product with the introduction of slaves from Africa, but by the end of the 16th century it still had failed to spur the development of the island.

The exposed position of the island, however, enhanced its strategic value to Spain and its enemies. It was attacked successively by the French, by the English under Sir Francis Drake in 1595 and the 3rd earl of Cumberland in 1598, and by the Dutch in 1625—attacks that forced Spain to turn the city of Puerto Rico into the most fortified place in the West Indies.

Puerto Rico remained largely undeveloped until the late 18th century, when efforts were made to improve conditions. The population increased from about 45,000 in 1765 to 155,000 in 1800, about which time trade, no longer restricted to the Spanish empire, began to develop with the United States and other nations.

The 19th century. Puerto Rico remained loyal to Spain throughout the Napoleonic Wars and the wars of Latin-American independence. In 1815 a royal order issued by Spain opened the island to trade and to colonization, especially by loyalists fleeing from rebellious colonies in South America. After 1830 Puerto Rico gradually developed into a plantation economy, based on three main crops: sugar, coffee, and tobacco. Sugar and molasses, sold mainly in the U.S. market, provided an important source of income for the Spanish government. Foreign settlers contributed to economic development, though the Spanish element attempted to maintain a tight monopoly and gave strong support to the military and administrative bureaucracies.

Reform movements

After the U.S. Civil War and Spain's attempted reconquest of Santo Domingo, a new generation pressed for the abolition of slavery, free trade, and political rights. The more radical members of the generation opted for independence and were responsible for a revolution in 1868 that was quelled quickly by Spanish forces. Though separatist elements, led by Ramon Emeterio Betances, joined the Cubans who were struggling for independence, they were unable to challenge Spanish power effectively. Moderate reformist groups eventually joined forces with Roman Baldorioty de Castro, a leader advocating self-government under Spain. In 1897 they succeeded in obtaining a charter from Spain granting the island broad powers of self-government.

Period of U.S. influence. The Spanish–American War (1898) soon ended this promising period of reform. Largely unopposed invading U.S. troops were received cordially by large segments of the population, and there was great hope for increased political rights and economic benefits. The Treaty of Paris ceded Puerto Rico to the United States and left to the U.S. Congress the determination of its political future.

The U.S. military ruled with little regard for political sensitivities. The Foraker Act of 1900, which provided for civil government and helped pave the way for free trade with the United States, was a step backward in the struggle for political rights, since most power was held by federal appointees.

Early U.S. governors were mainly preoccupied with Americanizing Puerto Rican institutions, language, and political habits, but had no clear policy on the island's eventual political status. This approach created strong resistance from many native leaders led by Luis Muñoz Rivera, who had fought for autonomy under Spain. In the meantime, free access of sugar to the mainland market created a profound change in the economy, with 75 percent of the population coming to depend on the sugar industry by 1920. The population increased from about 950,000 in 1899 to more than 1,540,000 in 1930. Glaring inequalities of wealth contributed to sharpened social and political tensions.

Politically, the U.S. Congress broadened the very limited basis of Puerto Rican self-government by granting an elective senate in 1917 and extending U.S. citizenship to Puerto Ricans, but the governor and other key executive officials continued to be appointed by the president. According to Supreme Court decisions, Puerto Rico was an organized but unincorporated territory of the United States.

Beginnings of status controversies

As economic conditions worsened, the 1930s became an era of hidden, potentially explosive crises. The Nationalist Party insisted on complete and immediate independence, while statehood was defended by the Republican Party. The Socialist Party, more concerned with social and economic reforms, formed a coalition with the Republicans that dominated the island's legislature in the 1930s. The Popular Democratic Party, founded by Luis Muiioz Marín, won the election of 1940 and pushed through a program with strong support from the rural electorate. In 1946 Pres. Harry S. Truman appointed Jesus T. Piñero as the first native Puerto Rican governor; a popularly elected governor followed in 1948. A congressional law of 1950, approved in a referendum by the people of Puerto Rico, called for a constitution to be drafted and approved by the insular electorate. On July 25, 1952, the Commonwealth of Puerto Rico was established, with Luis Muiioz Marín elected as its first governor.

Though enjoying strong popular support, the commonwealth failed to satisfy the independence and statehood groups. A moderate Independence Party was formed, and from 1952 to 1956 it was the second party on the island. Statehood-oriented leaders staged a comeback by 1960 and narrowly captured the governorship in 1968. An island-wide referendum in 1967 showed that 60 percent favoured the commonwealth and 39 percent preferred statehood, but most of the voters favouring independence abstained and continued to agitate for separation. In 1972 the Popular Democratic Party was returned to power over the New Progressive Party, while the Independence Party made small gains. The New Progressive Party won the governorship in 1976 and 1980 over the Popular Democratic Party, and the independence Party polled third.

THE NATURAL LANDSCAPE

Mountainous landscape

Surface features. Puerto Rico is a rugged and hilly island. Nearly half of the island lies 500 feet (150 metres) or more above sea level—about 20 percent between 500 and 1,000 feet and about 25 percent more than 1,000 feet. The island is divided into three main geographical regions: the mountainous interior, the northern plateau, and the coastal plains. The central mountain range, known as the Cordillera Central, rises to more than 3,000 feet, with the highest points at Cerro de Punta, 4,389 feet, and Monte Guilarte, 3,949 feet. The range slopes very steeply to the southeast. Although the northern slope is less steep, the rivers have eroded the area more thoroughly. The south-running rivers are short and torrential, but they are dry most of the time.

In the northwest the elevation of the northern plateau averages 100 feet near the coast and 700 feet toward the interior. The plateau is crossed by small hills, and toward the interior the land is covered by hundreds of hillocks and gullies. In the northeast the Sierra de Luquillo includes the rain forest of El Yunque, a jungle of tropical and subtropical trees and plants—giant ferns, orchids, and trailing vines. The whole area of 29,000 acres (12,000 hectares) is included in the Caribbean National Forest and is a major tourist attraction.

In the north the coastal plains run from Punta Borinquen in the west to Cabezas de San Juan in the extreme northeast. Adjacent to the coast the land is quite level, interrupted only by a few rock promontories and by lines of sand dunes along the shore. The only flatlands of importance are found in the alluvial plains of such rivers as the Grande de Arecibo, Cibuco, Grande de Loiza, and La Plata. The mountains reach close to the shore in the east, the rivers forming deep valleys; in the west the valleys are even deeper. In the south the coastal plains are narrower and more regular than on the northern coast and are studded with hillocks and sand dunes.

Relation of topography and precipitation

The island's varied precipitation is the direct result of its topography. The east–west mountains form a barrier to the dominant east-to-northeasterly winds, giving the north an abundance of rain. On rising over the Cordillera Central, the warm, humid air masses cool and lose much of their moisture, so that rain on the southern coast is scarce, and a dry climate predominates. The rugged and irregular topography accounts for the nearly 1,300 streams, but only 50 are true rivers. The northern slopes carry the main currents, many of them flowing into plains so low that marshes, moors, and some lakes are formed. Drainage is deficient and floods are common. The shorter rivers on the southern slopes are dry in winter but torrential in the wet season.

Climate. Lying within the tropical zone, Puerto Rico has a pleasant climate greatly influenced by the sea and the warm North Equatorial Current. Moisture-laden winds from the east and northeast bring on the frequent rainy periods of winter as they encounter occasional cold fronts that extend southward into the West Indies from the U.S. mainland. Temperatures in Puerto Rico very seldom fall below 60° F (16" C). Extreme temperatures are rare, with the highest recorded daily average at 89° F (32° C) and the lowest at 66° F (19° C).

Vegetation and animal life. Puerto Rico has relatively little animal life. Wildlife includes nonpoisonous snakes, several lizards, mongooses, and birds. The most common birds are the thrushes, tanagers, bullfinches, flycatchers, warblers, plovers, terns, and sandpipers. Fish abound in great variety, but with little economic exploitation. Plant life includes palm trees and mangrove, which flourish along the coast, and bamboo in great clumps along the roads and streams. African tulip trees, bougainvillea, hibiscus, poinsettias, a golden trumpet known as *canario,* and other plants splash vivid colour against a green and brown landscape throughout the year.

THE PEOPLE OF PUERTO RICO

Ethnic and racial blending. The people of Puerto Rico are historical products of a mixture of diverse ethnic strains. The main ethnic stocks are Spanish and African, and though the aboriginal Indians were either absorbed

Composite character of the people

or eliminated, some of their physical characteristics remain, particularly in the peoples of the mountains. Settlers from several European nations arrived at the island in the 19th century—Danish, French, Corsican, and some English and German. During the 20th century there was a limited flow of people from the United States and, during the 1950s and 1960s, a major influx of Cubans. Slavery, introduced in the early days of the Spanish conquest, never flourished as it did in Saint-Dorningue (Haiti under French control), Jamaica, and Barbados. In the early 19th century, when the emphasis was on sugar cultivation, thousands of African slaves were brought into Puerto Rico, reaching a total of more than 50,000 around 1850. Under Spanish rule many slaves earned their freedom. In 1846, for instance, free blacks numbered more than 175,000. Abolition of slavery was achieved in 1873 without violence.

Since the end of the 18th century the population gradually has become a blend of its various ethnic strains. The independent, isolated small farmers of the interior, known as jibaros, have become a symbol of the social and cultural heritage of the island. Despite the mixture of peoples and traditions, the Puerto Ricans are a very homogeneous people; no group is looked upon as a minority in either racial, ethnic, or linguistic terms.

Patterns of migration

Demography. Puerto Rico's annual growth rate increased from little more than 1 percent in the late 1960s to almost 3 percent in the 1970s, representing one of the world's highest growth rates. The establishment of family planning programs and other measures aimed at birth control have contributed to a sharp decline in birth rates since 1966. The birth rate still exceeds the death rate, however, yielding a natural rate of increase in 1977 of 1.7 percent, compared with 0.6 percent for the United States. Internal population growth has been affected by migrations to and from the United States. Prior to 1960 emigration was largely responsible for an extremely low rate of growth. From 1960 to 1965 migration declined, birth rates dropped slightly, and the annual growth rate rose to 2.5 percent. Migration increased again after 1965, though the great number of returning Puerto Ricans held the net emigration to about 7,000 persons in 1969. During the 1970s, however, the number of returning migrants exceeded the number of emigrants, resulting in an average in-migration of about 25,000 residents per year. In 1977 this trend reversed again, with a net emigration of approximately 20,000 people. Of the migratory workers and families that have stayed in the United States, most have concentrated in the New York City area, although there are growing Puerto Rican settlements in the Eastern and Midwestern states.

The majority of migrants are from rural areas. With low educational levels, little work experience, and often a poor command of English, their lot has not been easy in urban areas on the mainland, where they have suffered from discrimination, unemployment, cultural deprivation, and loss of identity.

Puerto Rico's population is predominantly young. The median age by 1978 was 22.2 years for women and 24.4 years for men. There has been a definite increase in the numbers of persons of middle or advanced years, along with steadily rising life-expectancy rates. About 60 percent of the Puerto Ricans lived in urban areas in the early 1970s, compared with 44 percent in 1960. Urban growth, one of Puerto Rico's most pressing problems, has increased the demand for housing, transportation, and services, problems that the government must resolve if it is to sustain and improve living standards.

THE COMMONWEALTH'S ECONOMY

Industry and agriculture. Since the end of World War II the island has undergone an industrial transformation that has had profound social and economic effects. The shift from agriculture to industrial production has been largely the result of commonwealth policies that, since 1948, have encouraged private investors. Efforts at industrialization were begun in the 1940s by the Puerto Rico Industrial Development Company, a governmental corporation that was revamped in 1950 as the Economic Development Administration, popularly known as Fomento. Its program has been known as "Operation Bootstrap." Its early achievements were modest: 82 factories were created in the first three years and 6,200 people were employed. This well-published pioneer work succeeded in attracting new industries to the island. Income from manufacturing

Economic expansion

surpassed that from agriculture in 1955 and by 1978 was nine times greater. Net manufacturing income in 1978 was more than $3,000,000,000, whereas the agricultural income was less than $350,000,000. Per capita personal income rose steadily from about $280 to about $2,500 in 1977.

Natural resources. Puerto Rico's industrial achievement is the more remarkable because the island is poor in minerals. Iron, manganese, lead, and zinc occur in such small quantities that there is no important commercial exploitation. Explorations, however, have revealed rich copper deposits; negotiations between the government and the mining companies on their development have been undertaken. Several nickel deposits also have been discovered.

Trade relations. Rising living standards and purchasing power have made Puerto Rico one of the best customers of the United States; Puerto Rico's imports increased more than threefold from 1960 to 1976. The United States, in turn, has been Puerto Rico's best customer, though the balance of trade remains in favour of the United States. Puerto Rico's position is worsened by unfavourable trade balances with foreign countries. Tourism has become an important source of income, with tourist expenditures increasing more than sixfold from 1960 to 1977. Tourism expenditures represent about 5 percent of the gross national product, and the tourist industry is the third largest sector.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of *government.* The commonwealth government resembles the government of a **U.S.** state. Separate

PUERTO RICO

executive, legislative, and judicial branches are spelled out in the constitution of 1952, which may be altered by the commonwealth so long as the articles are not in conflict with the U.S. Constitution or the legal stipulations of Puerto Rican–U.S. relations.

Executive, legislature, and judiciary

The governor, who is elected by direct popular vote to a four-year term, heads the executive branch. The legislature comprises the Senate and the House of Representatives, whose members are elected for four years. There are eight senatorial and 40 representative districts, and in addition, 11 senators and 11 representatives are elected at large. A complicated formula is used to assure proportional representation of minority parties.

Puerto Rico has a unified court system, which is administered by the island's Supreme Court, whose justices are appointed by the governor with the advice and consent of the commonwealth Senate. Civil law has been influenced largely by Spanish traditions and the code system of French law setting forth basic legal principles, though common law has influenced administrative law and many other areas of the legal system. A federal court has jurisdiction over the application of federal laws in Puerto Rico, and appeals may be carried to the Supreme Court in Washington, D.C.

Relations with the United States. Commonwealth voters elect a resident commissioner who has a voice, but no vote, in the U.S. House of Representatives. On the other hand, Puerto Ricans do not pay federal taxes on income received from island sources. Customs taxes on foreign goods imported into Puerto Rico and excise taxes on goods sold in the United States are collected by the federal treasury and returned to the commonwealth. Relations between Puerto Rico and the United States are defined in the Puerto Rico-Federal Relations Act, which retains many provisions of the Foraker (1900) and the Jones (1917) acts. Such matters as currency, defense, external relations, communications, and interstate commerce are within the province of the federal government. Local government—excluding San Juan, which has a city-management rule—is run by a mayor and council, both elected by popular vote.

Diversity of political parties

Politics. Elections are held every four years, supervised by an electoral board comprising representatives from majority and minority parties. There are four principal registered parties: the New Progressive, the Popular Democratic, the Puerto Rican Independence Party, and the Puerto Rican Socialist Party. The two leading parties are the pro-statehood New Progressive Party, which narrowly won the 1980 gubernatorial election with slightly more than 47 percent of the vote, and the Popular Democratic Party, which won 47 percent and supports the continuation of commonwealth status. Although the Popular Democratic Party was the strongest party from 1940 to 1968, the New Progressive Party won three of the four elections between 1968 and 1980. The Puerto Rican Independence Party, which polled third in the 1980 election, and the Puerto Rican Socialist Party advocate independence.

Education. Puerto Rico is deeply committed to the expansion of public education. About one-third of the overall governmental budget is allocated to education. Illiteracy has been reduced from more than 30 percent in 1940 to less than 10 percent by the late 1970s. Vocational and technical education has been stressed to combat the high rate of unemployment among the young.

The system of higher education is diversified. The University of Puerto Rico comprises a state university system, with three main campuses and a number of regional colleges. There are also two private universities, the Inter-American university of Puerto Rico and the Catholic University of Puerto Rico, as well as the Ana G. Mendez Educational Foundation, comprising two junior colleges, and other private colleges. Total higher education enrollment is about 125,000. Scholarships and aid have become important sources of income for universities and colleges, and private institutions especially are dependent on federal assistance to students. Although island universities generally are patterned after U.S. institutions, their atmosphere is distinctly Latin American. There are strong Spanish and Latin-American influences, especially in the humanities, whereas U.S. influence is strongest in the natural sciences and public administration.

Health. About 25 percent of the commonwealth budget is spent on health and welfare services. Health programs include malaria control and the building of pure water supplies and modern sewage disposal systems in cities and towns throughout the island. A network of urban clinics and rural health centres has been created to provide treatment for communicable diseases, basic medical care, and instruction in hygiene, nutrition, and prenatal and child care. The number of physicians rose from one per 1,000 population in 1969 to one per 640 by 1978. The rise in admissions to health centres indicates more widespread treatment.

Crises in housing and employment

Housing. Puerto Rico has made impressive strides in meeting the housing shortage, although the pressures continue to build. Home construction accounts for about 5 percent of the gross national product. The Urban Renewal and Housing Corporation is in charge of broad and diversified housing programs, with concentration on low-income projects. The corporation has taken advantage of assistance from several housing programs, but credit restrictions have affected both public and private housing. In spite of new construction, the proportion of housing that lacks essential services to the total supply of housing has remained more or less constant. As in other areas of the island's life, population growth seems to be the major contributing factor.

Employment and welfare. Despite industrialization, unemployment has risen dramatically; the number of jobless persons actively seeking work increased from about 10 percent of the labour force in the early 1970s to about 20 percent by the late 1970s. The problem is most acute among the young, one-fifth of whom are not in school, and among the rural workers, who constitute the bulk of the unskilled labour and work only four to six months of the year. This doubling of unemployment stems primarily from population pressures. Federal and commonwealth minimum wages cover every important industry and agricultural enterprise.

General price levels in Puerto Rico closely follow the levels on the U.S. mainland, and inflationary pressures severely affect the islanders. Though increased incomes have promoted social and economic–mobility, the growth has helped the urban areas at the expense of the rural. Most of the extreme poverty is concentrated there or in the city slums. Income security programs have been extended to islanders by mutual consent of the Congress and the insular legislature.

CULTURAL LIFE AND INSTITUTIONS

Cultural traditions

Puerto Rico's culture has strong roots in the Hispanic world. The language, the literature, the arts, and the surviving folklore link Puerto Rico with Latin America. The strong influence of the United States since 1898 has not deeply changed Puerto Rico's cultural expression. Though popular culture, strongly abetted by modern commercialism, may reflect some North American traits, the island's traditions are strong and have become the subject of concern and care by such institutions as the Puerto Rican Institute of Culture and the Ateneo Puertorriqueiio. A new generation of poets, novelists, short-story writers, and essayists keeps alive the traditions of such 19th-century forerunners as the novelists Alejandro Tapia and Manuel Zeno Gandia, the essayists and sociologists Eugenio Maria de Hostos and Salvador Brau, and the poets Jose Gautier Benitez and Lola Rodriguez de Tio. New playwrights and artists have also received considerable encouragement from the Institute of Culture, while there has been renewed interest in historical studies.

An annual drama festival has helped to promote the theatre. The Festival Casals, established in 1956 by Pablo Casals, became a major musical event that brought world-renowned musicians to the island each summer. The Institute of Culture sponsors many groups preserving popular folklore and conducting exhibits of local art.

As in many Caribbean countries, Puerto Ricans are searching for a definition of the island's cultural identity.

Some residents advocate cultural nationalism and a strong rejection of U.S. values, while others have a more eclectic position. There is, however, a general consensus that the island's culture is distinct from that of the United States, and assimilation that would obliterate Puerto Rico's Hispanic-American profile is neither possible nor desirable. Though these feelings are very strong in intellectual circles, the press, radio, and television are influenced heavily by U.S. modes and trends. Most Puerto Rican newspapers are published in Spanish and are served by U.S. press agencies.

PROSPECTS

Although Puerto Rico has had a dramatic economic boom since World War II, its close ties with the United States deeply affect its industrial and trading possibilities. Recession and inflation on the mainland create backlashes in Puerto Rico, and during the 1970s economic growth declined. A reduction in tourism and in manufacturing, amid continued population growth, could further depress the economy. This possibility is a subject of continuing concern to both government and private enterprise.

Sentiments on political status

Politically, the island remains divided among advocates of statehood, of outright independence, and of a fuller development of self-government under the commonwealth status. Statehooders argue that incorporation into the U.S. political system represents political equality and full participation in national life. Pro-independence groups insist that separation is the only way to attain cultural identity and to liberate Puerto Rico from U.S. economic and political domination. Commonwealth supporters hold that imposition of the federal tax system under statehood would adversely affect the island's economic development. They maintain further that the autonomous relation preserves the island's cultural heritage and yet keeps the advantageous political and economic ties with the United States. Although tensions and conflicts occur, there remains a strong commitment to voting and the democratic processes of government that is unmatched elsewhere in the Spanish-speaking Caribbean.

Pufendorf, Samuel von

German publicist and jurist, Samuel von Pufendorf greatly influenced the philosophy of natural law in Germany and the rest of Europe from the latter part of the 17th century up to the French Revolution. His nontheological treatment of natural law still echoes in the opening lines of the U.S. Declaration of Independence.

Early life and works. Pufendorf was born in Dorfchemnitz near Thalheim, Saxony, on January 8, 1632, the son of a Lutheran pastor. Though the family was poor, financial help from a rich nobleman enabled his father to send both Samuel and his older brother Esaias to a well-known school in Grimma. There he acquired a sound classical education. He became a student of theology at Leipzig University, then a stronghold of Lutheran orthodoxy, but soon turned his attention to jurisprudence, philology, philosophy, and history. In 1656 he went to Jena, where he was introduced to the method of Descartes and also read the works of Hugo Grotius and Thomas Hobbes.

Pufendorf, oil painting by Carl Peter Morth, 1735, after David Klocker Ehrenstrahl (1629–98). In the Nationalmuseum. Stockholm.

First work on natural law

In 1658 Pufendorf took employment as a tutor in the household of the Swedish ambassador in Copenhagen. When war broke out between Sweden and Denmark, he was imprisoned along with the rest of the ambassador's retinue. During the eight months of confinement he occupied himself by elaborating his first work on natural law, *Elementorum Jurisprudentiae Universalis Libri Duo,* published in 1660. In it he developed the ideas of Grotius and Hobbes. The elector palatine Karl Ludwig, to whom the work was dedicated, created a chair of natural law for Pufendorf in the arts faculty at Heidelberg, the first of its kind in Germany. Pufendorf taught there from 1661 to 1668, writing during this time his next work, *De Statu Imperii Germanici ad Laelium Fratrem Dominum Trezolani Liber Unus.* It was published in 1667 and took the form of a bitter attack, supposedly by a Veronese nobleman, on the constitution of the Holy Roman Empire and the house of Austria. It was based on wide reading in constitutional law and history and created an immediate sensation throughout Europe. The work was banned by the imperial censor; perhaps for that very reason it was translated into many languages and published abroad.

Career in Sweden. In 1668 Pufendorf left Heidelberg to accept the chair of natural law at the new University of Lund in Sweden. The 20 years he was to spend there proved to be his most fruitful ones. In 1672 he published his great work on the law of nature and of nations, *De Jure Naturae et Gentium Libri Octo*, and in 1673 an excerpt from it titled *De Officio Hominis et Civis Juxta Legem Naturalem Libri Duo.* In these works Pufendorf departed from the traditional approach of the medieval theologians to natural law and based it on man's existence as a social being *(socialitas).* Every individual, he held, on the basis of human dignity has a right to equality and freedom. He insisted that despite the teaching of Aristotle, there is no such creature as a natural slave; master–servant relationships can exist only on the basis of an agreement. Pufendorf's theory of civil, penal, and constitutional law also derived from the same principle of *socialitas.*

His great influence was not won without a struggle. His views were subjected to numerous attacks by conservative Protestant theologians in Sweden and Germany. The philosopher Leibniz dismissed him as "a man not a lawyer and scarcely a philosopher at all." The Swedish government, however, protected him. In the pamphlets signed *Eris Scandica,* which he published in 1686, he defended his beliefs very effectively.

Royal historiographer of Sweden

In 1667, after the Danish occupation of Lund, Pufendorf became the royal historiographer in Stockholm, where he devoted much of his time to writing the history of Sweden from Gustavus II Adolphus to Charles X Gustavus. In 1687 he also published *De Habitu Religionis Christianae ad Vitam Civilem,* setting forth the civil superiority of the state over the church but at the same time defending the church's power in ecclesiastical matters as well as the freedom of conscience of the individual. His approach became the basis of the collegial, or council, system of church government that was further developed in the 18th century to become the basis of church and state relations in Germany. The book also contained a justification of the idea of tolerance in general and in particular of the elector of Brandenburg, who had offered asylum to the Huguenots when they were driven out of France in 1685.

In 1688 Pufendorf, a baron, went to Berlin as historiographer to the elector of Brandenburg. He died there in October 1694. A posthumous work, *Jus Feciale Sive Dc Consensu et Dissensu Protestantium,* was published in 1695. It expounded more of his ideas on ecclesiastical law and argued for the formation of a united Protestant church from the Reformed and Lutheran churches.

The 18th century saw many editions of Pufendorf's works. John Locke and Jean Jacques Rousseau recommended them as reading for young people. The emperor Joseph II of Austria was instructed in *De officio* as a boy. One of Pufendorf's disciples was John Wise (1652–1725), an American clergyman and pamphleteer who greatly influenced American ecclesiastical law and the struggle for civil and religious liberty in the colonies.

BIBLIOGRAPHY. The best biography of Pufendorf is the article by HARRY BRESSLAU in the *Allgemeine Deutsche Biographie,* vol. 26 (1888); see also the brief biography by PAUL MEYER, *Samuel Pufendorf* (1894). G.H. VON TREITSCHKE, *Historische und politische Aufsätze,* vol. 4 (1897); J.G. DROYSEN, *Abhandlungen zur neueren Geschichte* (1876): and F. MEINECKE, *Die Idee der Staatsräson in der neueren Geschiclzte,* 3rd ed. (1929), all treat his achievements as historian. For a discussion of Pufendorf's teaching of natural history, see HANS WELZEL, *Die Naturrechtslehre Samuel Pufendorfs (1958).*

(Ha.We.)

Pulsar

The discovery of pulsars in 1967 ranks as an important milestone in the history of astrophysics. The name, an abbreviation of "pulsating radio star," derives from the fact that pulsars emit all their recorded radiation in the form of short pulses. These pulses typically last a few hundredths of a second and are usually emitted at intervals of somewhat less than one second. With one exception, the detectable radiation from pulsars occurs entirely in the radio wavelength region of the electromagnetic spectrum, and observation of pulsars is possible only by the use of radio telescopes. The pulse rate varies from source to source, but individual pulsars maintain their own periodicity with astonishing accuracy. If the pulses were used for timekeeping, such a clock would be correct to within a fraction of a second per year.

The first pulsar was discovered by chance by A. Hewish and S.J. Bell during a sky survey carried out at Cambridge, England, using an unusual type of radio telescope. This instrument consisted of a large array of 2,048 dipoles, which covered an area of 20,000 square metres (4½ acres). It was designed to distinguish ordinary radio galaxies from quasars using the phenomenon of interplanetary scintillation, a rapid intensity variation caused by ionized gas clouds in space that occurs only for sources that subtend a very small angle, such as the compact quasars; it thus provides a powerful method of discriminating between these and other types of radio source.

In the Cambridge survey a list was made of every source that scintillated. One rather weak source, which apparently showed scintillation, was unusual in that it did not always appear on repeated scans of the same region of sky. At first it was dismissed as a man-made radio interference, but a recorder of higher sensitivity revealed the first indication of pulsed emission on Nov. 28, 1967, and this result was confirmed in early December. A detailed investigation was carried out immediately, the results of which were published on Feb. 24, 1968. In this account the basic physical nature of the emitter was outlined, and it was suggested that only a collapsed star, such as a white dwarf, or the hypothetical neutron star could offer a plausible explanation.

News of the discovery initiated a period of intense activity among astronomers all over the world. Many questions about pulsars are still far from solved, but it is now generally agreed that pulsars must be neutron stars. The main observed features of pulsars and some theories regarding them will be outlined briefly below.

Approximate Positions and Periods of 55 Pulsars

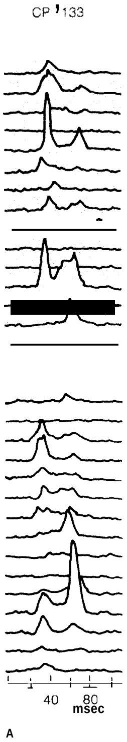
OBSERVED PROPERTIES

Periods. Searches for pulsars at several observatories led to the discovery of 49 sources by the end of 1969. The approximate positions and periods are listed in the Table. All of these sources exhibit similar behaviour, and the periods (intervals between successive pulses) range from 0.033 second to 3.7 seconds. The most rapid pulsar, NP 0532, lies in the Crab Nebula and was discovered at Green Bank, West Virginia. The most common period is close to one second, and approximately one half of the sources have periods between 0.5 and 1.0 second. The detection of pulsars becomes more difficult at the shortest periods, and it is possible that faster pulsars exist than can be detected at present, but there is no observational bias hindering the detection of slower pulsars, and if such sources exist, they must be exceedingly weak emitters.

Accurate timing of pulses indicates a systematic tendency for the period to increase with time. A useful measure of this trend is the number of years that must elapse before the period has doubled, assuming that the rate of slowing remains unchanged. For a typical pulsar about 10,000,000 years would be required, although the most rapid pulsar gives a measure of 2,400 years and one pulsar is so constant that over 100,000,000 years would be needed.

Timing measurements on those pulsars that emit the sharpest and strongest pulses enable the period to be measured with an error of less than one part in 1,000,000,000. Such studies have revealed occasional small, but sudden, changes of period in two cases. These results are of great interest and will be mentioned again (see below ***Theories***).

Pulse shapes. A typical record of pulses from the source CP 0950 is shown in Figure 1(B). Large variations of pulse intensity are clearly evident, and the pulse is sometimes undetectable. When records are made with a sufficiently sharp resolution in time it is found that the detailed shapes of the pulses also vary rapidly. Fine structure within individual pulses sometimes shows spikes that last for only a fraction of a millisecond. A series of consecutive pulses, shown in Figure 1(A), indicates the typically complicated shapes that are observed.



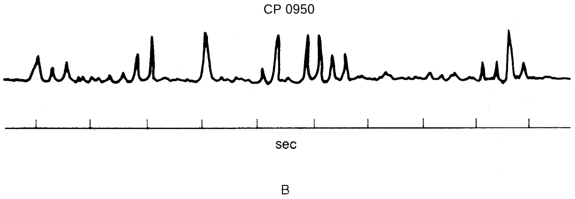


Figure 1: Pulse shapes.
(A) Consecutive pulses from CP 1133 indicating a rapidly changing fine structure within the pulses. (B) Train of pulses received from the pulsar CP 0950 at a wavelength of 3.j metres.

When many pulses from an individual source are superimposed and averaged, the mean pulse takes on a characteristic shape, the mean pulse envelope, which differs between one source and another and which is relatively unchanging for a given source. Some examples of characteristic mean pulse envelopes are given in Figure 2. For three of the known pulsars an interpulse occurs almost symmetrically placed in time between the main pulses. The interpulse is always weaker than the main pulse and has a different shape for the Crab Nebula pulsar, in which it is strong enough to be studied in some detail.

Pulsars have been observed at radio wavelengths ranging from eight metres to six centimetres, although the radiation is usually most intense near a wavelength of one to three metres. In one case (the pulsar in the Crab Nebula) both visible light and X-rays have been detected. It is important, for theoretical reasons, to see how the pulse shapes vary with wavelength, and the mean envelopes for the Crab Nebula pulsar are shown in Figure 2. Some differences are clearly evident, but the pulses at all wavelengths are emitted simultaneously from the source. In other cases a slight increase in width of the mean envelope is observed at the longest radio wavelengths, but the effect is usually small.

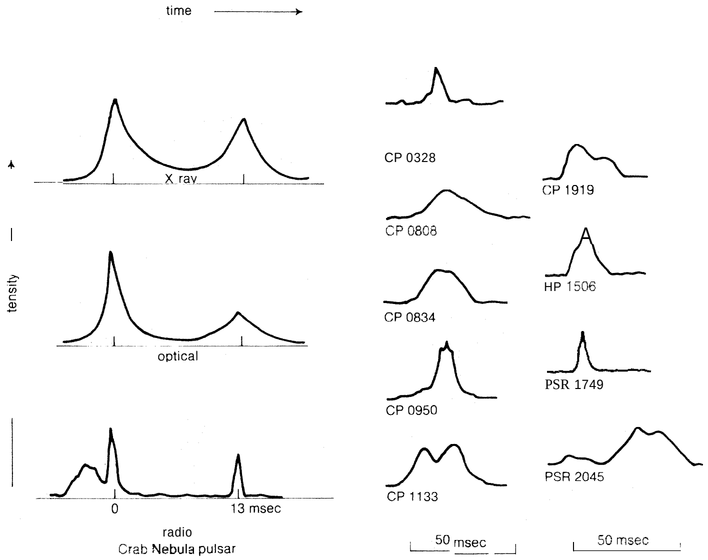

Figure 2: Examples of mean pulse envelopes (see text).

Intensity variations. One of the most remarkable features of pulsars is that their regular timekeeping is associated with extreme variability of emitted intensity. Not only do the pulses vary on a rapid time scale as shown in Figure 1; they also exhibit increases of intensity lasting for minutes, hours, days, and weeks. For the most part these effects seem to be entirely irregular, but careful studies of pulse trains have shown that certain pulsars exhibit slight intensity variations, which repeat at intervals corresponding to several pulse periods. This class II pulsation, as it has been called, is not commensurate with the main period and is related to an effect known as "marching sub-pulses" in which fine structure reappears in successive pulses and drifts steadily through the mean pulse envelope.

Intensity variations that last from several minutes to a few hours are probably caused by tenuous clouds of ionized gas in interstellar space. Such clouds will deviate the paths of radio waves as does the Earth's ionosphere, so that the radiation is received at slightly different angles. The mixing, or interference, of these waves gives rise to intensity variations analogous to the twinkling of visible stars. It is not possible, however, to explain such variations that persist longer than a few hours. To summarize, it appears that intensity fluctuations, which last for less than a few seconds or for longer than a day, must be genuine effects intrinsic to the pulsar emitter. Variations of an intermediate duration, on the other hand, can be ascribed to interstellar scintillation.

THE PHYSICAL NATURE OF PULSARS

Distribution of pulsars **in the Galaxy.** A map of the entire sky showing the positions of pulsars is given in Figure 3. This chart is plotted in galactic coordinates so that latitude 0° corresponds to the plane defined by the disk of the Galaxy; part of this disk is visible as the Milky Way.

The pulsars appear to be more or less randomly scattered over the sky, but there is a significant concentration

From Revista del Nuovo *Cimento* (1969)

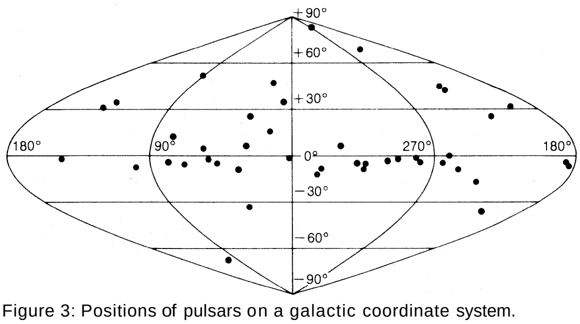

Figure 3: Positions of pulsars on a galactic coordinate system.

of sources toward the galactic plane. Pulsars are thus distributed similarly to the younger stars of the Galaxy and cannot be too distant. The Galaxy has a total extent of about 100,000 light-years, and the disk has a thickness of about 1,000 light-years. The known pulsars must be situated within a few thousand light-years of the solar system, or they would be expected to show a greater concentration within the Milky Way than is depicted in Figure 3. Thus, only the nearest pulsars have so far been found, and it is likely that some 10,000 pulsars are present in the entire Galaxy.

Pulsar concentrations

Distance measurement. Two methods have been used to find the distances of pulsars with greater accuracy than the statistical estimate discussed above. One of these relies upon the fact that the speed at which radio waves travel through an ionized gas depends upon the wavelength. It is known that interstellar space contains a trace of ionized hydrogen, and this means that receivers tuned to different wavelengths will record incoming pulses at slightly different instants, even though the pulses were emitted simultaneously at the source. In practice, the measurements are quite simple because the distance involved is so great that time delays of several seconds are usually observed. Unfortunately, the density of gas in interstellar space is not accurately known, and this uncertainty is the limiting factor.

Distance measurements using this technique, known as the method of pulse dispersion, usually assume a density of about 0.03 ions per cubic centimetre. On this basis, the nearest pulsar is at a distance of about 300 light-years, while the average distance is approximately ten times this value. It is encouraging that this method gives a result for the Crab Nebula pulsar that tallies well with the distance of the nebula determined by optical measurements.

The second way of estimating pulsar distances makes use of an absorption technique. Cold hydrogen gas in the form of atoms, as opposed to electrically charged ions, acts as a strong absorber of radiation having a wavelength of 21 centimetres. This fact has already been widely used in radio astronomy to study the spiral arms of the Galaxy (see RADIO SOURCES, ASTRONOMICAL). For a small number of intense pulsars it is possible to detect 21-centimetre absorption and hence to determine how many spiral arms lie between Earth and the source. This method also yields an estimated distance of about 3,000 light-years.

Size and energy. It has been obvious from the first detection of pulses that pulsars must be exceedingly small astronomical bodies. A large body cannot emit a sharp flash of radiation because of the different travel-time of radiation from different parts of its surface. Broadly speaking, the duration of a pulse multiplied by the velocity of light defines the greatest possible radius of the body. In the case of pulsars, the observed narrow pulses show that the emitter cannot have a radius exceeding a few thousand kilometres; that is, pulsars cannot be larger than small planets such as the Earth; and they could, of course, be smaller.

An estimate of the total power radiated by pulsars can be made because their distances are known with tolerable accuracy. The Crab Nebula pulsar turns out to be a more powerful radiator than the Sun. This is an exceptional case, and typical pulsars radiate less strongly. It is clear, however, that pulsars, although they are tiny objects, must be endowed with a prime source of energy that is comparable to that of a stellar body. The confinement of such energy within so small a volume is another remarkable feature of these sources.

Association with supernova **explosions.** Of great significance with regard to the physical nature of pulsars is the fact that two of them are found in the positions of old supernovas. The first evidence of this kind came from Australian astronomers who discovered the source PSR 0833 near the centre of a radio nebula called Vela X. This nebula emits no visible light, but its general characteristics are similar to those of other nebulae known to have resulted from stellar explosions that emit both light and radio waves.

The discovery of PSR 0833 was soon followed by that of NP 0532 at the centre of the Crab Nebula. This nebula is well known since the actual stellar explosion was witnessed and documented by the Chinese in AD 1054. The discoverers of NP 0532 were able to place only an upper limit on its pulse period, which was later determined by use of the large radio telescope at Arecibo. Finally, with the period established, optical astronomers were able to adopt pulse integration techniques, and a star at the centre of the nebula was found to be emitting light flashes synchronous with the radio pulses.

A photograph of the Crab Nebula, in which the flashing star is clearly visible, is shown in Figure 4. This star had been suspected for many years to be the remnant of the one that actually exploded, and its coincidence with the pulsar is most revealing as will be seen in the following section. The Table shows that PSR 0833 and NP 0532 possess the shortest known periods. Many unsuccessful attempts have been made to find rapid pulsars associated with nebulae resulting from other supernovas.

THEORIES

No fully satisfactory theory of pulsars yet exists. Much speculation is still involved, and adequate solutions to many of the problems can be expected only when astrophysicists are more familiar with the extreme physical conditions encountered in and near these bodies. What follows is an outline of the concepts that currently have achieved general acceptance.

The **pulsar** clock. Any theory of the pulsars must concentrate, initially, on a mechanism for maintaining the basic period of the pulses. Three possibilities have been discussed, only one of which now appears to be reasonable. These possibilities are orbital motion, radial vibration, or rotation of a stellar body. In all three cases the periodicity is related very simply to the material density of the body or system concerned, and the observed periods require densities between 100 and 10,000 tons per cubic centimetre.

White dwarf stars are comparable in size to the Earth and have densities of about one ton per cubic centimetre. Unfortunately, they would disrupt and fly apart before producing periods as short as those observed. These stars are formed by the gravitational collapse of common stars, such as the Sun, when nuclear fusion processes within them come to a halt. White dwarfs cannot possibly exist at densities greater than about 100 tons per cubic centimetre, as gravity then crushes the matter to nuclear density in the region of 10,000,000 tons per cubic centimetre. Under these conditions the material is largely composed of neutrons; such stars have been postulated but never found.

Neutron stars—one solution

Neutron stars offer a possible solution to the pulsar problem, and rotation gives a simple explanation of the periods. Orbital motion, on the other hand, would give a period decreasing with time, which contradicts the observations (see above ***Periods),*** while radial vibration predicts periods that are far too short. The rotation theory, which was advanced soon after the initial discovery, gained weight from the observed slowing down of the periods and from the fact that two pulsars coincide with supernova debris. The latter point is significant since the gravitational collapse, which might lead to the formation of a neutron star, is a violent process and had been discussed for some years as an explanation of supernova explosions. Further, the principle of conservation of angular momentum requires the neutron star to be spinning rapidly.

Neutron star models. The understanding of some process for producing the pulsar clock is but a start to pulsar theory. The energy source that maintains the radiated pulses and the mechanism for producing the pulses themselves must also be determined.

Given a rotating body, the simplest method of producing pulses is to confine the radiation to a single narrow beam, the basic "lighthouse" model of pulsars. The observed pulse duration in relation to the period suggests that the beam typically has a width of about 15". Most of the explanations of such a beam—and why the radiation produced should be largely at radio wavelengths—relyon the intense magnetization that a neutron star should contain.

During the collapse of matter to the neutron star configuration, a great deal of gravitational energy is released, while the angular momentum, which depends on the product of the spin and the star's radius, remains constant. It has been estimated that immediately following collapse a neutron star will be spinning so rapidly (around 1,000 revolutions per second) that its energy of motion is comparable to that derived from nuclear fusion during the whole of its previous history as an ordinary radiating star. Collapse has therefore revitalized the star to a remarkable degree. In addition, the magnetization of the star will have been concentrated by a factor of about 10^{10}, since its radius has shrunk from about 1,000,000 kilometres to a mere 10 kilometres.

If the direction of the magnetic axis of the star does not coincide with the rotation axis, extremely large fluctuating magnetic fields will be produced in space. Even if this were not so, the voltages caused by dynamo action at the surface of the star will exert forces sufficient to tear charged particles from the star and fling them outward. These particles may either be swept around by magnetic forces or accelerated radially in the fluctuating fields until they are travelling at speeds close to that of light. When this happens the particles will generate radiation, and the theory of relativity shows that this will be cast forward into a narrow beam. Such processes should be sufficient to account for pulsar radiation, but detailed theories have not yet been formulated. Examples of the type of model currently under consideration are illustrated in Figure 5.

Outstanding problems. The association of pulsars with neutron stars and supernova explosions has focussed attention on the question of the final collapse of stars too heavy to reach equilibrium as white dwarfs. This process is not well understood; and, if pulsars had not been found, it is likely that recent theoretical work would have cast doubt on the possible creation of neutron stars according to earlier theories.

From *Annual Review of Astronomy and Astrophysics* (1970)

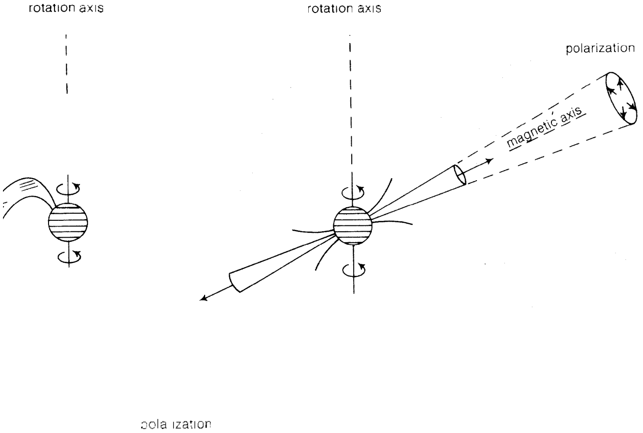

Figure 5: Two neutron star models that have been suggested to account for pulsed emission. (Left) Gold's model. (Right) Radhakrishnan's model.

It is also necessary to consider the sudden changes in period that have been observed in NP 0532 and PSR 0833. Superdense matter, such as that which must exist inside neutron stars. has peculiar properties in addition to its enormous density. It is possible that neutron stars are surrounded by a shell of more or less rigid material, within which a fluid core is contained. This fluid core may exist in a state similar to that of liquid helium at extremely low temperature, when the viscosity virtually disappears. The superfluidity of liquid helium is analogous to the superconductivity of certain metals in which, again at very low temperature, an electrical current once started will flow without ceasing for a great length of time.

Solid shell is possible

As the neutron star slows down, the shell undergoes a varying stress and will deform, at intervals, to achieve a less ellipsoidal shape. Such a momentary deformation will cause a sudden decrease of period; as is observed, but the fluid core will continue to spin at the original speed. Eventually viscous forces will cause the whole star to rotate at the same, slightly modified speed, and for PSR 0833 this process appears to take several years. Calculations show that the angular speeds of the core and the shell would equalize far more quickly if a superfluid state did not exist within the neutron star. A full understanding of the behaviour of neutron stars, therefore, involves a more accurate theory of this peculiar property of superdense matter than is currently available.

Still another problem is that of explaining the nonexistence of pulsars having periods longer than two or three seconds. It would be expected that the gradual loss of energy in the form of radiation would cause pulsars to spin more and more slowly. One suggestion is that the magnetization of the neutron star decays, causing the radiation to cease, before the spin rate has fallen much below one revolution per second. There are, however, divergent estimates of how long the magnetization will persist.

CONCLUSIONS

In the present state of knowledge it appears that pulsars can be explained only in terms of neutron stars. The discovery that such stars exist has opened a new chapter in astrophysics. The realization that gravitational collapse can cause a star to be reborn, at least from an energetic standpoint, may well have far-reaching consequences. The Crab Nebula, for example, has long been known to contain some source of energy by which it maintains the radiation that it emits at X-ray, light, and radio wavelengths. This radiation, from the whole of the nebula, contains considerably more power than that emitted from the pulsar NP 0532 itself. It now seems highly probable that the spinning neutron star provides this energy. It has been further postulated that spinning neutron stars may eject the fast-moving particles known as cosmic rays. The latter, which permeate the Galaxy, have been widely studied for many years, but their origin has remained a mystery.

The study of pulsars has also led to the resurrection of the question of the ultimate fate of stars too heavy to reach stability as neutron stars. According to present theory, matter at a density slightly greater than that inside neutron stars is unstable with respect to further gravitational collapse; that is, gravitational forces are so strong that the matter is crushed into an ever decreasing volume, and no known forces are available to resist the process.

In addition to providing what is, in a sense, a laboratory for the study of matter and physical laws under conditions that could not conceivably be attained on earth, pulsars may also be regarded as a new tool for astronomical purposes. They supply a form of clock that may prove to be sufficiently accurate for observational tests of general relativity. They are also being used to study the propagation of radio waves in interstellar space, which yields valuable information on such questions as gas density in interstellar space and the galactic magnetic field. There can be no question that pulsars have made, and will continue to make, a considerable impact on the development of astronomy.

BIBLIOGRAPHY. *Pulsating Stars,* 2 vol. (1968–70), contains a collection of research papers that originally appeared in *Nature,* a weekly journal. An extensive review of this subject by A. HEWISH may be found in the *A. Rev. Astron. Astrophys., 8*:265–296 (1970).

Pump

A pump is a device that uses mechanical force and motion to raise, transport, or compress fluids. The earliest pumps were devices for raising water, such as the Persian and Roman waterwheels and, more technologically sophisticated, the famous Archimedean screw, invented by Archimedes of Syracuse (287–212 BC) to raise water from the hold of a ship. The screw turned in a tightly fitting cylinder whose inclination caused the water to be raised on the screw threads as the screw was rotated. Similar devices were used in dewatering operations in bridge building as late as the 18th century.

The mining operations of the Middle Ages led to development of the suction (piston) pump, many types of which are described by Agricola in *De re metallica* (1556). One such device consisted of three suction pumps driven by a single crank powered by a waterwheel. A suction pump works by atmospheric pressure; when the piston is raised, creating a partial vacuum, atmospheric pressure outside forces water into the cylinder, whence it is permitted to escape by an outlet valve. Atmospheric pressure alone can only force water to a maximum height of about 34 feet, so the force pump was developed to drain deeper mines. In the force pump the downward stroke of the piston forces water out through a side valve to a height that depends simply on the force applied to the piston. The search for bigger power sources for such mining pumps led to the invention of the steam engine.

GENERAL CONSIDERATIONS

Classification of pumps. Pumps are classified according to the way energy is imparted to the fluid. The basic methods are (1) volumetric displacement, (2) addition of kinetic energy, and (3) use of electromagnetic force.

The volumetric displacement of a fluid can be achieved either mechanically or by the use of another fluid. Kinetic energy may be added to a fluid either by rotating it at high speed or by providing an impulse in the direction of flow. In order to use electromagnetic force, the fluid being pumped must be a good electrical conductor.

Fluids include both liquids and gases. Pumps used to transport or pressurize gases are called compressors, blowers, or fans.

Pumps in which the volumetric displacement is accomplished mechanically are called positive displacement pumps. Volumetric displacement is also accomplished with other fluids, as in air lifts and blow cases.

Kinetic pumps

Kinetic pumps impart kinetic energy to the fluid by means of a rapidly rotating impeller.

Broadly speaking, positive displacement pumps provide relatively low volume at high pressure, while kinetic pumps produce relatively high volume at low pressure.

Uses. The pumping of fluids is an extremely common operation and the most basic operation in modern industry. The heart is a pump that causes blood to flow through the body. In the home, pumps are used to circulate water in hot-water heating systems and air in air-circulating heating and cooling systems. In automobiles, airplanes, and other vehicles, pumps circulate oil, water, and fuel.

Since fluids are so much more easily transported than solids, it is common industrial practice to convert solid materials into the fluid state by melting them, dissolving them in a liquid, or fluidizing them as a suspension of solid particles in a liquid or gas preparatory to movement. As early as 1850, gold-bearing gravels suspended in water were transported through pipelines in California. In 1913, coal suspended in water was transported through a pipeline in England. Typical of modern installations is a 72-mile pipeline that carries 700 tons of gilsonite per day from Utah to Colorado. Live fish, canned products, boxes, sewage, etc., suspended in water, are also pumped through pipelines.

Although very large pumps do exist, such as the ones used for irrigation service at the Hiwassee Dam (1,750,000 U.S. gallons per minute), the vast majority of pumps are relatively small, with capacities up to 2,000 gallons per minute and generated heads of between 5 and 300 feet. (One gallon is 3.785 litres.)

Efficiency of pumping. If a pump is installed at the wrong location in a pipeline, it cannot deliver its rated capacity. A certain amount of pressure is required to get the fluid to flow into the pump before additional pressure or velocity can be added. This head (energy per pound due to pressure, velocity, or elevation) is called the net positive suction head (NPSH) and is an integral part of the pump rating. A pump must be installed so that the head available at the intake is equal to or greater than the rated NPSH requirement. If the head available is less than the required NPSH, pumps will "cavitate." Cavitation is the formation of a vacuous space in the pump, which is normally occupied by liquid. Vaporization of liquid in the suction line is a common cause of cavitation. Vapour bubbles carried into the pump with the liquid collapse when they enter a region of higher pressure, resulting in excessive noise and vibration. Cavitation not only reduces the capacity of the pump but it leads to increased corrosion and erosion and a shorter life and may even destroy the pump.

Pump parameters

The important parameters of a pump are the required NPSH, the capacity against a given total head, and the overall percentage efficiency for pumping a particular fluid.

The dominant factor controlling the overall pumping efficiency is the viscosity of the fluid being pumped. Viscosity is that property of a fluid that resists any force tending to produce flow. Pumping efficiency is much higher for low viscosity liquids such as water than for a highly viscous fluid such as molasses. Since the viscosity of a liquid normally decreases as the temperature is increased, it is common industrial practice to heat very viscous liquids in order to pump them more efficiently.

Materials of construction. Pumps are manufactured in quantity in only a few standard materials such as cast iron, carbon steel, high-chrome steel, chrome-nickel-stainless steel, bronze, etc. In addition, pumps are fabricated from more specialized materials such as ceramics, glass, rubber, plastics, carbon, lead, aluminum and its alloys, titanium, zirconium, etc. Pumps are frequently fabricated with individual parts of different materials.

MAIN TYPES

Positive displacement. Positive displacement pumps (that is, pumps that lift a given volume for each cycle of operation) can be divided into two main classes, reciprocating and rotary. Reciprocating pumps include piston, plunger, and diaphragm types, while rotary pumps include gear, lobe, screw, vane, and cam pumps.

Piston and plunger pumps. The plunger pump is the oldest type in common use. Piston and plunger pumps consist of a cylinder in which a piston or plunger moves back and forth. In plunger pumps the plunger moves through a stationary packed seal and is pushed into the fluid, while in piston pumps the packed seal is carried on the piston which pushes the fluid out of the cylinder. The movement of the piston or plunger creates an alternating increase and decrease in volume. As the piston moves outward, the volume available in the cylinder increases, and fluid enters through the inlet one-way check valve. As the piston moves inward, the volume available in the cylinder decreases, the pressure of the fluid increases, and the fluid is forced out through the outlet one-way check valve. The pumping rate varies from zero at the point at which the piston changes direction to a maximum when the piston is approximately halfway through its stroke. The variation in pumping rate can be reduced by using both sides of the piston to pump fluid. Pumps of this type are called double acting. Fluctuations in pumping rate can be further reduced by using more than one cylinder.

Pumps with one, two, three, and four cylinders are called simplex, duplex, triplex, and quadruplex pumps respectively. An air chamber at the pump's discharge is sometimes used to smooth out the pulsations resulting from individual cylinder discharges. Overall pumping rates of piston pumps may be varied by changing either the reciprocating speed of the piston rod or the stroke length of the piston. The piston may either be driven directly by steam, compressed air, or hydraulic oil or through a mechanical linkage that transforms the rotary motion of a drive wheel to a reciprocating motion on the piston rod. The latter are called power-piston pumps and the former direct-acting piston pumps. Pumps that can be driven by air or steam are useful in remote locations where electricity may not be available.

Piston drives

Piston and plunger pumps are available with either vertical or horizontal cylinders. Although relatively expensive, they are extremely reliable and have an exceptionally long life. Piston pumps are known to have been running without repair or replacement for well over 100 years, Capacities range from as low as 0.15 gallon per minute for plunger pumps to 2,000 gallons per minute for steam-driven piston pumps. Most piston pumps are designed to generate discharge pressures up to 1,000 pounds force per square inch, and plunger pumps are available that are designed to generate discharge pressures up to 50,000 pounds force per square inch. If operated against a closed discharge, a power piston pump will continue to generate head until the pump bursts, unless provided with a relief valve.

Piston pumps can pump either liquids or gases or a mixture of both but are unsuitable for pumping fluids containing solid particles because of a tendency to clog.

Diaphragm pumps. The action of a diaphragm pump is similar to that of a piston pump in which the piston is replaced by a pulsating flexible diaphragm. This overcomes the disadvantage of having piston packings in contact with the fluid being pumped. As in the case of piston pumps, fluid enters and leaves the pump through one-way check valves. The diaphragm may be actuated mechanically by a piston directly attached to the diaphragm or by a fluid such as compressed air or oil. Oil may be supplied externally, or it may be pumped by a piston that forms an integral part of the pump.

Diaphragms are made from many materials, including rubber and elastomeric plastics. Diaphragm pumps can pump either liquids or gases or a mixture of both but share with piston pumps the disadvantage of a pulsating output. They are useful for pumping liquids that contain solid particles and for pumping expensive, toxic, or corrosive chemicals where leaks through packing cannot be tolerated.

Diaphragms normally last for six months to one year and can be speedily and easily replaced. Diaphragm pumps have the advantage that they can be run dry for an extended period of time. Furthermore, the overall pumping rate of most such pumps can be changed during operation. They normally range in capacity from 4 to 100 gallons per minute. Diaphragm metring pumps are available with capacities as low as one gallon per minute, designed to generate discharge pressures up to 3,500 pounds of force per square inch.

Pump capacities

***Gear** pumps.* The most common type of gear pump is the external gear pump illustrated in Figure 1. Two meshing gears of equal size are contained in a fixed casing. One of the gears is driven and the other (idler gear) normally runs free. Various types of gears are used. A partial vacuum, created by the unmeshing of the rotating gears, draws fluid into the pump. This fluid is then transferred to the other side of the pump between the rotating gear teeth and the fixed casing. As the rotating gears mesh together, they generate an increase in pressure that forces the fluid into the outlet line. If operated against a closed discharge, a gear pump will continue to generate head until the pump bursts. They are, therefore, normally provided with a relief valve. A basic external gear pump can discharge fluid in either direction, depending on the direction of the gear rotation. However, because of the position of the relief valve, the direction is fixed and usually clearly marked on the pump.

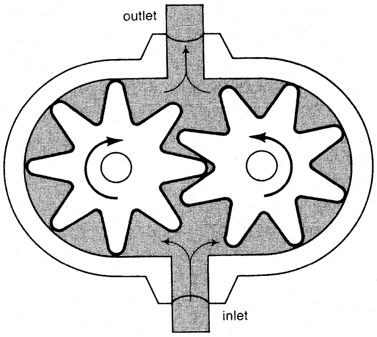

Figure 1: External gear pump.

An internal gear pump is shown in Figure 2. The driven gear is a rotor with internally cut gear teeth, which mesh with the teeth of an externally cut idler gear, set off-centre from the rotor. The crescent part of the fixed casing divides the fluid flow between the idler gear and the rotor. Gear pumps can pump liquids containing vapours or gases. Since they depend on the liquid pumped to lubricate the internal moving parts, they are not suitable for pumping gases alone. They deliver a constant output with negligible pulsations for a given rotor speed but have the disadvantage that a variable-speed drive is required to provide changes in pumping rate. Close clearances are essential between the moving parts, so that alignment is critical. Erosion and corrosion lead to an increase in the amount of liquid slipping back through the pump. Since gear pumps are subject to clogging, they are not suitable for pumping liquids containing solid particles. Since they do not need inlet and outlet one-way check valves, however, they can be used to pump very viscous liquids. External gear pumps normally range in capacity up to 200 gallons per minute and are designed to generate discharge pressures up to 500 pounds force per square inch, although pumps are available that operate at much higher capacities and discharge pressures. Internal gear pumps are available with capacities up to 1,100 gallons per minute, and discharge pressures are usually limited to 100 pounds force per square inch.

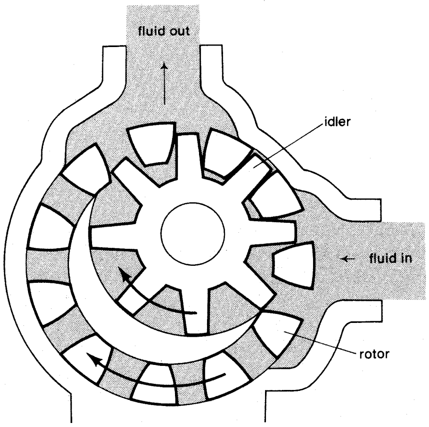

Figure 2: Internal gear pump.

Limitations of gear pumps

Lobe pumps. Lobe pumps operate on the same principle as external gear pumps. Rotors having two, three, or four lobes are used in place of gears. The two rotors are independently driven and usually have a small clearance between them. Lobe pumps have a more pulsating output than external gear pumps and are less subject to wear. Lobe pumps normally range in capacity up to 600 gallons per minute and are designed to generate discharge pressures up to 400 pounds force per square inch, although some have had capacities up to 2,000 gallons per minute. Lobe-type compressors are also used to pump gases. Each of the two rotors has two lobes.

Screw pumps. Screw pumps work on a different principle from the Archimedes screw, which rotates in a cylinder. A helical screw rotor revolves in a fixed casing that is shaped so that cavities formed at the intake move toward the discharge as the screw rotates. As a cavity forms, a partial vacuum is created, which draws fluid into the pump. This fluid is then transferred to the other side of the pump inside the progressing cavity. The shape of the fixed casing is such that at the discharge end of the pump the cavity closes, generating an increase in pressure that forces the fluid into the outlet line. The longer the length of the screw and the shorter the pitch, the greater the pressure developed. If operated against a closed discharge, a screw pump will continue to generate head until the pump bursts; relief valves are necessary to prevent this.

Screw pumps can pump liquids containing vapours or solid particles. They deliver a steady output with negligible pulsations for a given rotor speed but have the disadvantage that a variable-speed drive is required to provide changes in pumping rate. Since screw pumps do not need inlet and outlet one-way check valves, they can be used to pump very viscous liquids. Although screw pumps are bulky, heavy, and relatively expensive, they are robust, slow to wear, and have an exceptionally long life. Screw pumps normally range in capacity up to 3,000 gallons per minute and are designed to generate discharge pressures up to 1,000 pounds force per square inch.

Vane pumps. A sliding vane pump is illustrated in Figure **3.** The rotor is mounted off-centre. Rectangular vanes are positioned at regular intervals around the curved surface of the rotor. Each vane is free to move in a slot. The centrifugal force from rotation throws the vanes outward to form a seal against the fixed casing. As the eccentric rotor revolves, a partial vacuum is created at the suction side of the pump, drawing in fluid. This fluid is then transferred to the other side of the pump in the space between the rotor and the fixed casing. At the discharge side, the available volume is decreased, and the resultant increase in pressure forces the fluid into the outlet line. If operated against a closed discharge, a vane pump will continue to generate head until the pump bursts; relief valves will prevent this. Vane pumps have the advantage that the pumping rate can be varied by changing the degree of eccentricity of the rotor, making them useful in automatic-control systems. They do not need inlet and outlet one-way check valves. They can pump liquids containing vapours or gases but are not suitable for pumping liquids containing solid particles. Vane-type compressors are also used to pump gases.

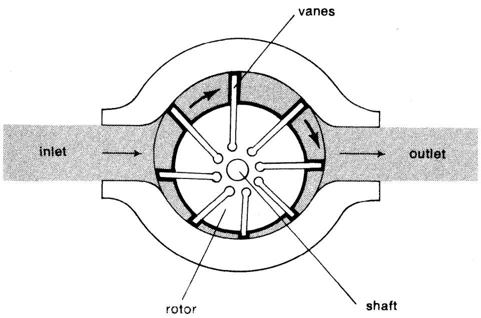

Figure 3: Vane pump.

Advantages of vane pumps

Vane pumps deliver a constant output with negligible pulsations for a given rotor speed. They are robust, and their vanes, easily replaced, are self-compensating for wear. Pumping capacity is not affected until the vanes are badly worn. Vane pumps normally range in capacity up to 2,000 gallons per minute and are designed to generate discharge pressures up to 150 pounds force per square inch. Specially made vane pumps can generate discharge pressures up to 2,000 pounds force per square inch.

Cam pumps. Cam pumps are sometimes called rotating piston or plunger pumps. A variety of cam pumps exists, but all operate on the basis of a rotating eccentric cam.

A rotary plunger pump differs from a true rotary pump in not having a rotating surface in contact with the fluid being pumped. The rotating eccentric cam moves inside a cylindrical plunger that is in direct contact with the fluid. The plunger creates a cavity at the suction side of the pump. This cavity progressively increases as the cam rotates, creating a partial vacuum that draws fluid into the pump. The volume available for the fluid progressively decreases during the cam cycle, and the resultant increase in pressure at the discharge side of the pump forces the fluid into the outlet line.

Cam pumps can pump liquids containing vapours or gases, and do not need inlet and outlet one-way check valves. They are light in weight and require only a small amount of space. They normally range in capacity up to 40 gallons per minute and are designed to generate discharge pressures up to 100 pounds force per square inch. Cam pumps are used only to pump liquids with a relatively low viscosity.

Kinetic. Kinetic pumps can be divided into two classes, centrifugal and regenerative. In kinetic pumps a velocity is imparted to the fluid. Most of this velocity head is then converted to pressure head. Kinetic pumps are a much more recent development than reciprocating positive displacement pumps. Even though the first centrifugal pump was introduced about 1680, the bulk of the development has occurred in this century.

Centrifugal pumps. These include radial, axial, and mixed flow units. 4 radial flow pump is commonly referred to as a straight centrifugal pump. The most common type is the volute pump. The principle is illustrated in Figure 4. Fluid enters the pump near the axis of an impeller rotating at high speed. The fluid is thrown radially outward into the pump casing. A partial vacuum is created that draws more fluid into the pump. The velocity head imparted to the fluid by the vanes of the impeller is converted into pressure head in a progressively widening spiral casing. Flow is continuous.

Volute pump

Volute centrifugal pumps are by far the most common type of pump. They are produced in standard designs for pumping liquids to provide a large capacity range using a relatively few interchangeable parts such as impellers, casings, motor-end frames, etc., with the advantage that industrial users require a smaller inventory of parts. Standard pumps range in capacity from 5 to 500 gallons per minute and generate total heads up to 250 feet, but centrifugal pumps are available in the capacity range 1 to 1,750,000 gallons per minute. Volute centrifugal pumps are robust and relatively inexpensive, quiet, and dependable, and their performance is relatively unaffected by corrosion and erosion. They are compact, simple in construction, and do not require inlet and outlet one-way check valves.

Volute centrifugal pumps can pump liquids containing solid particles, but when pumping liquids containing more than a small amount of vapour, they tend to lose prime; *i.e.*, their suction is broken owing to voids in the fluid. They have the advantage that they do not continue to

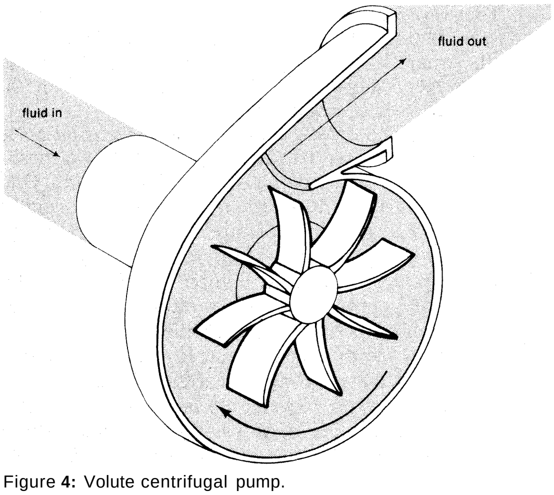

Figure 4: Volute centrifugal pump.

generate pressure when operated against a closed discharge. Volute centrifugal pumps operate best when pumping relatively nonviscous liquids, and their capacity is greatly reduced when used to pump viscous liquids.

The vide variety of volute centrifugal pumps available include vertical and horizontal units and also in-line units, which are designed to fit directly into pipelines. There are also specially designed self-priming pumps, pumps with long drive shafts that are designed to operate in wells, and pumps with several stages.

Another type of radial flow centrifugal pump is the diffuser pump, in which, after the fluid has left the impeller, it is passed through a ring of fixed vanes that diffuse the liquid, providing a more controlled flow and a more efficient conversion of velocity head into pressure head.

In axial flow centrifugal pumps the rotor is a propeller. Fluid flows parallel to the axis as illustrated in Figure 5, and head is generated by the lifting action of the propeller vanes. Diffusion vanes are located in the discharge port of the pump to eliminate the rotational velocity of the fluid imparted by the propeller. Axial flow propeller pumps normally range in capacity from 300 to 100,000 gallons per minute and are designed to generate total heads up to 40 feet. Axial flow compressors are also used to pump gases. In mixed flow pumps, fluid is discharged both radially and axially into a volute-type casing.

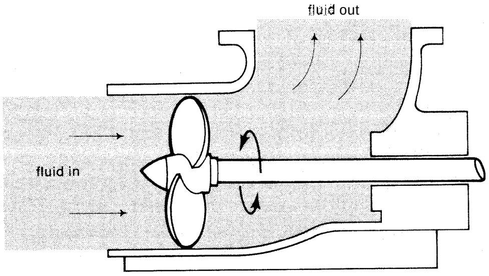

Figure 5. Axial flow centrifugal pump.

Regenerative pumps. A regenerative pump is also called a turbine or peripheral pump. The impeller has vanes on both sides of the rim that rotate in a ringlike channel in the pump's casing. The fluid does not discharge freely from the tip of the impeller but is recirculated back to a lower point on the impeller diameter. This recirculation or regeneration increases the head developed. Because of close clearances, regenerative pumps cannot be used to pump liquids containing solid particles. They can pump liquids containing vapours and gases, and in fact they can pump gases provided that they contain sufficient liquid to seal the close clearances. Regenerative pumps are only suitable for pumping liquids with a relatively low viscosity. Their life span is only about one quarter that of a volute centrifugal pump on comparable service. Regenerative pumps normally range in capacity from one to 200 gallons per minute, and they are designed to generate heads up to 500 feet. Multistage units are used to develop higher heads.

Other types. The air or gas lift pump works on the principle of the displacement of one fluid by a secondary fluid. Gas lifts are used to raise liquids from the bottoms of wells. Compressed gas is introduced into the liquid near the bottom of the well as in Figure 6. The resulting mixture of gas and liquid is lighter and more buoyant than the liquid alone so that the mixture rises and is discharged. Gas lifts have the advantage of no moving parts. Furthermore, they can be used to pump liquids containing solid particles. Capacities range up to 1,000 gallons per minute. Although air or gas lifts are now little used, air lifts were once widely used for pumping water, brine, and oil.

Capacity of gas lift pumps

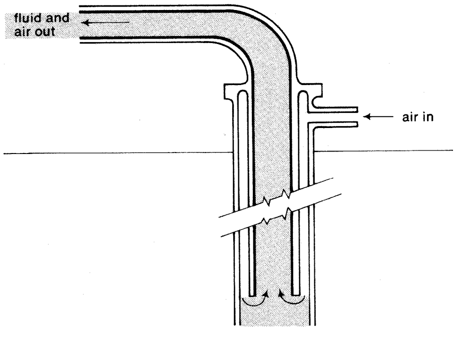

Figure 6: Air or gas lift pump.

Blow case pumps. The blow case or acid egg pump (so named because of its shape) also operates on the principle of the displacement of one fluid by a secondary fluid. The liquid to be pumped is admitted to the egg-shaped container through a one-way check valve. Compressed gas is then admitted to the container and the liquid is forced out through a discharge pipe. The valves can be controlled automatically. In this case two blow cases are used alternately to provide a smoother output. Although blow cases are now little used, they were once widely used for pumping acids.

Jet ejector pumps. in this type of pump, fluid passes through a venturi nozzle (a nozzle with an opening smaller than the pipe to which it is attached) and develops a suction that causes a second stream of fluid to be entrained. (Siphons are jet ejectors.) They are still commonly used to transfer a liquid from one tank to another. In the aspirator pump, water flows through a venturi nozzle and develops a suction for drawing in air. Steam ejectors are widely used for pumping large volumes of vapours and gases at low pressures. Steam at high velocity enters the main body of the pump. The steam transfers some of its momentum to the gas, which is sucked in from the inlet line. A mixture of steam and gas enters the main venturi nozzle known as the diffuser. Kinetic energy is converted to pressure energy and the mixture of steam and gas is compressed. Thus energy in the steam is used to compress gas from a low to a higher pressure. Jet ejector pumps have the advantage of no moving parts. They have been used since about 1850.

Steam ejectors

Hydraulic ram pumps. This type of pump uses the energy of a downward flowing stream of water to lift a proportion of the water to a higher level. Flowing water in the inlet pipe causes a one-way check valve to close. As in a water hammer (in which a flow of water is suddenly stopped, producing a hammering action), kinetic energy is converted to pressure energy, and a second one-way check valve is opened to force some water into the air chamber and up the discharge pipe. The pressure falls in the inlet water pipe, and the first one-way check valve reopens. The compressed air closes the one-way check valve to the air chamber, and the whole cycle is repeated. Approximately 15 percent of the water flowing in the inlet pipe may be raised to a height of five times the fall in the inlet pipe. Hydraulic ram pumps were developed in the late 18th century and are still used in some domestic water systems.

Electromagnetic pumps. These can only be used to pump fluids that are good electrical conductors. The pipe carrying the fluid is placed in a magnetic field and a current passed crosswise through the fluid, so that it is subjected to an electromagnetic force in the direction of flow. The current and the field can be produced in a variety of ways. The principle of the electromagnetic pump is the same as that of the electric motor. Electromagnetic pumps are used for pumping liquid metals, which are used for cooling nuclear reactors.

Applications. Pump manufacturers can provide invaluable help in selecting the right pump for a particular application. The cheapest pump is not the best if it breaks down after a relatively short life. On the other hand, there is little point in buying an expensive pump that will outlast its intended period of use. The properties of the fluid to be pumped and the availability of services such as electricity, steam, compressed air, and water are important factors in deciding the pump to be used. The volute centrifugal pump is easily the most common type of pump for general use. It is versatile, reliable, relatively inexpensive, and well suited to pumping most liquids.

If the liquid being pumped has a tendency to vaporize, as is often the case with warm liquids, it is better to use a positive displacement pump. But if the temperature is too high, pumps with close clearances such as gear pumps run the risk of seizing. Again, a volute centrifugal pump would not be used for a very viscous liquid. If the viscous liquid also contains solid particles, many positive displacement pumps would not be suitable. For this case either a screw or a diaphragm pump would be used.

Vacuum pumps

Vacuum. The atmosphere at sea level normally exerts a pressure of about 14.7 pounds force per square inch. Lower pressures than atmospheric are referred to as vacuum. Vacuum pumps are simply compressors that take in gas at a pressure lower than atmospheric pressure, compress it, and discharge the gas at atmospheric pressure. Since gas at low pressures has a large volume, vacuum pumps tend to be bulky. Steam jet ejectors are extensively used industrially for creating vacuum. Reciprocating piston and rotary-vane-type pumps are also widely used for producing vacuum (see also VACUUM TECHNOLOGY).

Oil and chemical industry. Most types of positive displacement and kinetic pumps can be found in the oil and chemical industry. However, by far the most common type is the volute centrifugal pump. Specially made volute centrifugal chemical pumps are available that have an extra erosion and corrosion allowance and maximum interchangeability of parts. Provision can also be made for leak collection and the water cooling of bearings. Leakage of chemicals may be expensive or even dangerous. Materials of construction must be carefully chosen. In addition to possible erosion and corrosion of the pump, the chemical being pumped may become contaminated. Glass and stoneware volute centrifugal pumps are also available in addition to those made of corrosion resistant alloys. Jacketed pumps for heating with steam or hot water are also used in the chemical industry. Canned pumps in which rotating members are enclosed are used to pump hazardous chemicals. These pumps do not require packed or mechanical seals to prevent leakage. A combined rotor and impeller assembly is driven by the rotating magnetic field of an induction motor that acts, without contact, through the pump housing.

Irrigation and drainage. Irrigation and drainage pumps are of high capacity and normally generate heads up to about 30 feet. Volute centrifugal, axial flow propeller, and mixed flow centrifugal pumps are all used in this work. The most common materials of construction are cast iron for pump casings, bronze for impellers and shaft sleeves, and carbon steel for shafts. In the case of highly polluted water, more corrosion resistant materials may be used. The pumped water usually contains solid particles of silt and mud. Clean water is used to lubricate the bearings on the pump shaft. These pumps are required to stand long continuous service.

Hydrokinetic transmissions

Hydraulic power transmission. Power is transmitted hydraulically by combining a pump and a turbine. Hydraulic power transmission is more flexible than mechanical systems and cheaper and more compact than electrical systems. The pump and turbine can either be housed in a single casing or interconnected by flow and return pipes. The latter system allows the output turbine to be installed in inaccessible locations. By controlling either the pump or the turbine, a continuous variation of speed ratio between the input and output units can be obtained. Centrifugal units are used for systems housed in a single casing. These are called hydrokinetic transmissions and are used in transport vehicles. Interconnected pumps and turbines are usually positive displacement units. Both external gear and reciprocating piston units are in common use.

Deep wells. A special type of volute centrifugal pump is used to raise water from deep, narrow wells. This is a bottom suction pump with a vertical shaft, to which one or more impellers are attached. These pumps are also sometimes called turbine pumps. Discharge occurs along the shaft axis, and they can either be water or oil lubricated. In the latter, a tube enclosing the drive shaft is filled with oil. Long shafts can be avoided by using a close-coupled, totally submersible motor located beneath the pump chamber.

Handling of sewage, wastes, and solids. Specially designed volute centrifugal pumps are used to pump liquids containing solids. Sewerage and industrial waste pumps have large suction and discharge ports that are free from obstructions. They have nonclogging impellers with rounded edges, which are specially designed to be self-cleaning. Some of these pumps are rubber lined. Others have replaceable casing liners.

Condensate pumps. Condensate pumps are usually large volute centrifugal pumps with a number of stages. They are used to extract water at a very low pressure from the hot well of a steam condenser, the container in which condensed steam collects. Condensate pumps have casings of cast iron, impellers of bronze; and shafts of chrome steel. Usually the bearings are lubricated with water to avoid any possible contamination of the feed water with oil. Condensate pumps are generally automatically controlled by the level in the hot well.

Barrel pump

Feed pumps. Multistage volute centrifugal pumps are used to feed hot water to boilers. The impellers are operated at very high rotational speeds, and control of the impeller speed is used to regulate the flow. The pumps must be heated to the temperature of the hot water before starting the feed. Initially the hot water cools and tends to accumulate in the lower part of the pump. The uneven thermal expansion tends to distort the pump casing and shaft. The barrel pump was developed to overcome this problem. It consists of an outer and inner casing. The latter is continually subjected to the discharge pressure of the pump to keep it leak tight. The pumps are made of chrome steel.

Metring pumps. Positive displacement pumps are used to supply a constant rate of liquid irrespective of the discharge pressure. Most metring pumps are of the reciprocating plunger type, although diaphragm metring pumps are common. The rate of liquid is varied by altering the length of the stroke of the plunger. Two or more pumps can be driven by the same motor to provide a constant ratio of two or more rates. To a lesser extent gear pumps are also used to metre liquids.

Statistics on production and use. The manufacture of pumps is a major industry. The most commonly pumped liquid is water. Petrochemical liquids are the second most commonly pumped liquids. The following gives the water requirement in various industries:

1 ton of steel production requires 65,000 U.S. gallons of water

1 ton of paper production requires 70,000 U.S. gallons of water

1 ton of rubber production requires 30,000 U.S. gallons of water

1 ton of petroleum production requires 35,000 U.S. gallons of water

All these industries and many others require pumps.

Punctuation

Punctuation is the use of spacing, conventional signs, and certain typographical devices as aids to the understanding and correct reading, both silently and aloud, of handwritten and printed texts. The word is derived from the Latin *punctus*, "point." From the 15th century to the early 18th the subject was known in English as pointing; and the term punctuation, first recorded in the middle of the 16th century, was reserved for the insertion of vowel points (marks placed near consonants to indicate preceding or following vowels) in Hebrew texts. The two words exchanged meanings between 1650 and 1750.

Since the late 16th century the theory and practice of punctuation have varied between two main schools of thought: the elocutionary school, following late medieval practice, treated points or stops as indications of the pauses of various lengths that might be observed by a reader, particularly when he was reading aloud to an audience; the syntactical school, which had won the argument by the end of the 17th century, saw them as something less arbitrary, namely, as guides to the grammatical construction of sentences. Pauses in speech and breaks in syntax tend in any case to coincide; and although English-speaking writers are now agreed that the main purpose of punctuation is to clarify the grammar of a text, they also require it to take account of the speed and rhythm of actual speech.

Syntactical punctuation is, by definition, bad when it obscures rather than clarifies the construction of sentences. Good punctuation, however, may be of many kinds: to take two extreme examples—Henry James would be unintelligible without his numerous commas, but Ernest Hemingway seldom needs any stop but the full point. In poetry, in which the elocutionary aspect of punctuation is still important, and to a lesser degree in fiction, especially when the style is close to actual speech, punctuation is much at the author's discretion. In nonfictional writing there is less room for experiment. Stimulating variant models for general use might be the light punctuation of George Bernard Shaw's prefaces to his plays and the heavier punctuation of T.S. Eliot's literary and political essays.

Ancient Greek practices

Punctuation in Greek and Latin to 1600. The punctuation now used with English and other western European languages is derived ultimately from the punctuation used with Greek and Latin during the Classical period. Much work remains to be done on the history of the subject, but the outlines are clear enough. Greek inscriptions were normally written continuously, with no divisions between words or sentences; but in a few inscriptions earlier than the 5th century BC, phrases were sometimes separated by a vertical row of two or three points. In the oldest Greek literary texts, written on papyrus during the 4th century BC, a horizontal line called the paragraphos was placed under the beginning of a line in which a new topic was introduced. This is the only form of punctuation mentioned by Aristotle. Aristophanes of Byzantium, who became librarian of the museum at Alexandria about 200 BC, is usually credited with the invention of the critical signs, marks of quantity, accents, breathings, and so on, still employed in Greek texts, and with the beginnings of the Greek system of punctuation. Rhetorical theory divided discourse into sections of different lengths. Aristophanes marked the end of the short section (called a comma) by a point after the middle of its last letter, that of the longer section (*colon*) by a point after the bottom of the letter, and that of the longest section (periodos) by a point after the top of the letter. Since books were still being written in tall majuscule letters, like those used in inscriptions and like modern capital letters, the three positions were easily distinguishable. Aristophanes' system was seldom actually used, except in a degenerated version involving only two points. In the 8th or 9th century it was supplemented by the Greek form of question mark (;). The modern system of punctuating Greek texts was established by the Italian and French printers of the Renaissance, whose practice was incorporated in the Greek types cut by Claude Garamond for Francis I of France between 1541 and 1550. The colon is not used in Greek, and the semicolon is represented by a high point. Quotation marks and the exclamation mark were added more recently.

Roman practice

In almost all Roman inscriptions points were used to separate words. In the oldest Latin documents and books, dating from the end of the 1st century BC to the beginning of the 2nd century AD, words were divided by points, and a change of topic was sometimes indicated by paragraphing: the first letter or two of the new paragraph projected into the margin instead of being indented, as they have been since the 17th century. Roman scholars, including the 4th-century grammarian Donatus and the 6th-century patron of monastic learning Cassiodorus, recommended the three-point system of Aristophanes, which was perfectly workable with the majuscule Latin scripts then in use. In practice, however, Latin books in their period were written continuously—the point between words had been abandoned. The ends of sentences were marked, if at all, only by a gap (which might be followed by an enlarged letter) or by an occasional point. The only books that were well punctuated at that time were copies of the Vulgate Bible, for which its translator, St. Jerome (died 419/420), devised punctuation per cola et *commata* ("by phrases"), a rhetorical system, based on manuscripts of Demosthenes and Cicero, which was especially designed to assist reading aloud. Each phrase began with a letter projecting into the margin and was in fact treated as a minute paragraph, before which the reader was expected to take a new breath.

Early medieval practice

During the 7th and 8th centuries, which saw the transition from majuscule to minuscule handwriting (minuscule scripts were usually smaller than majuscule and had projections above and below the body of the letters, as in modern lowercase letters), scribes to whom the Latin language was no longer as well-known as it had been, especially Irish, Anglo-Saxon, and German scribes, to whom it was a foreign language, began to separate words. It was only in the 13th century that monosyllables, especially prepositions, were finally detached from the word following them. To mark sentences, a space at the end became the rule; and an enlarged letter, often a majuscule, generally stood at the beginning of sentences and paragraphs alike. The use of points was somewhat confused by St. Isidore of Seville (died 636), whose encyclopaedia recommended an aberrant version of the three-point system; but a point, high or low, was still used within or after sentences. The ends of sentences were often marked by a group of two or three marks, one of which might be a comma and not a simple point.

St. Jerome's concern for the punctuation of sacred texts was shared by Charlemagne, king of the Franks and Holy Roman emperor, and his Anglo-Saxon adviser Alcuin, who directed the palace school at Aachen from 782 to 796. An important element in the educational revival over which they presided was the improvement of spelling and punctuation in biblical and liturgical manuscripts. It is in the earliest specimens of the new Caroline minuscule script, written at Corbie and Aachen (now in northern France and West Germany, respectively), about 780–800, that the first evidence for a new system of punctuation appears. It soon spread, with the script itself, throughout Europe, reaching its perfection in the 12th century. Single interior stops in the form of points or commas and final groups of stops continued in use; but they were joined by the mark later known as punctus *elevatus* (⹎) and by the question mark (punctus *interrogativus*), of much the same shape as the modern one but inclined to the right. The source of these two new marks was apparently the system of musical notation, called neums, which is known to have been used for Gregorian chant from at least the beginning of the 9th century. *Punctus* elevatus and punctus interrogativus indicated not only a pause and a syntactical break but also an appropriate inflection of the voice. By the 12th century another mark, punctus *circumflexus* (7), had been added to *elevatus* to indicate a rising inflection at the end of a subordinate clause, especially when the grammatical sense of the sentence was still not complete. Liturgical manuscripts in particular, between the 10th and the 13th century, made full use of this inflectional system: it is the origin of the "colon" still used to divide verses of the Psalms in breviaries and prayer books. In the later Middle Ages it was especially the Cistercian, Dominican, and Carthusian orders and the members of religious communities such as the Brethren of the Common Life who troubled to preserve a mode of punctuation admirably adapted to the constant reading aloud, in church and refectory, that characterized the religious life. The hyphen, to mark words divided at the ends of lines, appears late in the 10th century; single at first, it was often doubled in the period between the 14th and 18th centuries.

Late medieval practice

Most late medieval punctuation was haphazard by comparison with 12th-century work—notably in the university textbooks produced at Paris, Bologna, and Oxford in the 13th and 14th centuries. In them, as elsewhere, a form of paragraph mark representing *c* for *capitulum* ("chapter") is freely used at the beginning of sentences. Within the same period the plain point and *punctus elevatus* are joined by the virgule (/), as an alternative form of light stop. Vernacular literature followed the less formal types of Latin literature; and the printers, as usual, followed the scribes. The first printed texts of the Bible and the liturgy are, as a rule, carefully punctuated on the inflectional principle. The profusion of points and virgules in the English books of the printer William Caxton pays remarkably little attention to syntax. Parentheses, used in the same way as now, appear by about 1500. During the 15th century some English legal documents were already being written without punctuation; and British and American lawyers still use extremely light punctuation in the hope of avoiding possible ambiguities.

The beginnings of postmedieval punctuation can be traced to the excellent manuscripts of classical and contemporary Latin texts copied in the new humanistic scripts by Italian scribes of the 15th century. To about 1450 the point and the *punctus elevatus* seem to have been preferred for minor pauses; after that date they are often replaced by the virgule and what is now called the colon (:). The virgule, originally placed high, sank to the base line and developed a curve—turned, in fact, into a modern comma. The Venetian editor and printer Aldus Manutius (Aldo Manuzio; died 1515) made improvements in the humanistic system, and in 1566 his grandson of the same name expounded a similar system in his *Orthographiae ratio* ("System of Orthography"); it included, under different names, the modern comma, semicolon, colon, and full point, or period. Most importantly, the younger Aldo stated plainly for the first time the view that clarification of syntax is the main object of punctuation. By the end of the 17th century the various marks had received their modern names, and the exclamation mark, quotation marks, and the dash had been added to the system.

Punctuation in English since 1600. By the end of the 16th century writers of English were using most of the marks described by the younger Aldo in 1566; but their purpose was elocutionary, not syntactical. When George Puttenham, in his treatise *The Arte* of *English Poesie* (1589), and Simon Daines, in *Orthoepia Anglicana* (1640), specified *a* pause of one unit for a comma, of two units for a semicolon, and of three for a colon, they were no doubt trying to bring some sort of order into a basically confused and unsatisfactory situation. The punctuation of Elizabethan drama, of the devotional prose of John Donne or of Richard Hooker, and indeed of Bunyan's *Pilgrim's Progress* (1678) was almost wholly elocutionary; and it lacked the inflectional element that had been the making of 12th-century punctuation. It was Ben Jonson, in his *English Grammar*, a work composed about 1617 and published posthumously in 1640, who first recommended syntactical punctuation in England. An early example is the 1625 edition of Francis Bacon's *Essayes;* and from the Restoration onward syntactical punctuation was in general use. Influential treatises on syntactical punctuation were published by Robert Monteith in 1704 and Joseph Robertson in 1795. Excessive punctuation was common in the 18th century: at its worst it used commas with every subordinate clause and separable phrase. Vestiges of this attitude are found in a handbook published in London as late as 1880. It was the lexicographers Henry Watson Fowler and Francis George Fowler, in *The King's English,* published in 1906, who established the current British practice of light punctuation. Punctuation in the United States has followed much the same path as in Britain, but the rules laid down by American authorities have in general been more rigid than the British rules.

Shift to syntactical punctuation

The system of punctuation now used by writers of English has been complete since the 17th century. Three of its most important components are the space left blank between words; the indentation of the first line of a new paragraph; and the uppercase, or capital, letter written at the beginning of a sentence and at the beginning of a proper name or a title. The marks of punctuation, also known as points or stops, and the chief parts that they play in the system are as follows.

The end of a grammatically complete sentence is marked by a full point, full stop, or period. The period may also be used to mark abbreviations. The colon (:), which was once used like a full point and was followed by an uppercase letter, now serves mainly to indicate the beginning of a list, summary, or quotation. The semicolon (;) ranks halfway between a comma and a full point. It may be substituted for a period between two grammatically complete sentences that are closely connected in sense; in a long or complicated sentence, it may precede a coordinate conjunction (such as "or," "and," or "but"). A comma (,) is the "lightest" of the four basic stops. As the most usual means of indicating the syntactical turning points in a sentence, it is exposed to abuse. It may be used to separate the elements of a series, before a relative clause that does not limit or define its antecedent, in pairs to set off or isolate words or phrases, or in combination with coordinating conjunctions.

Other punctuation marks used in modern English include parentheses, which serve, like a pair of commas, to isolate a word or phrase; question, exclamation, and quotation marks; the hyphen; and the apostrophe.

Punctuation in French, Spanish, German, and Russian. Since the modern punctuation of all the western European languages stems from the practice of the great Italian and French printers of the 15th and 16th centuries, national differences are not considerable. In French, guillemets (« ») or dashes are used to mark quotations. In Spanish, since the middle of the 18th century, an inverted mark of interrogation or exclamation has stood at the beginning of sentences as well as the normal mark at the end; and quotations may be marked either as in French or as in English. German punctuation, which is still based on rules propounded in 1781, is more rigorously syntactical than the rest: all relative clauses and all clauses beginning with *dass* ("that") must be preceded by a comma. Quotations are marked either by pairs of commas („“) or by reversed guillemets (» «). Letter spacing, as well as italic type, is used for emphasis. Early Russian punctuation was based on Greek practice, since the Cyrillic alphabet is derived from the Greek; and by the 17th century several quite elaborate systems had evolved in different areas. Since the 18th century Russia has used a form of western European punctuation that has much in common with German practice: notably an even wider obligatory use of commas with subordinate and indeed coordinate clauses, and letter spacing (as well as italics) for emphasis. German quotation marks, French guillemets, and dashes may be used for direct speech.

Characteristics of German punctuation

Punctuation in Oriental and African languages. In Hebrew manuscripts written since the 9th century the main use of points is to indicate the vowel sounds, the alphabet being consonantal only. In Biblical texts points and commas are used to mark the middle and end of verses; and in the commentaries points mark the end of sentences. Since the late 18th century, when Jews in Germany began to compose secular texts in Hebrew, the punctuation of such texts has been based on German practice. Early Arabic manuscripts had no punctuation, since the structure of the language ensured that the main and subordinate clauses were readily distinguishable without it. After Arabic began to be printed, European punctuation marks were gradually adopted. The first such mark was the reversed comma; it is now the commonest and indicates a suitable point at which to pause and draw breath.

In Sanskrit, prose texts use one vertical stroke to mark the end of the sentence, and verse texts use one vertical stroke for the end of a line, two for the end of a couplet. In Bengali, Gujarati, Hindi, and Marathi, the vertical stroke is used as in Sanskrit, in conjunction with other marks borrowed from English. The diacritical signs and elements of punctuation found in Tamil were introduced early in the 18th century by a Jesuit missionary.

Before the modern period, the grammatical structure of written Chinese was such that no punctuation was required; but in the 19th century editors of texts began to add hollow circles, intended either to mark the ends of phrases or to emphasize particular passages. Since 1912 some of the European punctuation marks have been adopted, notably the marks of interrogation and exclamation and the comma (the hollow circle serves as full point). Direct speech is indicated either by double inverted commas or by an L-shaped mark placed at a corner of the first and last characters. Characters are capitalized by the addition of a straight or wavy line underneath or at the side, according to whether the text is written horizontally or vertically.

In Japan a complicated system of *kaeriten* and *kunten* marks was used from the 8th century onward to clarify the meaning and grammatical construction of texts in Chinese. As a result of contact with Europeans in the 15th and 16th centuries, a hollow point (O)and a reversed virgule (') were used during the Edo period (1603–1868) as equivalents of the European full point and comma. Since 1868 they have been joined by the solid point (to separate items in a list), by the dash used as in English, and, finally, by the European marks of exclamation and interrogation.

The history of punctuation in Africa is part of the history of the scripts used in different parts of the continent: the Coptic script, based on the Greek alphabet with some additions from demotic writing, for the ancient language of Egypt; a derivative of South Semitic script, known as Ethiopic, for the languages of Ethiopia; Arabic script for speakers of Arabic, Berber, and Swahili; Latin—*i.e.,* European — script for the languages first recorded during and since the 19th century.

BIBLIOGRAPHY, G.V. CAREY, *Mind the Stop,* rev. ed. (1958); and E.H. PARTRIDGE, *You Have a Point There* (1953), are the best guides to modern punctuation as practiced in Britain. The former is short and stimulating; the latter is more exhaustive and includes a chapter on American practice by J.W. CLARK. A comparable American work is the chapter on punctuation in P.G. PERRIN, *Writer's Guide and Index to English,* 4th ed. (1966). The following describe the practice of two famous presses, Oxford University Press and the University of Chicago Press: HORACE HART, *Rules for Compositors and Readers at the University Press,* 37th ed. rev. (1967); and *A Manual of Style,* 12th ed. rev. (1969). For punctuation in antiquity and the Middle Ages, see E.M. THOMPSON, *An Introduction to Greek and Latin Palaeography* (1912); FRANZ STEFFENS, *Lateinische Palaographie,* 2nd ed. (1909); PETER CLEMOES, *Liturgicnl Influence on Punctuation in Late Old English and Early Middle English Manuscripts* (1952); and R.W. SOUTHERN, *The Life of St. Anselm by Eadmer,* pp. 25–34 (1962). For punctuation in and since the Renaissance, especially in Britain, see A.C. PARTRIDGE, *Orthography* in *Shakespeare and Elizabetharz Drama* (1964), of which ch. 14 and 15 and appendix VIII are on punctuation; T.F. and M.F.A. HUSBAND, *Punctuation* (1905); and R.A. SKELTON, *Modern English Punctuation,* 2nd ed. (1950). ALEXANDER BIELING, *Das Princip der deutschen Interpunktion, nebst einer übersichtlichen Darstellung ihrer Geschiclzte* (1880), is useful not only for German practice bat for European punctuation in general since the 15th century.

(T.J.Br.)

Punic Wars

The Punic (Carthaginian) Wars is a name specially given to the wars between Rome and Carthage in the 3rd and 2nd centuries BC. The origin of these conflicts is to be found in the position that Rome acquired about 275 BC as leader and protector of all Italy. Rome's subsequent desire to safeguard the peninsula against foreign interference made it necessary to prevent the neighbouring island of Sicily from falling into the hands of a strong and expansive power. Carthage, on the other hand, had long been anxious to conquer Sicily and to complete the chain of island posts by which it controlled the western Mediterranean from its base in North Africa.

First Punic War (264–241 BC). The proximate cause of the first outbreak was a crisis in the city of Messana (Messina), commanding the straits between Italy and Sicily. A band of Campanian mercenaries, the Mamertini, who had forcibly established themselves within the town and were being hard-pressed in 264 by Hieron II of Syracuse, applied for help to both Rome and Carthage. The Carthaginians, arriving first, occupied Messana and effected a reconciliation with Hieron. The Roman commander, nevertheless, persisted in throwing troops into the city and by seizing the Carthaginian admiral during a parley induced him to withdraw. This aggression involved Rome in war with Carthage and Syracuse.

Operations began with a joint attack upon Messana, which the Romans easily repelled. In 263 the Romans advanced with a considerabl: force into Hieron's territory and induced him to seek peace and alliance with them. In 262 they besieged and captured the enemy's hase at Agrigentum. But they made little impression upon the Carthaginian fortresses in the west of the island and upon the towns of the interior.

In 260 the Romans built their first large fleet of standard battleships. At Mylae (Milazzo), off the north Sicilian coast, their admiral Gaius Duilius defeated a Carthaginian squadron of superior manoeuvring capacity by grappling and boarding. This left Rome free to land a force on Corsica (259) and expel the Carthaginians but did not suffice to loosen their grasp on Sicily. A large Roman fleet sailed out in 256, repelled the entire Carthaginian fleet off Cape Ecnomus (near modern Licata), and established a fortified camp on African soil at Clypea (Kélibia in Tunisia). The Carthaginians, whose citizen levy was utterly disorganized, could neither keep the field against the invaders nor prevent their subjects from revolting. After one campaign they were ready to sue for peace, but the terms that the Roman commander M. Atilius Regulus offered were intolerably harsh. Accordingly, the Carthaginians equipped a new army in which, by the advice of a Greek captain of mercenaries named Xanthippus, cavalry and elephants formed the strongest arm. In 255, under Xanthippus' command, they offered battle to Regulus, who had taken up position with an inadequate force near Tunis, outnianoeuvred him, and destroyed the bulk of his army. A second Roman fleet, which reached Africa after defeating the full Carthaginian fleet off Cape Hermaeum (Cape Bon), withdrew all the remaining troops.

The campaign against Sicily

The Romans now directed their efforts once more against Sicily. In 254 they captured the important fortress of Panormus (Palermo), but when Carthage threw reinforcements into the island the war again came to a standstill. In 251 or 250 the Roman general Caecilus Metellus at last brought about a pitched battle near Panormus, in which the enemy's force was effectively crippled. This victory was followed by an investment of the chief Punic base at Lilybaeum (Marsala), together with Drepanum (Trapani), by land and sea. The besiegers met with a gallant resistance and in 249 were compelled to withdraw by the loss of their fleet in a surprise attack upon Drepanum, in which the admiral P. Claudius Pulcher was repulsed with a loss of 93 ships. This was the Romans' only naval defeat in the war, but their fleet had suffered a series of grievous losses by storm, and now it was so reduced that the attack upon Sicily had to be suspended. At the same time, the Carthaginians, who felt no less severely the financial strain of the prolonged struggle, reduced their forces and made no attempt to deliver a counterattack. The only noteworthy feature of the ensuing campaigns is the skillful guerrilla war waged by a new Carthaginian commander, Hamilcar Barca, from his strong positions on Mt. Ercte (247/246–244) and Mt. Eryx (modern Erice; 244–242) in western Sicily, by which he effectually screened Lilybaeum from any attempt on it by the Roman land army.

In 242 Rome resumed operations at sea. By a magnificent effort on the part of private citizens, a fleet of 200 warships was equipped and sent out to renew the blockade of Lilybaeum. The Carthaginians hastily collected a relief force but in a battle fought off the Aegates, or Aegusae (Aegadian) Islands, west of Drepana, their fleet was

caught at a disadvantage and mostly sunk or captured (March 10, 241). This victory, by giving the Romans undisputed command of the sea, rendered certain the ultimate fall of the Punic strongholds in Sicily. The Carthaginians accordingly opened negotiations and consented to a peace by which they ceded Sicily and the Lipari Islands to Rome and paid an indemnity of 3,200 talents.

The interval between the First and Second wars (241–218 BC). The loss of naval supremacy not only deprived the Carthaginians of their predominance in the western Mediterranean but exposed their overseas empire to disintegration under renewed attacks by Rome. The temper of the Roman people was soon made manifest during a conflict that broke out between the Carthaginians and their discontented mercenaries. A gross breach of the treaty was perpetrated when a Roman force was sent to occupy Sardinia, whose insurgent garrison had offeredto surrender the island (238). To the remonstrances of Carthage the Romans replied with a declaration of war and only withheld their attack upon the cession of Sardinia and Corsica and the payment of a further indemnity.

From this episode it became clear that Rome intended to use the victory to the utmost. To avoid complete humiliation Carthage had no resource but to humiliate its adversary. The recent complications of foreign and internal strife had indeed so weakened the Punic power that the prospect of renewing the war under favourable circumstances seemed remote. But the scheme of preparing for a fresh conflict found a worthy champion in Hamilcar Barca, who sought to compensate for the loss of Sicily by acquiring a dominion in Spain where Carthage might gain new wealth and form a fresh base of operations against Rome. Invested with an unrestricted foreign command, he spent the rest of his life in founding a Spanish empire (237–228). His work was continued by his son-in-law Hasdrubal and his son Hannibal, who was placed at the head of the army in 221. These conquests aroused the suspicions of Rome, which in a treaty with Hasdrubal confined the Carthaginians to the south of the Ebro. At some point Rome also entered into relations with Saguntum (Sagunto), a town on the east coast, south of the Ebro. In 219 Hannibal laid siege to Saguntum and carried the town in spite of a stubborn defense.

It has always been a debatable point whether or not his attack contravened the new treaty. The Romans certainly took this view and sent to Carthage to demand Hannibal's surrender. But his defiant policy was too popular to be disavowed; the Carthaginian council upheld Hannibal's action and drew upon itself a declaration of war.

Second Punic War (218–201 BC). It seemed as though the superiority of the Romans at sea must enable them to choose the field of battle. They decided to embark one army for Spain and another for Sicily and Africa. But before their preparations were complete, Hannibal began that series of operations by which he dictated the course of the war for the greater part of its duration. Realizing that, so long as the Romans commanded the resources of an undivided Italian confederacy, no foreign attack could beat them down beyond recovery, he conceived the plan of cutting off their supply of strength at the source by carrying the war into Italy and causing a disruption of the league. His chances of ever reaching Italy seemed small, for the sea was guarded by the Roman fleets and the land route was long and arduous.

Hannibal's strategy

But the very boldness of his enterprise contributed to its success; after a six months' march through Spain and Gaul and over the Alps, which the Romans were nowhere in time to oppose, Hannibal arrived (autumn 218) in the plain of the Po with 20,000 foot and 6,000 horses, the pick of his African and Spanish levies.

His further advance was here disputed by some Roman troops, but the superiority of the Carthaginian cavalry and the spread of insurrection among the Gaulish inhabitants forced the defenders to fall back upon the Apennines. At the end of the year the Roman army was reinforced by the division from Sicily and led out to battle on the banks of the Trebbia. Hannibal, by superior tactics, repelled the assailants with heavy loss and thus made his position in north Italy secure.

In 217 the campaign opened in Etruria, into which the invading army, largely reinforced by Gauls, penetrated by an unguarded pass. A rash pursuit by the Roman field force led to its being entrapped on the shore of Lake Trasimene (Trasimeno) and destroyed with a loss of at least 15,000 men. This catastrophe left Rome completely uncovered; but Hannibal, having resolved not to attack the capital before he could collect a more overwhelming force, directed his march toward the south of Italy, where he hoped to stir up the peoples who had formerly been the most stubborn enemies of Rome. The Italians, however, were slow everywhere to join the Carthaginians; and a new Roman army under the dictator Q. Fabius Maximus ("Cunctator") that, without ever daring to close with Hannibal, dogged his steps on his forays through Apulia and Campania, prevented his acquiring a permanent base of operations.

The Battle of Cannae

The eventful campaign of 216 was begun by a new, aggressive move on the part of Rome. An exceptionally strong field army, variously estimated at between 48,000 and 85,000 men, was sent to crush the Carthaginians in open battle. On a level plain near Cannae in Apulia, which Hannibal had chosen for his battleground, the Roman legions delivered their attack. Hannibal deliberately allowed his centre to be driven in by their superior numbers, while Hasdrubal's cavalry wheeled round so as to take the enemy in flank and rear. The Romans, surrounded on all sides and so cramped that their superior numbers aggravated their flight, were practically annihilated; and the loss of citizens was perhaps greater than in any other defeat that befell the republic.

The moral effect of the battle was no less momentous. The south Italian peoples at least found courage to secede from Rome, the leaders of the movement being the people of Capua, at the time the second greatest town of Italy. Reinforcements were sent from Carthage, and several neutral powers prepared to throw their weight into the scale on Hannibal's behalf. At first sight it seems strange that the Battle of Cannae did not decide the war. But the great resources of Rome, though terribly reduced in respect to both men and money, were not yet exhausted. In north and central Italy the insurrection spread but little and could be sufficiently guarded against with small detachments. In the south, the Greek towns of the coast remained loyal, and the numerous Latin colonies continued to render important service by interrupting free communication between the rebels and detaining part of their forces.

In Rome itself the quarrels between the nobles and commons, which had previously unsettled Roman policy, gave way to a unanimity unparalleled in the annals of the republic. The guidance of operations was henceforth left to the Senate, which, by maintaining a persistent policy until the conflict was brought to a successful end, earned its greatest title to fame.

The subsequent campaigns of the war in Italy assumed a new character. Though the Romans contrived at times to raise 200,000 men, they could spare only a moderate force for field operations. Their generals, among whom the veterans Fabius and M. Claudius Marcellus frequently held the most important commands, rarely ventured to engage Hannibal in the open and contented themselves with observing him or skirmishing against his detachments. Hannibal, whose recent accessions of strength were largely discounted by the necessity of assigning troops to protect his new allies or secure their wavering loyalty, was still too weak to undertake a vigorous offensive. In the ensuing years the war resolved itself into a multiplicity of minor engagements, which need not be followed out in detail. In 216 and 215 the chief seat of war was Campania, where Hannibal, vainly attempting to establish himself on the coast, experienced a severe repulse at Nola.

In 214 the main Carthaginian force was transferred from Apulia in hopes of capturing Tarentum (Taranto). Though Croton and Locri on the southern coast had fallen into his hands, Hannibal still lacked a suitable harbour by which he might have secured his overseas communications. For two years he watched in vain for an opportunity to surprise the town, while the Romans narrowed down the sphere of revolt in Campania and defeated other Carthaginian commanders.

In 213–212 the greater part of Tarentum and other cities of the southern seaboard at last came into Hannibal's power. But in 212 the Romans found themselves strong enough to place Capua under blockade. They severely defeated a Carthaginian relief force and could not be permanently dislodged even by Hannibal himself. In 211 Hannibal made a last effort to relieve his allies by a feint upon Rome itself, but the besiegers refused to be drawn away from their entrenchments, and eventually Capua was starved into surrender.

Its fall was a sign that no power could in the long run uphold a rival Italian coalition against Rome. After a year of desultory fighting, the Romans in 209 gained a further important success by recovering Tarentum. Though Hannibal still won isolated engagements, he was slowly being driven back into the extreme south of the peninsula.

The campaign of 207

In 207 the arrival of a fresh invading force produced a new crisis. Hasdrubal, who in 208–207 had marched overland from Spain, appeared in northern Italy with a force scarcely inferior to the army that his brother had brought in 218. After levying contingents of Gauls and Ligurians, he marched down the east coast with the object of joining his brother in central Italy for a direct attack upon Rome itself. By this time the steady drain of men and money was telling so severely upon the confederacy that some of the most loyal allies protested their inability to render further help. Yet by exerting a supreme effort the Romans raised their war establishment to the highest total yet attained and sent a strong field army against each Carthaginian leader.

The danger to Rome was chiefly averted by the prompt insight and enterprise of the consul Gaius Nero, who commanded the main army in the south. Having discovered that Hannibal would not advance beyond Apulia until his brother had established communications with him, Nero slipped away with part of his troops and arrived in time to reinforce his colleague Livius, whose force had recently got into touch with Hasdrubal near Sena Gallica (Senigallia).

The combined Roman army frustrated an attempt of Hasdrubal to elude it and forced him to fight on the banks of the Metaurus (Metauro). The battle was evenly contested until Nero, by a dexterous flanking movement, cut the enemy's retreat. Hasdrubal himself fell, and the bulk of his army was destroyed.

The campaign of 207 decided the war in Italy. Though Hannibal still maintained himself for some years in southern Italy, this was chiefly due to the exhaustion of Rome after the prodigious strain of past years and the consequent reduction of Roman forces. In 203 Italy was finally cleared of Carthaginian troops. Hannibal, in accordance with orders received from home, sailed back to Africa; and another expedition under his brother, Mago, which had sailed to Liguria in 205 and endeavoured to rouse the slumbering discontent of the people in Cisalpine Gaul and Etruria, was forced to withdraw.

Campaigns in Sicily and Spain. Concurrently with the great struggle in Italy, the Second Punic War was fought out on several other fields. It will suffice merely to allude to the First Macedonian War (214–205), which King Philip V commenced when the Roman power seemed to be breaking up after Cannae. This compelled the Romans to stretch their already severely strained resources still further by sending troops to Greece, but the diversions that Roman diplomacy provided for Philip in Greece, and the maintenance of a patrol squadron in the Adriatic Sea, prevented any effective cooperation on his part with Hannibal.

In view of the complete stagnation of agriculture in Italy the Romans had to look to Sardinia and Sicily for their food supply. Sardinia was attacked by Carthaginians in 215, but a small Roman force sufficed to repel the invasion. In Sicily a more serious conflict broke out. Some isolated attacks by Punic squadrons were easily frustrated by the strong Roman fleet. But in 215 internal complications arose. The death of Hieron II, Rome's steadfast friend, left the realm of Syracuse to his inexperienced grandson, Hieronymus. Flattered by the promises of Carthaginian emissaries, the young prince abruptly broke with the Romans, but before hostilities commenced he was assassinated. The Syracusan people now repudiated the monarchy and resumed their republican constitution; but, by threats of terrible punishment at the hands of Rome, they were led to cooperate with the Carthaginians.

Roman attack on Syracuse

The attacks of a Roman army and fleet under Marcellus, which speedily appeared before the town, were completely baffled by the mechanical contrivances of the Syracusan mathematician Archimedes (213). Meantime, the revolt against Rome spread in the interior, and a Carthaginian fleet gained control of towns on the south coast.

In 212 Marcellus at last broke through the defense of Syracuse and, in spite of the arrival of a Carthaginian relief force, mastered the whole town in 211. A guerrilla warfare followed in which the Carthaginians maintained the upper hand until in 210 they lost their base at Agrigentum. They were dislodged from their remaining positions, and by the end of the year Sicily was wholly under the power of Rome.

The conflict in Spain was second in importance only to the Italian war. From this country the Carthaginians drew large supplies of troops and money that might serve to reinforce Hannibal; hence it was in the interest of the Romans to challenge their enemy within Spain. Though the force that Rome at first spared for this war was small in numbers and rested entirely upon its own resources, the generals Pnblius and Gnaeus Scipio, by skillful strategy and diplomacy, not only won over the peoples north of the Ebro and defeated the Carthaginian leader Hasdrubal Barca in his attempts to restore communication with Italy but carried their arms along the east coast into the heart of the enemy's domain.

But eventually their successes were nullified by a rash advance. Deserted by their native contingents and cut off by Carthaginian cavalry, among which the Numidian prince Masinissa rendered conspicuous service, the Roman generals were killed and their troops destroyed (211).

The Battle of Ilipa

Disturbances in Africa prevented the Punic commanders from exploiting their success. Before long the fall of Capua enabled Rome to transfer troops from Italy to Spain; and in 210 the best Roman general of the day, the young son and namesake of P. Scipio, was placed in command. He signalized his arrival by a bold and successful *coup de main* upon the great arsenal of Carthago Nova (Cartagena) in 209. Though after an engagement at Baecula (Bailen; 208) he was unable to prevent Hasdrubal Barca from marching away to Italy, Scipio profited by his departure to push back the remaining hostile forces the more rapidly. A last effort by the Carthaginians to retrieve their losses with a fresh army was frustrated by a great victory at Ilipa, near Seville, and by the end of the year 206 they had been driven out of Spain.

The war in Africa. In 205 Scipio, who had returned to Rome to hold the consulship, proposed to follow up his victories by an attack upon the home territory of Carthage. Though the presence of Hannibal in Italy deterrred Fabius and other senators from sanctioning this policy, Scipio gradually overbore all resistance. He built up a force, which he organized and supplemented in Sicily, and in 204 sailed across to Africa. He was met there by a combined levy of Carthage and King Syphax of Numidia and for a time was penned to the shore near Utica. But in the spring he extricated himself by a surprise attack upon the enemy's camp, which resulted in the total loss of the allied force by sword or fire.

In the campaign of 203 a new Carthaginian force was destroyed by Scipio on the Great Plains 75 miles from Utica, their ally Syphax was captured, and the renegade Masinissa reinstated in the kingdom from which Syphax had recently expelled him. These disasters induced the Carthaginians to sue for peace; but before the very moderate terms that Scipio offered could be definitely accepted, a sudden reversal of opinion caused them to recall Hannibal's army for a final trial of war and to break off negotiations. In 202 Hannibal assumed command of a composite force of citizen and mercenary levies stiffened with a corps of his veteran Italian troops.

After an abortive conference with Scipio he prepared for a decisive battle near Zama. Scipio's force was smaller in numbers but well trained throughout and greatly superior in cavalry. His infantry, after evading an attack by the Carthaginian elephants, cut through the first two lines of the enemy but was unable to break the reserve corps of Hannibal's veterans. The battle was ultimately decided by the cavalry of the Romans and their new ally Masinissa, which by a manoeuvre recalling the tactics of Cannae took Hannibal's line in the rear and destroyed it.

The Carthaginians having thus lost their last army again applied for peace and accepted the terms that Scipio offered. They were compelled to cede Spain and the Mediterranean islands still in their hands, to surrender their warships, to pay an indemnity of 10,000 talents within 50 years, and to forfeit their independence in affairs of war and foreign policy.

The Second Punic War, by far the greatest struggle in which either power engaged, had thus ended in the complete triumph of Rome. This triumph is not to be explained in the main by any faultiness in the Carthaginians' method of attack. The history of the First Punic War and that of the Second outside of Italy prove that the Romans were irresistible on neutral or Carthaginian ground. Carthage could only hope to win by invading Italy and using the enemy's home resources against him. The failure of Hannibal's brilliant endeavour to realize these conditions was not due to any strategical mistakes on his part. It was caused by the indomitable strength of will of the Romans, whose character during this period appears at its best, and to the compactness of their Italian confederacy, which no shock of defeat or strain of war could entirely disintegrate.

It is this spectacle of individual genius overborne by corporate and persevering effort that lends to the Second Punic War its peculiar interest.

Cato's influence

The Third Punic War (149–146 BC). The political power of Carthage henceforth remained quite insignificant, but its commerce and material resources revived in the 2nd century with such rapidity as to excite the jealousy of the growing mercantile population of Rome and the alarm of its more timid statesmen. Under the influence of these feelings the conviction—sedulously fostered by Cato the Censor—that "Carthage must be destroyed" overbore the scruples of more clear-sighted statesmen. A *casus belli* was readily found in a formal breach of the treaty, committed by the Carthaginians in 150 when they resisted Masinissa's aggressions by force of arms. A Roman army was dispatched to Africa; and although the Carthaginians consented to make reparation by giving hostages and surrendering their arms, they were goaded into revolt by the further stipulation that they must emigrate to some inland site where they would be debarred from commerce.

By a desperate effort they created new war equipment and prepared their city for a siege (149). The Roman attack for two years completely miscarried until in 147 the command was given to a young officer who had distinguished himself in the early operations of the war—Scipio Aemilianus, the adopted grandson of the former conqueror of Carthage. Scipio made the blockade stringent by walling off the isthmus on which the town lay and by cutting off its sources of supplies from overseas. His main attack was delivered on the harbour side, where he effected an entrance in the face of a determined and ingenious resistance. The struggle did not cease until he had captured house by house the streets that led up to the citadel.

Of a city population which, according to Strabo, had exceeded a quarter of a million, only 50,000 remained at the final surrender. The survivors were sold into slavery; the city was razed to the ground and its site condemned by solemn imprecations to lie desolate forever. The territory of Carthage, which had recently been much narrowed by Masinissa's encroachments, was converted into a Roman province under the name of "Africa."

BIBLIOGRAPHY

Ancient sources: The two main surviving authorities are Polybius and Livy, namely Polybius bk. 1 (First War), bks. 2 and 3, and fragmentary accounts in books 7–15 (Second War), and fragments of bks. 36–38 (Third War); and Livy bks. 21–30 (Second War), based partly on Polybius and partly on less reliable Roman annalists. Apart from Appian's account of the Third War (*Libyca*, 67–135, based partly upon Polybius), the subsidiary authors add little of value.

Modern works: Two general accounts are given by TENNEY FRANK *et al.*, *Cambridge Ancient History*, vol. 7, ch. 21, and vol. 8, ch. 2–5, 15 (1928–30); and by H.H. SCULLARD, *A History of the Roman World, 753 to 146 B.C.*, 3rd ed. (1961), while ARNOLD J. TOYNBEE, *Hannibal's Legacy*, 2 vols. (1965), provides much background information. An indispensable work is F.W. WALBANK, *Historical Commerztary on Polybius*, vol. 1 (1957), vol. 2 (1967), for full discussion of all problems, G. DE SANCTIS, *Storia dei Romani*, vol. 3, pt. 1–2 (1916–17), and vol. 4, pt. 3 (1964), is fundamental. U. KAHRSTEDT, *Geschichte der Karthager von 218–146* (1913), provides detailed source-criticism. J. KROMAYER and G. VEITH, *Antike Schlnchtfelder*, vol. 3–4 (1912–31), and *Schlachten-Atlas zur antiken Kriegsgeschichte*, Rom. Abt. 1–2 (1922), are the standard works on purely military aspects, while the role of sea-power is handled by J.H. THIEL, *History of Roman Sea-Power Before the Second Punic War* (1954), and *Studies on the History of Roman Sea-Power in Republican Times* (1946),

ch. 2 for the Second Punic War. S. GSELL, *Histoire ancienne de l'Afrique du Nord,* vol. 1–4, esp. vol. 3 (1913–20), deals fully with the Carthaginian side. Punishment

Punishment may be defined as the infliction of some pain, suffering, loss, or social disability as a direct consequence of some action or omission on the part of the person punished. The punishment may consist of death, physical assault, detention, loss of civil and political rights, or banishment. There must be a perceived relationship of legitimacy between the punisher and the punished: the agent of punishment must be in a position of legitimate authority over the punished, and the action or omission must be seen to merit the punishment by reference to a set of pre-existing criteria by which such acts or omissions may be judged.

The legitimacy of the actions of the punisher is the primary distinction between punishment and other forms of coercion and constraint, for unless the agent who inflicts the pain or deprivation has authority to do so, his action constitutes a form of assault or civil wrong, both of which are themselves transgressions. Thus, for example, in Western society, a parent is the lawful guardian of a minor and is expected to constrain the activities of his child, if necessary by punishment. But whereas the law permits the parent to slap a child for misbehaviour in the street, it does not accord such a right to each and every adult who may be present, and a stranger who intervened might well be held accountable in the courts for assault.

Punishment is normally personalized, in that it is applied to particular individuals on the basis of their perceived wrongdoing. It is occasionally applied in a collective context without reference to the extent of individual responsibility or accountability. So-called collective punishments are generally regarded as of dubious or marginal legality, and their use, apart from that in the schoolroom, is to all intents and purposes confined to situations in which the state or an occupying army has resort to extreme methods of coercion. The Nazi army of occupation in Czechoslovakia thus put the entire adult male population of the village of Lidice to death as a punishment for the shooting of Reinhard Heydrich, the country's Gestapo ruler; in the 19th century the Austrian general Julius Haynau ordered the wholesale flogging of women after putting down the Hungarian revolt against Austrian rule in 1849. Such actions are nowadays defined as war crimes.

THE ROLE OF PUNISHMENT IN SOCIETY

Punishment in the family. Punishment may be inflicted in a variety of social contexts, as, for example, in the family and the school and by such corporate bodies as professional associations and trade unions.

In all human societies the family is seen as having authority over its members. In the simpler societies of hunters and food-gatherers the social and economic unit of society is usually so small that all social authority is vested within the family. In larger scale but technologically undeveloped peasant societies, the family is still vested with considerable authority over its members, notwithstanding that the state may possess a comparatively well-developed political structure. In the Rome of classical antiquity, the law thus underwrote the authority of the paterfamilias (male head of the family), who exercised control over all the members of his household, including those who had married into it, as yell as slaves and free servants. Similarly, in the later Middle Ages and well into the preindustrial era in the English-speaking world, young men who were apprenticed to master craftsmen were not only regarded as part of the household but were subject to the discipline of the master. A parallel situation obtained in the universities, where the masters of colleges were seen as having both the right and the duty to control the behaviour of students, if necessary by the infliction of punishment.

Analogies of the family in other social structures

In understanding the role of the family as a legitimate agent of social control through punishment, it is important to bear in mind the connection between the family and other social institutions, such as religious organizations and the state. Many primitive religions, and many sophisticated ones, emphasize a connection between the structure of the family and the transcendental social order. Among primitive peoples, reverence for ancestors is related to the part played by the spirits of the dead in controlling the living. Thus, for example, among the people of Ontong Java, British Solomon Islands, the dead will uncomfortably haunt the living who fail to honour their obligations to kin. In the strongly anthropomorphic Judeo-Christian tradition the human family is seen as mirroring in greater or less degree the divine family.

The role of punishment within the family in the modern period may best be considered by reference to Victorian attitudes and the reaction to them. Within what may be loosely termed the Victorian family there is reason to believe that the punishment of children was both frequent and harsh, inflicted for transgressions against a moral code that was itself starkly puritanical. Punishments covered a range of behaviour. Children were required to be not only honest and truthful but also industrious, obedient, and respectful toward their elders. They were also constrained in their attempts to acquire sexual information; and as sex was regarded as wholly sinful outside marriage and a guilty necessity within it, such an activity as masturbation was discouraged not merely by punishment but by the assertion that it resulted in blindness and insanity.

Insofar as the social attitudes of most sections of the community tend to reflect those of the most dominant and prestigious groups, the puritanical authoritarianism that characterized the Victorian upper and middle class family was mirrored throughout society. What was true of Victorian England was also true to a greater or lesser extent among the well-to-do in the United States and in continental Europe. It was not until the publication of the early work of Sigmund Freud that doubt began seriously to be cast upon child-rearing practices that leaned so heavily upon repression and physical punishments. Perhaps the most important conclusion to be drawn from Freud's work in this context is that punishment, particularly of a physical nature, is often related at an unconscious level with disturbances and anxieties within the punisher. Through the mechanism of projection the parent may thus punish what he feels guilty about himself; a parent who is himself sexually repressed may, for example, punish a child for looking at representations of the female body or for masturbation. Punishment may also be inspired by the sadistic sexual tendencies of the parent. Equally, it is now generally accepted among experts in the field of child care that physical punishments, especially when applied in the anal region, may result in erotic stimulation of an unhealthy nature.

The effect of Freudian psychology on the character of punishment within the family in the last 50 years has been considerable, as it has been on the character of punishment in educational institutions and, to a lesser extent, within the penal system. The writings of Dr. Benjamin Spock have had a very wide influence on middle class parents, especially in the United States, in establishing a concept of normality regarding discipline that is functional rather than specifically moral in content.

Punishment in moral and religious thought. As indicated above, the connection between the family and religious beliefs is a long and complex one. This is especially the case with regard to religions of a distinctly anthropomorphic character in which ancestors (often the recently dead) play an important part in sanctioning the activities of the living or in which the social organization of the gods is perceived as being essentially similar to that of earthly society.

Among primitive peoples it is, broadly speaking, the case that the sanctions of ancestors are directed toward the maintenance of the status quo, which in turn depends upon the adequate performance of those kinship obligations upon which so much of social and economic life in primitive society revolves. Punishments may take a variety of forms, among which haunting by ghosts is extremely common. The incest taboo is also sometimes supported by religious sanctions, and the failure of crops, death of cattle, human sickness, or the visitation of natural disaster is perceived as a consequential punishment for unlawful intercourse or failure to marry according to the prescribed rules of selection.

Divine sanction in the Judeo-Christian tradition

In more sophisticated cultures there tends to be a greater distinction between ethical systems maintained by punishments imposed by men themselves and those maintained by religious beliefs. In classical mythology the gods were often guilty of actions that, if committed by men, would justify sanctions. Thus, if a local chief carried away the nubile daughter of a neighbour, a violent reaction might follow; for a god to carry away a maiden while disguised as a swan or a bull could, on the other hand, be classified as a form of divine right. In the Judeo-Christian tradition, however, the connection between ethical beliefs and divine sanctions is extremely clear. Yahweh, the tribal god of the ancient Israelites, was distinct from the tribal deities of other pastoral peoples in that he existed within a distinctly monotheistic context. The Israelites were told unambiguously, "You shall have no other gods before me." Yahweh not merely created the world and all that was in it but in the Ten Commandments set out a comprehensive code of social as well as ritual regulations. These were designed to enforce both tribal order and tribal identity. Defiance of these divinely instituted rules, as well as of specific injunctions, was followed by dramatic and severe punishment. Adam and Eve were cast from the garden, women were turned into salt pillars, and cities destroyed. Those, such as the Egyptians, who failed to accord with divine requirements, ran the risk of being visited by plague and death.

It has been suggested by psychoanalytic writers that the vengeful and sometimes unpredictable God of the Old Testament, who indulged in such sadistic testing of loyalty and faith as the projected sacrifice of Isaac or the endless trials of Job, represents the projection of the powerful and feared father. In *Totem and Taboo*, Freud argued that the fear of incest derives from the guilt attendant upon the slaying of the father (the elder of the tribe) by his sons in order that they might have sexual access to the nubile women whom the father monopolized. This Oedipal theme is, in fact, recurrent in the mythology of a wide range of cultures.

The coming of Christianity marked a change in the pattern of divine–human relations in that the death of Christ, the Messiah, was the sacrificial reconciliation between God and man. Henceforth, the doctrine of the Atonement guaranteed that man could be absolved from his sin. He had a clear choice: to obey the law of God and enjoy eternal bliss or defy it at the cost of certain and eternal damnation.

An essential component of punishment in the Judeo-Christian tradition is the guilt of the recipient. In the Old Testament the punitive situations described are all paradigmatic examples of the fate awaiting transgressors. Christian teaching, however, modified the position by introducing the concept of mercy. Jesus, when the woman taken in adultery is brought before him, thus not only suggests to the crowd that the most blameless among them should cast the first stone of the traditional punishment but merely tells the woman to "sin no more." At an early stage the church thus developed the rituals of confession and penance. After the Resurrection the disciples are told, "Whose sins you shall forgive, they are forgiven them." A condition of absolution from guilt was the performance of penance, and in the early church this was often severe, involving fasting, physical degradation, and often self-inflicted corporal punishment. By the later Middle Ages, penances had become more symbolic and in the case of the rich could be performed by the donation of land or precious goods to the church.

The relationship between guilt and punishment so clearly worked out in medieval theology has had a profound influence on the position of punishment within the criminal law. The legal doctrine of *mens rea* ("guilty mind"), holding that there can be no crime without intent, derives directly from it and has for centuries enabled the English common law to protect those whose actions, although intrinsically unlawful, were committed without malice. The increase in administrative legislation has considerably eroded the traditional concept of guilt based upon *mens rea.*

An equally important feature of Christian thinking concerned with punishment is that it is related to the offender's responsibility. Roman law had always regarded a child of less than seven years as being incapable of guilt on the grounds that he was too young to comprehend the distinctions between right and wrong, and the church similarly did not make confession available to children below this age on the grounds that Baptism, having absolved them of the original sin of Adam, was sufficient to ensure their salvation in case of death. A characteristic of penance was that it was tailored, so to speak, to the degree of responsibility of the penitent.

A young man sorely tempted by the wiles of women to commit fornication might thus be given a lesser penance than an experienced lecher. A condition of penance or expiation was, however, the honest resolve to sin no more, any mental reservations on the subject by the penitent automatically invalidating the absolution. Although this latter feature was never adopted by the criminal law, one may observe in penance the early origins of the individualized sentence, which is nowadays regarded as an important part of sentencing under the criminal law.

Secularization of penal philosophy in the Enlightenment

The destruction of the unity of Christendom and its universal theology by the Reformation was followed by the increasing secularization of the European nation-state, not least in the administration of punishment. Although the churches still preached the doctrine of divine punishment, it was that imposed by the state that came to assume immediate importance in society. Increasingly, the infliction of punishment by the state through the courts became dominated by the pragmatic necessity of maintaining order in the face of social change. It was the philosophers of the Enlightenment, rather than theologians, who came to offer–new views on the subject. According to the 13th-century philosopher St. Thomas Aquinas, the order of society was the result of a divine plan; according to the 17th-century English philosopher Thomas Hobbes, man had voluntarily abdicated the right of self-help against transgressors of his rights to the sovereign in order to avoid the chaos of the state of nature. Both theories justified the existence of temporal power, the right of the state or sovereign to make laws and punish offenders. The thinkers of the Enlightenment were, however, concerned to emphasize both the rationality of human action and the extent to which the state oppressed the liberty of the subject through harsh and essentially unreasonable laws, resulting from a combination of political tyranny and judicial corruption. By the middle of the 18th century an intellectual climate had developed that produced not only the American and French revolutions but a fundamental re-examination of penal philosophy.

THEORIES OF PUNISHMENT

The most influential writer of the period was the Italian Cesare Beccaria (1738–94), whose *Dei deletti e delle pene (An Essay on Crimes and Punishments)* was published in Italian in 1764 and in English three years later. It had the public approval of Voltaire and was one of the most widely read polemics of the time. Beccaria was committed to a contractual theory of society as being necessary to avoid war and social anarchy. He argued that the rightful source of law was in the legislature, and that its interpretation ought not to be left to the judiciary. Beccaria tended to equate flexibility on the bench with judicial tyranny. He took the view that the function of the judges was the determination of guilt, else the spirit of the law would represent no more than the capricious logic of the judiciary. He argued that the state had a right to punish, and that there should be set out a scale of crimes and punishments ranging from acts that would bring about a dissolution of the state to those that caused the smallest harm to an individual citizen, between these poles lying all actions that, being contrary to the common good, were punishable. The act, and not the intention, was the measure of harm done. The end of punishment, he reasoned, was not to make the offender miserable, nor to compensate for the harm that had been done, but was solely preventive. Punishments ought therefore to make the greatest deterrent impact consistent with the infliction of the least pain on the offender. To be effective, punishment should be certain, speedy, and uniform for particular crimes. When punishments were seen to have no preventive value, they should be abolished. Prisons should be used as a means of training offenders to be useful citizens. Above all, the laws should be clear and unambiguous and be widely known to all citizens.

The weaknesses of some of Beccaria's otherwise enlightened and humane thinking became evident when some of his proposals were incorporated into the French Revolutionary Penal Code of 1791. In ignoring individual social differences between offenders and assuming that the pursuit of pleasure and the avoidance of pain were the mainsprings of human behaviour, he had placed reliance on a deceptively simple concept of crime. The importance of Beccaria's *Essay,* however, lies less in the substance of his particular views and more in the fact of its galvanic effect upon the penal reformers of the time. In his critical challenging of existing modes cf punishment, he paved the way for a radical re-appraisal of many aspects of criminal law.

Bentham's penal philosophy

The writings of the English philosopher and legal reformer Jeremy Bentham brought some of Beccaria's ideas into closer focus. His most important ideas are contained in *An Introduction to the Principles of Morals and Legislation* (1789). As a philosopher, Bentham belonged to the Utilitarian school, which believed that men seek pleasure and avoid pain and that society ought to be so organized as to secure the greatest happiness of the greatest number. By constructing a great "felicific calculus" that enabled him to demonstrate the goodness or badness of particular acts, Bentham evolved an enormously complicated catalog of crimes and punishments. In essence, his penal philosophy was based upon the notion that punishment ought to be sufficient to prevent crime but no more. Like Beccaria before him, he thought that the ineffectiveness of savage penal laws was self-evident, and none could deny that the penal systems of 18th-century Europe were brutal in the extreme. The strength of Bentham's view lay in the usefulness of the idea that excessive punishment might be counter-productive—men argued that they might as well be hanged for a sheep as for a lamb. The prime weakness was not unlike Beccaria's; that is, a reliance on hedonistic psychology and an assumption that all men act rationally.

Toward the end of the 19th century the study of crime, which had been developing along sociological lines, shifted its emphasis as a result of the work of the Italian Cesare Lombroso, a surgeon who had been influenced not only by the positivism of the French sociologist Auguste Comte but also by the work of Charles Darwin. In *L'uomo delinquente* (1876) he argued that the criminal was an atavistic biological specimen who could be identified by a number of physical stigmata; and although the theory of atavism was to undergo considerable modification both by Lombroso and his disciples, the views of this school of criminology remained consistently positivist. In positivist terms, moral responsibility is of no account, only social responsibility. There could be no degrees of responsibility, for either the act was injurious to the public welfare or it was not. If a public building had been destroyed by arson, for example, the character of the arsonist was in that context irrelevant. Hence, punishment, which some philosophers had argued ought to embody retribution, should consist only of those measures that, taking into account the dangerousness of the offender, needed to be taken to protect society.

Functions of punishment in society. *Deterrence and social control.* Theories of deterrence rely on two assumptions: first, that the potential offender will act rationally in his own best interest and seek to avoid pain; second, that he will both remember past experiences and anticipate the consequences of his intended future actions. For this reason, penal systems from early times have frequently been characterized by the public infliction of punishment, often of a brutal nature. The death penalty has been almost universally used, although less among the simpler peoples than the more advanced. It has taken a variety of forms, among which decapitation by sword or ax and hanging are the most common. In imperial Rome, crucifixion was commonly employed for thieves and slaves, and being hurled alive from the l'arpeian Rock was a penalty in Rome itself, as was being fed to the wild animals in the Colosseum. Crucifixion was also used in Japan until the 19th century. In medieval Europe, hanging was used for offenders of low status and decapitation reserved for persons of quality. Heretics were burned, as were witches. In England the penalty of hanging, drawing, and quartering was especially brutal. The victim was first partly strangled and then while still aiive drawn or disemboweled; his entrails were burned and his body then literally butchered into four pieces. This punishment was normally reserved for treason. In France, traitors were dispatched either by being pulled apart by draft horses, or by being broked upon a large wheel to which they were attached.

Apart from death the physical maiming of offenders was commonplace. In the Middle Ages and well into the 17th century, branding with hot irons, blinding, and the amputation of ears, hands, and tongues were practiced, along with flogging. The effect of such punishments was often the death of the offender. Placing the offender in the stocks or pillory enabled him to be pelted by the crowd and to sustain serious physical injury. Stoning appears to have been employed from ancient times among the pastoral peoples of the Middle East and has frequent biblical mention.

Seamen and soldiers were, until recent times, also subjected to a considerable degree of corporal punishment as well as the death sentence for disciplinary offenses, invariably inflicted before an assembled company. During the period of colonial settlement, transportation to plantations or dispatch to serve as galley rowers was used as an alternative to capital punishment.

Rationale of publicly inflicted punishment

Publicly inflicted punishment has the effect of encouraging the spectators to participate in a situation in which the values that have been violated are reaffirmed; alternatively, it demonstrates the power of the political authority and the price to be paid for disobedience. The deterrent theory varies in its effectiveness. Where the potential offender is rational and the penalty not so severe as to be counterproductive, it may be reasonably successful as a medium of social control. It is least effective in dealing with mentally abnormal offenders. Its success also relies very heavily on certainty of detection and conviction, and many criminologists and police officers argue that certainty of detection is more important than severity of sentence in the prevention of crime.

Retribution. The lex talionis, typified in the doctrine of "an eye for an eye," formed part of the law of many cultures and may be seen in residual form in many popular expressions of opinion about crime and punishment in present-day society. The notion that the offender ought to suffer in proportion to his wickedness has support from a wide range of philosophical and theological sources. At a psychological level, suffering on the part of the criminal may give some comfort to the victim, but it is less easy to match one injury for another than is always realized. Although death may be matched by death, a sexual murder or a rape cannot be replicated. A further difficulty lies in estimating the degree of wickedness of the offender as distinct from the intrinsic evil of the crime. Thus, the rape-murders of young children may be classified as wicked, and acts from which reasonable men ought properly to shrink, but such acts are usually committed by persons of distinctly unsound mind. Another weakness of the retributive view is that the provision of punishment that matches the putative wickedness of the offender may be so severe as to be of no use in deterring crime. It may lead to a point at which punishment is inflicted whether it has any deterrent value for others or not, and for this reason penologists and judges are cautious not to accord retribution too great an emphasis in sentencing. The exception to this is situations in which sentences are passed in order to express the horror of society at the crime, as, for example, at incest or homosexual offenses in certain cultures.

Reformation. It is important in this context to distinguish between constructive penal treatment, aimed at bringing about a change in the offender's behaviour by whatever means, and the infliction of punishment, which must, by definition, involve some pain or suffering by him. Some penologists argue that it is not possible to punish and reform simultaneously, as punishment is essentially damaging to the offender, and if retributive, totally at variance with the course of action most likely to achieve reform. Others would prefer to strip punishment of its moral overtones and regard it as a form of conditioning, which properly used may bring about change. Thus, the deprivation of liberty by imprisonment may produce a degree of shock such as to enable the offender to examine realistically the consequences of his behaviour.

While many legislatures and most penologists have supported the idea that reform ought to take priority in dealing with offenders, many judges—especially in Britain and the United States, where rising crime rates are the source of much public concern—have expressed grave doubts about the wisdom of this view. They have argued that the courts must reflect a public abhorrence of crime and that justice demands that some attempt be made to impose punishment fitting to the crime. There is, of course, no reason why reform and deterrence should not coexist, providing there is adequate information about the offender's mental state and social competence and that commonsense distinctions are made between types of crime. It is thus reasonable to assume that traffic violations may be largely controlled by deterrent sentences, but unreasonable to assume that sex offenses can be similarly contained.

Difficulties of preventive sentencing

The protection of society. Attitudes toward punishment are shaped to some extent by the assumed social danger that some offenders present to society. In some cases this danger may be removed by treating the offender either by medical means or by social retraining. In others the prognosis may be very poor, such that after a period of incarceration the offender may return again to be a danger in the community. For such offenders it may be argued that a preventive sentence—their removal for an indefinite period or for natural life, for example—is the proper course. While many societies have accepted life imprisonment as the just penalty for certain crimes such as murder, notwithstanding that many murderers can be safely returned to the community, most have been reluctant to use long or indeterminate sentences to deal with those who, though their prognosis may be poor, have not yet committed the most serious crimes. An example of this is the violent sex offender who may be a potential killer but about whose future criminal career there may still be uncertainty. It can be argued that to condemn a man in advance is essentially unjust. On the other hand, many legislatures have evolved statutes enabling persistent offenders of all kinds to be detained for longer periods than a particular offense would merit in terms of the tariff system. Both the effectiveness and the social acceptability of preventive sentences must rest upon the accuracy of predictive techniques. Although prediction methods in criminology have improved considerably over the last three decades, they are still insufficiently exact to be acceptable as the sole basis of preventive sentencing.

The effectiveness of punishment. To be effective, punishment, whether in the familial, educational, or penal context, must be certain and relatively swift, else its conditioning characteristics are diluted or lost. It must not be excessive, or it will be subject to the law of diminishing returns. It must be of itself morally acceptable—that is, not seen as cruel or unreasonable either by society or the recipient, who must ideally accept the legitimacy of its imposition. It must also be limited to actions that are by consensus defined as unacceptable, for the application of penal sanctions for infringements of laws that have little or no public support brings the law into contempt. Punishment, or the application of the criminal sanction, must also bring about some general social results collectively as well as individually.

Importance of prisons in modern penal systems

The core of modern penal systems is imprisonment, although it is increasingly true that the proportion of offenders sentenced to noncustodial disposal is producing a situation in which it is becoming more rare for first offenders to be imprisoned. Evidence from the Western world suggests that the frequency of convictions is a better statistical predictor of future crime than the type of sentence imposed. Among noncustodial measures, fines and probation have a high rate of success except among those who have previous convictions, although the picture differs in detail among different countries. By and large, juveniles who have served custodial sentences have a poorer prognosis than those who have not. Of males who are imprisoned for the first time, between 65 and 85 percent are not reconvicted, but among those who are, the subsequent recidivism rate tends to increase progressively. Thus, most long-term prisons and penitentiaries are filled with men whose prognosis is poor, and the fact tends to be reflected in rates of parole violation. The ineffectiveness of imprisonment may be ascribed to various factors, including overcrowding, understaffing, and lack of resources, which result in the regime's becoming negatively custodial rather than constructively therapeutic; contact with other inmates that may reinforce rather than diminish criminal attitudes; criminogenic factors in the outside world, which on the prisoner's release may be more dominant than the attempts made by the prison at resocialization; the presence of a group of highly successful professional criminals who perceive prison as an occupational hazard; and the deleterious effects of institutionalization on socially inadequate offenders.

A major difficulty in assessing the effectiveness of penal sanctions stems from the fact that criminological data are very rarely gathered in the form of experimental observations. Thus, for example, the fact that in England and Wales the imposition of fines appears to be the most successful sanction may be related to the possibility that courts use fines in the cases of offenders who are least likely to persist in crime. They are also used for minor offenses as well as major ones. Without the possibility of controlled experiment, which might take a group of comparable offenders, fining some and dealing with others in alternative ways, evaluation is complex and fraught with technical difficulties.

BIBLIOGRAPHY. The literature on crime and punishment is considerable, and the subject has engaged the attention of many great writers, including Defoe, Dickens, Hugo, and Dostoevsky. The following references are largely confined to the more philosophical and academic writings readily available in English.

A.C. EWING, *The Morality of Punishment* (1929); F.A.P. LONGFORD, *The Idea of Punishment* (1961); B.F. WOOTTON, *Crime and the Criminal Law* (1963); and H.L.A. HART, *Punishment and Responsibility* (1968), contain broad discussions of the ethical problems involved in punishment and their application within the context of the criminal law. A.C. MacINTYRE, *A Short History of Ethics* (1966), may also be consulted. GEORG RUSCHE and OTTO KIRCHHEIMER, *Punishment and Social Structure* (1939, reprinted 1968), argue an interesting thesis, namely, that types of punishments are related to the prevailing conditions of the economic and social structure and less to abstract ethical principles. J.C. FLUGEL, *Man, Morals and Society* (1945); HENRY WEIHOFEN, *The Urge to Punish: New Approaches to the Problem of Mental Irresponsibility for Crime* (1956); and GILES PLAYFAIR, *The Punitive Obsession* (1971), consider the problem from a viewpoint that derives from the psychoanalytic approach to the study of crime and deviant behaviour, while the educational innovator A.S. NEILL, *Hearts Not Heads in the School* (1945), considers the problem in the context of the progressive school that relies on pupil self-government. F.G. JACOBS, *Criminal Responsibility* (1971), deals with the question of criminal

responsibility in law; while D.A. THOMAS, *Principles of Sentencing* (1970); NIGEL WALKER, *Crime and Punishment in Britain,* 2nd rev. ed. (1968), and *Sentencing in a Rational Society* (1969); and C.H. ROLPH, *Common Sense About Crime and Punishment* (1961), are concerned with relating criminal punishments to the needs and policy of a liberal society. MARC ANCEL, *La Défense sociale nouvelle* (1954; Eng. trans., *Social Defence: A Modern Approach to Criminal Problems,* 1965), is an important work, placing the matter in a broad European perspective. HERMANN MANNHEIM, *Group Problems in Crime and Punishment* (1955); EDWIN H. SUTHERLAND and DONALD R. CRESSEY, *Criminology,* 8th ed. (1970); H.E. BARNES and N.K. TEETERS, *New Horizons in Criminology,* 3rd ed. (1959); and NORMAN JOHNSTON, LEONARD SAVITZ, and MARVIN E. WOLFGANG (eds.), *The Sociology of Punishment and Correction,* 2nd ed. (1970), are primarily criminological texts from which much information on theories of punishment and penal systems may be derived. CHRISTOPHER HIBBERT, *The Roots of Evil* (1963), is a social history of crime and punishment; and J.P. CONRAD, *Crime and Its Correction* (1965), provides a wide international perspective on punishment within the penal context. D.C. GIBBONS, *Changing the Lawbreaker: The Treatment of Delinquents and Criminals* (1965); and DANIEL GLASER, *The Effectiveness of a Prison and Parole System* (1964), are examples of analyses of the effectiveness of various penal methods. L.W. FOX, *The English Prison and Borstal Systems* (1952), although primarily about the English system, has useful material on 19th-century penal thinking in both Britain and the United States.

(T.P.M.)

Punjab (India)

Punjab, a state in the Indian Union, is situated in northwest India. It is bounded on the north by Jammu and Kashmir, on the east by Himachal Pradesh, on the south by Haryāna and Rājasthān, and on the west by Pakistan.

Land of the five rivers

The word Punjab is a compound of two Persian words, *panj* ("five) and *āb* ("water"), thus signifying the land of five waters, or rivers. The first known use of it occurs in the writings of the Muslim traveller Ibn Baṭṭūṭah (*q.v.*), who visited India in the 14th century. The origin can perhaps be traced to *pañca nada,* Sanskrit for "five rivers," the word used before the advent of Muslims with a knowledge of Persian to describe the meeting point of the Jhelum, Chenāb, Rāvi, Beās, and Sutlej rivers, before they joined the Indus. The name Punjab subsequently came to be used for the land through which these rivers flow. As applied to the present Indian state of Punjab, it is strictly a misnomer, for, since the partition of India in 1947, only two rivers, the Sutlej and the Beās, lie within its territory.

The state in its present form came into existence on November 1, 1966, as a result of a territorial reorganization carried out on the basis of language. The capital city is Chandigarh, which is also the headquarters of the government of Haryāna, a new state comprising most of the residuary, non-Punjabi-speaking areas of the older unit. Chandigarh, planned by the Swiss architect and city planner Le Corbusier, was built as a capital city for what became the Indian Punjab after the partition.

Punjab covers an area of 19,495 square miles (50,491 square kilometres); its population in 1971 was 13,731,000. (For coverage of an associated physical feature, see INDUS RIVER.)

History. The foundations of the present Punjab (historical Pañjāb) may be said to have been laid by Bandā Singh Bahādur, a hermit who became a military leader and who, with his fighting band of Sikhs, temporarily liberated the eastern part of the province from Mughal rule in 1709–10. Bandā Singh's defeat and execution in 1716 were followed by a long, drawn-out struggle between the Sikhs on one side and the Mughals and Afghans on the other. In 1764–65 the Sikhs established their sway in the region. Ranjit Singh (1780–1839) built up the Punjab into a powerful kingdom and attached to it the provinces of Multān, Kashmir, and Peshāwar. In 1849 the Punjab fell to the troops of the British East India Company and came under British rule. When independence was achieved in 1947, the Punjab was split between the new sovereign states of India and Pakistan, the smaller, eastern portion becoming part of India.

Since independence, the history of the Indian sector of the Punjab has been dominated by Sikh agitation for a Punjabi-speaking state, first led by Master Tara Singh and later by his political successor, Sant Fateh Singh. In November 1956 the Punjab was enlarged by the merger with it of the state of Pepsu, short for Patiāla and East Punjab States Union, which was formed by the amalgamation of the princely territories of Patiāla, Jind, Nābha, Faridkot, Kapūrthala, Kalsia, Mālerkotla, and Nālagarh. Political and administrative leadership to the new Punjab was provided by Sardar Partap Singh Kairon, Congress chief minister of the state from 1956 to 1964. Demands for the formation of a new state by the consolidation of the Punjabi-speaking areas and the elimination of the Hindi-speaking portions were eventually agreed to by the government of India. On November 1, 1966, the state of Punjab was divided on the basis of language into the two new states of Punjab and Haryāna (the Hindi-speaking area).

The absorption of the princely states

Physical geography. More than 95 percent of the total area of Punjab is a flat plain, sloping gently from about 900 feet above sea level in the northeast to about 550 feet in the southwest. Physiographically, it is divisible into three parts: (1) the Siwālik Hills, in the northeast, about 900 to 3,000 feet high (covering a small fraction of the state's area); (2) the narrow, undulating foothill zone dissected by closely spaced seasonal torrents, locally known as *cos,* several of which terminate in the plain below without joining any stream; and (3) the flat tract, with fertile alluvial soils. The low-lying floodplains along the rivers and the slightly elevated flat uplands between them are distinguishable within the plain. Sand dunes occur in the southwest and six to nine miles west of the Sutlej River.

The climate. Punjab has an inland subtropical location, and its climate is continental, being semi-arid to subhumid. Summers are very hot, the mean temperature during June being 93" F (34" C), rising above 113" F (45" C) on exceptionally hot days. Winters are fairly cold, the January mean temperature being 55° F (13" C), with night temperatures occasionally touching the freezing point. Annual rainfall is highest in the Siwālik Hills in the northeast, where it is about 49 inches, and decreases gradually to about 14 inches in the southwest. More than 70 percent of the annual rainfall is concentrated in the months of the monsoon winds, July to September. Winter rains from the western cyclones that occur from December to March account for nearly 15 percent of the total rainfall.

Vegetation. With the growth of human settlement over the centuries, Punjab has been largely cleared of its vegetal cover. The existing vegetation is tropical and deciduous. The *shisham* or *sissoo* tree (of which the wood is used for construction and furniture making), the chinaberry, the *peepal* (which bears a small fig), and jujube tree, and *kikar* (gum arabic) are among the most common trees. Over large parts of the Siwālik Hills, bush vegetation has succeeded tree vegetation as a result of extensive deforestation. New types of trees have been planted on the hillsides and along roads in recent years.

Animal life. Wildlife in Punjab includes the blue bull (also called the nilgai, a large bluish-gray animal), the wild boar, rabbits, jackals, foxes, and deer of various kinds. The commonest birds are crows, sparrows, doves, pigeons, parrots, partridges and peacock. The koel (cuckoo) is a summer visitor and the mountain crane a winter one. Waterfowl include cranes, herons, and geese. Snakes abound in summer, being especially in evidence in the rainy months; the cobra, viper, and krait (an extremely venomous kind of snake) are poisonous. Land in Punjab is precious, and agriculture impinges heavily on wildlife.

Population. The people of Punjab are mainly descendants of Aryan tribes that entered India from the northwest about 1500 BC. Relics of a highly developed pre-Aryan civilization have been discovered at Rūpar, near Chandigarh. Successive waves of invaders—Greeks, Parthians, Kushans, and Huns—became assimilated with the early Aryans. The Jats, Rājputs, and other allied peoples are the products of this intermixture. Some members of the scheduled castes—formerly called the untouchables but named Harijan (people of God) by Gandhi—and of aboriginal tribes have traces of the physical features of the Dravidian people.

At the 1961 census, the population of Punjab was 11,255,056, and it is estimated that it had risen to almost 14,000,000 by April 1971. The annual growth rate rose from 1.6 percent in 1951 to 2.16 percent in 1961 and was 2.20 percent for the period 1961–71. The earlier increase was due to the rapid decline in mortality, the expectation of life at birth having gone up from an average of about 50 years (males) and 45 years (females) in 1951–60 to about 60 years (males) and 55 years (females) in 1966–70. Punjab's birthrate, about 42 per thousand (1966–70), is higher than the rate for all India (38.6), despite its unfavourable sex ratio of 871 females to 1,000 males.

The language pattern

In 1961 Punjabi was recorded as being the mother tongue of about two-thirds of the people and Hindi of one-third. Punjab is the only state in India with a majority of Sikhs, who account for 60 percent of the population. The Sikhs are followers of an Indian religion that had its origin in the teachings of Nānak, a 15th-century Gurū (teacher; see SIKHISM). Hindus account for 38 percent and Muslims and Christians for 1 percent each, while the remaining 1 percent are Jains, Buddhists, and followers of other religions.

Punjab is comparatively urbanized. Twenty-five percent of its population live in cities and towns, as compared with about 20 percent for the whole of India. It has four cities with populations of over 100,000 (Amritsar, 433,000; Ludhiāna, 401,000; Jullundur, 296,000; and Patiāla, 152,000). Though the cities are fast-growing centres of industry and manufacture, more than 70 percent of the state's population is still dependent on agriculture.

Administration. As in other states of the Indian Union, the governor, the constitutional head of the administration, is appointed by the president of India on the advice of the Union cabinet and acts through a council of ministers responsible to a legislative assembly of 104 members, elected every five years on the basis of adult franchise. The legislature was bicameral until January 1970, when the upper chamber (the legislative council) was abolished. The council of ministers is headed by a chief minister, who chooses its members from the legislative assembly.

The executive officials belong to a permanent, nonpolitical secretariat, members of which are selected by union or state public-service commissions. The administration is assisted in policy making and expertise both by the secretariat and by a number of standing boards and committees, such as the Planning Board, the Rural Development Board, and the Electricity Board.

The deputy commissioner is the chief executive of the district (which forms the basic unit of administration), and the state is divided into 11 such districts, grouped into the two divisions of Patiāla and Jullundur, each headed by a divisional commissioner, whose functions are chiefly supervisory. The 11 districts are Gurdāspur, Amritsar, Bhatinda, Jullundur, Hoshiārpur, Firozpur, Ludhiāna, Kapūrthala, Sangriir, Rūpar, and Patiāla.

The judiciary

The judiciary is independent of the executive. At its head is the high court, which, as constituted at present, is common to Punjab and Haryāna. Justice at the district level is administered by a district and sessions judge, assisted by subjudges and magistrates. Appeals from decisions of the high court are directed to the supreme court of the Union.

Social conditions. ***Education.*** In 1969 there were about 2,000,000 students in schools in the state. Of these, about 185,000 were in high schools. There were more than 7,000 primary schools, 900 middle schools, and 1,100 high schools. The number of teachers in primary and middle schools was about 31,000 and in high schools, 23,000. Schools are maintained largely by the state. Education is compulsory and free for pupils aged 6 to 11. Secondary education is also free in state schools.

According to the census of 1971, the rate of literacy among the population was about 34 percent (41 percent for males and 26 for females), as compared with the all-India percentage of 29 (40 percent for males and 18 for females).

There are three universities in the state: the Punjabi University at Patiāla, the Gurū Nānak University at Amritsar, and the Punjab Agricultural University at Ludhiāna. A fourth university, which serves three of the Punjab districts, is located at Chandigarh. Of 121 colleges in the state, 29 are professional, 6 medical, and 2 engineering. There are 106 technical institutes providing industrial and occupational courses. There is a state department to encourage and organize sports, and Punjab youth is well represented in Indian athletic teams.

Expenditure on education amounted to about 26 percent of the state budget in 1970–71.

Health. Punjab enjoys higher survival prospects and better health conditions than other states. The death rate has dropped from almost 19 per thousand in 1951–60 to about 8 per thousand in 1966–71. The number of hospitals is 510, with a total of 11,000 beds. There is one qualified doctor for every 2,600 persons. The state has undertaken an extensive family-planning program, especially in rural areas.

Welfare services. The state has schemes for the uplift of the scheduled castes—who form 22 percent of the population—through scholarships, recruitment to public services, and help in finding employment.

Developments that have had a revolutionary effect on the lives of the people are the spread of electrification in rural areas and the dissemination of vocational and cultural education through broadcasting.

Numerous social services are provided by government and voluntary organizations. These include the care of infirm or handicapped persons, neglected children, widows, and destitute persons. The government also provides pensions for the aged who have no means of subsistence. There is a network of employment exchanges to assist the unemployed.

Economy. The economy of the state is characterized by a dynamic agriculture; a developing small-scale industry; and a growing per capita income despite a rapid rise in population.

Although Punjab claims no more than 2.9 percent of India's total cultivated area, in 1969–70 it accounted for almost 7 percent of its total output of food grains and 24 percent of its total output of wheat. During the six years ending June 1970, the production of wheat in the state more than doubled, rising from 2,535,300 to 5,291,000 tons. This phenomenal progress has been described as the Green Revolution. In 1970 the state supplied 2,400,000 tons of wheat to the union government. The principal food-grain crops are wheat, maize (corn), rice, *bājrā* (millet), barley, and pulses (the edible seeds of various leguminous crops, such as peas, beans, and lentils). Other crops include cotton, sugarcane, potatoes, and oilseeds.

The Bhākra–Nāngal project

The increase in agricultural production is due largely to the successful application of modern agricultural technology. By June 1969, 67 percent of the net area sown had been brought under irrigation—the highest percentage of any Indian state. Canals watered about 49 percent of the irrigated area and wells, tube wells, and pumping sets the remaining 51 percent. The Bhākra–Nāngal multipurpose river-valley project, designed to irrigate 550,000 hectares (1,359,000 acres) of land in Punjab, 680,000 hectares (1,680,300 acres) in Haryāna, and 230,000 hectares (568,300 acres) in Rājasthān, is the largest of its kind in Asia. Other significant changes are the adoption of high-yielding varieties of semidwarf Mexican wheats and hybrids, the use of chemical fertilizers and pesticides, and increased mechanization.

The benefits of improved agriculture, augmented by co-operative societies and community-development programs, have tended to give comparatively more help to the bigger farmers, with the result that the disparity in farm-family incomes has increased considerably.

Punjab has practically no mineral or fossil-fuel resources, and only 4 percent of its total area is under forest. Consequently, industrial development in the state is associated with agriculture or devoted to consumer goods. In January 1970 there were about 23,000 small and 120 medium and large industrial units, employing 186,000 workers. The principal industries produce cotton, woollen, and silk textiles, sugar, machine tools, agricultural implements, cycles, sewing machines, sports goods, electrical goods, automobile parts, flour, and milk products or engage in cotton ginning and pressing.

The total revenue of the state for 1970–71 was estimated at 1,359,000,000 rupees (Rs. 7.28 = $1 U.S.; Rs. 19 = £1 sterling, in May 1972), two-thirds of which was tax revenue, with indirect taxes contributing the larger share. The total expenditure was estimated at Rs. 1,164,700,000, about 57 percent of which constituted development expenditure.

Increasing agricultural production

Since the introduction of planning in 1951, Punjab has maintained a growth rate higher than that of any other Indian state in agriculture and has achieved the highest per capita income. In 1967–68, its net industrial output was valued at Rs. 11,265,000,000, and per capita income was Rs. 828. Owing to the failure of the economy fully to utilize the growing manpower available, however, this represented an increase of only about 22 percent in real per capita income since 1960–61. The number of unemployed persons in 1969 was estimated at almost 500,000.

The state's fourth five-year plan (1969–74) postulated an investment of Rs. 2,935,600,000 and an annual growth rate in the total income of 6.7 percent.

Transportation and communication. Extension of road transport has taken priority in development plans. A network of roads has been constructed to link the remotest parts of the state with railway stations, marketing centres, and industrial towns, thus opening the countryside to commerce and facilitating the interflow of farm products and consumer and capital goods. The total road length in 1968 was 5,776 miles, of which 4,959 miles was paved. More than 40,000 motor vehicles were in use, of which 2,700 were public-service vehicles and almost 8,000 goods vehicles. The state, which has been following a policy of gradual nationalization of passenger transport, in 1969 operated a fleet of more than 1,000 buses.

Long-distance transport is confined largely to the railways. Punjab is served by a state-operated railway, which has its headquarters in Delhi. Regular air passenger service is available between Delhi and some of the Punjab towns, such as Amritsar, Ludhiāna, and Patiāla. Delhi and Chandigarh are similarly connected. Water transport is practically nonexistent. Like the railways, the posts and telegraph service and broadcasting service are owned and controlled by the Union government.

Cultural life and tradition. Folklore, ballads of love and war, fairs and festivals, dancing, music, and Punjabi literature are characteristic expressions of the state's cultural life. Old romances, such as *Heer Riinjhii, Sassi Punnūn*, and *Mirzii Ṣāḥibān*, have been told in verse many times over, and the names of their authors—especially Warris and Hasham, both Muslims—are household names in Punjab. Older than these folk romances is the mystical and religious verse of the 13th-century Muslim Ṣūfī (mystic) Shaikh Farīd and of the 15th–16th-century Gurū (spiritual teacher) Nānak, founder of the Sikh faith, who for the first time used Punjabi extensively as a medium of poetic expression. These are the origins of Punjabi literature, which, at the beginning of the 20th century, entered its modem phase with the writings of the poet and author Bhai Vir Singh, and the poets Puran Singh and Dhani Ram Chatrik.

The whole populace joins in religious and seasonal festivals, such as Dussehra, Dīwālī, Baisākhi, and in the anniversary celebrations in honour of gurus and saints. Secular dances were introduced by immigrants after partition. The *bhangra, jhumar*, and *sammi* are the popular forms. The *giddha*, a native Punjabi form, is a women's hilarious song-dance. In addition to Sikh religious music, semi-classical Mughal forms, such as the *kāfi, khayāl, ṭhumrī, ghazal*, and *qawwālī*, continue to be popular.

The outstanding architectural monument is the Golden Temple at Amritsar, blending Indian and Saracenic styles. Its chief motifs, such as the dome and the geometrical design, are repeated in most of the Sikh gurdwaras, or shrines. Mural paintings in some of the gurdwaras preserve specimens of Sikh art. The Golden Temple itself is rich in gold filigree work of the most delicate kind and in panels with floral designs and marble facings inlaid with coloured stones. Among other important buildings may be mentioned the Hindu Temple of Durgiāna (also at Amritsar), a Moorish mosque at Kapiirthala, and old forts at Bhatinda and Bahādurgarh.

A Punjabi painter who made a great impact on modern art in the first half of the 20th century was Amrita Sher-Gil (1913–41). Some of the leading present-day Punjabi painters are Satish Gujral, Sobha Singh, S.G. Thakur Singh, and Kirpal Singh.

Punjab (Pakistan)

The province of the Punjab (Pakistan) lies between the Himalayan foothills and the Indian state of Rājasthān, comprising an area of 79,704 square miles (206,432 square kilometres). Punjab means "five waters" or "five rivers" and signifies the land drained by the Jhelum, Chenāb, Rāvī, Beās, and Sutlej.

The land was once unfavourable for settlement, but its character changed after the building of an extensive irrigation network at the beginning of the 20th century. The area of settlement, which had formerly been limited to the north and northeast, was enlarged to include the whole province. The irrigated areas are laid out in rectangular blocks, or *chaks*. The more recently established villages and towns have a gridiron pattern, with an open square in the centre, contrasting with the older settlements of the province.

History. Archaeological excavations indicate that an urban civilization existed in this area from about 2500 BC to 1500 BC, when, it is believed, Aryan incursions brought it to an end. Of the following 1,000 years little is known. The early recorded history of the region begins with the annexation of Punjab and Sind to the Persian Empire by Darius I (*c.* 518 BC). Alexander descended on the Punjab in the spring of 326 BC to establish his transient rule; the Greek withdrawal was completed by about 317 BC. Candragupta incorporated the states of the Punjab into his Indian empire, which leached its zenith in the reign of his grandson Aśoka (ruled *c.* 265–238 BC). The Greeks of Bactria (northern Afghanistan) extended their rule to parts of the Punjab in the last decade of the 2nd century BC.

The 1st century BC and the first two centuries AD were marked by political chaos resulting from the incursions of the Sakas, the Parthians, and the Kushans. In the first half of the 3rd century AD, the Kushans yielded to the Sāsānians. Punjab formed a part of the Gupta domain, which was established in the middle of the 4th century and which in turn was shattered by the invasions of the Hephtalites in the third quarter of the 5th century. During a long period of anarchy, the Punjab changed hands between Kashmiri, Kābulī, and Hindu Shāhīs rulers.

Period of Mughal rule

The first Muslims to penetrate into northern India were the Arabs, who in 712 conquered the lower Punjab. The rest of the Punjab was conquered (1007–27) by Maḥmūd of Ghazna. From 1027 until the victories of Muʿizz-ud-Din Muhammad of Ghūr between 1176 and 1193, this part of the Indian subcontinent remained fragmented. In 1206 Punjab came under the Sultanate of Delhi. It was then successively ruled by the Khaljis (1290–1320), the Tughluqs (1320–98), the Sayyids (1414–50), and the Lodis (1451–1526). The Mughals made their entry with the victory of Bābur at Pānīpat on April 21, 1526. Under the Mughals the province enjoyed peace and prosperity for more than 200 years. The Mughals, who had strong artistic and cultural traditions, also made wide social reforms. Their power declined after 1738, and in 1747 Lahore fell to Afghan troops. The Afghan hold remained quite weak, giving rise to lawlessness and disorder. The religious sect called the Sikhs rose to power in the latter part of the 18th century.

The Punjab came under British occupation in 1849, after the British victory over Sikhs in the battles of Chiliānwāla and Gujrāt. After the British annexation of the territory, the Punjab was incorporated into a province that included areas northwest of the Jumna River extending to the Indo-Afghan border. There were later territorial adjustments. The Northwest Frontier Province was separated from the Punjab in 1901, as was the Delhi enclave in 1902. The province of Punjab was given autonomy, together with other provinces, in accordance with the Government of India Act of 1935.

When the Indian subcontinent received its independence in 1947, the British Indian province of Punjab was divided into West and East Punjab, which later became known, respectively, as Punjab (Pakistan) and Punjab (India). The boundary was drawn in such a way as to achieve, among other things, contiguous Muslim and non-Muslim majority areas; thus it lacked any physical or geographical basis. Preservation of some irrigation and communication systems was attempted, at a loss to Punjab (Pakistan) of areas in which there were Muslim majorities. Punjab (Pakistan) was part of the single province of West Pakistan from 1955 to 1970, when it was reconstituted as a separate province; it also included the former princely state of Bahāwalpur.

The natural environment. The province of Punjab lies on an alluvial plain formed by the Indus system of rivers. To the north are the hills of Murree and Rāwalpindi and the Pabbi hills of Gujrāt, forming part of the sub-Himalayas. The highest of these hills, Murree, has an altitude of 7,445 feet (2,269 metres). Potwar Plateau, in the far north, is a maze of uplands and small, alluvial, loessial flats, ranging in height from 1,000 to 2,000 feet above sea level. It is drained by the Haro and Soān rivers.

The plain of the Punjab has a compound slope. The general tilt of the land is from northeast to southwest, with an average gradient of one foot to the mile, but it rises in the areas between rivers. The plain has a diversity of landforms: an active floodplain, which is inundated by a river almost every rainy season and contains changing river channels; a meander floodplain, adjacent to the active floodplain and containing old channels; a covered floodplain, with deposits resulting from sheetflooding; a scalloped interfluve highland area between rivers comprised of older alluvium and with practically no relief. The deserts are studded with sand dunes.

Climatic variation

Punjab lies on the margin of the monsoon climate. The temperature is generally hot, with marked variations between summer and winter. The hottest month is June; the coldest is January. The average maximum and minimum temperatures of the hill station of Murree for June are 81° F (27" C) and 60" F (16" C), respectively; those for January are 45" F (7° C) and 31° F (—0.7" C). In the plain the mean June temperature is 97° F (36" C) at Multan and 93" F (34" C) at Lahore. The mean January temperature of those stations is, respectively, 56° F (13° C) and 54" F (12" C). Average annual rainfall is low, except in the sub-Himalayan and northern areas. It decreases markedly from north to south or southwest: 32 inches at Siālkot, 23 inches at Lahore, and seven inches at Multān.

The Murree hills carry subtropical and temperate forests. In the plain the natural vegetation consists of tough, wiry grass or dry stunted bushes, with few large trees. About 6.4 percent of the uncultivated area of the province is under forests. Wild animal life is scanty.

Population. Punjab is the most populous province of Pakistan, having in the early 1970s an estimated population of 37,000,000. According to the 1961 census, it had a population of 25,619,000, which constituted about 60 percent of the population of what was then West Pakistan. There were 875 females for every 1,000 males. While the density of population in Pakistan is 138 persons per square mile, that of the Punjab is 322. The density ranges from 724 persons per square mile in Lahore Division to 147 in Bahāwalpur Division. The urban population constitutes 21 percent of the total. There are seven cities: Lahore (population over 1,900,000); Lyallpur (425,000); Multān (358,000); Rāwalpindi (340,000); Gujrānwāla (196,000); Siālkot (164,000); and Sargodha (129,000). There is considerable rural–urban migration, particularly to the larger centres.

In religion, the province is almost entirely Muslim. About two percent of the population are Christians, and only 0.1 percent practice other religions.

Punjabi is the mother tongue of 90 percent of the population in all districts. The main written language is Urdu, followed by English. The dominant ethnic groups, which have inhabited the Punjab throughout recorded history, are Jats, Rājputs, Arain, Gūjars, and Awan. The caste system is gradually becoming blurred as a result of increasing social mobility, intercaste marriages, and changing opinion.

Administrationand social conditions. The provincial capital is Lahore. The chief executive is a governor, who is appointed by the president of Pakistan. The province prepares its own budget, based on provincial receipts and central grants. The governor is assisted by the provincial secretariat, headed by a chief secretary. Civil servants are recruited on the basis of merit.

The judicial function is vested in the High Court of the province. Its decisions can be appealed to the Supreme Court of Pakistan.

The province is divided for administrative purposes into five divisions, 19 districts, and 73 tahsils. A division is headed by a commissioner, a district by a deputy commissioner, and a *tahsil* by a *tahsildār*.

Literacy and education

The literacy rate in the Punjab in 1961 was about 16 percent. The percentage of females who were literate was much lower than that of males. Since 1961 the number of educational institutions has increased considerably, particularly at primary, middle, and secondary levels. A number of vocational and commercial institutes and professional colleges have been added. The total number of educational institutions in 1969–70 was 26,261 with an enrollment of 3,200,000.

Health facilities, though undergoing improvement, are still inadequate. There were only four hospital beds per 10,000 of the population in 1971. It was estimated that there were 14 doctors and seven nurses per 100,000 of the population. There was an acute housing shortage in urban centres. The number of persons per habitable room was 3.2 in Lahore, and similar figures obtained in other cities.

The economy. It was estimated in 1968–69 that agriculture accounted for about 38 percent of the Punjab's gross provincial product, manufacturing for 17 percent, wholesale and retail trade for 14 percent, services for 11 percent, and transport and communications for about 5 percent.

Agriculture. The Punjab's chief crops are wheat and cotton. Other crops include rice, grain, sugarcane, millet, corn (maize), oilseeds, pulses, fruits, and vegetables. About three-quarters of the cultivated land is irrigated. Livestock and poultry products make up about one-quarter of the output of the agricultural sector.

Manufacturing. The Punjab is one of the more industrialized regions of Pakistan. The more important industries are textiles, machinery, electrical appliances, surgical instruments, metal industries, bicycles and rickshas, floor-covering, and food industries.

Transportation. Road transport has been glowing at a rapid rate. The total number of motor vehicles in 1968–69 was 69,359, of which 10,998 were trucks and 5,481 were buses. In 1970, the province had 5,923 miles of surfaced roads. The growth of road transport was at the expense of the railroads, which increased their traffic very little in the 1960s.

Cultural life. Martial traditions, rural romanticism, and religion form the basis of Punjabi culture. These are reflected in Punjabi literature, particularly in the folklore. The oft recited folk romances *Heer Rānjhā*, *Sohni Māhīwal,* and *Mirzd Ṣāḥibān* form the basis of Punjabi mystic poetry.

Marriages are generally arranged by parents. While marriage is a social contract between the bride and groom, it is also considered a tie between families and a source of prestige. Punjabi parents, therefore, attach high importance to making good marriages for their children. The custom of dowry is also important, particularly in the opulent sections of the urban society.

The practice of *vartan bhanji,* the exchange of gifts, favours, and services, is widespread on ceremonial occasions. A woman's rights of *vartan bhanji,* or visits to her parental home for receiving gifts, are almost continuous. The system is essentially a device for distributing gifts and money at times when they are most needed.

Dress commonly consists of a long shirt and *shalwār*, trousers or *lungī* (unstitched cloth tied around the waist in place of trousers), and a turban. Women generally wear a veil.

BIBLIOGRAPHY. General works on the Indo-Pakistan subcontinent and the undivided British province of the Punjab include: *Gazetteer of the Punjab*, "Provincial Series" (1889); S.M. LATIF, *History of the Punjab* (1891, reprinted 1964); H.K. TREVASKIS, *The Land of Five Rivers* (1928) and *The Punjab of Today: An Economic Survey of the Punjab in Recent Years (1890–1925)*, 2 vol. (1931–32); D.N. WADIA, *Geology of India,* 3rd ed. rev. (1961); M.L. DARLING, *The Punjab Peasant in Prosperity and Debt,* 2nd ed. (1928); K. DAVIS, *The Population of Zndia and Pakistan* (1951); and O.H.K. SPATE and A.T.A. LEARMONTH, *India and Pakistan,* 3rd ed. rev. (1967). Some of the more important publications on Pakistan and West Pakistan, containing useful information relating to the Punjab, are: the *West Pakistan Year Books; Twenty Years of Pakistan* (1967); R.R. PLATT (ed.), *Pakistan: A Compendium* (1961); the *Five Year Plans of Pakistan;* and the *Food and Agriculture Commissions Report* (1960). Z.S. ELGAR, *A Punjabi Village in Pakistan* (1960), is a study in the cultural life of a village community of the Punjab. The periodical, *Pakistan Geographical Review,* contains useful articles on the subject.

Puppetry

A puppet is an inanimate object moved by human agency in some kind of theatrical show, and the puppet theatre includes any kind of theatrical show that is presented through the medium of puppets. These definitions are wide enough to include an enormous variety of shows and an enormous variety of puppet types, but they do exclude certain related activities and figures. A doll, for instance, is not a puppet, and a girl playing with her doll as if it were a living baby is not giving a puppet show; but, if before an audience of her mother and father she makes the doll walk along the top of a table and act the part of a baby, she is then presenting a primitive puppet show. Similarly, automaton figures moved by clockwork that appear when a clock strikes are not puppets, and such elaborate displays of automatons as those that perform at the cathedral clock in Strasbourg or the town hall clock in Munich must be excluded from consideration, but a dancer gyrating by clockwork that is introduced by the hand of a manipulator into a show *is* a puppet.

Puppet shows seem to have existed in almost all civilizations and in almost all periods. In Europe, written records of them go back to the 5th century BC (*e.g.,* the *Symposium* of the Greek historian Xenophon). Written records in other civilizations are less ancient, but in China, in India, in Java, and elsewhere in Asia there are ancient traditions of puppet theatre, the origins of which cannot now be determined. Among the American Indians, there are traditions of puppet-like figures used in ritual magic. In Africa, records of puppets are meagre, but the mask is an important feature in almost all African magical ceremonies, and the dividing line between the puppet and the masked actor, as will be seen, is not always easily drawn. It may certainly be said that puppet theatre has everywhere antedated written drama and, indeed, writing of any kind. It represents one of the most primitive instincts of the human race.

CHARACTER OF PUPPET THEATRE

It may well be asked why such an artificial and often complicated form of dramatic art should possess a universal appeal. The claim has, indeed, been made that puppet theatre is the most ancient form of theatre, the origin of the drama itself. Claims of this nature cannot be substantiated, nor can they be refuted; it is improbable that all human dramatic forms were directly inspired by puppets, but it seems certain that from a very early period in man's development puppet theatre and human theatre grew side by side, each perhaps influencing the other. Both find their origins in sympathetic magic, in fertility rituals, in the human instinct to act out that which one wishes to take place in reality. As it has developed, these magical origins of the puppet theatre have been forgotten, to be replaced by a mere childlike sense of wonder or by more sophisticated theories of art and drama, but the appeal of the puppet even for modern audiences lies nearer a primitive sense of magic than most spectators realize.

Appeal of puppetry

Granted the common origin of human and puppet theatre, one may still wonder about the particular features of puppet theatre that have given it its special appeal and that have ensured its survival over so many centuries. It is not, for instance, simpler to perform than human theatre; it is more complicated, less direct, and more expensive in time and labour to create. Once a show has been created, however, it can provide the advantage of economy in personnel and of portability; one man can carry a whole theatre (of certain types of puppet) on his back, and a cast of puppet actors will survive almost indefinitely. These are clear advantages, but it would be a mistake to imagine that they can explain the whole popularity of puppet theatre. They do not apply to every kind of puppet—some puppets need two or even three manipulators for each figure, and many puppets need one manipulator for each figure. The company employed by a major puppet theatre, whether it be a traditional puppet theatre from Japan or a modern one from eastern Europe, will not be fewer than for an equivalent human theatre. The appeal of the puppet must be sought at a deeper level.

The essence of a puppet is its impersonality. It is a type rather than a person. It shares this characteristic with masked actors or with actors whose make-up is so heavy that it constitutes a mask. Thus, the puppets have an affinity with the stock characters of ancient Greek and Roman drama, with the masked characters of the Renaissance commedia dell'arte (*q.v.*), with the circus clown, with the ballerina, with the mummers, and with the witch doctor and the priest.

In an impersonal theatre, where the projection of an actor's personality is lacking, the essential rapport between the player and his audience must be established by other means. The audience must work harder. The spectators must no longer be mere spectators; they must bring

their sympathetic imagination to bear and project upon the impersonal mask of the player the emotions of the drama. Spectators at a puppet show will often swear that they saw the expression of a puppet change. They saw nothing of the kind; but they were so wrapped up in the passion of the piece that their imaginations lent to the puppets their own fears and laughter and tears. The union between the actor and the audience is the very heart and soul of the theatre, and this union is possible in a very special way, indeed in a specially heightened way, when the actor is a puppet.

The unreality and universality of puppets

The impersonality of the puppet carries other characteristics. There is the sense of unreality. In the traditional English Punch and Judy puppet shows, for instance, no one minds when Punch throws the Baby out of the window or beats Judy till she is dead; everyone knows that it is not real and laughs at things that would horrify him if they were enacted by human actors. Psychologists agree that the effect is cathartic—one's innate aggressive instincts are released through the medium of these little inanimate figures.

The puppet also carries a sense of universality. This, too, springs from its impersonality. A puppet Charlemagne in a Sicilian puppet theatre is not merely an 8th-century Frankish king but a symbol of royal nobility; and the leader of his rear guard dying on the pass of Roncesvalles is not merely a petty knight ambushed in a skirmish but a type representing heroism and chivalry. Similarly, in the Javanese puppet theatre, a grotesque giant is a personification of the destructive principle, while an elegantly elongated local deity is a personification of the constructive principle. Here the puppet theatre reveals its close relationship with the whole spirit of folklore and legend.

The puppet achieves its elemental qualities of impersonality, unreality, and universality through the stylizations imposed upon it by its own limitations. It is a mistake to imagine that the more lifelike or natural a puppet can be, the more effective it is. Indeed, the opposite is often the case. A puppet that merely imitates nature inevitably fails to equal nature; the puppet only justifies itself when it adds something to nature—by selection, by elimination, or by caricature. Some of the most effective puppets are the crudest: at Liège, Belgium, for instance, there is a tradition of puppets whose arm and leg movements are not controlled but purely accidental. The Rajasthani puppets of India have no legs at all. Even less naturalistic and even more stylized are the hunchbacked grotesques of the European tradition, the birdlike profiles of the Indonesian shadow figures, and the intricately shaped leather cutouts of Thailand, but it is precisely among these most highly stylized types of puppets that the art reaches its highest manifestations.

While admiring these puppets that exist furthest from nature, it cannot be denied that there is a charm and a fascination in the miniaturization of life. Much of the appeal of the puppet theatre has come from the spectators' delight in watching a world in miniature. This can be appreciated best of all in a toy theatre, in which a tiny stage on a drawing room table can be filled with choruses of peasants, troops of banditti, or armies locked in combat, while the scenery behind them depicts far vistas of beetling cliffs or winding rivers. A toy theatre, more than any other type of puppet theatre, is the human theatre on a miniature scale, but even here there is something more than a mere arithmetical reduction in scale; there is a something special that belongs to the world of the puppet.

Manipulation—seen and unseen

And to the appreciation, often instinctive, of these characteristics that mark the puppet theatre, there must be added admiration for the sheer human skill that has gone into the making and manipulation of the figures. The manipulator is usually unseen; his art lies in hiding his art, but the audience is aware of it, and this knowledge adds an element to the dramatic whole. In some kinds of presentation—for instance, in a type of cabaret floor show that became popular in the mid-20th century—the manipulator works in full view of the audience, who may, if they wish, study his methods of manipulation. This is a far cry from the philosophy of the traditional European puppet players of earlier generations, who guarded the secrets of their craft as if they were conjuring tricks. It is, indeed, fair to say that any presentation that deliberately draws attention to the mechanics of how it is done is distorting the art of puppetry, but the realization, nevertheless, of the expertise involved in a performance and some knowl-

edge of the technical means by which it is achieved do add an extra dimension to the appreciation of this difficult and highly skilled art.

TYPES OF PUPPET:

There are many different types of puppets. Each type has its own individual characteristics, and for each there are certain kinds of suitable dramatic material. Certain types have developed only under specific cultural or geographical conditions. The most important types may be classified as follows:

Hand or glove puppets. These have a hollow cloth body that fits over the manipulator's hand; his fingers fit into the head and the arms and give them motion. The figure is seen from the waist upward, and there are normally no legs. The head is usually of wood, papier mâché, or rubber material, the hands of wood or felt. The most common way to fit the puppet on the hand is for the first finger to go into the head, and the thumb and second finger to go into the arms. There are, however, many variants of this. In the puppets of Catalufia, Spain, for instance, the first three fingers fit into a wooden shouider piece, carved in one with the head, while the thumb and the little finger fit into extensions running to the arms. The usual "first-two-fingers-and-thumb" method is used for Punch-type figures; it allows the puppet to pick up and grasp small props very well and is obviously useful when wielding the stick that plays a big part in the show, but it tends to produce a lopsided effect, with one arm higher than the other. The Catalan method produces a larger and more impressive figure. The performer normally holds his hands above his head and stands in a narrow booth with an opening just above head height. Most of the traditional puppet folk heroes of Europe are hand puppets; the booth is fairly easily portable, and the entire show can be presented by one person. This is the typical kind of puppet show presented in the open air all over Europe and also found in China. But it need not be limited to one manipulator; large booths with three or four manipulators provide excellent scope for the use of these figures. The virtue of the hand puppet is its agility and quickness; the limitation is small size and ineffective arm gestures.

Rod puppets. These figures are also manipulated from below, but they are full-length, supported by a rod running inside the body to the head. Separate thin rods may move the hands and, if necessary, the legs. Figures of this type are traditional on the Indonesian islands of Java and Bali, where they are known as ***wayang golek***. In Europe, they were for a long time confined to the Rhineland; but in the early 20th century Richard Teschner in Vienna developed the artistic potentialities of this type of figure. In Moscow, Nina Efimova carried out similar experimental productions, and these may have inspired the Central State Puppet Theatre in Moscow, directed by Sergep Obraztsov, to develop this type of puppet during the 1930s. After World War II Obraztsov's theatre made many tours, especially in eastern Europe, and a number of puppet theatres using rod puppets were founded as a result. Today, the rod puppet is the usual type of figure in the large state-supported puppet theatres of the U.S.S.R., Poland, Bulgaria, Romania, Hungary, and East Germany. In a similar movement in the United States, largely inspired by Marjorie Batchelder, the use of rod puppets was greatly developed in school and college theatres, and the hand-rod puppet was found to be of particular value. In this figure the hand passes inside the puppet's body to grasp a short rod to the head, the arms being manipulated by rods in the usual way. One great advantage of this technique is that it permits bending of the body, the manipulators' wrist corresponding to the puppet's waist. Although, in general, the rod puppet is suitable for slow and dignified types of drama, its potentialities are many and of great variety. It is, however, extravagant in its demands on manipulators, requiring always one person, and sometimes two or three, for each figure on stage.

Prevalence in eastern Europe

Marionettes or string puppets. These are full length figures controlled from above. Normally they are moved by strings or more often threads, leading from the limbs to a control or crutch held by the manipulator. Movement is imparted to a large extent by tilting or rocking the ontr[illegible] but individual strings are plucked when a decided movement is [illegible] d A simple marionette may have nine t[illegible] g[illegible] t each [illegible]g, one t[illegible] each [illegible] d, one t each shoulder, one to each ear [illegible] r [illegible] movements), and one to the base f the spine (for bowing); but special [illegible] t will q[illegible] sp[illegible] l strings th[illegible]t may double or tre[illegible] l[illegible] th[illegible] number. all, merely one rod to the head. Distinctive forms of marionette control are found in India: in Rajasthani a single string passes from one shoulder over the manipulator's hand and down to the other shoulder; in southern India there are marionettes whose weight is supported by strings attached to a ring on the manipulator's head, rods controlling the hands.

In European history the marionette represents the most advanced type of puppet; it is capable of imitating almost every human or animal gesture. By the early 20th century, however, there was a danger that it had achieved a sterile naturalism that allowed no further artistic development; some puppeteers found that the control of the figure through strings was too indirect and uncertain to give the firm dramatic effects that they required, and they turned to the rod puppet. But, in sensitive hands, the marionette remains the most delicate, if the most difficult, medium for the puppeteer's art.

Flat figures. Hitherto, all the types of puppets that have been considered have been three-dimensional rounded figures. But there is a whole family of two-dimensional flat figures. Flat figures, worked from above like marionettes, with hinged flaps that could be raised or lowered, were sometimes used for trick transformations; flat jointed figures, operated by piston-type arms attached to revolving wheels below, were used in displays that featured processions. But the greatest use of flat figures was in toy theatres. These seem to have originated in England by a printseller in about 1811 as a kind of theatrical souvenir; one bought engraved sheets of characters and scenery for popular plays of the time, mounted them and cut them out, and performed the play at home. The sheets were sold, in a phrase that has entered the language, for "a penny plain or twopence coloured," the colouring by hand in rapid, vivid strokes of the brush. During a period of about 50 years some 300 plays—all originally performed in the London theatres—were adapted and published for toy-theatre performance in what came to be called the "Juvenile Drama," and a hundred small printsellers were engaged in publishing the plays and the theatrical portraits for tinselling that often went with them. It was always a home activity, never a professional entertainment, and provided one of the most popular and creative fireside activities for Regency and Victorian families. Although few new plays were issued after the middle of the 19th century, a handful of publishers kept the old stock in print until the 20th century. After World War II this peculiarly English toy was revived. Toy theatres also flourished in other countries during the 19th century: Germany published many plays; Austria published some extremely impressive model-theatre scenery; in France toy-theatre sheets were issued; in Denmark a line of plays remains in print. The interest of these toy-theatre plays is largely social, as a form of domestic amusement, and theatrical, as a record of scenery, costume, and even dramatic gesture in a particular period of stage history. As genuine performances by flat figures, they represent one aspect of the puppet theatre.

Toy theatres

Shadow figures. These are a special type of flat figure, in which the shadow is seen through a translucent screen. They may be cut from leather or some other opaque material, as in the traditional theatres of Java, Bali, and-Thailand, in the so-called *ombres chinoises* (literally "Chinese shadows") of 18th-century Europe, and in the art theatres of 19th-century Paris; or they may be cut from coloured fish skins or some other translucent material, as in the traditional theatres of China, India, Turkey, and Greece, and in the recent work of several European theatres. They may be operated by rods from below, as in the Javanese theatres; by rods held at right angles to the screen, as in the Chinese and Greek theatres; or by threads concealed behind the figures, as in the *ombres chinoises* and in its successor that came to be known as the English galanty show. Shadow theatre need not be

Indonesian wayang shadow puppet and decoration. (Left) Spectators may sit on the same side of the screen as the performer, watching the performance as presented by colourful rod puppets. (Right) Connoisseurs of the wayang art usually prefer to sit on the other side of the screen, viewing the performance as a shadow play.

limited to two-dimensional figures; rounded figures may be used effectively and the blurring of the sharp edge of a shadow that comes when the figure is not pressed sharply against the screen can provide an additional artistic element in the presentation. A particular type of shadow show that was conceived in terms of film is the silhouette films first made by the German film maker Lotte Reiniger in the 1920s; for these films, the screen was placed horizontally, like a table top, a light was placed beneath it, the camera was above it, looking downward, and the figures were moved by hand on the screen, being photographed by the stop-action technique. Her early films were in black and white, with figures made from thin sheet lead and card, but she made a few colour films in the 1950s. The shadow theatre is a medium of great delicacy, and the insubstantial character of shadow puppets exemplifies all the truest features of puppetry as an art form.

Bunraku puppets

Other types. These five types by no means exhaust every kind of figure or every method of manipulation. There are, for instance, the puppets carried by their manipulators in full view of the audience. The most interesting of these are the Japanese *bunraku* puppets, which are named for a Japanese puppet master, Uemura Bunrakuken, of the 18th century. These figures, which are about two-thirds life size, may be operated by as many as three manipulators: the chief manipulator controls with one hand head movements by means of strings inside the body, which may raise the eyebrows or swivel the eyes, while with his other hand he moves the right arm of the puppet; the second manipulator moves the left arm of the puppet; and the third moves the legs; the coordination of movement between these three artists requires long and devoted training. The magnificent costumes and stylized carving of the *bunraku* puppets establish them as among the most striking figures of their kind in the world.

Japanese bunraku theatre; woodblock print by Utashige, 19th century. The puppeteers appear on stage with their puppets; the narrator is shown at the right.

Somewhat similar figures, though artistically altogether inferior, are the dummies used by ventriloquists; ventriloquism, as such, has no relation to puppetry, but the ventriloquists' figures, with their ingenious facial movements, are true puppets. The technique of the human actor carrying the puppet actor on to the stage and sometimes speaking for him is one that has been developed a great deal in some experimental puppet theatres in recent years. Sometimes the actor is invisible through the lighting technique of "black theatre," but sometimes he is fully visible. This represents a total rejection of much traditional thinking about the nature of puppetry, and it remains to be seen how widely the practice will become accepted.

Another minor form of puppet representation is provided by the jigging puppets, or *marionettes à la planchette,* that were, during the 18th and 19th centuries, frequently performed at street corners throughout Europe. These small figures were made to dance, more or less accidentally, by the slight variations in the tension of a thread passing through their chests horizontally from the performer's knee to an upright post. Similar were puppets held by short rods projecting from the figures' backs, which were made to dance by bouncing them on a springy board on the end of which the performer sat. The unrehearsed movements of figures like these, when loosely jointed, have a spontaneous vitality that more sophisticated puppets often miss. Another interesting, if elemental, type of puppet, the "scarecrow puppets," or *lileki,* of Slovenia, is constructed from two crossed sticks draped with old clothes; two of these figures are held up on either side of a bench draped with a cloth, under which the manipulator lies. The puppets talk with each other and with a human musician who always joins in the proceedings. The playlets usually end with a fight between the two puppets.

Lalance—Ziolo

Still another minor puppet form is the finger puppet, in which the manipulator's two fingers constitute the limbs of a puppet, whose body is attached over the manipulator's hand.

The giant figures that process through the streets of

Humans as puppets

some European towns in traditional festivities are puppets of a kind, though they do not normally enact any plays. The same applies to the dragons that are a feature of street processions in China and are to be found in some places in Europe — as, for example, at Tarascon, France. Indeed, when a man hides himself within any external frame or mask, the result may be called a puppet. Many of the puppet theatres in Poland today also present plays acted by actors in masks; the Bread and Puppet Theatre in the United States is another example of the same tendency. The divisions between human actors and puppet actors are becoming increasingly blurred; if, in the past, many puppets tried to look and act like humans, today many human actors are trying to look and act like puppets. Clearly, puppetry is being recognized not merely as a particular form of dramatic craft but as one manifestation of total theatre.

STYLES OF PUPPET THEATRE

Puppet theatre has been presented in many diverse styles and for many different kinds of audience. Throughout history, the chief of these has been the performance of folk or traditional plays to popular audiences. The most familiar examples are the puppet shows that have grown up around a number of national or regional comic heroes who appear in a whole repertory of little plays. Pulcinella, for example, was a human character in the Italian commedia dell'arte who began to appear on the puppet stages early in the 17th century; he was carried around Europe by Italian puppet showmen and everywhere became adopted as a new character, hunchbacked and hook-nosed, in the native puppet plays. In France he became Polichinelle, in England Punch, in Russia Petrushka, and so on. In England alone did this wide repertory of plays based on popular legend become limited to the one basic pattern of the Punch and Judy show. At about the time of the French Revolution, at the end of the 18th century, a great many local puppet heroes displaced the descendants of Pulcinella throughout Europe: in France it was Guignol, in Germany Kasperl, in the Netherlands Jan Klaassen, in Spain Christovita, and so on. All of these characters are glove puppets; most speak through a squeaker in the mouth of the performer which gives a piercing and unhuman timbre to their voices; and all indulge in the fights and other business typical of glove-puppet shows. It is a mistake, however, to regard them all as the same character; they are distinct national types. In Greece, the comic puppet hero is Karankiózis, a shadow puppet, who originally came from Turkey, where he is known as Karagoz.

Dramatic styles

The dramatic material in which these popular puppets play is sometimes biblical, sometimes based on folk tales, and sometimes from heroic sagas. A play on the Passion of Christ, for instance, is still presented by the Théâtre Toone in Brussels; the Faust legend has provided the classic theme for the German puppet theatre; the Temptation of St. Anthony for the French; and the poems of the Italian Renaissance poet Ariosto, handed on through many popular sources, provide the themes of crusading chivalry for the puppet theatres of Sicily and Liège. More specifically dramatic or literary sources were used by the travelling marionette theatres of England and the United States in the 19th century, when popular plays such as *East Lynne* and *Uncle Tom's Cabin* were played to village audiences almost everywhere.

In Asia, the same tradition of partly religious and partly legendary sources provides the repertory for the puppet theatres. Perhaps the most interesting of these is the *wayang purwa* of Java, from the Indian epics *Rāmāyaṇa* and *Mahābhārata,* in which a deposed deity (Semar) and his grotesque sons (Gareng and Petruk) provide the comic relief.

In distinction to these essentially popular shows, the puppet theatre has, at certain periods of history, provided a highly fashionable entertainment. In England, for instance, Punch's Theatre at Covent Garden, London, directed by Martin Powell from 1711 to 1713, was a popular attraction for high society and received many mentions in the letters and journalism of the day. In the 1770s to the 1790s, several Italian companies attracted fashionable audiences and the commendation of Dr. Samuel Johnson. In Italy, a magnificent puppet theatre was established in the Palazzo della Cancelleria in Rome in 1708, for which Alessandro Scarlatti, with other eminent composers, composed operas. In Austria-Hungary, Josef Haydn was the resident composer of operas for a puppet theatre erected by Prince Esterházy about 1770. In France, the *ombres chinoises* of François-Dominique Seraphin had been established at the Palais-Royal, in the heart of fashionable Paris, by 1781. The Italian scene designer Antonio Bibiena painted the scenery for a marionette theatre belonging to a young Bolognese prince, which performed in London in 1780. Exquisite Venetian marionette theatres preserved in the Bethnal Green Museum in London and the Cooper-Hewitt Museum in New York indicate the elegance of these fashionable puppet theatres of the 18th century.

During the 18th century English writers began to turn to the puppet theatre as a medium, chiefly for satire. The novelist Henry Fielding presented a satirical puppet show, under the pseudonym of Madame de la Nash, in 1748. The caustic playwright and actor Samuel Foote used puppets to burlesque heroic tragedy in 1758 and sentimental comedy in 1773. In a similar vein, the dramatist Charles Dibdin presented a satirical puppet revue in 1775, and a group of Irish wits ran the Patagonian Theatre in London from 1776 to 1781 with a program of ballad operas and literary burlesques. In France there was a great vogue for the puppet theatre among literary men during the second half of the 19th century. This seems to have begun with the theatre created in 1847 at Nohant by George Sand and her son Maurice, who wrote the plays; well over a hundred plays were produced during a period of 30 years. These productions were purely for guests at the house; they are witty, graceful, and whimsical. Some years later another artistic dilettante conceived the idea of presenting a literary puppet show, but this time for the public; Louis Duranty opened his theatre in the Tuileries Gardens in Paris in 1861, but it lacked popular appeal and did not survive in its original form for very long. The next year Duranty's experiment inspired a group of literary and artistic friends to found the Theatron Erotikon, a tiny private puppet theatre, which only ran for two years, presenting seven plays to invited audiences. The moving spirit, however, was Lemercier de Neuville, who went on to create a personal puppet theatre that played in drawing rooms all over France until nearly the end of the century.

National preferences

All these literary puppet theatres in France had made use of hand puppets, while the English literary puppeteers of the previous century had used marionettes. In 1887 a French artist, Henri Rivière, created a shadow theatre that enjoyed considerable success for a decade at the Chat Noir café in Paris; Rivikre was joined by Caran d'Ache and other artists, and the delicacy of the silhouettes was matched by especially composed music and a spoken commentary. Another type of puppet was introduced to Paris in 1888 when Henri Signoret founded the Petit Théâtre; this theatre used rod puppets mounted on a base that ran on rails below the stage, the movement of the limbs being controlled by strings attached to pedals. The plays presented were pieces by classic authors—Cervantes, Aristophanes, Shakespeare — and new plays by French poets. The Petit Théâtre, like all the 19th-century French literary puppet theatres, performed infrequently to small audiences in a bohemian milieu; as a movement, this literary enthusiasm for the puppet theatre had little popular influence, but it served as a witness to the potential qualities of puppet theatre.

The puppet theatre in Japan entered literature with the plays of Chikamatsu (1653–1724). This writer, known as the Shakespeare of Japan, took the form of the existing crude Japanese puppet dramas and developed it into a great art form with over a hundred pieces, many of which remain in the repertory of the *bunraku* theatre today. In this form of theatre the text is chanted by a *jōruri* who is accompanied by a musician on a three-stringed instrument called a samisen.

20th-century styles

In Europe, the art-puppet movement was continued into the 20th century by writers and artists associated with the Bauhaus, the highly influential German school of design, which advocated a "total" or "organic" theatre. One of its most illustrious teachers, the Swiss painter Paul Klee, created figures of great interest for a home puppet theatre, and others designed marionettes that reflected the ideas of Cubism. The eminent English man of the theatre Gordon Craig campaigned vigorously for the puppet as a medium for the thoughts of the artist. Between World Wars I and II and through the 1950s and 1960s, a number of artists endeavoured, in difficult economic conditions, to demonstrate that puppets could present entertainment of high artistic quality for adult audiences. The marionettes of the Art Puppet Theatre in Munich, for instance, were striking exemplars of the German tradition in deeply cut wood carving. A marionette theatre in Brunswick introduced a somewhat lighter and more satirical element. Both these theatres presented impressive productions of the traditional German puppet play of *Doktor Faustus.* In Austria, the Salzburg Marionette Theatre specializes in Mozart operas and has achieved a high degree of naturalism and technical expertise. In Czechoslovakia—a country with a fine puppet tradition—a marionette theatre presented musical turns interspersed with witty satirical sketches introducing the two characters who gave their names to the theatre: Hurvínek, a precocious boy, and Spejbl, his slow-witted father. In France, the prominent artists who designed for Les Comédiens de Bois included the painter Fernand Léger. Géza Blattner, a Hungarian living in Paris, created a theatre with ingenious, sophisticated rod puppets controlled by pedals and keys from below. Yves Joly stripped the art of the puppet to its bare essentials by performing hand puppet acts with his bare hands, without any puppets. The same effect was achieved by the Russian puppeteer Sergey Obraztsov, whose performance has a charm and a wit that are quite different from those of the great rod-puppet theatre that he directs. In England, the fine craftsman Waldo Lanchester played an important part in the marionette revival; his productions included the early madrigal opera *L'Amfiparnaso.* Jan Bussell, with the Hogarth Puppets, achieved an international reputation with his marionette ballets and light operas and also with his shadow-theatre productions designed by Lotte Reiniger.

In the United States, the artistic puppet revival was largely inspired by Ellen Van Volkenburg at the Chicago Little Theatre with productions that included *A Midsummer Night's Dream* in 1916. She later directed plays for Tony Sarg, who became the most important influence in American puppetry, with such large-scale marionette plays as *Rip Van Winkle, The Rose and the Ring,* and *Alice in Wonderland.* The Tatterman Marionettes, founded by William Duncan and Edward Mabley, followed the Sarg tradition with a wide repertory of plays, mostly commercially sponsored, and their touring production of *Peer Gynt* in 1937 represented an important artistic achievement. An important step in the development of puppetry in the United States was taken in 1967 with the opening of a permanent marionette theatre, the Bil Baird Theatre, in Greenwich Village, New York City; Bil Baird's marionettes were already well known from tours and television programs.

Meanwhile, the puppet theatre was continuing on a less exalted plane to demonstrate that it could still provide enjoyable entertainment for popular audiences. From the 1870s a number of English marionette companies had developed the technique of their art to an extraordinarily high level, and their influence was widely spread through Europe, Asia, and America by a series of world tours. Their performances made a great feature of trick effects: there was the dissecting skeleton, whose limbs came apart and then came together again; the Grand Turk, whose arms and legs dropped off to turn into a brood of children while his body turned into their mother; the crinolined lady, who turned into a balloon; the Scaramouch, with three heads; and a host of jugglers and acrobats. The last of the great touring marionette theatres in this tradition was the Teatro dei Piccoli of Vittorio Podrecca, which introduced the marionette pianist and the soprano with heaving bosom that have been widely copied ever since; this theatre closed down shortly after the founder's death in 1959.

During the 20th century there has been an increasing tendency to regard the puppet theatre as an entertainment for children. One of the first people to encourage this development was Count Franz Pocci, a Bavarian court official of the mid-19th century, who wrote a large number of children's plays for the traditional marionette theatre of Papa Schmid in Munich. Important also was Max Jacob, who developed the traditional folk repertory of the German Kasperltheater, between the 1920s and 1950s, into something more suited to modern ideas of what is suitable for children's entertainment. Almost all contemporary puppeteers have created programs for audiences of children.

The "interpreter

In this survey of the various styles of puppet theatre in different countries and in different cultures, there are certain features that are common to many otherwise differing forms. In many forms of puppet theatre, for instance, the dialogue is not conducted as if through the mouths of the puppets, but instead the story is recited or explained by a person who stands outside the theatre to serve as a link with the audience. This technique was certainly in use in England in Elizabethan times, when the "interpreter" of the puppets is frequently referred to; this character is well illustrated in Ben Jonson's *Bartholomew Fair,* in which one of the puppets leans out of the booth (they were hand puppets) and hits him on the head because it does not like the way he is telling the story. The same technique of the reciter outside the theatre is found in the Japanese *bunraku* theatre, in which the chanter contributes enormously to the full effect and is, indeed, regarded as the star of the company. The same technique is found in the French shadow theatre at the Chat Noir, and its imitators and successors, which depended to a great extent upon the chansonnier. Many recent puppet productions utilize the same technique. In traditional puppet theatres of Java, Greece, Sicily, and elsewhere, all the speaking is done by the manipulator. The plays consist of a mixture of narration and dialogue, and, though the performer will certainly vary his voice for the different characters, the whole inevitably acquires a certain unity that is one of the most precious attributes of the puppet theatre.

Music and lighting

Musical accompaniment is an important feature of many puppet shows. The gamelan gong and cymbal orchestra that accompanies a Javanese *wayang* performance is an essential part of the show; it establishes the mood, provides the cadence of the puppets' movements, and gives respite between major actions. Similarly, the Japanese samisen supports and complements the chanter. In the operatic puppet theatre of 18th-century Rome, the refined musical scores of Scarlatti and the stilted conventions and long-held gestures of the opera of that time must have been admirably matched by the slow, contrived but strangely impressive movements of the rod puppets. When, in 1662, Samuel Pepys visited the first theatre to present Punch in England, he noted in his famous diary that "here among the fiddlers I first saw a dulcimer played on with sticks knocking of the strings, and it is very pretty." Even an old-fashioned Punch and Judy show had a drum and panpipes as an overture. Puppets without music can seem rather bald. At one time the gramophone was used extensively by puppeteers, and more recently the tape recorder has provided a more adaptable means of accompanying a puppet performance with music and other sound effects.

Lighting effects can also play an important part in a puppet production. The flickering oil lamp of the Javanese *wayang* enhances the shadows of the figures on the screen; as long ago as 1781, the scene painter Philip James de Loutherbourg used a large model theatre called the Eidophusikon to demonstrate the range of lighting effects that could be achieved with lamps. Modern methods of dimming electric lamps have enabled directors of puppet productions to achieve astonishing and spectacular effects.

PUPPETRY IN THE CONTEMPORARY WORLD

Opportunities and problems

The puppet theatre in the contemporary world faces great difficulties and great opportunities. The audiences for the traditional folk theatres have almost disappeared. Punch and Judy on the English beaches and Guignol in the parks of Paris still draw a crowd, but the indoor theatres that once attracted humble audiences survive with difficulty, usually with the aid of a sympathetic town council or in the shelter of a local museum. Puppets are increasingly regarded as an entertainment only for children. They certainly do provide a kind of theatre to which children respond with great enthusiasm, and, in the general development of children's theatre, the puppet theatre has a part to play. Some puppeteers are happy to play only for children. But others are eager, today as in the past, to play also on an adult level; and for these, audiences are few. No professional puppet theatre can exist, in the West, on a purely adult repertory. Even those theatres that do play for children face great economic difficulties from the small size of audience to which puppets can play and from the modest admission charges that can be charged to children. If a few companies do continue to present performances of quality, this is a tribute to their dedication to their art.

There are some possible means of performance beyond the children's theatre. There are cabarets or night clubs, which provide an opportunity for slickly presented short turns but obviously no scope for serious drama. And there is television. At first sight, television would seem an ideal medium for puppetry, and many puppet shows have in fact appeared on it, but the great possibilities that it once seemed to offer have not been fully realized. Some puppets, indeed, have become national idols. In England, for instance, Muffin the Mule and his animal friends, manipulated by Ann Hogarth, appeared from 1946 on the top of a piano at which Annette Mills played and sang. Sooty is an endearing little animal whose adventures are guided by his friend and manipulator, Harry Corbett. In the United States, the Kuklapolitans were created by Burr Tillstrom in 1947; Kukla, a small boy, had a host of friends, including Ollie the Dragon, Beulah Witch, Fletcher Rabbit, and Madame Ooglepuss, who exchanged repartee with Fran, a human actress standing outside the booth. The show had enormous popularity for some ten years and presented a social message based upon friendliness and cooperation. The same spirit lies behind the puppets introduced into the more specifically educational "Sesame Street" show; some of the monsters, for instance, do all the wrong things, but, because they are such monsters, the moral is clearly that these things should *not* be done. It must be noted, however, that all these phenomenally successful television puppet characters appeared in association with human actors, whose personalities were an important constituent in the program. Pure puppet programs have not, in general, made quite the same impact. The truth would seem to be that a puppet theatre, more than any other kind of theatre, needs audience response to bring it alive, and this the television screen cannot provide.

State subsidies

The economic difficulties facing puppet companies in western Europe and the United States have been lifted in eastern Europe and China, where the state provides generous subsidies for puppet theatres. Whereas in the West a puppet theatre is lucky if it can afford to pay a company of five or six performers, it is not unusual for a puppet theatre in the East to employ 50 or 60 performers, artists, and technicians. There has been an extraordinary surge of interest in puppet theatre in eastern Europe since World War II, and while the state supports these theatres, there is very little sign of any direct political propaganda in their programs. The results of all this aid have often been impressive in the sheer weight of numbers and scenic effects, and the productions have often been experimental and imaginative. Mere size, however, does not necessarily guarantee artistic success, and some of the best of these theatres would seem to feel a lack of confidence in their medium by their restless searching for new methods of presentation through "black theatre," mask theatre, and other techniques.

Puppetry in schools

A great feature of education during the 20th century has been the introduction of puppet making into schools as a craft activity. The difficulties facing professional puppet theatre are entirely absent here, and a puppet performance can synthesize many of the arts and skills of a group of children in making, costuming, and manipulating puppets, in writing plays for them, and in acting them. When this activity was first introduced, undue importance was often placed upon the mere construction of figures according to certain set methods and upon the painstaking preparation of a showing, so that the creative release of the performance was long delayed and sometimes never reached. Today the tendency is to create puppets quickly from scrap materials or from natural objects and to perform them impromptu, without rehearsal, as a form of dramatic self-expression. It is from such activities that the therapeutic potentialities of puppets have been utilized by psychiatrists working with disturbed children.

The future of the puppet theatre will certainly be greatly influenced by the cross-fertilization between different traditions in puppetry that will result from puppeteers meeting each other and seeing each other's performances at international festivals of the puppet theatre, These festivals now take place almost every year and are usually sponsored by Unima, the Union Internationale des Marionnettes, an international society of puppeteers. This body was originally founded in 1929 and was reconstituted in 19.57; it has members in more than 50 countries and provides a common meeting ground for professional and amateur performers, critics, and enthusiasts. In the past the differing local traditions of puppet theatre have provided a rich variety for this minor but fascinating art. In the future the local traditions may need some form of self-conscious protection to preserve them, but an even richer variety will surely spring from the interplay of artistic experiment and achievement on an international level.

Purcell, Henry

The most important English composer of his time, Henry Purcell composed music covering a wide field: the church, the stage, the court, and private entertainment. In all these branches of composition he showed an obvious admiration for the past combined with a willingness to learn from the present, particularly from his contemporaries in Italy. With alertness of mind went an individual inventiveness that marked him as the most original English composer of his time as well as one of the most original in Europe.

Birth and early life

Not very much is known of Purcell's life. He was probably born in the summer or autumn of 1659. His father was a gentleman of the Chapel Royal, in which musicians for the royal service were trained, and the son received his earliest education there as a chorister. When his voice broke in 1673, he was appointed assistant to John Hingston, keeper of the king's instruments, whom he succeeded in 1683. From 1674 to 1678 he tuned the organ at Westminster Abbey and was employed there in 1675–76 to copy organ parts of anthems. In 1677 he succeeded Mathew Locke as the composer for Charles II's string orchestra and in 1679 was appointed organist of Westminster Abbey in succession to the composer John Blow. A further appointment as one of the three organists of the Chapel Royal followed in 1682. He retained all his official posts through the reigns of James II and William III and Mary. He married in 1680 or 1681 and had at least six children, three of whom died in infancy. His son Edward was also a musician, as was Edward's son Edward Henry (died 1765). Purcell seems to have spent all his life in Westminster; he died there on November 21, 1695. His fatal illness prevented him from finishing the music for the operatic version of John Dryden and Sir Robert Howard's verse tragedy *The Indian Queen* (1664), which was completed by his brother Daniel (died 1717). Daniel Purcell had also been brought up as a chorister in the Chapel Royal and was organist of Magdalen College, Oxford, from 1688 to 1695. Before his brother's death, he was little known as a composer, but from 1695 to 1707 he was in considerable demand for music for stage productions in London until the advent of Italian opera brought his activities to an end.

To later ages Purcell was best known as a songwriter because so many of his songs were printed in his lifetime and were reprinted again and again after his death. The first evidence of his mastery as a composer, however, is an instrumental work—a series of fantasias (or "fancies") for viols in three, four, five, six, and seven parts. The nine four-part fantasias all bear dates in the summer of 1680, and the others can hardly be later. Purcell was here reviving a form of music that was already out of date and doing it with the skill of a veteran. Probably about the same time he started to work on a more fashionable type of instrumental music—a series of sonatas for two violins, bass viol, and organ (or harpsichord). Twelve of these were published in 1683, with a dedication to Charles II, and a further nine, together with a chaconne for the same combination, were issued by his widow in 1697. The foreword to the 1683 set claimed that the composer had "faithfully endeavour'd a just imitation of the most fam'd Italian Masters"; but side by side with the Italianate manner there was a good deal that derived from the English chamber music tradition.

The instrumental movements are the most striking part of the earliest of Purcell's *Welcome Songs* for Charles II —a series of ceremonial odes that began to appear in 1680. Possibly he lacked experience in writing for voices, at any rate on the scale required for works of this kind; or else he had not yet achieved the art of cloaking insipid words in significant music. By 1683 he had acquired a surer touch, and from that time until 1694, when he wrote the last of his birthday odes for Queen Mary, he produced a series of compositions for the court in which the vitality of the music makes it easy to ignore the poverty of the words. The same qualities are apparent in the last of his odes for St. Cecilia's Day, written in 1692.

Compositions for the theatre

Purcell's genius as a composer for the stage was hampered by there being no public opera in London during his lifetime. Most of his theatre music consists simply of instrumental music and songs interpolated into spoken drama, though occasionally there were opportunities for more extended musical scenes. His contribution to the stage was in fact very modest until 1689, when he wrote *Dido and Aeneas* (libretto by Nahum Tate) for performance at a girls' school in Chelsea; this miniature opera achieves a high degree of dramatic intensity within a narrow framework. From that time until his death, he was constantly employed in writing music for the public theatres. These productions included some that gave scope for more than merely incidental music—notably music for *Dioclesian* (1690), adapted by Thomas Betterton from the tragedy *The Prophetess,* by John Fletcher and Philip Massinger; for *King Arthur* (1691), by John Dryden, designed from the first as an entertainment with music; and for *The Fairy Queen* (1692), an anonymous adaptation of Shakespeare's *Midsummer Night's Dream,* in which the texts set to music are all interpolations. In these works Purcell showed not only a lively sense of comedy but also a gift of passionate musical expression that is often more exalted than the words. The tendency to identify himself still more closely with the Italian style is very noticeable in the later dramatic works, which often demand considerable agility from the soloists.

Composer of anthems

Purcell's four-part fantasias, his first court ode, and his first music for the theatre, *Theodosius,* a play by Nathaniel Lee, all date from 1680. Some of his church music may be earlier than that, but it is not possible to assign definite dates. As far as is known, most of his anthems, whether for the full choir (full anthems) or with sections for soloists (verse anthems), were written between 1680 and 1685, the year of Charles II's death. The decline of the Chapel Royal during the reigns of James II and of William and Mary may have been responsible for the comparatively few works he produced during that period; or, alternatively, he may have been so busy with stage music and odes that he had little time or inclination for church music. The style of his full anthems, like that of the fantasias, shows a great respect for older traditions. His verse anthems, on the other hand, were obviously influenced, in the first instance, by his master at the Chapel Royal, Pelham Humfrey, who had acquired a knowledge of Continental styles when he was sent abroad to study in the mid-1660s. The most notable feature of these latter works is the use of expressive vocal declamation that is pathetic without being mawkish. The same characteristics appear in the sacred songs he wrote for private performance. Since composers for the Chapel Royal in Charles II's reign had the string orchestra at their disposal, Purcell took the opportunity to include overtures and ritornellos that are both dignified and lively. The most elaborate of all his compositions for the church are the anthem My *heart is inditing,* performed in Westminster Abbey at the coronation of James II in 1685, and the festal *Te Deum and Jubilate,* written for St. Cecilia's Day in 1694. Of these the anthem is the more impressive; the *Te Deum and Jubilate* suffers on the whole from a forced brilliance that seems to have faded with the passage of time.

Though the main period of Purcell's creative activity lasted for little more than the last 15 years of his life, he managed to crowd into it a very large number of compositions, including more than 100 secular songs and about 40 duets, apart from those that he contributed to plays. Many of the songs are quite substantial pieces, incorporating recitative and arias on the lines of the Italian solo cantata. A favourite device used widely by Purcell in his secular music, though rarely in his anthems, was the ground bass (a short melodic phrase repeated over and over again as a bass line, with varying music for the upper parts). This device can have an invigorating effect in lively pieces, while in laments, such as Dido's farewell, it can intensify the expression of grief. The chaconne in the second set of sonatas uses the same technique with impressive results. Works of this kind represent the composer at the height of his capacity. The numerous catches (rounds for three or more unaccompanied voices written as one melody with each singer taking up a part in turn), on the other hand, though accomplished enough are little more than an experienced musician's contribution to social merrymaking. Purcell seems to have abandoned instrumental chamber music after his early years. His keyboard music forms an even smaller part of his work: it consists of suites and shorter pieces for harpsichord and a handful of pieces for organ.

Works published during his lifetime

Apart from a large number of songs that appeared in vocal collections, very little of Purcell's music was published in his lifetime. The principal works were the *Sonatas of III Parts* (1683); *Welcome to all the pleasures,* an ode for St. Cecilia's Day, written in 1683 (published in 1684); and *Dioclesian,* composed in 1690 (1691). After his death his widow published a collection of his harpsichord pieces (1696), instrumental music for the theatre (1697), and the *Te Deum and Jubilate* (1697); and the publisher Henry Playford issued a two-volume collection of songs entitled *Orpheus Britannicus* (1698 and 1702), which went through three editions, last appearing at mid-18th century.

A few of Purcell's dramatic works, odes, and anthems were printed in the late 18th and early 19th centuries; but not until 1876, when the Purcell Society was founded, was a serious attempt made to issue all of Purcell's works. The first volume was published in 1878, the second in 1882. From 1889 to 1928 volumes appeared at intervals. Then the scheme was in abeyance until 1957, when a volume of miscellaneous odes and cantatas was published. It was finally completed in 32 volumes in 1965. Revision of earlier volumes proceeded simultaneously with the issue of later ones, beginning with a revised edition of *Dioclesian* in 1961.

MAJOR WORKS

STAGE WORKS: One opera, *Dido and Aeneas* (first performed 1689); semi-operas, *Dioclesiarz* (1690), *King Arthur* (1691), *The Fairy Queen* (adaptation of *A Midsummer Night's Dream,* 1692), *The Indian Queen* (1695), *The Tempest* (composed ? 1695); incidental music to 43 plays.

VOCAL MUSIC: 15 odes, including six for Queen Mary's birthday and four for St. Cecilia's Day; anthems, including the coronation anthem, *My heart is inditing* (composed 1685); *Te Deum and Jubilate* (1694); sacred songs, catches, duets, and secular songs.

INSTRUMENTAL MUSIC: *Chacony in G Minor;* 13 *Fantasias* (1680); two *In Nomines;* five *Pavans;* 12 *Sonatas of III Parts* (1683); 10 *Sonatas of IV Parts* (published 1697); violin sonata; three overtures.

KEYBOARD WORKS: Eight harpsichord suites (1696); *Musick's Handmaid,* part 2 only (published 1689); miscellaneous pieces and transcriptions.

Purification Rites and Customs

Purification rites and customs, based on concepts of purity and pollution, are found in all known cultures and religions, both ancient and modern, preliterate and sophisticated. Assuming a wide variety of types and forms, these rites and customs attempt to re-establish lost purity or to create a higher degree of purity in relation to the Sacred or Holy (the transcendent realm) or the sociocultural realm.

General concepts of purity and pollution. Every culture has an idea, in one form or another, that the inner essence of man can be either pure or defiled. This idea presupposes a general view of man in which his active or vitalizing forces, the energies that stimulate and regulate his optimum individual and social functioning, are distinguished from his body, on the one hand, and his mental or spiritual faculties, on the other. These energies are believed to be disturbed or "polluted" by certain contacts or experiences that have consequences for a person's entire system, including both the physical and the mental aspects. Furthermore, the natural elements, animals and plants, the supernatural, and even certain aspects of technology may be viewed as operating on similar energies of their own: they too may therefore be subject to the disturbing effects of pollution. Because lost purity can be re-established only by ritual and also because purity is often a precondition for the performance of rituals of many kinds, anthropologists refer to this general field of cultural phenomena as "ritual purity" and "ritual pollution."

The rituals for re-establishing lost purity, or for creating a higher degree of purity, take many different forms in the various contemporary and historical cultures for which information is available. Some purification rituals involve one or two simple gestures, such as washing the hands or body, changing the clothes, fumigating the person oı object with incense, reciting a prayer or an incantation, anointing the person or object with some ritually pure substance. Some involve ordeals, including blood-letting, vomiting, and beating, which have a purgative effect. Some work on the scapegoat principle, in which the impurities are ritually transferred onto an animal, or even in some cases (as among the ancient Greeks) onto another human being; the animal or human scapegoat is then run out of town and/or killed, or at least killed symbolically. Many purification rites are very complex and incorporate several different types of purifying actions (see also RITUAL).

Ritual purity and pollution are matters of general social concern because pollution, it is believed, may spread from one individual or object to other members of society. Each culture defines what is pure and impure—and the consequences of purity and pollution—differently from every other culture, although there is considerable cross-cultural overlapping on certain beliefs. Cultures also vary greatly in the extent to which purity and pollution are pervasive concerns: Hinduism, Judaism, and certain tribal groups such as the Lovedu of the African Transvaal or the Yurok of northern California in the United States seem highly pollution-conscious, whereas among other peoples pollution concerns are relatively isolated and occasional. Even within the so-called pollution-conscious cultures, attitudes toward the cultural regulations may vary considerably: the Yurok, on the one hand, are said to consider their purification rituals to be rather a nuisance, albeit necessary for the success of their economic endeavours; but Hindus, on the other hand, seem to incorporate and embrace more fully the many regulations and rituals concerning purity prescribed in their belief and social systems.

The transmission and symptoms of pollution

Pollution is most commonly transmitted by physical contact or proximity, although it may also spread by means of kinship ties or co-residence in an area in which pollution has occurred. Because purity and pollution are inner states (though there usually are outer or observable symptoms of pollution). the defiled man—or artifact, temple, or natural phenomenon—may at first show no outward features of his inner corruption. Eventually, however, the effects of pollution will make themselves known; the appearance of a symptom or disaster that is culturally defined as a consequence of pollution, for example, may be the first indication that a defiling contact has occurred. Common cross-cultural, human symptoms of pollution include: skin disease, physical deformity, insanity and feeblemindedness, sterility, and barrenness. Nature also may become barren as a result of pollution; but, on the other hand, the natural elements and magical or supernatural forces may run amok as a result of pollution.

In general, the vital energies of man, nature, or the supernatural, as a consequence of pollution, may become either hypoactive or hyperactive. The vital energies may tend to operate in a manner that leads toward decline, loss of potencies and fertility, and death; they may also. however, tend to operate in an opposite manner that leads toward excess, increase and perversion of potencies, and chaos. Both of these tendencies presumably contrast with the tendencies of a state of purity, although the properties, symptoms, or consequences of purity rarely are explicitly defined in cultural ideologies, in contrast to the wealth of detail elaborated on the consequences of pollution.

On the whole, purity seems to be equated with whatever a culture considers to be the most advantageous mode of being and functioning for achieving the paramount ideals of that culture. Thus, throughout most Asian religions (*e.g.*, Hinduism, Buddhism, Jainism, and Taoism), purity is equated with calmness (physical, mental, and emotional equilibrium) in keeping with the ideal goal—at least for religious adepts—of achieving spiritual transcendence or liberation. In contrast to such Asian religions, groups whose dominant cultural orientation is pragmatic and this-worldly, such as the Yurok, often equate the state of purity with vigour and quickness of mind and body.

Purity and pollution in relation to religious concepts. Concepts of purity and pollution may tend to merge with several concepts of religion: the sacred, sin, and the forces of evil.

Consequences of contact with the sacred or the polluted

Pollution and the sacred. The consequences of contact with both the sacred (the transcendent realm and objects infused with transcendent qualities) and the polluted may be identical, although the reasons for the consequences in the two cases are quite different. The dangers of contact with the sacred may also arise from the belief that the gods are offended by pollution; they will punish a person who defiles a sacred precinct or object (for example, a menstruating woman who enters a temple or shrine in Buddhism and many other religions). The gods may even punish an entire village or tribe for such an offense. To come into contact with the sacred is also viewed as dangerous because the sacred is highly powerful or "charged" with energy; thus, one must be properly strengthened (usually by purification) for the encounter. If one is not thus strengthened, he will be overwhelmed. Although contact with the sacred may have negative consequences for a person, this is not because the sacred is polluting. On the other hand, the dangers of encounter with a polluted person (*e.g.*, an "untouchable" in India) or object (*e.g.*, feces, in most cultures) arise directly from the pollution that passes from that person or object to oneself.

Pollution and sin. Purity and pollution beliefs may become incorporated into a religious morality system in which pollution becomes a type of sin and an offense against God or the moral order, and purity becomes a moral or spiritual virtue. Thus, for example, in the Old Testament, the pollution of birth must not only be cleansed by symbolic or ritual gestures; it must also be atoned for as a cultic sin that offends the sacred precincts of the Lord. In general, the more universalistic religions—Christianity, Buddhism, and Islām—seem to de-emphasize true pollution concerns, and to subsume them within their frameworks of moral and religious beliefs. Both the Qur'ān of Islam and the New Testament of Christianity show a sharp decrease in rules of specific pollution avoidances (*e.g.*, fewer food prohibitions) compared to the Old Testament. Similarly, the sacred texts of Buddhism stress the unimportance of specific avoidances and rituals (in implicit contrast to the multiple and detailed purity regulations of Hinduism) and the necessity for cultivating one's spiritual and moral development instead.

Pollution and the forces of evil. Ideas of pollution are often closely associated with beliefs in demons, sorcerers, and witches. All of the latter may be viewed, in part, as personifications of the powers of pollution. People in polluted states are believed to be dangerous not only to others because they may spread their pollution, but they themselves are often thought to be in danger of attack by demons, who are attracted by the defiled person's impurities (see also ANGELS AND DEMONS; MAGIC; WITCHCRAFT).

CATEGORIES AND THEORIES OF POLLUTION AND IMPURITY

Categories of pollution and impurity. Four major categories of what various religions and societies have regarded as polluting or inherently impure phenomena may be distinguished. Virtually any type of impure person, object, or state (as defined in various cultures) may be assigned to one of these four categories, or may be shown to have symbolic associations with one (or sometimes with several) of these four sets.

Universal belief that bodily functions involve pollution

Physiological processes. The functions of the human body are, for the most part, universally considered polluting, although all functions are not considered polluting in all cultures. The intensity with which the various processes are abhorred also varies from culture to culture. The list of polluting organic processes and things includes menstruation, sexual intercourse, birth, illness, death, and all bodily excretions and exuviae (urine, feces, saliva, sweat, vomit, blood, menstrual blood, semen, nasal and oral mucous, and hair and nail cuttings). Associated with this category symbolically may be various persons, animals, natural objects, sense-related objects, and professions: women in general (because they menstruate), pregnant women, prostitutes, and widows (the latter because of their additional association with death); pigs, dogs, and other scavengers because they eat or associate with excrement and garbage; carrion-eating animals because of their association with death; leftover food, because it has come in contact with saliva via the fingers or utensils that have touched the mouth, or because it may visually resemble vomit or the undigested contents of the stomach; pungent vegetables or spices (such as garlic, onions, and leeks) and strong-smelling meats or fish because they cause foul breath odours; food in general because of its ultimate state as excrement; certain professions because their members are required to handle corpses or bodily exuviae; and things associated with lowness—the entire body below the navel, the feet, the hem of the garment, the floor or ground—because most bodily excretions derive from the lower part of the body.

Violence and associated processes. A second major category of polluting phenomena involves violence and all associated aspects. This entire category may be reduced to beliefs in the polluting nature of blood and death, but the extensive development of various ideas connected with violence pollution merit its being classified as a separate category. Violence pollution involves a wide variety of activities: murder, hunting, warfare, physical fights, quarrelling, cursing or speech that is considered foul, aggressive language, lying, and various aggressive human passions (*e.g.,* greed, anger, and hatred). Various phenomena considered polluting in one culture or another may be placed in this category because of their symbolic associations with violence: Satan, demons, witches, predatory ghosts, and the practice of black magic; alcohol because it stimulates aggressive impulses; carnivorous, predatory, and aggressive animals; meat because of the act of slaughtering the animal; certain professions because their members manufacture weapons or kill or fight for a living.

Anomalies. The third major category includes strange, unusual, or unclassifiable phenomena: (1) certain events of nature (*e.g.,* comets or lunar or solar eclipses); (2) unusual deaths (*e.g.,* death by lightning); (3) unusual births (*e.g.,* twins or other multiple births, breech deliveries, miscarriages, or stillbirths); (4) physical deformities, especially sexual deformities (*e.g.,* monorchids [men having one testicle], hermaphrodites, or eunuchs); (5) speech defects and voices appropriate to the opposite sex; (6) unusual developmental sequences (*e.g.,* children who cut their upper teeth before their lower); (7) anomalous animals or types of plants that have features of several species; (8) anomalous states of matter, such as viscosity, which is neither solid nor liquid; (9) persons in liminal (threshold or transitional) categories or states (*e.g.,* persons undergoing initiation rites, strangers, or captives); (10) persons not considered fully in control of their faculties (*e.g.,* children, drunken persons, the insane, or the mentally or physically handicapped, such as cretins); and (11) perversions of social relationships, especially sexual, that a culture generally considers to be normal (*e.g.,* adultery, homosexuality, bestiality, incest, births of children to unwed parents or as a result of adulterous relationships, or the breaking of vows of celibacy by monks or nuns). That pollution results from a confusion of classification rules may explain beliefs that certain objects must not be mixed lest pollution result. The Old Testament prohibition (also found in certain African groups) that meat and milk should not be mixed with one another or the prohibition in the Vedas (ancient Hindu scriptures) against carrying water and fire at the same time are examples of attempts to maintain classificatory purification rules (see also ANIMALS AND PLANTS IN MYTH AND LEGEND; DIETARY LAWS AND CUSTOMS).

Pollution in relation to caste professions and ethnic structures

Social classifications: classes and castes. The belief that the lower castes pollute the upper castes has been explicit in India, where a true caste system has existed. These lower castes, to some extent, are considered polluting because they engage in professions that have been or are associated with the physiological processes or with violence. Many lower caste occupations (*e.g.,* pottery making or basket weaving), however, do not have such associations, and thus the categorization of pollution attached to all lower castes cannot be so explained. Outside true caste systems, there are de facto systems of racial or ethnic hierarchy, in which certain races or ethnic groups are considered to be inherently lower than others. In most such systems, the notion that the lower groups pollute the higher is not stated explicitly in terms of pollution; the language of racial or ethnic prejudices in such systems, however, is often strongly reminiscent of pollution concepts—*e.g.,* that the lower groups are "dirty," have peculiar bodily odours, engage in sexual promiscuity or perversions, are "animals," or are violent and dangerous. Relations between the dominant race or ethnic group and the subordinate one often resemble the relations between upper and lower castes in India. In such social systems, eating together and intermarriage generally are not condoned, and segregated neighbourhoods and public facilities to maintain minimal physical contact are encouraged by law or custom (see also CASTE SYSTEMS).

Theories of pollution and impurity. Though these four major categories indicate the great diversity of phenomena considered polluting cross-culturally, no one culture considers every item noted in these categories as polluting. Furthermore, within a single culture, not every item considered polluting is necessarily polluting to every member of the society, because the connotation of pollution often is dependent upon the occasion and on the status of a person. The pollution of death, for example, may be confined to those who have actual contact with the corpse, the immediate family of the deceased, certain categories of kinsmen, or all members of the village in which the death has occurred.

The rules dictating avoidance of certain groups or individuals because of the threat of pollution may be seen as means that a society has at its disposal for emphasizing its important social categories. Thus, in the case of death, if relatives on the father's side but not on the mother's side are considered polluted by the death, it may be theorized that this is one of the society's ways of emphasizing the greater social significance of the patrilateral relatives in the kinship system. Sociologists and anthropologists, on the one hand, tend to stress such social implications of pollution rules. On the other hand, some psychologists, philosophers, and theologians are more interested in explaining what there is about polluting events and processes (*e.g.,* death and menstruation) in themselves that would result in their being considered polluting in so many cultures.

Psychoanalytic and social-classification theories

Two general theories have been proposed in relation to these emphases or questions. The first theory derives primarily from psychoanalytic theories developed by Sigmund Freud in which the quest for sexual, excretory, and aggressive pleasures are viewed as instinctual drives in man that are repressed or greatly limited in the socialization of the individual. Hence, because many of the phenomena viewed as polluting cross-culturally are related to these concerns, pollution fears are interpreted as projections or symbolizations of these repressed instincts. The second theory that attempts to explain the specific content of pollution-belief systems (as opposed to the social effects of those beliefs) maintains that, in a very broad sense, things are considered polluting by virtue of their relationship to cultural classification. This theory holds that everything considered polluting in any culture either is anomalous in relation to basic cultural categories or is positioned at the extremities—*i.e.*, the margins—of major conditions or situations of individual or social existence. Birth and death, for example, are at the margins of an individual's life, and the lower castes are at the margin of society.

Both of these theories, however, contain certain problems that may be resolved by subsuming them under a more general theory. The theory derived from psychological considerations is regarded by many scholars as being too narrow in scope because it ignores many types of pollution data; the theory based upon cultural classification, because it is capable of such broad interpretation, loses its coherence as a theory. A more general view incorporates these two theories within a single more fundamental one based on denial. Thus, pollution fears might be interpreted as symbolizations of any material that is denied full expression—psychologically, culturally, or socially. The Freudian theory, emphasizing the psychoanalytic notion of repression of instinctual drives, thus becomes significant in interpreting the first two categories—physiological processes and aggression (*i.e.*, violent emotional processes). The classification theory, which emphasizes cultural attempts to ignore or suppress phenomena that do not fit its cognitive-classification schemes, then becomes significant in interpreting the third category of polluting things—anomalies, unusual occurrences or types of persons, and "mixings." To account for the fourth category, involving the fear of lower castes, classes, and ethnic groups as polluting, the sociopolitical notion of oppression may thus be introduced. All these concepts—repression, suppression, and oppression—are related to the notion of something or someone being forcibly prevented from expression; that is, of being under some sort of pressure. This idea suggests why polluting things are viewed as threatening and not simply as interesting peculiarities of the world, because things under pressure are volatile, liable to escape, or capable of erupting at any moment.

TYPES OF PURIFICATION RITES

Occasions and symbolism of purification rites. Purification rites are required whenever there has been some kind of polluting contact. In addition, cultures may institutionalize regular, periodic purification rituals on the general principle that pollution occurs all the time. Important changes of status or quests for special or sacred status may be viewed as progressions from lesser to greater states of purity, and such changes or quests thus entail rites that promote the anticipated progressions. Purification is invariably required before any contact with the sacred. Purification also is generally considered necessary after any kind of traffic with the demonic forces and black magic, because these contacts with the nether realm are viewed as polluting experiences. Purification rites also may be required before undertaking a major endeavour in order to ensure the participant's success and a right relationship with the special powers involved in the project.

Rites before or after contact with the sacred

Though every culture has rituals to rectify unavoidable pollution, prescriptions of avoidance, abstention, separation, and seclusion are utilized to minimize contacts with polluting persons, objects, or places. Seclusion devices, which confine the very pure or the very polluted within an enclosed area away from other members of society, include menstrual huts, nuptial huts, and birth huts. Initiates are generally confined to special houses or isolated from the community by living for certain required periods of time in the bush or forest. Priests often withdraw to the inner rooms of temples to prepare for or to participate in contacts with the sacred; monks and nuns confine themselves or are confined to monasteries in order to remain undefiled by the world, among other reasons. Seclusion or containment may also be symbolically effected by the use of veils or by the drawing of circles or other enclosures around the object in question. Under the general heading of segregation, groups of different grades of purity may retire to their respective parts of a town when their periods of contact with other members of their community are completed for the day. Men may have special houses for their esoteric activities from which women are excluded. Impure persons may be required to cook over a separate fire; persons of different grades of purity often are not permitted to eat together, to sleep under the same roof or in the same room, and, almost universally, to marry or have sexual relations with one another. Finally, complete abstention, for a fixed period of time, from such polluting activities as sex, eating, and other sensuous indulgences is a significant aspect of purification processes in many societies around the world.

Classification of purification rites. Various kinds of avoidances and abstentions represent the passive aspect of purification. The active aspect consists of the purification rites themselves. Such rites may be classified according to the principle on which they operate.

Rites of cleansing

The removal of pollution. Based on the analogy of cleansing outer dirt or stains by means of bathing or washing in everyday life, purification of man's inner state of being is almost universally believed to be effected by rituals involving various forms of washing. The polluted individual might be required to swim or bathe in the sea, a river, a pond, or special tank. Bathing in swift-flowing streams is often considered especially effective because the rapidly flowing water not only removes the impurities but carries them away. A polluted person might wash his entire body with water or only certain parts of the body that represent the body or person as a whole—rinsing or cleaning the mouth by other means is common. Water may be poured, sprinkled, thrown, or blown upon a polluted person or object. Simply touching water is a purifying gesture in the Vedas; gazing at it is considered purificatory in Sri Lanka (Ceylon). In the absence of water various kinds of moist substances may be used—clay, mud, wet herbs, or plants. The Qur'ān (the Islāmic sacred scriptures) directs desert dwellers and travellers to rub themselves with high clean soil because of the scarcity of water. In cultures in which saliva is not considered polluting, expectorating or breathing on something may be viewed as purificatory gestures.

Other modes of purification based on the analogy of cleansing outer dirt include: the use of wind or aeration to blow or carry away the impurities; sweeping a house or certain area of the ground or brushing the polluted person or object, often with a brush made of fibres from a symbolically pure source; scraping the surface of a polluted object or utensil; shaving and cutting the hair and nails; removing clothing and washing it or destroying it; and putting on clean or new clothes.

The expulsion of pollution. Based on the analogy of expelling internal physical poisoning or corruption, a second category of purification rites involves the actions of expelling, ejecting, purging, or drawing out the pollution from the defiled person or object. The use of purgatives in purification rites to induce vomiting is not uncommon. Sweat baths and steam baths are believed to bring the impurities out of the person as symbolized by the emerging sweat. Some purification rites involve bloodletting in order to drain out impurities. The use of salt in some rites may be based on the fact that salt has drawing or draining properties. In corporate acts of expelling pollution, an entire community may purge itself of a polluted individual in its midst by excommunicating him and forcing him to leave the religious group, caste, tribe, or area.

Ceremonies involving scapegoats

The *transfer* of pollution. Closely connected with the practice of drawing pollution from the defiled person or object is the notion that pollution may be transferred from a person or community to another object that is either immune to pollution itself or that can be discarded or destroyed. The most dramatic rites embodying this principle are scapegoat ceremonies in which pollution is transferred to an animal or person by either touching, bathing with, or simply pronouncing the pollution transferred to the scapegoat. The scapegoat is then run out of town or killed, actually or symbolically. The victim may further be made into an offering or sacrifice to the gods on the general ritual principle of keeping the gods satisfied. In the classic scapegoat ceremony of the Old Testament, as noted in Leviticus, chapter 16, the animal—called Azazel (a desert demon)—was simply released to wander the wilderness; in Bali (in Indonesia) birds act as scapegoats and are then released to fly away.

Less dramatically, pollution may be transferred to a relatively worthless talisman (charm). Some talismans are regarded as convenient because they are disposable and of little value; after they have served their purposes in specific situations they are thrown away. In Bali a three-month-old child is purified by transferring his impurities to a chicken; this chicken may then become his pet and continue to absorb the pollutions to which the child is exposed. It may never be killed or eaten, and when it dies it is buried with respect.

Forms and objects of pollution-destroying rites

The destruction of pollution. Pollution is also believed to be eliminated by destroying the polluted object. The killing of the scapegoat belongs to this general category; more dramatically, a severely polluted person may himself be killed rather than being allowed the opportunity to transfer his impurities onto a more dispensable animal or object. The execution of a polluted person or a scapegoat animal often takes the form of drowning, choking, suffocating, or clubbing so that the pollution might not escape with a flow of blood. Polluted metal objects may be melted down; polluted fires are extinguished; polluted clothing, utensils, and other items are torn, broken, and often buried.

The most common means of destroying pollution is by burning the polluted objects. Fire is a most efficient destroyer; when the flame no longer exists there is virtually nothing left of the objects. Fire is generally conceived, however, as having more positive purifying properties, not only destroying pollution but creating purity.

The *transformation* of pollution into purity. Fire is perhaps one of the most symbolically complex phenomena in the history of human culture. It renders raw meats and vegetables into cooked and edible food, base minerals into useful and durable metals, and porous dirt and clay into watertight pottery. It destroys the forests and brushlands, but its ashes make the earth fertile and productive. Fire is thus viewed as a powerful transformer of the negative to the positive. Because of such properties, fire is commonly found in purification rites throughout the world. Polluted persons may be required to walk around, jump over, or jump through fire. Polluted items may be singed, fumigated, or smoked. The widespread use of incense smoke in purification rites is based on the transforming powers of fire, as well as on the additional purificatory powers of sweet smells. Polluted persons or things may be rubbed with ashes or soot, and polluted objects may be boiled, subject to the double purifactory powers of fire and water. Exposure to sun and to intense heat are also regarded as practices falling into this same general category. The extinguishing of old fires in temples and villages and the kindling of new ones are common practices after a death or as part of annual renewal and purification ceremonies. Alchemic experiments, which attempt to purify mineral substances and turn them into gold, involve boiling or melting down the solution or elements over pure and intense heat and then recrystallizing them in newer and higher forms (see also ALCHEMY; TAOISM).

Phenomena viewed as intrinsically pure

The introduction of purity. In addition to the cleansing, purging, destruction, and transformation of pollution, most purification rites involve the positive introduction of purity. Many phenomena are considered inherently pure; ingestion of, or contact with, or simply exposure to such phenomena is believed to bring purity to the object of the ritual.

Objects, activities, or persons commonly considered to have intrinsic purity cross-culturally include: fire; water; sweet smells created by flowers, fragrant plants and herbs, perfumes, fragrant oils, or incense; milk, ghee, and other dairy products; white objects; earth in its natural form; sacred objects (*e.g.*, relics) and sacred personages (*e.g.*, priests); the recitation of spells, incantations, and names of gods; magical amulets and stones; gold and, in one culture or another, silver, bronze, jade, and crystal; virgins; the right as opposed to the left side of things in many cultures (*e.g.*, the Abaluyia of Kenya); morning, sunshine, and daylight as opposed to darkness; whole or perfect objects, including circles and wheels and perfect numbers—*e.g.*, the number nine (because the digits of any of its square products always add up to nine) or four (because quaternity is viewed as perfection); and physically perfect specimens of their species. In addition, cultures idiosyncratically define certain things as pure because of special cultural associations: cow dung and cow urine are pure in Hinduism because of the sacredness of the cow; dogs are considered to be pure in Zoroastrianism (a religion founded in the 6th century BC by the Iranian prophet Zoroaster) because as scavengers they purify the world for everyone else (most cultures view dogs as impure because of their scavenging habits); and all cool things are considered pure among the Lovedu of the Transvaal because pollution is associated with heat.

Use of pollution to achieve purity

Other purification rites. Purification practices in which pollution is introduced qua pollution in order to achieve purity are also found in various religions and cultures. These rather paradoxical practices work on several different principles. The use of garlic, sulfur, or an amulet made of impure materials apparently operates on the principle of like attracting like; the impure amulet draws the impurity encountered in some situation toward itself, thus preventing it from polluting the wearer of the charm. Another set of practices apparently works on an inoculation principle—a baby, a magical implement, or a special work area may be briefly exposed to menstrual blood, for example, to protect it against future pollution from the same kind of item. A third group of such paradoxical practices, found primarily in Asian religions, involves immersing oneself in what is viewed as utter pollution, either by meditating on foul things or by actually keeping oneself permanently unclean, in order to achieve transcendence over pollution. Ordeals, mutilations, and blood rituals in general may also be regarded as fitting the transcendence pattern.

In highly developed and elaborated systems of thought, purity and pollution meet and merge. Buddhist monks are considered to be extremely pure, yet they are directed to make their robes from cemetery cloths, and beds or litters used in funerals may be donated to their monasteries. Buddhist relics with great purifying power are often composed of bits of hair, nails, and bones (albeit of the Buddha or other great saints); in Sri Lanka the word (*dhātu*) for such relics is the same as the word for semen. Monks and nuns of Jainism (an Indian religion founded by Mahavira in the 6th century BC) are ordered not to bathe and under no circumstances to clean their teeth. In Hinduism, if a Brahmin (a member of the highest caste) enters a street of the untouchables (outcastes), he is polluted, but the whole street also falls prey to disease, famine, and sterility. In a Burmese folktale, an alchemist became discouraged with his experiments and threw his alchemic stone into a latrine pit; on contact with the excrement, the stone achieved purity—thus indicating that contacts with pollution may bring about purity.

Ritual renewal and sacrificial rites

Many rituals considered to effect purification do not utilize any of the specific purifying techniques outlined above. They simply make use of techniques believed to have generalized ritual efficacy, no matter what the disorder. Thus, some purification rites involve reversals, especially reversals of roles between men and women, on the general principle that they represent a return to chaos and then a change back to order. Another widely practiced ritual principle involving the symbolism of reversal is that of death and rebirth; man and the world, with all their disorders, are symbolically put to death and then symbolically renewed in a purer and better state. Because blood is associated with both life and death, the use of blood in purification rites is often central to the symbolic renewal process. Nearly all rituals involve the reading or reciting of spells, texts, or prayers that have a generalized efficacy over negative forces, and in many cases purification may be accomplished by these means without any further symbolization of cleansing or a re-creation of purity. When pollution becomes one of many possible offenses against the gods, purification may be accomplished simply by making sacrifices or offerings to the gods. Pollution often becomes identified with immoral or sinful behaviour and in such instances purification may be effected by punishment of the offender, by the offender's spiritual atonement, or by acts of penance and virtue, such as giving alms. Purity also may become identified with the struggle against the demonic forces, and in this transcendent dimension purification is effected in rites of exorcism or in rites that placate the demons. The use of weapons in purification rites is often based on a symbolic battle with the forces of evil; the use of firecrackers in some purification rites is viewed as a means of frightening away the demons; the use of curses, abuse, ridicule, and ribaldry in purification rites among the ancient Greeks, for example, was regarded as forms of protection against the demons. Some purification rites involving blood are structured in terms of giving demons what they want in order to turn away their polluting presences (see also SACRIFICE).

EXAMPLES OF COMPLETE PURIFICATION RITES

Most full-scale purification rites combine several of the principles outlined above. A few of the immense number of complex purification rites in the religions and cultures of the world follow.

Rite for purifying a cured leper in ancient Judaism. In the Old Testament purification rites for a person who has been cured of leprosy, as described in Leviticus, the leper and the priest meet outside the camp, and the priest examines the man to ascertain that he is cured. The priest then calls for two live, clean birds, cedar wood, a scarlet item, and hyssop (an aromatic herb). One of the birds is killed in an earthen vessel over running water. The live bird and the other ingredients are then dipped in the blood of the dead bird and used to sprinkle blood seven times upon the leper while the priest pronounces him clean. The live bird is then allowed to fly away. The leper washes his clothes, shaves off all his hair, and washes himself, after which he is allowed to enter the camp, although he must remain outdoors for seven days. On the seventh day he once again shaves off his hair, including his eyebrows, and washes his clothes and body. On the eighth day he goes to the temple to make various offerings to the Lord. The priest then takes some of the blood of one of the offerings and places it on the man's right ear, thumb, and large toe of the right foot, after which he does the same with some oil that is being offered, also pouring some oil on the man's head. The sacrifices are then offered to the Lord upon the altar, thus completing the required ritual: "the priest shall make atonement for him, and he shall be clean."

The Navajo sweat-emetic rite. The Navajo sweat-emetic rite is part of most major Navajo ceremonials for curing illness or rectifying other ritual disturbances. It is specifically viewed as a rite of purification.

A ritual hut is prepared with sand paintings, and a fire is then built. A procession of patients, led by the chanter, enters the hut and circumambulates the fire, pausing at each of the four directions to sing an appropriate chant. In some cases there is fire jumping; the men are required to jump over the fire, and the women to walk as close to it as possible. The audience then enters, with men and women sitting in segregated groups. The chanter heats wooden pokers in the fire and applies them to himself, mainly on the legs, and then to all the patients. Basins in front of each patient are filled with the emetic formula, the fire procession is repeated, and the emetic is then drunk. Everyone is expected to vomit; if they do not, it is regarded as inauspicious. Vomiting is done into receptacles containing sand, and the contents of these receptacles may then be sprinkled with ashes from the pokers. A bull-roarer (a heavy stone on a string that produces a deep roaring sound when whirled) is sounded outside six times and then brought in and applied to the patients. The audience leaves the hogan (hut) in procession, this time led by assistants who carry out the basins with their contents. The contents of the basins are deposited neatly in a row outside the hogan and allowed to be dispersed by the natural elements. The patients, however, remain inside the hogan, perspiring in the heat. Later, the audience re-enters; the fire is broken up and extinguished, and all remnants of it are removed to a place near the basin area. The chanter sprinkles all present with a medicinal lotion and then fumigates everyone with incense. All then leave in procession and dress outside.

The Zoroastrian "Great Purification" rite. The "Great Purification" rite (*baresnum*) of Zoroastrianism originally was intended for purification from serious polluting contacts, especially for corpse bearers after contact with death. The rite was later pre-empted for initiation into the priesthood, or for attaining higher statuses within it.

In preparation for this rite a priest seeks a piece of ground regarded as clean (*i.e.*, dry and unfrequented by men or animals). He then cuts down any trees located on the area selected. Nine pits are dug in a certain arrangement; furrows are drawn around three, then around six. and finally around all nine pits. Thereafter, the whole area is covered with sand. After these activities have been completed, the priest stands outside the outer furrow, and the subject requiring purification advances to the first pit and is told to recite praises to the "Purity of Thought." The priest, holding a stick with nine knots and with a spoon fastened to the end, uses the spoon to pour consecrated cow's urine (gomez) upon the hands of the subject, who washes his hands with the urine three times. He then washes his entire body with gomez, progressing from the head down to the feet. The pollution is said to leave the toes in the form of a foul-smelling fly. After the one seeking purification has washed himself with *gomez,* the priest recites purifying formulas. This process is iepeated at each of the first six pits; at a prescribed distance from the seventh pit, the subject. sits down and rubs himself 15 times with sand, making sure that he is completely dry. At the seventh pit he washes his body once, from head to toe, with water; at the eighth pit he does this twice and at the ninth pit three times. His body is then fumigated with the smoke of fragrant wood, after which he dresses in clean clothes. In certain versions of the ceremony, a dog is presented to the candidate, who, after each washing at each pit, must touch the left ear of the dog with his left hand. At the end of the ceremony the candidate is required to recite the following formula: “The Evil Spirit of pollution is put down. The head and the body have become purified. The soul has been purified. The dog is holy, the priest is holy."

The candidate then retires to a house and is required to have no contact with fire, water, cultivated land, trees, cattle, men, or women. On the fourth, seventh, and tenth days he again bathes with gomez and then with water. After the final bath he is considered "perfectly purified."

POLLUTION BELIEFS IN MODERN SOCIETY

Pollution beliefs and fears occur in modern society as well as in any other, although they are not systematized and usually not understood as such. Racism and other forms of prejudice apparently play upon pollution fears. Of less serious consequence are such notions that warts result from masturbation (traditionally considered a polluting or impure practice in conventional Western societies), that there is something dangerous or polluting in intercourse with menstruating women, and that (as in a New York state law) men and women should not have their hair cut or beauty services performed in the same room. Physiological processes (*e.g.*, urination and other forms of elimination) are often viewed with disgust, and as a result many modern notions of sanitation are based on not entirely rational principles. The highly developed mortuary profession (especially in Western countries) protects persons in contact with death not only from grief but probably from pollution fears as well. On the whole, however, there are fewer pollution beliefs in modern society than in traditional societies. This trend may be attributed in part to the assimilation of these beliefs into moral and religious concepts.

BIBLIOGRAPHY. Few works deal directly with the subject of purification rites. MARY DOUGLAS, *Purity and Danger* (1966), is a major recent work dealing with the problems of purity and impurity. HUTTON WEBSTER, *Taboo: A Sociological Study* (1942); and FRANZ STEINER, *Taboo* (1956), deal with pollution taboos as part of the general field of ritual prohibitions. The *Encyclopaedia of Religion and Ethics,* vol. 10 (1919), though very dated, has a long article on "Purification" with many examples. Religious texts are among the best available sources: The *Old Testament,* the Egyptian *Book of the Dead,* and the *Sacred Books of the East.* The latter includes texts of Hinduism, Buddhism, Islām, Zoroastrianism, and Taoism. For a good summary of Zoroastrian purification rites (which are extensive and elaborate), see J.J. MODI, *The Religious Ceremonies and Customs of the Parsees,* 2nd ed. (1937). For ancient Greece, see LOUIS MOULINIER, *Le Pur et l'impur dans la pensée des grecs, d'Homère à Aristote* (1952); and JANE HARRISON, *Prolegomena to the Study of Greek Religion,* 3rd ed. (1922). The material on purity and pollution in primitive and other traditional societies is found in many sources. For excellent synopses of African thought systems, see DARYLL FORDE (ed.), *African Worlds* (1963); and for a North American tribe, see GLADYS REICHARD, *Navaho Religion,* 2nd ed. (1963). MARGARET MEAD, *Sex and Temperament in Three Primitive Societies* (1935 and 1963), brings together material on three Pacific Islands societies.

(S.B.O.)

Puritanism

Puritanism, a reform movement in the Church of England during the late 16th and 17th centuries, sought to carry the Reformation beyond the stage it reached at the beginning of the reign of Queen Elizabeth I (1588–1603). The name Puritan apparently was first used in the 1560s against those who thought it was necessary to "purify" the Church of England from remnants of Roman Catholic "popery."

NATURE AND SIGNIFICANCE

Puritans became noted for a spirit of moral and religious earnestness that determined their whole way of life. Their ideal life style was prefigured in Geoffrey Chaucer's description of the parson in *The Canterbury Tales,* almost two centuries earlier. What made the Puritans of the 16th and 17th centuries different from Chaucer's parson, however, was their heroic attempt through church reform to make their own life style the pattern for a nation.

Goals of the Puritan reform

The Puritan program for reform aimed to develop the Church of England by placing in every parish a pastor who would proclaim the Word truly (in a Protestant sense), administer the sacraments rightly (with no semblance of "popish idolatry"), and maintain discipline seriously (admonishing and correcting members of the parish in order to transform profane lives into holy lives).

In their efforts to transform the nation, Puritans were responsible both for revolutionary activities that led to civil war in England and for the founding of colonies in America as working models through which the people could be instructed. The religious, social, economic, political, literary, artistic, and intellectual institutions of the modern English-speaking world have been influenced by the Puritan spirit. The nature of that influence continues to be a matter of lively debate.

HISTORY

Origins of Puritanism (from the Reformation to 1603). The ideas that gave Puritanism its energy were rooted in the thought of England's earliest Protestants, of whom the most important was William Tyndale (c. 1494–1536). Tyndale viewed England as a covenant nation, like ancient Israel, existing under the judgment and mercy of God. He spoke of the Protestant Reformation as a means through which God in his grace was giving England an opportunity to renew that covenant. If England repented and purged the land of "popish idolatry" and sought to keep the laws of God, Tyndale contended, God would make good his promises. Otherwise, England would suffer the wrath of God in the form of war, famine, or plague. Temporal prosperity was possible, he said, in a reformed England.

Reformation origins. When the Church of England under Henry VIII was separated from Rome by the Act of Supremacy in 1534, much Roman Catholic form and substance remained. English Protestants worked for further reformation but had to proceed with extreme caution for fear of being burned at the stake as heretics.

On his ascension to the throne in 1547, young Edward VI was hailed by Archbishop Thomas Cranmer and other Protestants as England's Josiah, the young 7th-century-BC king of Judah who enforced the Deuteronomic reform. Edward, it was held, would rid the land of idolatry so that England might be blessed. Protestantism advanced rapidly during his reign through the systematic reformation of doctrine, worship and discipline—the three external marks of the true church. A reformed confession of faith and a prayer book were adopted, but the reformation of the ecclesiastical laws that would have defined the basis of discipline was blocked in Parliament by the most powerful of the English nobility.

The external marks of the church

The death of Edward and England's return to Roman Catholicism in 1553 under Queen Mary was interpreted by Protestants as a judgment by God upon a nation that had not taken the Reformation seriously enough. Many, including Cranmer, died as martyrs to the Protestant cause. Others fled to the European continent. Those in exile experimented with more radical forms of worship and discipline. Leading clergymen published material justifying rebellion against an idolatrous ruler. Many saw in Geneva, which was a haven for English exiles, a working model of a disciplined church. Exiles produced two large volumes of incalculable consequence for English religious thought. John Foxe's *Actes and Monuments,* popularly known as *The Book of Martyrs,* and the Geneva Bible were the most popular books in England for many years after they were published. They provided a view of England as an elect nation chosen by God to bring the power of the Antichrist (understood to be the pope) to an end. An England obedient to God would receive his favour. Otherwise, it would experience his plagues.

The Book of Martyrs and the Geneva Bible

Elizabeth, beginning her rule in 1558, was hailed as the glorious Deborah (12th-century-BC Israelite leader), the "restorer of Israel." She did not restore it far enough for English Protestants, however. Two statutes promulgated in her first year—the Act of Supremacy, stating that the queen was "supreme governor" of the Church of England, and the Act of Uniformity, ensuring that English worship should follow *The Book of Common Prayer*—defined the nature of the English religious establishment. In 1563 the primary church legislative body, the Convocations of Canterbury and York, defined standard doctrine in the Thirty-nine Articles, but attempts in the Convocation to reform the prayerbook further and to produce a reformed discipline failed. Defeated there, the reformers came to rely more on Parliament where they could always depend on strong support.

Emergence of Puritanism. Puritanism surfaced during a controversy over vestments when the Queen demanded that a reluctant archbishop, Matthew Parker, enforce uniformity in the dress of the clergy. Parker did so with the publication of his *Advertisements* in 1566. Those who regarded the prescribed garb as remnants of popery were called "Precisians" or "Puritans" at this time. Later opponents of Puritans, such as John Whitgift (professor and vice chancellor of Cambridge University and later archbishop of Canterbury), were sympathetic on this point, and they urged the higher authorities not to make such an issue of dress. The issue was more serious than dress, however, for it involved the maintenance of the Queen's supremacy.

Thomas Cartwright's contributions

In 1570 Thomas Cartwright, in lectures delivered at Cambridge University, proposed that the presbyterian form of church government was the type ordained by God in the Bible. He was dismissed from his position as Lady Margaret professor of divinity by Whitgift and fled to Geneva. Two years later an anonymously published *Admonition to the Parliament* called for the abolition of the entire hierarchy of the Church of England in order to establish the right scriptural government there and thereby save England from plagues to be sent by God. It advocated a form of government in which there would be equality of all clergy and a body of elders and pastors in each congregation who would correct and punish "all willful persons and contemners" of the Law of God. Whitgift, in reply, maintained that the government of the church should be suited to the government of the state and that Episcopal government best suited monarchy. Cartwright took up the pamphlet war and insisted that the government of the civil state should be determined by what best suited the divinely ordained government of the church.

Later, informal groups of clergy and laymen from several churches met together to expound and to discuss the Scriptures. These groups were viewed by the Queen as a political threat. Edmund Grindal, who succeeded Matthew Parker as archbishop of Canterbury, favoured these meetings (called prophesyings) for their educational value. He refused to carry out the Queen's orders to have them suppressed and wrote to her, "Remember, Madam, that you are a mortal creature . . . and although ye are a mighty prince, yet remember that He which dwelleth in heaven is mightier." The Queen could find no precedent to deprive Grindal of his archbishopric, but she did suspend him from the exercise of his office.

In the 1580s there was a concerted effort in England to set up area presbyteries, or classes, that could help the congregations under them develop their programs of discipline. The *Second Book of Discipline* (1578) recommended supplanting bishops with supervisory assemblies of pastors and elders on area, provincial, national, and world levels. This Presbyterian Puritan program was defeated through the joint efforts of John Whitgift, then archbishop of Canterbury, and Richard Bancroft, a member of the High Commission and later archbishop of Canterbury, who set up an intelligence system to keep abreast of Puritan activities. Extended ecclesiastical Court of High Commission and Star Chamber proceedings effectively brought this Presbyterian movement to a halt.

The Separatists

Some Puritans, concerned with the long delay in reform, decided upon a "reformation without tarrying for any." As Separatists they rejected compromise and repudiated the state church. Around the Separatist movement arose voluntary congregations that covenanted with God and with themselves, chose ministers by common consent, and put into practice the Puritan marks of the true church. The leaders of the Presbyterian movement, such as Thomas Cartwright, repudiated such activity and sought to disassociate themselves from the Separatists. The state repressed Separatists more savagely than it did the Presbyterians, and two laymen were hanged in 1583 for selling Separatist tracts. Three Separatist clerical leaders, John Greenwood, Henry Barrow, and John Penry, were hanged in 1593; others went to Holland as exiles.

In the last decade of Elizabeth's reign, Puritan reformers had to put aside their grand plan for the nation and concentrate on the cultivation of individuals and parishes. There were still many pastors through whom this work could be accomplished and bishops who were friendly to them. Also, there were noble patrons who placed Puritans in parish positions and members of Parliament who made common cause with them. Puritans controlled colleges and professorships at Oxford and Cambridge, and people of means contributed to lectureships assuring large audiences for Puritan preaching. Thus the Puritan spirit continued to spread.

Puritanism under the Stuarts (from 1603 to 1649). *Events under James I.* Puritan hopes were raised when James VI of Scotland succeeded Elizabeth as James I of England in 1603. James was known to be Calvinist in theology, and he had once signed the Negative Confession of 1581 favouring the Puritan position. In 1603 the Millenary Petition (with a claimed thousand signatures) presented Puritan grievances to the King, and in 1604 the

The Hampton Court Conference

Hampton Court Conference was held to deal with them. The petitioners were sadly in error in their estimate of the King, who had learned by personal experience to resent Presbyterian clericalism. At Hampton Court he coined the phrase, "no bishop, no king." Outmanoeuvred in the conference, the Puritans were made to appear petty in their requests.

As a seal upon the Hampton Court Conference, James appointed Richard Bancroft to be Whitgift's successor as archbishop of Canterbury and encouraged the Convocation of 1604 to draw up the *Constitutions and Canons* against Nonconformists. Conformity in ecclesiastical matters became a pattern in areas where forms of nonconformity had survived under Elizabeth. Though a number of the clergy were deprived of their positions, others took evasive action and got by with minimal conformity. Members of Parliament supported them in their position by arguing that since the canons had not been ratified by Parliament they did not have the force of law.

Puritans remained under pressure, but men of Puritan sympathies still came close to the seat of power in James's reign. The enforced reading from pulpits of James's *Book of Sports,* dealing with recreations permissible on Sundays, in 1618, however, was a further affront to those who espoused strict observance of the sabbath, making compromise more difficult.

Increasing numbers of Separatist groups could not accept compromise, and in 1607 a congregation from Scrooby, England, fled to Holland and then migrated on the "Mayflower" to establish the Plymouth Colony on the shore of Cape Cod Bay in 1620.

Events under Charles I. William Laud emerged as an effective opponent of Puritans, and, in 1628, he was appointed bishop of London by Charles I. London was regarded as the centre of Puritanism, and a policy of "thorough" (so called from Laud's expressed determination to carry his schemes "thorough" [*i.e.*, "through"] any obstacle) was begun there in order to destroy Puritan power. Men who were not Separatists found their positions increasingly difficult to maintain; hence, plans were laid for the founding of the Massachusetts Bay Colony.

Laud became archbishop of Canterbury in 1633 and was an effective leader under Charles in dealing with ecclesiastical matters in England. He misjudged Scotland's loyalty to the episcopal system, however, when he attempted to introduce into the Church of Scotland a liturgy comparable to the Anglican *Book of Common Prayer.* When "Laud's Liturgy" was introduced at the Church of St. Giles, at Edinburgh, a riot broke out that led to a popular uprising that restored Presbyterianism in Scotland.

Charles sought to put down the Scots, but his armies were no match for the Scottish forces. In 1640 he was faced with an army of occupation in northern England demanding money as a part of their settlement. Short of funds, Charles was forced to call Parliament, without which he had been trying to rule since 1629.

The Long Parliament

Suddenly Puritans were in a situation where they not only could preach freely but were being looked to for their leadership by people in power. The first act of the Long Parliament, as it came to be called (1640–53), was to set aside Nov. 17, 1640, as a day of fasting and humiliation. Cornelius Burges and Stephen Marshall were appointed to preach that day to members of Parliament. It was a time of great opportunity for the Puritans. Their sermons urged the nation to renew its covenant with God in order to bring about true religion through the maintenance of "an able, godly, faithful, zealous, profitable, preaching ministry in every parish church and chapel throughout England and Wales" and through the establishment of a civil magistracy that would be "ever at hand to back such a ministry."

Hundreds of similar sermons were preached on monthly fast days and on other occasions before Parliament during the next few years, urging the people to adopt true doctrine, pure worship, and the maintenance of discipline as a means to claim God's blessing so that England might become "our Jerusalem, a praise in the midst of the earth."

The Westminster Assembly

Civil war. An acceptable compromise between King and Parliament could not be found, and civil war broke out between those loyal to the King and those committed to the Parliament. Members of Parliament called together a committee of over a hundred clergymen from all over England to advise them on "the good government of the

Church." This body, the Westminster Assembly of Divines, convened on July 1, 1643, and continued daily meetings for more than five years.

A majority of the Puritan clergy of England probably would have opted for a modified episcopal church government. Parliament, however, needed Scotland's military help. It adopted the Solemn League and Covenant, which committed the Westminster Assembly to develop a church polity close to Scotland's presbyterian form. A small, determined Assembly group of "Dissenting Brethren" held out for the freedom of the congregation, or "Independency," as opposed to the power of presbytery. Others, called Erastians, wanted to limit the offenses under the power of church discipline. Because both groups had support in Parliament, the reform of church government and discipline was frustrated.

The New Model Army

Dissent within the assembly was negligible compared with dissent outside it. Pamphlets by John Milton, Roger Williams, and others schooled in Puritanism pleaded for greater freedom of the press and of religion. Such dissent was supported in the New Model Army, a Parliamentarian army of 22,000 men organized and disciplined under Sir Thomas Fairfax (1612–71) as commander in chief and Oliver Cromwell (1599–1658), and the real power in England was passing to the military leaders who had defeated all royalist forces. Late in 1648 the victors feared that the Westminster Assembly and Parliament would reach a compromise with the defeated King Charles that would destroy their gains for Puritanism. In December 1648 Parliament was purged of members unsatisfactory to the Army, and in January 1649 King Charles was tried and executed.

The age of Cromwell (1649–60). Both Parliament and the assembly continued to sit on a "rump" basis (containing only a remnant after the purges), and Oliver Cromwell emerged as England's Lord Protector. Cromwell was a typical Puritan in his seeing the judgment and mercy of God in events. Military successes to him were definite signs of the blessing of God upon his work.

The Independent clergyman John Owen guided the religious settlement under Cromwell. He maintained that the "reformation of England shall be more glorious than of any Nation in the world, being carried on, neither by might nor power, but only by the spirit of the Lord of Hosts." Error was a problem for both Cromwell and Owen, but, as Owen expressed it, it was better for 500 errors to be scattered among individuals than for one error to have power and jurisdiction over all others.

Such was the basis for a pluralistic religious settlement in England under the Commonwealth in which parish churches were led by men of Presbyterian, Independent, Baptist, or other opinions. Though Jews were permitted to live in England, those publicly holding religious views, such as Roman Catholics or Unitarians, were unacceptable. Cromwell was personally willing to tolerate *The Book of Common Prayer,* but his Parliament was not. Voluntary associations of churches were formed, such as the Worcestershire Association to keep up a semblance of church order among churches and pastors of differing persuasions. The latter association was organized by Richard Baxter (1615–91), whose persuasive and successful use of a mild discipline in Kidderminster served as an example for other pastors.

Radical reform groups

Radical groups appeared, each seeking to implement its particular vision of the New Jerusalem. The Levellers (a republican and democratic political party) in the New Model Army, in 1647 and 1648, interpreted the liberty that comes from the free grace of God offered to all men in Christ as having direct implications for political democracy. The Diggers (agrarian communists) in 1649 planted crops on common land, first at St. George's Hill near Kingston and later at Cobham Manor, also near Kingston, to encourage God to bring soon the day when all men would live in an unstructured community of love with a communal economy. The Fifth Monarchy Men (an extreme Puritan millennialist sect) in 1649 presented their message of no compromise with the old political structures and advocated a new structure, composed of saints joined together in congregations with ascending representative assemblies, to bring all men under the kingship of Jesus Christ. All these radical groups that accepted variations on Puritan themes eventually died out. A group of lasting significance, however, was the Society of Friends, or Quakers, under George Fox (1624–91). With their program of no minister, no sacraments, and no liturgy, they pushed the Puritan logic of no remnants of popery to its ultimate limit.

Though Cromwell believed that it would be better to permit Islām to be proclaimed in the land than to have "one of God's children persecuted" and though he had respect for George Fox personally, Quakers were persecuted for their refusal to pay tithes. One Quaker, James Nayler, was punished cruelly for blasphemy—his tongue was bored with a hot iron, he was whipped on two occasions, and he was imprisoned for two years at hard labour.

The Restoration (1660–85). After the death of Cromwell (1658), conservative Puritans supported the restoration of King Charles II. They hoped for a modified episcopal government, such as had been suggested in 1641 by the late archbishop of Armagh, James Ussher (1581–1656). Such a proposal was satisfactory to many of Episcopal, Presbyterian, or Independent persuasion. When some veterans of the Westminster Assembly went to Holland in 1660 to meet with Charles before he returned, the King made it clear that there would be modifications to satisfy "tender consciences."

These Puritans were outmanoeuvred in their attempt to obtain a comprehensive church, however, by those who favoured the strict episcopal pattern of Laud. A new Act of Uniformity was passed on May 19, 1662, by the Cavalier Parliament. The act required reordination of many pastors, gave unconditional consent to *The Book of Common Prayer,* advocated the taking of the oath of canonical obedience, and renounced the Solemn League and Covenant. Between 1660 and when the act was enforced on August 24, 1662, almost 2,000 Puritan ministers were ejected from their positions.

Persecution of Puritans

As a result of the Act of Uniformity, English Puritanism entered the period of the Great Persecution. One effect of the Civil War on English politics was that Parliament had become more secure in its power. After 1660 the Puritans were faced with a Parliament that did not favour them as a result of the acceptance of the return of the royalist and episcopal positions. Shortly before the Act of Uniformity (1662), the Corporation Act was enacted; it eliminated many Puritan magistrates. The Conventicle Act of 1664 punished any person over 16 years of age for attending a religious meeting not conducted according to *The Book of Common Prayer.* The Five Mile Act of 1665 prohibited any ejected minister from living within five miles of a corporate town or any place where he had formerly served.

Conservative Puritans, although forced into separatism, did not give up the idea of comprehension (inclusiveness of various persuasions). There were conferences with sympathetic bishops and brief periods of indulgence in Puritan preaching that were initiated by the King. Fines and jailings, however, set the tone.

The Glorious Revolution

During the short reign of Charles's Roman Catholic brother, James II (1685–88), fear of Roman Catholic tyranny united politically both establishment and Nonconformist Protestants. This new unity brought about the "Glorious Revolution" (1688), establishing William and Mary on the throne. The last attempt at comprehension failed to receive approval by either Parliament or the Convocation under the new rulers. In 1689 England's religious solution was defined by an Act of Toleration that continued the established church as episcopal but also made it possible for dissenting groups to have licensed chapels. The Puritan goal to further reform the nation as a whole was transmuted into the more individualistic spiritual concerns of Pietism or else the more secular concerns of the Age of Reason.

Puritanism in America. *Virginia.* A decade before the landing of the "Mayflower" (1620) in Massachusetts a strong Puritan influence was planted in Virginia. Leaders of the Virginia Company who settled Jamestown in 1607 saw themselves in a covenant relation to God and they carefully read the message of their successes and failures. A typical Puritan vision was held by the Virginia settler Sir Thomas Dale. His strict application of severe laws disciplining the Jamestown community in 1611 probably saved the colony from extinction, but he also earned a reputation as a tyrant. Dale thought of himself as a labourer in the vineyard of the Lord, as a member of Israel building up a "heavenly New Jerusalem." Like Oliver Cromwell later, whom he resembled, Dale interpreted his military success as a direct sign of God's lending "a helping hand."

Puritan clergymen saw excellent opportunity for their cause in Virginia. The Rev. Alexander Whitaker, the "apostle of Virginia," wrote to his London Puritan cousin in 1614, "But I much more muse, that so few of our English ministers, that were so hot against the surplice and subscription, come hither where neither is spoken of."

The church in Virginia, however, became more directly aligned with the English establishment when the settlements were made into a royal colony in 1624.

The Puritan experiment in America

Massachusetts Bay. In New England, however, the Puritans had their greatest opportunity. Between 1628 and 1640 the Massachusetts Bay Colony was developed as a covenant community. Gov. John Winthrop stated the case concisely in his lay sermon on board the "Arbella" before the colonists landed,

> Thus stands the cause between God and us; we are entered into covenant with Him for this work; we have taken out a commission; the Lord hath given us leave to draw our own articles . . . Now if the Lord shall be pleased to hear us and bring us in peace to the place we desire, then hath He ratified this covenant and sealed our Commission, [and] will expect a strict performance of the articles contained in it.

Lack of performance of the articles, in this view, would bring down the wrath of God.

The pattern for church organization in the colony was determined by John Cotton, who pursued "that very Middle-way" between English Separatism and the presbyterian form of government. Unlike the Separatists, he held the Church of England to be a true church, though blemished; and, unlike the Presbyterians, he held that there should be no ecclesiastical authority between the congregation and the Lordship of Christ. Cotton proposed that the church maintain its purity by permitting only those who could make a "declaration of their experience of a work of grace" to be members. Cotton's plan ensured that church government should be in the hands of the elect, the chosen of God.

Taking their cue from Thomas Cartwright, the Puritans of the Bay Colony fashioned the civil commonwealth according to the framework of the church. Only the elect could vote and rule in the commonwealth. The church was not itself to govern, but it was the means through which were prepared "instruments both to rule and to choose rulers." Biblical law was the primary law for the ordering of both church and state.

The colony prospered; thus it seemed evident that God was blessing Puritan performance. As a result, the leadership could not take kindly to those who were publicly critical of their basic program. Hence, Roger Williams in 1635 and Anne Hutchinson in 1638 were banished from the colony in spite of their ability to declare experience of the work of grace.

More troublesome than these dissenters were persons such as Mary Dyer, who followed Anne Hutchinson across the border and who later became a Quaker and then returned to Massachusetts Bay. She and other Quakers who returned again and again after being punished and banished were finally hanged. It was difficult for the state to keep the church pure.

The Cambridge Platform and the Half-Way Covenant

In order to head off a possible new form of church government dictated from England at the time of the Westminster Assembly, churches from the four Puritan colonies of Massachusetts Bay, Plymouth, Connecticut, and New Haven met in a voluntary synod in 1648. They adopted the Cambridge Platform, in which the congregational form of church government was worked out in detail. The standard for church membership came under question when it was found that numbers of second generation residents could not testify to the experience of grace in their lives. This resulted in the Half-Way Covenant of 1657 and 1662 that permitted baptized, moral, and orthodox persons to share in the privileges of church membership except for partaking of communion.

Late in the 17th century it was apparent to all that the ideal commonwealth was not being maintained. Ministers pointed to wars with the Indians and other problems as signs of God's judgment. Visitation by demonic powers in the form of witches was believable to people expecting the wrath of God. The Salem witchcraft trials and hangings took place in 1692 at a period of declining confidence in the old ideal.

Other colonies. Massachusetts Bay, Plymouth, Connecticut, and New Haven were variations on the main theme of realizing the Holy Commonwealth in America. Roger Williams and the other founders of Rhode Island must also be regarded as Puritans with the "one principle, that every one should have liberty to worship God according to the light of their consciences."

William Penn's "holy experiment" in Pennsylvania represented another Puritan variation, only this time under Quaker norms. When Penn came into the ownership of this vast tract of land he saw it as a mandate from God to form an ideal commonwealth. In New Jersey, Puritans from the New Haven colony who were dissatisfied with the Half-Way Convenant sought to re-establish the pristine Puritan community at Newark. Maryland, which had been established under Roman Catholic auspices, soon had a strong Puritan majority among its settlers.

There was no colony in which the Puritan influence was not strong in one form or another. One estimate is that 85 percent of the churches in the original 13 colonies were Puritan in spirit.

BELIEF, WORSHIP, AND PRACTICES

Belief. Puritan belief developed from the manner in which William Tyndale, Thomas Cranmer, and other early English Protestants sought to be faithful to the Bible. England's first Protestants were humanists, in the tradition of Desiderius Erasmus, before they became acquainted with the work of Martin Luther. They fitted the humanist concern for the "discipline of Christ" into their adaptation of Protestant theology. Huldrych Zwingli, Martin Bucer, Heinrich Bullinger, and Pietro Martire Vermigli had great influence on Puritan thought. In the last decade of the 16th century John Calvin's influence reached its peak among Puritans. They systematized Calvin's ideas and put them into the context of their English theological tradition to produce a "covenant theology." As John Robinson, the pastor to the Pilgrim Fathers, stated, Puritans did not "stick fast where they were left by that great man of God [Calvin], who yet saw not all things," for "the Lord hath more truth yet to break forth out of his holy Word."

Influence of continental reformers

Worship. Puritans sought to purify worship according to a biblical model, eliminating anything that suggested idolatry. Central to their worship was the preaching of the Word, prayers, and the singing of Psalms. Plain preaching that involved explicating the meaning of a biblical text and then applying it to the congregation was emphasized. Sermons lasting from one to two hours were often given both in the morning and the afternoon on Sundays and also during the week, especially on market days.

Extemporaneous prayers were preferred, and these tended to be much longer than those in *The Book of Common Prayer.* To safeguard the biblical character of worship, the Psalms became the basic hymnbook for Puritans. Many paraphrases of the Psalms were published, including the *Bay Psalm Book,* the first book printed in the English colonies of America.

The *Bay Psalm Book*

The sacrament of the Lord's Supper was celebrated frequently in some churches and more rarely in others. There was a great concern that no unworthy person be admitted. They celebrated the sacrament around a table rather than before an altar.

Daily family worship was practiced, with the pastor's household providing the example for his people.

Ecclesiastical polity. Puritans experimented with many types of episcopal, presbyterian and congregational forms of church organization. They went from a more functional approach in the early days of Elizabeth, where the primary concern was the workability of the government, to a concern for finding and reduplicating the biblical pattern. Yet, even at the end of the Puritan period in 1690, one finds Functionalists, such as Richard Baxter, who saw truth in each form of church government but whose greatest concern was to find a working formula. In almost all cases, Puritan church government on the local level consisted of a pastor governing along with lay leaders elected by the congregation. Any church structure above the congregational level was maintained for the welfare of the local congregations.

The maintenance of discipline. The purpose of church government was to ensure that true doctrine was proclaimed, proper worship was performed, and that the discipline was maintained. The key to the Puritan understanding of discipline is Matt. 18:15–17, which deals with the admonition to confront fellow believers with their faults and if they are unresponsive to reject them. Separatists sought to maintain this discipline only among members of their congregations and to use persuasion upon the rest of mankind. The more conservative Puritans believed that it was their duty to maintain the discipline in the whole community.

Puritans sought to bring order out of the disorder that the "Fall of Adam" had brought to all mankind. Their, degree of achievement was indicated by events interpreted as signs of God's blessing or judgment. Individual Puritans kept diaries by which they could measure their personal "pilgrim's progress," and Puritan preachers in their sermons assessed the state of the community.

Ministers. Since the interpretation and proclamation of the Word of God was central to the laws, the life, and the very sense of meaning in the community, the ministers of the Word were of paramount importance. Through them the congregation and the community came to know who they were, where they were, and where they were going. It was desirable that a minister be highly educated in his vocation by becoming "conversant with Hebrew and Greek and in such arts and sciences as are handmaids unto divinity."

Education of ministers

The schools and universities of England were shaped to produce such men first by the humanists and then by their Protestant successors. The English models were brought to America by the Massachusetts Bay colonists who founded the Boston Latin School, Harvard College, and the rudiments of the American public school system within ten years of their landing.

"Blue laws." The attempt to enforce discipline upon the whole community resulted in the production of "blue laws," so named from some laws bound in blue paper in the New Haven colony. The Puritans were not so different in their moral ideals from Roman Catholics, Lutherans, Jews, and the adherents of other faiths for whom the biblical injunctions were normative. The Puritans, however, tried harder to enforce the Ten Commandments and other precepts.

Many laws had to do with observing the sabbath commandment. Sabbatarianism was not peculiar to Puritans, for the Anglican Lancelot Andrewes recommended the same. Some Puritan sermons, however, seemed to take the position that if the sabbath were observed rightly just once, the Kingdom of God would come.

Missionary activities. One reason for establishing colonies in America was the conversion of Indians. John Eliot pioneered in this endeavour in Massachusetts by translating the Bible into an Indian language. His translation was the first Bible printed in North America. Though he had considerable success in making converts, his work was frustrated by the demand for land by settlers who pushed the Indians back until a last desperate attempt to forestall the inevitable took place in King Philip's War of 1675. That war scattered Eliot's Indian congregations and communities. Great interest in his work had been evidenced among Puritans in England who organized a missionary society to raise money for his cause.

INFLUENCES OF PURITANISM

The original Puritans had committed themselves to the authority of the Word of God without any intervening human agency. They had expected to produce religious uniformity, but they actually contributed to greater diversity. The logic of their position eventually resulted first in an attempt to accommodate variety, then in religious toleration, and finally in religious freedom.

Contributions to religious freedom and the development of democracy

The contribution of Puritanism to the development of democracy followed a similar course. Their theology of election seemed to indicate an aristocracy of the chosen of God, rather than democracy. Those who were the elect of God were all on the same level, however, and the rule of the saints in New England was democratic as far as the saints themselves were concerned. When men became less sure of their ability to distinguish the true saints from others, they extended the franchise until eventually the democracy of the saints became the democracy of the community.

Fear of the tendency to sin that was in every man encouraged the view that all power on earth be limited. Puritan influence can thus be seen in the checks and balances that were written into the Constitution of the United States. To counteract sin, Puritan institutions of home, family, and church were all schools for character that produced individuals with a strong enough sense of personal morality and civic responsibility to make constitutional democracy workable.

Traces of the Puritan vision live on in the basic commitments of the United States. Thomas Jefferson's Latin motto on the reverse side of the one-dollar bill reminds Americans that their nation is the foundation of that "new order of the ages" for which men have hoped. The second inaugural address of Abraham Lincoln resounds with the Puritan theme of God's judgment and grace to be seen in human events. When Dwight D. Eisenhower reminded Americans that their nation was based upon a deeply felt religious faith and that he personally did not care whether one was Protestant, Catholic, or Jew, Oliver Cromwell would have understood.

Pushkin, Aleksandr

The greatest Russian poet, Aleksandr Pushkin (1799–1837) was also the founder of his country's modern literature. His use of language, astonishing in its simplicity and profundity, formed the basis of the style of novelists Ivan Turgenev, Ivan Goncharov, and Leo Tolstoy. His novel in verse, *Yevgeny Onegin*, the first Russian work to take contemporary society as its subject, pointed the way to the Russian realistic novel of the 19th century.

LIFE

Pushkin was born in Moscow on June 6 (May 26, old style), 1799. His father came of an old boyar family; his mother was a granddaughter of Abram Hannibal, who, according to family tradition, was an Abyssinian princeling bought as a slave at Constantinople and adopted by

Peter the Great, whose comrade in arms he became. Pushkin immortalized him in an unfinished historical novel, Arap Petra Velikogo (published 1837; The Negro of Peter the Great).

Pushkin, oil painting by Orest Kiprensky. 1827. In the State Tretyakov Gallery, Moscow.

Early years. Like many aristocratic families in early 19th-century Russia, Pushkin's parents adopted French culture, and he and his brother and sister learned to talk and to read in French. They were left much to the care of their maternal grandmother, who told Aleksandr, especially, stories of his ancestors in Russian. From Arina Rodionovna, his old nurse, a freed serf (immortalized as Tatyana's nurse in Yevgeny *Onegin*), he heard Russian folktales. During summers at his grandmother's estate near Moscow, he talked to the peasants and spent hours alone, living in the dream world of a precocious, imaginative child. He read widely in his father's library and gained stimulus from the literary guests who came to the house—Vasili Pushkin, his father's brother, a minor poet; I.I. Dmitriev; N.M. Karamzin; V.A. Zhukovsky; and K.N. Batyushkov—young writers opposed to the prevailing French Classicism.

First published work

In 1811 Pushkin entered the newly founded Imperial Lyceum at Tsarskoye Selo (later renamed Pushkin) and while there began his literary career with the publication (1814, in Vestnik Evropy, "The Messenger of Europe") of his verse epistle "To My Friend, the Poet." In his early verse, he followed the style of his older contemporaries, the Romantic poets Batyushkov and Zhukovsky, and of the French 17th- and 18th-century poets, especially the Vicomte de Parny, and their tradition of light verse.

While at the Lyceum he also began his first completed major work, the romantic poem Ruslan and Lyudmila (published 1820), written in the style of the narrative poems of Ariosto and Voltaire but with an old Russian setting and making use of Russian folklore. Ruslan, modelled on the traditional Russian epic hero, encounters various adventures before rescuing his bride, Lyudmila, daughter of Vladimir, grand prince of Kiev, who, on her wedding night, has been kidnapped by the evil magician Chernomor. The poem flouted accepted rules and genres and was violently attacked by both of the established literary schools of the day, Classicism and Sentimentalism. It brought Pushkin fame, however, and Zhukovsky presented his portrait to the poet with the inscription "To the victorious pupil from the defeated master."

St. Petersburg. In 1817 Pushkin left the Lyceum and, accepting a post in the foreign office at St. Petersburg, plunged into social life. He was elected to the exclusive Arzamás, a literary society founded by his uncle's friends, and also became an active member of the liberating movement that had begun among the progressive aristocracy as a result of the upsurge of patriotism after the Napoleonic invasion of 1812.

Pushkin joined the Green Lamp association, which, though founded (in 1818) for discussion of literature and history, became a clandestine branch of a secret society, the Union of Welfare. In his political verses and epigrams, widely circulated in manuscript; in the ode to liberty "Volnost" (1817); and in "Derevnya" (1819: "The Village"), written under the influence of the 18th-century radical thinker and writer A.N. Radishchev, he made himself the spokesman for the ideas and aspirations of those who were to take part in the Decembrist rising of 1825, the unsuccessful culmination of a Russian revolutionary movement in its earliest stage.

Exile in the south. For these political poems, in May 1820 Pushkin was banished from St. Petersburg to a remote southern province. Sent first to Yekaterinoslav (now Dnepropetrovsk), he was there taken ill and, while convalescing, travelled in the northern Caucasus and later to the Crimea with General Rayevski, a hero of 1812, and his family. The impressions he gained provided material for his "southern cycle" of romantic narrative poems.

Influence of Byron

The "*southern* cycle." Like many western European writers, Pushkin had fallen under the spell of Byron's poetry, and, as he himself said, his southern poems "smack of Byron." They introduced Byronic Romanticism to Russia. But even in the first of them, *Kavkazski* plennik (1822; *The* Prisoner of the Caucasus), realist tendencies are discernible. Pushkin here creates from his own experience a psychologically exact portrait of a typical representative of the rising generation in Russia, who, disappointed in love and friendship and dissatisfied with social life in the capital, seeks freedom in the primitive beauty of the Caucasus and in the simple life of its inhabitants, untainted by "civilization." Taken prisoner by the Circassians and finally liberated by a Circassian girl who loves him, he is unable to respond to the passion of this "maid of the mountains" because at heart he is cold and prematurely aged; and she, in despair, throws herself into a mountain torrent and is drowned.

In the second poem of the cycle, *Bratya razboiniki* (1821–22, published 1827; The Robber Brothers), a work permeated with passionate ardour for freedom and based on an event that took place during his stay at Yekaterinoslav, he describes the courageous escape from prison of two brothers, who, although chained and fettered, had swum across the Dnieper and got away.

Bakhchisaraisky *fontan* (1821–23, published 1824; *The* Fountain of Bakhchisarai) is based on a legend. Girei, a warlike nomad, khan of the Crimea, conceives a deep and pure love for his captive, the Polish princess Maria Potocka; but one of his wives murders her out of jealousy. In her memory, Girei erects a fountain (which Pushkin had seen in the khan's palace) surrounded by marble basins into which tearlike drops of water fall melodiously.

Yevgeny *Onegin.* Although this "southern cycle" of poems confirmed the reputation of the author of Ruslan and Lyudmila and Pushkin was hailed as the leading Russian poet of the day and as the leader of the romantic, liberty-loving generation of the 1820s, he himself was not satisfied with it. In May 1823 he started work on his central masterpiece, the novel in verse, Yevgeny *Onegin* (published 1833), on which he continued to work intermittently until 1831. In it he returned to the idea (which had first found artistic expression in *The* Prisoner of the Caucasus) of presenting a typical figure of his own age but in a wider setting and by means of new artistic methods and techniques.

Yevgeny *Onegin* unfolds a panoramic picture of Russian life. The characters it depicts and immortalizes—Onegin, the disenchanted skeptic; Lensky, the romantic, freedom-loving poet; and Tatyana, the heroine, a profoundly affectionate study of Russian womanhood: a "precious ideal," in the poet's own words—are typically Russian and are shown in relationship to the social and environmental forces by which they are molded. Although formally the work resembles Don Juan, Pushkin rejects Byron's subjective, romanticized treatment in favour of objective description and shows his hero not in exotic surroundings but at the heart of a Russian way of life. Thus, the action begins at St. Petersburg, continues on a provincial estate, then switches to Moscow, and finally returns to St. Petersburg.

At Kishinyov and Odessa. Pushkin had meanwhile been transferred first to Kishinyov (1820–23) and then to Odessa (1823–24). His bitterness at continued exile is expressed in letters to his friends—the first of a collection of correspondence that became an outstanding and enduring monument of Russian prose. At Kishinyov, a remote outpost in Moldavia, he devoted much time to writing, though also he plunged into the life of a society engaged in amorous intrigue, hard drinking, gaming, and violence. At Odessa he made passionate love to the wife of his superior, Count Vorontsov, governor general of the province. He fought several duels, and eventually the count asked for his discharge. Pushkin, in a letter to a friend intercepted by the police, had stated that he was now taking "lessons in pure atheism." This finally led to his being again exiled to his mother's estate of Mikhaylovskoye, near Pskov, at the other end of Russia.

Russian features of his poetry

At Mikhaylovskoye. Although the two years at Mikhaylovskoye were unhappy for Pushkin, they were to prove one of his most productive periods. Alone and isolated, he embarked on a close study of Russian history; he came to know the peasants on the estate and interested himself in noting folktales and songs. During this period the specifically Russian features of his poetry became steadily more marked. His ballad "Zhenikh" (1825; "The Bridegroom"), for instance, is based on motifs from Russian folklore; and its simple, swift-moving style, very different from the brilliant extravagance of *Ruslan and Lyudmila* or the romantic, melodious music of the "southern" poems, emphasizes its stark tragedy.

In 1824 he completed *Tsygane* (published 1827; *The Gypsies),* begun earlier as part of the "southern cycle." In this, the most mature of his verse romances, he puts into the mouth of an old gypsy, a representative of the people, a condemnation of the individual romantic hero who wants freedom "only for himself." The style is dramatically harsh and spare, and the descriptive passages and dialogue are vigorous and realistic. At Mikhaylovskoye, too, he wrote the provincial chapters of *Yevgeny Onegin;* the poem *Count Nulin* (1825, published 1827), based on the life of the iural gentry; and, finally, one of his major works, the historical tragedy *Borir Godunov* (1824–25, published 1831).

His debt to Shakespeare

Boris Godunov. This tragedy marks a break with the Classicism of the French theatre and is constructed on the "folk-principles" of Shakespeare's plays, especially the histories and tragedies, plays wiitten "for the people" in the widest sense and thus universal in their appeal. Written just before the Decembrist rising, it treats the burning question of the relations between the ruling classes, headed by the tsar, and the masses; it is the moral and political significance of the latter, "the judgment of the people," that Pushkin emphasizes. Set in Russia in a period of political and social chaos on the brink of the 17th century, its theme is the tragic guilt and inexorable fate of a great hero—Boris Godunov, son-in-law of Malyuta Skuratov, a favourite of Ivan the Terrible, and here presented as the murderer of Ivan's little son, Dmitri. The development of the action on two planes, one political and historical, the other psychological, is masterly and is set against a background of turbulent events and ruthless ambitions. The play owes much to Pushkin's reading of early Russian annals and chronicles, as well as to Shakespeare, who, as Pushkin said, was his master in bold, free treatment of character, simplicity, and truth to nature. Although lacking the heightened, poetic passion of Shakespeare's tragedies, *Boris* excels in the "convincingness of situation and naturalness of dialogue" at which Pushkin aimed, sometimes using conversational prose, sometimes a five-foot iambic line of great flexibility. The character of the pretender, the false Dmitri, is subtly and sympathetically drawn; and the power of the people, who eventually bring him to the throne, is so greatly emphasized that the play's publication was delayed by censorship. Pushkin's ability to create psychological and dramatic unity, despite the episodic construction, and to heighten the dramatic tension by economy of language, detail, and characterization make this play an outstanding achievement and a revolutionary event in the history of Russian drama.

Return from exile. After the suppression of the rising of Dec. 14 (O.S.), 1825, the new tsar Nicholas I, aware of Pushkin's immense popularity and knowing that he had taken no part in the Decembrist "conspiracy," allowed him to return to Moscow in the autumn of 1826. During a long conversation between them, the Tsar met the poet's complaints about censorship with a promise that in the future he himself would be Pushkin's censor and told him of his plans to introduce several pressing reforms from above and, in particular, to prepare the way for liberation of the serfs. The collapse of the rising had been a grievous experience for Pushkin, whose heart was wholly with the "guilty" Decembrists, five of whom had been executed, while others were exiled to forced labour in Siberia. Among them had been his closest friends at the Lyceum, I.I. Pushchin and the poet V.K. Kyukelbeker (see the poem "Arion" and the epistle to Siberia, "Vo glubine sibirskikh rud . . ." ["In the depths of Siberia's mines . . ."], both written in 1827). Thus, when the Tsar asked him outright how he would have acted had he been in St. Petersburg on December 14, he answered that he would have joined the ranks of the insurgents.

Pushkin's interest in reforms

Pushkin saw, however, that without the support of the people, the struggle against autocracy was doomed. He considered that the only possible way of achieving essential reforms was from above, "on the tsar's initiative," as he had written in "Derevnya." This is the reason for his persistent interest in the age of reforms at the beginning of the 18th century and in the figure of Peter the Great, the "tsar-educator," whose example he held up to the present tsar in the poem "Stansy" (1826; "Stanzas"), in *The Negro of Peter the Great,* in the historical poem *Poltava* (1828, published 1829), and in the poem *Medny vsadnik* (1833, published 1837; *The Bronze Horseman).* In this last, Pushkin poses the problem of the "little man" whose happiness is destroyed by the great leader in pursuit of ambition, by telling a "story of St. Petersburg" set against the background of the flood of 1824, when the river took its revenge against Peter I's achievement in building the city. The poem describes how the "little hero," Yevgeny, driven mad by the drowning of his sweetheart, wanders through the streets. Seeing the bronze statue of Peter I seated on a rearing horse and realizing that the Tsar, seen triumphing over the waves, is the cause of his grief, Yevgeny threatens him and, in a climax of growing horror, is pursued through the streets by the "Bronze Horseman." Its descriptive and emotional powers give the poem an unforgettable impact and makes it one of the greatest in Russian literature.

After returning from exile, Pushkin found himself in an awkward and invidious position. The Tsar's censorship proved even more exacting than that of the official censors, and his personal freedom was curtailed. Not only was he put under secret observation from the police but he was openly supervised by its chief, Count Benckendorf. When in 1829, during the Russo-Turkish War, after his applications to go to Transcaucasia had been refused, he managed to visit the front lines without permission, for which he was severely reprimanded by Count Benckendorf. This visit, on which he met several of the exiled Decembrists, is described in *Puteshestviye v Arzrum* (published 1836; *A Journey to Erzuıum).*

Reaction of critics and friends

Moreover, his works of this period met with little comprehension from the critics, and even some of his friends accused him of apostasy, forcing him to justify his political position in the poem "Druzyam" (1828; "To My Friends"). The anguish of his spiritual isolation at this time is reflected in a cycle of poems about the poet and the mob (1827–30) and in the unfinished *Egipetskiye nochi* (published 1837; *Egyptian Nights).*

Yet it was during this period that Pushkin's genius came to its fullest flowering. His art acquired new dimensions, and almost every one of the works written between 1829 and 1836 opened a new chapter in the history of Russian literature. He spent the autumn of 1830 at his family's Nizhny Novgorod (now Gorky) estate Boldino, and these months are the most remarkable in the whole of his artistic career. During them he wrote the four *malenkiye tragedii* ("little tragedies"): *Skupoy rytsar* (1836; *The Covetous*

Knight); Mozart i Salieri (1831; Mozart and Salieri); Kamenny *gost* (1839; The Stone Guest); Pir vo vremya chumy (1832; Feast in Time of the Plague); and the five short prose tales collected as Povesti pokoynogo Z.P. Belkina (1831; Tales of the Late *I.P.* Belkin); the comic poem of everyday lower class life Domik v Kolomne (1833; A Small House in Kolomna); and many lyrics in widely differing styles; as well as several critical and polemical articles, rough drafts, sketches, and so on.

One of Pushkin's most characteristic features was his wide knowledge of world literature, shown in particular by his interest in English literature from Shakespeare and Byron to Sir Walter Scott and the Lake poets, in Dostoyevsky's phrase, his "universal sensibility," his ability to re-create the spirit of different races at different historical epochs without ever losing his own individuality. This is particularly marked in the "little tragedies," which are concerned with an analysis of the "evil passions" and, like Pikovaya *Dama* (1834; The Queen of Spades), exerted a direct influence on the subject matter and techniques of the novels of Dostoyevsky.

Last years. In 1831 Pushkin, after a turbulent courtship and objections from her mother, married Natalya Nikolayevna Goncharova and settled in St. Petersburg. Once more he took up government service and was commissioned to write a history of Peter the Great. Three years later he received the rank of Kammerjunker (gentleman of the emperor's bedchamber), partly because the Tsar wished Natalya to have the entree to court functions. The social life at court, which he was now obliged to lead and which his wife enjoyed, was ill suited to creative work, but he stubbornly continued to write. Without abandoning poetry altogether (the fairy tales in verse, skazki, belong to this period, as well as Medny vsadnik, or The Bronze Horseman), he turned increasingly to prose. Alongside the theme of Peter the Great, the motif of a popular peasant rising acquired growing importance in his work, as is shown by the unfinished satirical Istoriya sela Goryukhina (1830, published 1837; History of the Village of Goryukhino); the novel Dubrovsky (1832–33, published 1841); Stseny *iz* rytsarskikh vremen (1835, published 1837; dramatic Scenes from the Age of Chivalry); and finally, the most important of his prose works, the historical novel of the Pugachov Rebellion, *Kapitan*skaya dochka (1833–36, published 1836; The Captain's Daughter), which had been preceded by a historical study of the rebellion, Istoriya Pugachova (1833, published 1834).

Prose writings

Meanwhile, both in his domestic affairs and in his official duties, his life was becoming more intolerable. In court circles he was regarded with mounting suspicion and resentment, and his repeated petitions to be allowed to resign his post, retire to the country, and devote himself entirely to literature were all rejected. Finally, on February 8, 1837, in a duel forced on him by influential enemies, defending his wife's honour, Pushkin fell, mortally wounded. His adversary, Georges d'Anthès, an officer in the guards and the adopted son of the Dutch ambassador Baron Heeckeren, had emigrated from France after the revolution of 1830 and was the husband of Natalya's sister. Pushkin died of his wound at St. Petersburg on February 10 (January 29, O.S.), 1837.

ASSESSMENT

Even during his lifetime Pushkin's importance as a great national poet had been recognized by Nikolay Vasilyevich Gogol, his successor and pupil; and it was his younger contemporary, the great Russian critic, democrat, and revolutionary Vissarion Grigoryevich Belinsky, who produced the fullest and deepest critical study of Pushkin's work, which still retains much of its relevance. To the later classical writers of the 19th century, Pushkin, the creator of the Russian literary language, the author of the standard works of Russian literature, the "poet of reality" (as he said of himself), stands as the cornerstone of Russian literature, in Maksim Gorky's words "the beginning of beginnings."

Pushkin has become an inseparable part of the cultural and spiritual world of the Russian people and of the other peoples of the former tsarist empire to whom he bequeathed his work (in the poem "Ya pamyatnik sebye vozdvig" [1836; "Exegi monumenturn"]). He has exerted, too, a profound influence on other aspects of Russian culture: most notably, in opera.

Pushkin's work—with its nobility of conception and its emphasis on civic responsibility (shown in his command to the poet-prophet to "fire the hearts of men with his words"); its life-affirming vigour; and its confidence in the triumph of reason over prejudice, of light over darkness, of human charity over slavery and oppression—has struck an echo all over the world. Translated into all the major languages, his works are regarded both as expressing most completely Russian national consciousness and as transcending national barriers.

MAJOR WORKS

Poetic works

NARRATIVE POEMS: *Ruslan i* Lyudmila (1820; *Ruslan* and Lyudmila), a mock-heroic folk epic. The "southern cycle": Kavkazsky plennik (1822; The Prisoner of the Caucasus); Bratya razboiniki (written 1821–22, published 1827; The Robber Brothers); Bakhchisaraysky *fontan* (1824; The Fountain of Bakhchisaray); Tsygany (1827; The Gypsies); begun as part of the "southern cycle" but completed at Mikhaylovskoye. (EPIC POEMS): *Poltava* (1829; Eng. trans.): Medny vsadnik (1837; The Bronze Horseman). (HUMOROUS EPICS): Graf Nulin (1827; Count Nulin); "Tazit," or "Galub" (published posthumously 1837); Domik v Kolomne (1833; A Small House in Kolomna). (NOVEL IN VERSE): Yevgeny *Onegin* (written 1823–31, published complete 1833; Eugene *Onegin*). (BALLADS): "Kazakh (1815; "The Cossack"); "Zhenikh (1825; "The Bridegroom"). (FAIRY TALES IN VERSE): "Skazka o pope i o rabotnike yego Balde" (1840; "The Tale of the Priest and His Helper Bald"); "Skazka o tsare Saltane" (1832; "The Tale of Tsar Saltan"); "Skazka o mertvoy tsarevne" (1834; "The Tale of the Dead Princess"); "Skazka o rybake i rybke" (1835; "The Tale of the Fisherman and the Fish); "Skazka o zolotom petushke" (1835; "The Tale of the Golden Cockerel").

POLITICAL POEMS: (circulated in manuscript, all posthumously published): "Volnost" (written 1817; "Ode to Freedom"); "Skazki Noel" (1818); "Derevnya" (written 1819; 'The Village"; "In the Country"); "Kinzhal" (1821); "Vo glubine Sibirskikh rud . . ." (written 1827; "In the depths of Siberia's mines . . ."; "Message to Siberia"); "Druzyam" (written 1828; "To My Friends").

Dramatic works

Boris Godunov (written 1824–25, published 1831; Eng. trans.), historical tragedy in blank verse and prose. The "little tragedies" (malenkiye tragedii), written 1830: Skupoy rytsar (1836; The Covetous Knight); Kamenny *gost* (1839; The Stone Guest); Pir vo vremya chumy (1832; Feast in Time of the Plague); and Mozart i Salieri (1831; Mozart and Salieri), short dramatic episodes in blank verse; Rusalka (published posthumously 1837); Stseny iz rytsarskikh vremen (published posthumously 1837; Scenes from the Age of Chivalry).

Prose works

SHORT STORIES: *Povesti pokoynogo* I.P. Belkina (1831; Tales of the Late I.P. Belkin); Pikovaya *Dama* (1834; The Queen of Spades).

NOVELS: Kapitanskaya dochka (1836; The Captain's Daughter); Arap Petra Velikogo (1837; The Negro of Peter the Great); Egipetskiye *nochi* (1837; Egyptian *Nights*); Dubrovsky (1841; Eng. trans.).

OTHER PROSE: *Puteshestviye* v *Arzrum* (1836; *A* Journey to *Erzurum*); Istoriya Pugachova (written 1833, published 1834).

English translations

The most comprehensive selection is in A. Yarmolinsky (ed.), The Works of Alexander *Pushkin* (1939, new ed. 1946). There are translations of selected poems, ballads, and fairy tales by Maurice Baring in Poems Translated from *Pushkin* (1931); by Oliver Elton in Verse from *Pushkin* and Others (1935); and by Walter Morison in Pushkin's Poems (1945; shorter poems only). Selected fairy tales are translated by B.L. Brasol in The Russian Wonderland (1936). The Little Tragedies (1946) have been translated by V. de S. Pinto and W.H. Marshall. Translations of Evgeni *Onegin* include those by O. Elton (1937; rev. ed. 1948); D. Paull Radin and G.Z. Patrick (1937); V. Nabokov (4 vol., 1964); and B. Deutsch (1965). Thomas Keane, The Prose Tales of *Pushkin* (1894), has been superseded by G. Aitken, The Complete Prose Tales of *Pushkin* (1966). There is a translation of the novels and some stories by N. Duddington in The Captain's Daughter and Other Tales (1933, rev. ed. 1961).

BIBLIOGRAPHY. The most detailed biographical and critical studies of Pushkin in English are: D.S. MIRSKY, *Pushkin* (1926, reprinted 1963); ERNEST J. SIMMONS, *Pushkin* (1937, reprinted 1964); and "Pushkin: The Poet As Novelist," in *An Introduction to Russian Realism* (1965); DAVID MAGARSHACK, *Pushkin: A Biography* (1967); WALTER N. VICKERY, *Pushkin: Death of a Poet* (1968); V.V. VERESAYEV, *Pushkin: A Biographical Sketch* (1937; orig. pub. in Russian, 1936); IRAKLY ANDRONIKOV, *The Last Days of Pushkin* (Eng. trans. 1957), an essay on Pushkin's duel and death, written after the discovery of new materials; JANKO LAVRIN, *Pushkin and Russian Literature* (1947, reprinted 1969), on Pushkin's place and significance in the development of Russian literature; and SAMUEL H. CROSS and ERNEST J. SIMMONS (eds.), *Centennial Essays for Pushkin* (1937, reprinted 1967), a collection of essays published on the centenary of Pushkin's death, including Simmons's "Biographical Study of Pushkin"; GEORGE V. VERNADSKY, "Pushkin and the Decembrists"; and ARTHUR P. COLEMAN, "Pushkin and Mickiewicz."

There are thousands of books and articles in Russian that cover all aspects of Pushkin's life and works. Б.П. ГОРОДЕЦКИЙ, Н.В. ИЗМАЙЛОВ, and Б.С. МЕЙЛАХ (eds.), *Пушкин: Итоги и проблемы изучения* (1966), is an excellent collection of articles on Pushkin by 14 Russian authorities. The fundamental biographies in Russian are НИКОЛАЙ ЛЕОНТЬЕВИЧ БРОДСКИЙ, *А.С. Пушкин, биография* (1937); and ЛЕОНИД ПЕТРОВИЧ ГРОССМАН, *Пушкин*, 3rd ed. (1960).

(D.D.B.)

Pym, John

The English statesman John Pym, the architect of Parliament's victory over Charles I in the Civil War (1642–46), laid the foundations of the parliamentary sovereignty that prevailed in England from the 17th century onward. Pym also was largely responsible for the system of taxation that survived in England until the 19th century and for the enduring close relations between the English government and the City of London.

By courtesy of the trustees of the British Museum

Pym, engraving by G. Glover, 1644, after a portrait by Edward Bower.

Pyrn was born in 1583 or 1584, the eldest son of Alexander Pym of Brymore, Somerset, who died when John was a child; his mother married Sir Anthony Rous, a client of the Russells, the earls of Bedford. Pyrn was educated at Oxford but took no degree, and at the Middle Temple, but was not called to the bar. Through Bedford influence he became a local official of the Exchequer. From 1621 to his death Pym sat in every Parliament, usually for the Russell borough of Tavistock. He soon made a name as an enemy of popery and Arminianism (high-church Anglicanism) in high places, as a sound financier, an expert on colonial affairs, and a good committeeman. He was no extremist, however, but a loyal subject anxious to maintain good relations between crown and Parliament.

From 1630 Pym was treasurer of the Providence Island Company, which sought to open trade with Spanish America—peacefully, if possible, by force, if not. In the 11 years from 1629 to 1640, during which the King chose to ıule without Parliament, this company brought together the men, mostly Puritans, who were to lead the Parliamentary party in the 1640s. Opposition to Charles's tax of Ship Money to support the Royal Navy (a tax without parliamentary approval) was organized by adventurers of the company; in August 1640 the petition of 12 peers demanding a Parliament was drafted by Pyrn and another adventurer.

Leader of the middle group in Parliament

When the Long Parliament met in November 1640, Pyrn headed what has been called the middle group, whose central position allowed it to dominate the House of Commons. His policy was that of his patron, the earl of Bedford: to force the King to accept a government in which Parliament, representing the wealth of the country, had confidence. Their main obstacle was Charles's toughest adviser, Thomas Wentworth, 1st earl of Strafford, who was executed as a traitor in May 1641. It was difficult to prove a man deep in the King's confidence a traitor, but Pym argued that "to endeavour the subversion of the laws of this kingdom was treason of the highest nature." Thus, by implication, even a king was capable of committing treason: here was the germ of the charge on which Charles was to be executed in 1649. There were great popular demonstrations in London calling for Strafford's execution, and Pyrn was accused of fomenting them.

Pym forced Charles to accept an act forbidding the dissolution of Parliament without its consent. This was followed by acts abolishing the whole apparatus of personal government and finance. On paper Charles had accepted that he must rule through Parliament, but he had no real intention of accepting this, and he had to be coerced. The main issue became control of the armed forces. When rebellion broke out in Ireland (October 1641), all agreed that it must be crushed; but Parliament rightly feared a military coup if the King were given command of the army. The House of Commons said it would act in Ireland without the King unless Charles changed his ministers. This virtual declaration of revolution was reinforced by the Grand Remonstrance, listing the grievances of the kingdom as Pym's group saw them and demanding ministers trusted by Parliament and an Assembly of Divines nominated by Parliament to reform the church. This Remonstrance, carried by 159 votes to 148, was printed and circulated to rally support outside Parliament; its opponents henceforth formed a Royalist party. Pym was one of five members of Parliament whom Charles tried to arrest in January 1642. They took refuge in the City, from which they returned in triumph when the King quitted London.

Pym's political philosophy

Before and during the Civil War, Pym's political philosophy was summed up in the phrase "I know how to add sovereign to [the King's] person, but not to his power." He believed that the King reigned but did not rule alone: power should be balanced between him and Parliament. "To have printed liberties," Pym once said, "and not to have liberties in truth and realities, is but to mock the kingdom." Pyrn never seems to have contemplated abolishing the monarchy, and he was certainly no democrat; but he used popular pressure to achieve his ends. When war started, he set about creating an army, the machinery to administer it, and the excise and assessment (later the land tax) to pay for it. His City connections helped him to raise loans. He created the network of committees at Westminster and in the counties that ran the country for the next 17 years. When military stalemate threatened, Pyrn called in Scottish assistance even at the price of concessions to Presbyterianism that went further than he wished. Ever pragmatic, when the House of Lords made difficulties, he told them that the Commons could run the country alone.

Pym was a sonorously eloquent speaker, arguing each particular issue from first principles without ever being doctrinaire. His skill as a parliamentary tactician was unrivalled. He balanced between radicals—some of whom were republicans—and the peace party, which was so frightened of social upheaval that it would have accepted almost any terms from the King.

Pym preserved the unity of Parliament for three years with no party organization, no discipline, no whips. This great achievement wore him out, and when he died on December 8, 1643, no one could replace him; Parliament's supporters split into wrangling groups. But by then Pym had laid the basis for victory and had sketched the shape of the England that was to survive the 17th century.

BIBLIOGRAPHY. There is no definitive biography. Those by JOHN FORSTER, *John Pyin* (1837); C.E. WADE, *John Pym* (1912); and S.R. BRETT, *John Pym, 1583–1643: The Statesman of the Puritan Revolution* (1940), are all inadequate. J.H. HEXTER, *The Reign of King Pym* (1941), is the most important modern book, dealing primarily with the period after 1640. A.P. NEWTON, *The Colonising Activities of the English Puritans* (1914), discusses the Providence Island Company.

(J.E.C.H.)

P'yongyang

P'ybngyang, capital and largest city of the Democratic People's Republic of (North) Korea, is the second largest city (after Seoul) of all Korea. P'ybngyang still appears on many maps as Heijo, which is the Japanese pronunciation of the Chinese characters for the name. The name itself means "large flat [*p'yŏng*] field [*yang*]," which describes the plain on which the city was established. Located in the heavily populated northwestern region of North Korea, P'yirngyang is built on both sides of the Taedong-gang (Taedong River) about 30 miles from the Yellow Sea. The area of the metropolitan city (1967) is 77 square miles (199 square kilometres), and its population in 1967 was 1,364,000.

Founding by the Chinese

History. P'ybngyang is reputed to be the oldest city in Korea. The ancient capital of the legendary Tangun dynasty (2333 BC) was located on the site where, according to legend, the present city of P'ybngyang was founded in 1122 BC. The city's recorded history begins in 108 BC with the founding of a Chinese trading colony at Lolang (Nangnang in Korean) near P'ybngyang. A walled fortress lying on the route of march for Chinese or Mongol armies invading Korea and Japanese armies invading China, P'yŏngyang figured prominently in the wars that signalled shifts in power among the nations of northeastern Asia.

In 427 P'ybngyang became the capital of Koguryb, one of the several rival kingdoms that had established themselves in Korea, and in the 7th century it was besieged on several occasions by Chinese invaders. The first of these invasions, in 612, ended in a disastrous defeat for the Chinese army when it was ambushed inside the city. Chinese armies returned in 644 and again in 661 but did not capture the city until 668. The fall of P'ybngyang marked the end of the Koguryb dynasty. Later, the kings of the Kbryo dynasty (918–1392) made P'ybngyang their secondary capital. Japanese invaders attacked and briefly occupied P'ybngyang in 1359. In 1592 the Japanese again attacked. This time the city fell. A year later Chinese armies, as allies of the Koreans, retook the city after an exceptionally bloody battle. Thirty-four years later an army of the Manchus captured P'ybngyang and burned it to the ground before they withdrew.

Attack on the "General Sherman"

The scars of successive invasions left their mark on the Koreans, who became suspicious of all foreigners. In 1866 an American ship, the USS "General Sherman," sailed up the Taedong-gang with the object of opening Korea to foreign trade. Undeterred by Korean demands that it turn back, the "General Sherman" sailed on until it ran aground just opposite P'ybngyang. The Koreans attacked the ship, set it on fire, and killed the survivors who swam ashore. Today the "General Sherman" is to North Koreans a symbol of United States aggression and of Korea's victory. Two five-inch guns from the ship still guard the entrances of two of P'ybngyang's historical museums.

When Korea finally opened its doors to foreigners, P'ybngyang soon became the base of an intensive campaign to bring Christianity to Korea. Over a hundred churches were built in the city, which in the 1880s was reputed to have more Protestant missionaries than any other city in Asia.

During the Sino-Japanese War (1894–95), P'ybngyang was the site of yet another major battle and again suffered great destruction. Plague followed war, and in 1895 P'ybngyang was left a virtually deserted and ruined city. During the Japanese occupation of Korea (1910–45), P'ybngyang was built up as an industrial centre, and its population grew rapidly. The city escaped destruction in World War II.

In the Korean War (1950–53), P'ydngyang was captured by United Nations forces in 1950 and recaptured by Chinese and Korean Communist forces shortly after. During the remainder of the war the city was subjected to intensive United States bombing and almost totally destroyed. Since 1953 the city has been rebuilt with Soviet and Chinese assistance.

The contemporary city. *The city site.* From its original site on the northern bank of the Taedong-gang, the city has expanded in all directions. New residential areas have been built on the southern bank of the river, which is crossed by several bridges; and the river itself is being straightened and made deeper, while trees have been planted on both of its sides. The city's recreational park and an educational centre are located atop a cluster of hills in the city.

Although remnants of the old stone walls and gates can still be found, as a result of the Korean War few buildings are more than 18 years old. Under North Korea's socialist economy, the present city did not simply grow; it was planned. The government has made it a show place with numerous parks and gardens. Row after row of prefabricated concrete apartment houses were erected along wide, tree-lined boulevards.

Climate. P'yŏngyang's proximity to the sea does not protect it from the harsh continental climate of North China and the Northeast (Manchuria). Winters are cold; the average temperature in January is about 18° F (−8° C). Summers are warm, with average temperatures in July and August in the upper 70s and wet. Over half of the total yearly rainfall, which averages 37 inches, falls during these two months.

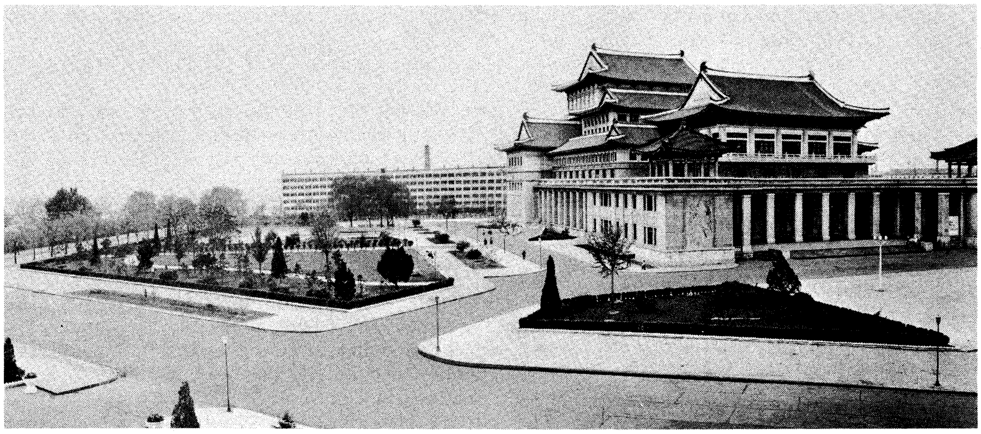
International air and rail connections

Transportation. Invariably on the itinerary for Communist dignitaries and delegations from various revolutionary movements touring Asia, P'ybngyang is normally closed to other visitors. From Sunan airport, ten miles north of the city, flights connect P'yŏngyang with Peking; there are also air connections with Irkustsk, Moscow, and Omsk; and regularly scheduled domestic air service links P'ybngyang with Ch'bngjin on the east coast of North Korea. P'yirngyang is the hub of North Korea's rail system, which is being electrified. There is direct international rail passenger car service with both Moscow and Peking. Ocean vessels call at Namp'o at the mouth of the Taedong-gang on the west coast, and smaller boats on the river provide regular passenger and freight service between that port and P'ybngyang.

Buses provide public transportation within P'ybngyang. Trucks also carry workers to the factories each morning. Only high government officials are allowed private autos. Most people live near the places where they work.

Demography. P'ybngyang's population at the start of the 1970s was estimated to be slightly over 1,000,000 with another 500,000 to 600,000 in the outside metropolitan area. The population density of the city is about 18,000 per square mile. During the later years of the Japanese occupation, thousands of Koreans left the farms to work in the new factories being built by the Japanese to support their war effort. Urbanization continued after the war when thousands more who had been conscripted to work in factories in Japan and Manchuria were repatriated. The returning workers preferred to remain in the cities, although the government tried to get them to accept agricultural jobs in the rural areas.

The growth of P'ybngyang was reversed briefly during the Korean War, as thousands were evacuated from the city to avoid the bombing. At the end of the war, the city, which had more than 340,000 people in 1944, had only



Bolshoi **Theatre,** P'ydngyang.
Tass—Sovfoto

80,000. Since then its population has increased more than tenfold, putting heavy pressure on government construction of urban housing.

Effect of the city on traditional ways of life

City life has had a profound impact on the social structure of the Korean people. Confucian concepts and clan ties have broken down. The typical apartment in the city is far too small to accommodate the extended families of old Korea. Family units have to be smaller, and, as the apartments are assigned by the government, neighbours can no longer claim to have known each other since childhood.

P'yŏngyang, unlike most other Asian cities, does not have a large Chinese minority. North Korea's population is remarkably homogeneous, with only 24,000 resident aliens, mainly Chinese, in the entire country. During the years of Japan's rule, there had been a large resident Japanese population in P'ybngyang, but hardly any remain and intermarriage between the Koreans and Japanese was rare.

Class distinctions are founded not on race but on a person's role in the economy and position in the Communist Party. Housing is assigned according to one's job title. Preference is shown to party members, especially in the purchase of scarce consumer goods.

Housing. The government constructs all urban housing and regulates rents according to the income of the tenants. Tenants are assigned to an apartment and cannot move unless they are promoted to a better apartment. There are four categories of apartments. Workers are entitled to group one housing: a single room with a half-size kitchen. Group four housing, which consists of two rooms, one room with a wood floor, storage room, and a bathroom with toilet, is reserved for such people as department or bureau chiefs in the central government, managers of state enterprises, and college professors. Only top-ranking officials of the government and the Communist Party may have individual houses. Rents are low; an average person reportedly spends no more than 3 percent of his salary on rent, including utilities.

Architecturalfeatures. A huge bronze statue of Ch'bllima, a winged horse of Korean legend, atop a pedestal 150 feet high dominates the skyline of P'ybngyang. According to legend, Ch'ŏllima was able to carry its riders a thousand *li* a day (a *li* is a Chinese unit of measurement that equals about one-third of a mile). To North Koreans, Ch'bllima symbolizes the economic progress made after the end of the Korean War. Sections of the Inner and Northern walls and Hyunmoo Gate are still standing, and several old temples and pavilions that date from the Koguryb kingdom have been reconstructed in the original architectural style. Modern landmarks include the Grand Theatre; the Okryoo Hall, which contains a large banquet hall for official functions and recreation facilities for the workers; and the Moranbong Stadium, which seats 70,000 people. Beneath Moran-bong (Moran Hill), the city's main recreational centre, is a huge underground theatre. A large television antenna marks the northern boundary of the city.

Mills, factories, and commerce

Economy. Located in the midst of North Korea's industrial heartland, P'ybngyang is a major textile and food-processing centre. Coal deposits near the city provide fuel for its factories. Two of the country's largest textile mills are in P'ybngyang: the P'ybngyang Cotton Works, which employs more than 11,000 people, and the P'yŏngyang Silk Works, which employs more than 5,000. While silkworms are raised in North Korea, ginned cotton, raw wool, and rayon yarn used by the mills must be imported. The city also contains sugar refineries, rubber factories, ceramics factories, railroad workshops, and an arsenal.

As the political capital of a thoroughly Socialist country, P'ybngyang is also the country's economic headquarters. An army of bureaucrats is employed in planning and managing the economy. The major commercial institutions are operated by the government. These include the Korean Central Bank, which supervises the flow of all capital; the Korean Industrial Bank, the only bank that grants loans; and the Foreign Trade Bank, which handles all financial settlements resulting from foreign trade.

The People's Assembly and the People's Committee

Government. Urban government in North Korea consists of a People's Assembly and People's Committee. Members of the People's Assembly are locally elected and serve a four-year term. They meet twice a year in regular session to review the work of the People's Committee. Members of the People's Committee are elected by the People's Assembly and are responsible to it. Composed of a chairman, vice chairman, secretary general, and committee members, the People's Committee draws up economic plans and directly supervises the work of the functional bureaus. An important function of the People's Committee is the regulation of prices in the state-owned retail stores. Being the capital, P'ybngyang is a "special city," in which the central government probably plays a larger role than in other directly ruled cities. Below the city government are the people's assemblies and people's committees of the *tong,* or wards, of the city, and the *kun* or counties located on the lightly populated outskirts of P'ybngyang. Below these are people's assemblies and committees for each street or block.

Electricity and water. The city's power supply comes from hydroelectric plants on the Yalu River to the north and a 500,000-kw thermal electric plant in the city. Little power is available to consumers. Few apartment buildings have elevators; electrical appliances are used only by high-ranking officials; the average tenant is limited to the use of two 40-watt light bulbs.

The city's water supply is adequate, but plumbing facilities are not. Even in modern apartment buildings, water may have to be carried up to the apartment by hand. Usually there is one toilet facility on each floor, and outhouses are still in evidence in the backyard of modern buildings.

Public health. Modern hospitals have been built in P'yŏngyang with assistance from the Soviet Union and Communist bloc countries. Medical care is provided by the state at little or no cost. Immunization teams regularly comb the city block by block, immunizing those who cannot show satisfactory shot records.

Education. Education begins in state-run nurseries where working parents deliver their children each morning. This is followed by primary school, middle school, then vocational training, higher technical schooling, or entrance into a university. At the top of the educational system is Kim 11-sung University (founded 1946), located on the outskirts of P'ybngyang overlooking the Taedong-gang. P'ybngyang also has a medical school and a Communist university for training party leaders. Adult education is encouraged through classes taught in the factories.

Cultural life. P'ybngyang is the centre of North Korea's cultural life. It is the home of the P'ybngyang Theatre, where performances are given by the P'ybngyang Song and Dance Troupe, the National People's Opera, and the National Opera; the National Dancing Theatre; and the P'ybngyang Young Students Palace, where children are trained in art, music, and drama. Cultural halls where workers put on simple skits rich in ideological content are located in each district. During the Korean War, dramatic performances were given at the huge underground theatre beneath Moran-bong. The city's museums include the Fatherland Liberation War Memorial Hall, the State Central Historical Museum, the State Central Fine Arts Museum, and the Korean National Folk Museum. The annual National Fine Arts Exhibition is held in P'ybngyang, and the State Central Library is located there.

Communications media

All of North Korea's ten principal newspapers are published in P'ybngyang. These include "Democratic Korea," official paper of the Presidium of the Supreme People's Assembly, and "Labour Daily," put out by the Central Committee of the Korean Workers Party. There are also a number of foreign language newspapers published in P'ybngyang, including, in English, *The Pyongyang Times* (weekly) and *The People's Korea* (daily), but these are intended primarily for distribution overseas. Numerous journals are published by various agencies of the government and mass organizations.

As in other Communist countries in Asia, there are few private wireless radio receivers in North Korea. Radio broadcasting is by direct wire to loudspeakers, which are set up in factories and in open spaces in the towns and cities, and to receivers in private homes. A television broadcasting station has been established in P'ybngyang with Soviet guidance, although in the early 1970s there were only a few thousand television sets in the city.

Leisure time is scarce. Only high-ranking officials have every Sunday off. Workers usually have only one day off every other week and can expect to work overtime to meet demands for higher production. An average day begins at 6:00 AM, with mandatory calisthenics. Fourteen-hour workdays are not uncommon.

The city has a zoo and numerous parks for recreation. Boating on the Taedong-gang is popular in the summer, as is soccer. Winter sports include ice skating, sledding, and skiing.

BIBLIOGRAPHY. Few Western visitors have been allowed to visit North Korea. As a result, there are few sources of information in English that are up to date. Current information must be distilled from North Korean publications and broadcasts or gathered second hand from the few journalists and Japanese businessmen who have visited the city. *Communist North Korea: Bibliographical Survey* (1971), published by the United States Department of the Army, is the most recent guide to other sources in English. Its appendixes contain useful information about government and military organization as well as various statistics. The *Area Handbook for North Korea*, published also by the United States Department of the Army (1969), is the most complete source of information on P'yongyang. Some additional information may be gleaned from the *North Korean Central Yearbook* published annually by the government of North Korea and translated by the Joint Publications Research Service of the United States Department of Commerce. RYU HUN, *Study of North Korea* (1966); and ROBERT A. SCALAPINO (ed.), *North Korea Today* (1963), are useful only for their description of the government. SHANNON MCCUNE, *Korea, Land of Broken Calm* (1966), contains good descriptive material but is already dated. *Again Korea* (1968), by WILFRED G. BURCHETT, an Australian Communist, tends to be more of a political diatribe but does contain some descriptive material.

(B.M.J.)

PyreneesRange

A mountain chain stretching from the shores of the Mediterranean Sea on the east to the Bay of Biscay on the Atlantic Ocean on the west, the Pyrenees (French, Pyrénées; Spanish, Pirineos) form a high wall between France and Spain that has played a significant role in the history of both countries and of Europe as a whole. The range is some 270 miles (430 kilometres) long; it is barely six miles wide at its eastern end, but at its centre it reaches 100 miles in width. At its western end it blends imperceptibly into the Cordillera Cantábrica (Cantabrian Mountains) along the northern coast of the Iberian Peninsula. Except in a few places, where Spanish territory juts northward or French southward, the crest of the chain marks the boundary between the two countries, though the tiny, autonomous principality of Andorra (*q.v.*) lies among its peaks. The highest point is the Pico de Aneto, at 11,169 feet (3,404 metres), in the Maladeta (Accursed) region of the Central Pyrenees.

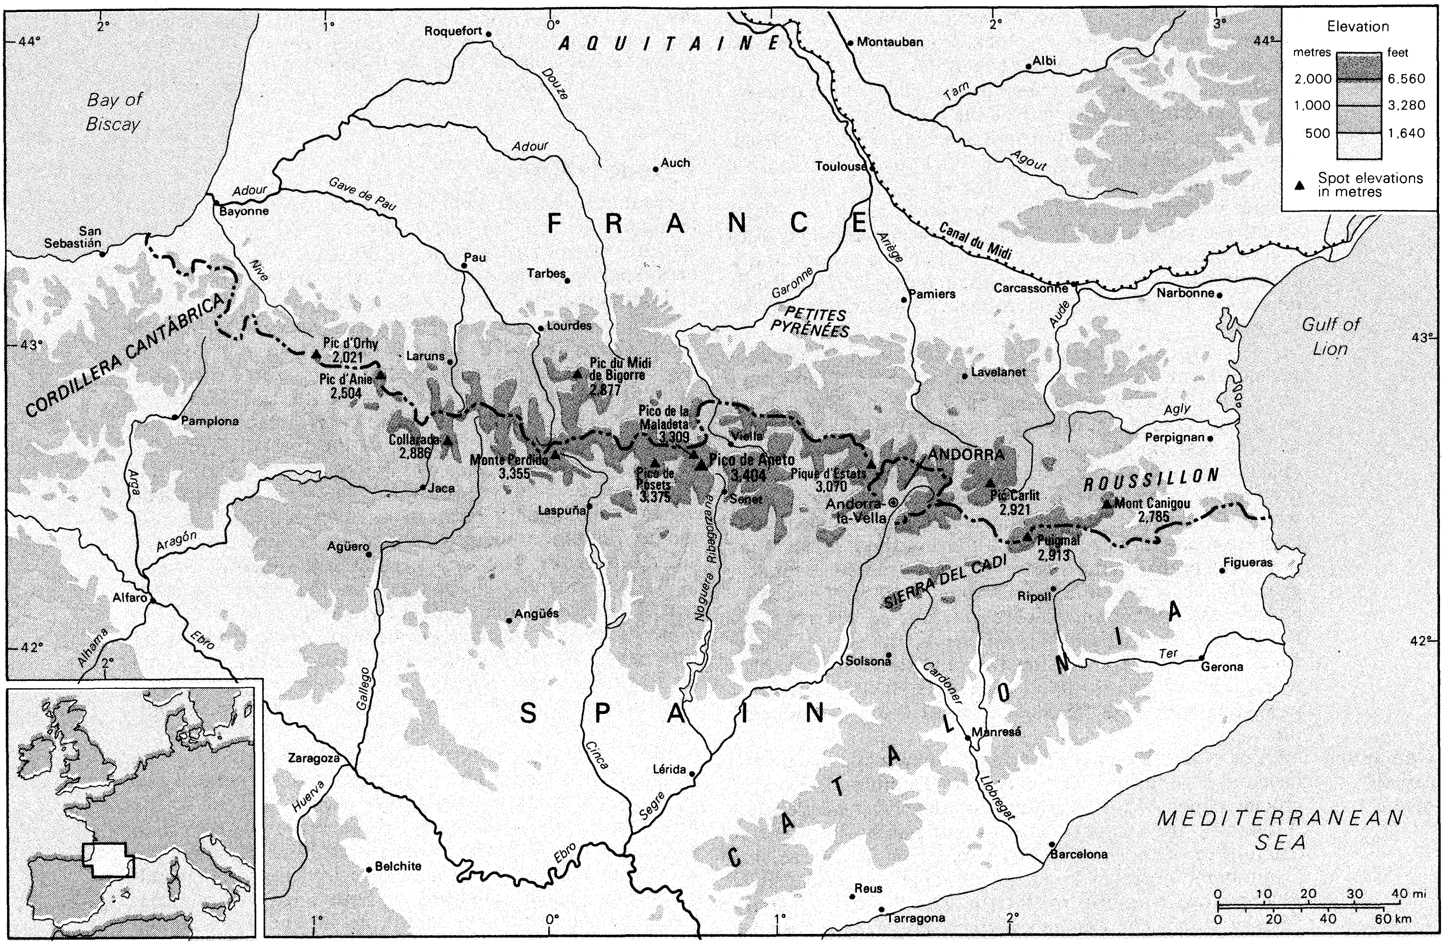
The Pyrenees long have been a formidable land barrier between Spain and Portugal on the Iberian Peninsula and the rest of Europe, helping in some way to tie these two countries more closely to Africa than the rest of Europe, and to the sea. From Pio Carlit (9,583 feet [2,921 metres]) near the eastern limit of the Pyrenees to the peaks of Orhy and Anie, a succession of mountains rise nearly 9,800 feet; at only a few places, all well to the west, can the chain be crossed through passes lower than 6,500 feet. In both the lower eastern and northwestern sectors, rivers dissect the landscape into numerous small basins. The range is flanked on both sides by broad depressions, the Aquitaine to the north, the Ebro to the south, both receiving waters from the major rivers flowing out of the mountains, the Garonne of France and the Ebro of Spain.

Scientificstudy. Until the 17th century, a general lack of knowledge about the Pyrenees permitted the repetition over centuries of errors and misconceptions about the mountains that had been propounded by such authors of antiquity as Diodorus Siculus of Sicily and the Greek geographer-historian Strabo (both, 1st century BC). In 1582 the first explorations were made, followed by botanical works from the academies at Montpellier-de-Médillan, France, and by other studies, including those of the 18th-century Swiss pioneer alpinist Horace Bénédict de Saussure. The earliest military map of the region dates from 1719, while early topographical studies were the bases of frontier treaties.

In the 19th century the first topographical and geological maps were made of the mountains, the latter beginning a series of geological interpretations and controversies among French and Spanish scientists. German studies added to the interpretive geology, but only in 1933 was the first study made that was based on modern research methods. In 1951 Luis Sol6 Sabaris published ***Los Pirineos,*** which dealt with many aspects of the range from various sources. More recent studies by universities, technical institutes, and national councils for research in France and Spain have produced an increasing amount of knowledge, and scholars of the subject have banded together in the International Union of Pyrenean Studies, which sponsors congresses to coordinate all phases of Pyrenean research.

International studies of the region

The physical environment. *The relief and its origins.* The Pyrenees represent the geological renewal of an old mountain chain rather than a more recent and vigorous mountain-building process that characterizes the Alps. Some 500,000,000 years ago the region now occupied by the Pyrenees was covered with the folded mountains created during the Paleozoic Era, a type known as Hercynian, which is represented by the Massif Central in France, the Ardennes, and the Meseta Central. Although these other massifs have had a comparatively quiet history of



The Pyrenees mountain range.

internal deformation, or tectonism, since their emergence, the Pyrenean block was submerged in a relatively unstable area of the Earth's crust, and its history was a troubled one from the beginning of the Mesozoic Era about *225,000,000* years ago.

The earliest formations, which were sediments severely folded over a granitic base, were submerged and covered by secondary sediments. They later were lifted once again into two parallel chains running to the north and south of the original Hercynian massif. These became the two zones of pre-Pyrenean ridges, of which the Spanish is the more fully developed and which are now great spurs of the main Pyrenean chain.

Under the forces of folding, the more recent and comparatively more plastic layers folded without breaking, but the original rigid base was split and dislocated. In the vicinity of the breaks, hot springs appeared and some metal-containing deposits formed. This upheaval affected chiefly the central and eastern regions. During this era, erosion was incessant, and, in the most exposed of the raised areas, weathering wore away the softer terrain and uncovered the old Hercynian sedimentary formations, occasionally reaching the deeper granitic bedrock.

Even today the old rocks, slates, schists, limestones transformed into marble (all of which come from old sediments transformed by great pressures and enormous heat), and granites of various kinds make up the spine, or axial zone, of the chain. The geological phases of this zone, which rises and widens from west to east and ends by sinking, with a steep drop of nearly 9,800 feet, into the depths of the Mediterranean, have determined the evolution of the massif as a whole.

North–south sequences of topography

The structure of the Pyrenees, therefore, is characterized by patterns of relief and of underlying structure running in a north–south sequence (like the base rock); these alternate with depressions, some of which are the result of internal deformations, others of erosion of less resistant overlying deposits. In a cross section directly through the central area, where the tectonic activity reached its fullest width and development, it is possible to distinguish, from north to south, two strips of the comparatively recent pre-Pyrenean fold, one Spanish and one French, in juxtaposition with the axial massifs. An outer strip to the north consists of folds constituting the Petites Pyrénées. Cut into channels, they permit the passage of rivers. Nearer the middle of the range rise the Inner Ridges, represented by the mighty cliffs of the Ariège, which contain the primary, or granitic, axial zones. On the Spanish side, the series is repeated in the opposite direction, but it is more highly developed and thicker. Thus the Interior Ridges—*e.g.*, Monte Perdido and the massif of Collarada—are sometimes higher than the neighbouring primary axial peaks. They are followed, going south, by a broad, pre-Pyrenean, middle depression, with a succession of marine and continental deposits of varying hardness that constitute the valleys of such tributaries of the Ebro as the Aragón. This depression continues across the rest of the pre-Pyrenean ridges, among which are new secondary outcrops that form the fringe of Exterior Ridges and the northern rim of the depression of the Ebro; they are not, however, as thick or as important as the Interior Ridges.

From the structure of their relief and from the climatic conditions (especially on the south) that derive from the geographical situation of the chain, the Pyrenees have been divided into three natural regions: the Eastern, or Mediterranean, Pyrenees (in Spanish, Pirineos Orientales, and Pyrénées Orientales in French); the Central Pyrenees; and the Western Pyrenees. The different vegetation, the linguistic divisions of the people, and—to a point—the racial characteristics and certain cultural distinctions would appear to confirm this classification.

Pyrenean climate and climatic effects. Major factors in the climate are the two abutting bodies of water and the extensive continental areas to the north and south. The oceanic influence penetrates southward across the

Marine and terrestrial influences on climate

low peaks of the Western Pyrenees, as far south as Pamplona, tempering somewhat the differences of climate between the northern and southern slopes. This is not the case in the rest of the chain, especially the Central Pyrenees. The contrast in humidity between the French and Spanish sides is remarkable. To the north, the oceanic influence, meeting no obstacles on the French plains of the Aquitaine, penetrates and goes a little beyond the north–south watershed of the French rivers flowing into the Mediterranean. To the east, the levanters, winds from the east and southeast, carry damp air from the Mediterranean, some of which falls as precipitation over the southeastern part of the eastern spurs. As a result, these regions are humid, while to the northeast the French depressions of the Roussillon acquire very Mediterranean characteristics.

South of the Central Pyrenees the valley of the Ebro—which runs in a general northwest–southeast direction and is blocked by the southwest–northeast-trending Catalonian ranges near the eastern coast of Spain—acts as a "little continent." Hence, its climate is one of great thermal contrasts that are exaggerated by the generally high altitude of the peninsula, but it is Mediterranean and unlike anything known in other European countries. Thus the variegated climatic pattern of the Pyrenees ranges from the limpid, sunny atmosphere of the continental zone to the mild mists of the northwest and includes all transition stages in between.

River systems. The hydrographic system consists basically of series of parallel valleys that descend from peaks of over 9,800 feet and from passes, most of which in the Central and Central-Eastern areas are above 6,500 feet. They are bordered by high, dividing ridges in a north–south direction, perpendicular to the axis of the chain. This type of valley produces short, torrential rivers that drop a long distance over short stretches; only seldom do these rivers flow, like the Aragón, through valleys that, as in the Alps, have both gentle slope and greater length. Their flow, extremely variable, especially on the southern side, is heavily influenced by the climate, as well as by the relief. Different maximum low waters occur in summer and winter; the spring, with maximum rain and melting snow, usually sees the greatest flows. In the Western Pyrenees and the northern zone, the rainfall pattern helps produce greater regularity; hence, flow is only slightly lower in summer. On the south, a few torrential rivers are fed principally by melting snows, a few largely by rain, but most from a combination of sources.

The river patterns and flow have been most important since antiquity in man's utilization of both the land and the rivers—from the floating of timber rafts downstream, which can only be done in the spring, to harnessing waterpower for industry and irrigation on the southern side by means of dams. The torrential flow of many of the rivers is the cause both of the crystalline purity of the Pyrenean waters and of their excellence and richness as fishing streams.

Glaciation. The present Pyrenean glaciers, perhaps more frequent on the northern than on the southern slopes, have been reduced to high basins—cirques or hanging valleys—at heights of over 9,800 feet. During the Pleistocene and Recent epochs (within the past 2,500,000 years), however, especially in the Central and much of the Eastern Pyrenees, glaciers left widespread erosion and various important sediments. The present-day lower lakes, or *ibdnes*, and idyllic meadows with their winding rivulets are among their marks. Glacier tongues were also the main causes of the deep valleys containing the river system.

Hotsprings. The fractured areas have many hot springs, both sulfurous and saline. The former are found throughout the axial massif, while the latter occur at the edges. These springs were exploited in Roman times, rediscovered in the 17th century, and reorganized and modernized toward the end of the 19th century. Over 20 famous examples occur on the French side; those in Spain are as numerous but are less fully exploited.

Bioecology and human uses. Forms of life in the Pyrenees have some remarkable characteristics that cannot be explained merely by the influences of climate and soil. The historical vicissitudes of the chain and its isolation at the southwestern limit of the main European peninsula, far from the centres of dispersion and variation of the various species (including man), have influenced the structure and character of its population.

Animal life. Some groups among the fauna, such as the cave-dwelling animals and frogs and toads, represent a migratory wave that come from ancient Tyrrhenia, associated with Corsica and Sardinia, and displaced certain native European species, relegating them to the Cordillera Cantábrica. The Pyrenean fauna is rich today, both in larger herbivores as well as in the variety and abundance of predators, though some species—*e.g.*, the wolf and the lynx—have disappeared. The southern Pyrenees represent one of the last important reserves for wild European fauna driven out of sectors more heavily populated by man. The present distribution and differentiation of large, warm-blooded animals is undoubtedly connected with the climate and the landscape, but the dominant feature is evidence of central European origin.

Distant origins of plant and animal life

Vegetative types. Similar comments may be made as to the origin of all cold-blooded animals, as well as of the vegetation. Basic differentiations exist among the latter. Pyrenean flora of tropical origin differentiated without any ancient European competition as the new chain replaced the old Hercynian; flora of Arctic origin, brought southward during relatively recent ice ages, are represented by two different branches of orophiles, or plants adapted to mountain life, from central Europe and from Siberia. Other orophiles have long been differentiated, but they are of Mediterranean origin and are dominant in the drier, sunnier parts of the southern slopes. An Atlantic group of flora predominates in the Western Pyrenees.

Climate and to a lesser extent soil are the conditioning elements in the vegetation of the Pyrenees, and there are two traditional methods of classifying vegetative types. One is classified by horizontally defined geographical regions, the other by vertically defined variations of climate, which varies with altitude.

In the northwest–southeast direction, the vegetation shows a marked and gradually decreasing oceanic influence; the contrary is the case with the Mediterranean influence from southeast to northwest. The exposure of the mountain surfaces and the conditions of local climate caused by mountain relief create special localized enclaves of all kinds. The most characteristic feature of the oceanic influence is the predominance of flat-leaf deciduous trees in the forests of the lower levels and the medium-height mountains, while the Mediterranean influence, represented by evergreen flat-leaved trees, is not only dominant in hot surroundings but also bears drought conditions better.

The variety of altitudinal vegetation shows itself in levels. From the medium-height mountain upwards, the flat-leaf woods at about 5,200 feet are replaced by needled conifers that require less water. This subalpine level, sometimes as low as 6,500 feet but usually above 7,800, gives way to the more sparsely covered pastures of the alpine level. This altitudinal scheme pertains in the vegetation east of the Orhy and Anie peaks. The oceanic influence, however, with its greater rainfall gives the west of the chain a different pattern. Flat-leaved deciduous beeches may be found as high as 5,850 feet, with some mix of the subalpine conifers, and there the high pastures are more resistant to damp and permanent snow. Overall the landscape is more like that of the high mountains of western Europe.

The Mediterranean influence expands through the entire valley of the Ebro, but it acquires marked signs of a more variable continental climate in the Central Pyrenees. Here, great quantities of mountain pines, which are more drought resistant, take the place of all kinds of flat-leaved deciduous trees in the higher, colder, and drier parts of the medium and higher levels of the southern slopes.

Patterns of human settlement. Similar factors influence man's utilization of the land, the kinds of crop, and the farming system of each district. In the Eastern Pyrenees and at the foot of the southern slope, summer droughts

Interactions of man and his environments

make irrigation and the development of a variety of horticultural crops imperative: plots of vegetables require borders of fruit trees. In this dry land, the woods have not been properly used, and the typical Mediterranean trilogy of olives, vines, and cereals predominates. In the Western Pyrenees, the abundant rainfall makes irrigation unnecessary for obtaining potatoes, sweet corn, and forage crops. The landscape there is profoundly marked by the traditional European checkering of tilled fields framed by more or less luxuriant hedgerows, shrubs, and climbing plants.

Few crops reach the mountain fringe of deciduous trees, and there the wood is used for firewood, furniture industries, and construction. At the subalpine level, meadows and pasture occupy nearly all the land; at 4,500 feet lies a zone balanced between woodland and pasture, while higher up the land is devoted almost entirely to stock breeding. This last activity must be intensive, for only about 90 days a year are suitable for grazing at the higher altitudes. The seasonal process of moving the flocks up and down the mountains maintains all the rich flavour of old traditions, but this way of life faces an increasing number of obstacles. The intensive farming of the plain lessens the acreage available for winter pasturing, and modern communications and economics eat away at the old ways.

As in all mountains, history has shown that the three basic resources are water, forests, and livestock. Agriculture, which has scant possibilities here, is always subordinate to stock breeding. Mining remains of little importance because it is so scattered. The hydroelectric potential is considerable. The ibdnes hanging at over 6,500 feet and the great rivers that can be dammed permit the establishment of industries without great transportation costs —*e.g.*, textiles and chemicals and above all those that utilize wood. Thus, there is a certain specialization or at least a tendency toward specialization in each of the three Pyrenean areas. The woodland and pastoral character is most apparent on the north side of the central area. The Western Pyrenees are markedly industrialized, while the Eastern Pyrenees are essentially agricultural, but industrial expansion is growing in their lower valleys. The transformation achieved goes hand in hand with the gradual development of communications, which is more noticeable at the two ends of the chain. The other regions remain in somewhat of an archaic substratum of economic life, and it will be difficult to stop the flight from the land without intelligent renovation of equipment and variation in the traditional modes of living. Finally, tourism, which began with the old Roman spas, is being revitalized with winter sports, hunting and fishing, and by a love of nature in general. This pathway offers the people of the Pyrenees a growing sense of forward movement.

BIBLIOGRAPHY. In English the reader will find the following of particular interest: NINA EPTON, *Navarre* (1957); HENRY R. FEDDEN, *The Enchanted Mountains* (1962); J.B. MORTON, *Pyrenean* (1938); and HENRY MYHILL, *The Spanish Pyrenees* (1966). In Spanish, LUIS SOLE SABARIS, *Los Pirineos* (1951), covers both sides of the Pyrenees with scholarly detail and illuminating generalizations; R VIOLANT Y SIMORRA, El *Pirineo espaiiol: Vida, usos, costumbres, creencias y tradiciones de una cultura inilenaria que desaparece* (1949), is a more popular volume with hundreds of photographs, giving greater emphasis to the human aspects of Spanish Pyrenean life. In French, the classic M. SORRE, *Les Pyrénées* (1922), is the first modern scientific study; P. ARQUE, *Géographie des Pyrénées Francaises* (1943), deals with the French Pyrenees.

Pyroxenes

Occurrence and use

The pyroxenes are an important group of rock-forming silicate minerals of variable composition, among which calcium-, magnesium-, and iron-rich varieties predominate. The name is derived from the Greek pyro, "fire," and *xenos*, "stranger," in allusion to their occurrence in volcanic rocks, which was initially thought to be accidental rather than indigenous. Pyroxenes are the principal minerals in many kinds of igneous (crystalline) and metamorphic (altered) rocks, however, and they occur in meteorites and lunar samples as well. Omphacite, a variety rich in sodium and aluminum, and aluminous enstatite are thought to be abundant in the Earth's mantle—the zone directly beneath the crust—and analysis of the ıadiation emitted by certain cool stars reveals the probable presence of pyroxenes throughout the known universe.

Certain pyroxenes are useful as economic mineral guides, or indicators: johannsenite is generally associated with copper, zinc, and lead ores; omphacite occurs with diamond in kimberlites (relatively rare igneous rocks that are rich in iron and magnesium); and spodumene and aegirine (lithium aluminosilicate and sodium ferrisilicate minerals, respectively) are often indicators of pegmatites—very coarse-grained crystalline rocks that commonly contain a rare-mineral assemblage. Aside from this usage as indicators or guide minerals, only jadeite, nephrite—ornamental jade—and spodumene, a commercial source of lithium, are of economic importance.

Form, habit, and colour

All pyroxene species exhibit a prismatic crystal form in which the angles between crystal faces are about 87° and 93°. The pyroxenes have good cleavages parallel to these directions—*i.e.*, they tend to split along planes that have these trends. As a consequence, the pyroxenes possess nearly square cross sections when viewed perpendicularly to their principal cleavage directions, and this characteristic is diagnostic. Most of the pyroxenes in rocks in the Earth's crust, however, occur as irregularly shaped grains; short, stubby, prismatic crystals are less common.

Aegirine commonly occurs as long, needle-like crystals, and spodumene as prismatic crystals that are as large as 12 metres (40 feet) long and two to six feet wide. These two minerals are associated with very coarse-grained pegmatites.

The colour of pyroxenes varies with slight changes of chemical composition: augite is brown or green; diopside is either colourless or white to green; and aegirine is green to greenish black. Some varieties of jadeite and spodumene may be violet or pink.

This article treats the crystal structure and chemical composition of the pyroxenes and their natural formation and synthesis. For further information on crystal structure in general, see CRYSTALLOGRAPHY; and for an overview of rock-forming minerals and their place within the hierarchy of all minerals, see SILICATE MINERALS; and MINERALS. Ornamental varieties of pyroxenes are further considered in the article GEMSTONES. See also GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES for relevant coverage of conditions of pyroxene formation.

CLASSIFICATION AND PROPERTIES

Variation of composition and physical properties

Mineral names and groups. The naming of a pyroxene depends upon its major element composition and crystal system, and the more refined aspects of minor element content and crystal structure often require prefixes. Diopside, for example, is primarily a calcium (Ca) magnesium (Mg) silicate ($CaMgSi_2O_6$) and crystallizes in the monoclinic system, which refers to three unequal crystallographic axes, two intersecting obliquely and the third perpendicular to these two. Diopside has the basic pyroxene crystal structure but differs in detail from another monoclinic pyroxene such as spodumene. A trace content of chromium also is sufficient in some cases to warrant the name chrome diopside. Enstatite is primarily magnesium silicate ($Mg_2Si_2O_6$) and usually crystallizes in the orthorhombic system, which refers to three unequal crystallographic axes that are mutually perpendicular, but polymorphism (the ability of a mineral species to occur in different forms) gives rise to other crystal structures with the same composition. These may be orthorhombic such as protoenstatite or monoclinic such as clinoenstatite. A trace content of aluminum may warrant the name aluminous enstatite. For diopside, a marked increase of iron in place of magnesium leads to hedenbergite; magnesium in place of calcium leads to clinoenstatite; and magnesium and iron in place of calcium yield augite and ultimately pigeonite. This subgroup of pyroxenes, which is by far the most common, can first be expressed chemically in terms of three end-members (pure compounds): calcium silicate ($Ca_2Si_2O_6$), magnesium silicate ($Mg_2Si_2O_6$), and iron (Fe) silicate ($Fe_2Si_2O_6$).

The pyroxene formulas listed in the Table are relevant only to these end-member compositions, and the sections of this article on crystal structure and chemical composition explain the relationships between these and the more common intermediate variants. The general composition of the pyroxenes, in fact, must be expressed as: XYZ_2O_6, in which X is zero or one, Y is one or two, and X + Y = 2. The compositional range can be indicated by the array of possible substituting elements—*i.e.*, X = calcium, sodium, or, less commonly, lithium; Y = magnesium, iron, aluminum, or, less commonly, manganese, nickel, chromium, and titanium; and Z = silicon, but aluminum or ferric iron also may occur.

Certain optical properties serve to differentiate the pyroxenes, but other physical properties tend to be rather uniform. The hardness of these minerals is 6 to 6½ on Mohs' scale (ranging from talc = 1 to diamond = 10), the lustre is vitreous or glassy, and the form and habit also tend to be rather similar because of the good cleavage at 87" and 93" as previously noted. Density variations (see the Table) are diagnostic of iron enrichment.

The Pyroxene Minerals

mineral	chemical formula	unit-cell dimensions*			density (g/cm³)
		a	*b*	*c*	
Diopside	$CaMgSi_2O_6$	9.73	8.91	5.25	3.25
Hedenberaite	$CaFe^{2+}Si_2O_6$	9.85	9.02	5.26	3.54
Enstatite	$Mg_2Si_2O_6$	18.23	8.81	5.19	3.21
Ferrosilite (Ortho)	$Fe_2^{2+}Si_2O_6$	18.43	9.06	5.26	3.96
Aegirine (or Acmite)	$NaFe^{3+}Si_2O_6$	9.65	8.79	5.29	3.56
Jadeite	$NaAlSi_2O_6$	9.50	8.61	5.24	3.25
Spodumene	$LiAlSi_2O_6$	9.50	8.30	5.24	3.16
Johannsenite	$CaMnSi_2O_6$	9.83	9.04	5.27	3.45

*The unit cell is the smallest volume that will provide a representative sample of the atomic and molecular groups that comprise a mineral. Dimensions are given along the three crystallographic axes (designated *a*, *b*, and *c*) in angstrom units (one angstrom unit equals 10^{-8} centimetre).

Basic pyroxene chain structure

Crystal structure. The crystalline structure of all pyroxene minerals consists basically of four oxygen atoms arranged as a tetrahedron with a silicon atom at its centre. These tetrahedrons are linked in the form of chains, a structure similar to that of the amphiboles. The linkage is effected by the sharing of two oxygens between neighbouring tetrahedrons in the chain, so that the basic formula becomes one silicon (Si) to three oxygens (0), or SiO_3. Identical units of the chain are repeated at approximately 5.3-A (one angstrom unit [A] equals 10^{-8} centimetre) intervals; this direction defines the c-axis of the crystal, and the distance is the dimension of the unit cell in the c-direction. The linkage of a pyroxene chain viewed from various directions is shown in Figure 1.

The diopside structure consists of only one type of chain, which is also characteristic of jadeite, augite, and protoenstatite. In contrast, the clinoenstatite and pigeonite structures consist of two structurally distinct SiO_3 chains. The orthorhombic pyroxenes have a unit cell that is derived by twinning (repetitive intergrowth) of the latter structure along the a-axis. In spodumene there is a slight deviation whereby two different kinds of SiO_4 tetrahedrons alternate along one kind of chain, and in omphacite this alternation occurs along each of two kinds of chain to produce a low-symmetry structure capable of accommodating a wide variety of cation (positively charged atom) sizes.

The diopside structure

The tetrahedrons may show some substitution of silicon by aluminum and, less commonly, by traces of ferric iron or titanium. Most of the important cations other than silicon, however, occur as layer cations that are linked to the chain oxygens to form cation–oxygen polyhedrons. Thus, the chains themselves are linked together by these cations to form a structure that is weakest parallel to the dominant cleavage direction of all pyroxenes.

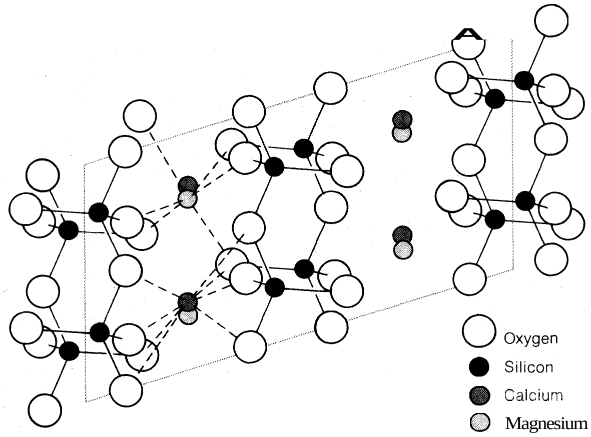

Figure 2: Idealized structure of diopside as viewed along the y direction.

The diopside structure may be taken as an example. Calcium and magnesium are divalent (doubly charged) cations that fulfill charge balance requirements to give the formula $CaMg(SiO_3)_2$. These cations lie in octahedral layers parallel to (100)—*i.e.*, a plane that intersects the a-axis and is parallel to b and c (see CRYSTALLOGRAPHY)—but occur in two crystallographically distinct cation sites. The small magnesium ion (ionic radius = 0.78 A) lies in the M_1 site and is linked with six oxygen atoms to form a fairly regular octahedron. The larger calcium ion (ionic radius = 1.06 A) in the M_2 site, however, is linked with eight oxygens. Chemical substitution within the pyroxene group allows the M_1 site to be occupied by many small cations such as magnesium, ferrous and ferric iron, aluminum, or manganese. The M_2 site is usually occupied by the larger cations such as calcium or sodium, but in calcium-poor pyroxenes the site is occupied by smaller cations such as magnesium or ferrous iron in hypersthene or sodium in jadeite; the M_2 polyhedrons are then distorted octahedrons. In the pigeonite structure, which is somewhat problematical, disordered calcium and ferrous iron probably occupy the M_2 site in irregular 7-fold coordination (*i.e.*, surrounded by and bonded to seven oxygens), whereas M_1 is occupied by disordered magnesium and ferrous iron in regular 6-fold coordination. This condition may, in fact, be an average of randomly arranged domains of diopside-type and clinoenstatite-type structures.

The simpler structure of diopside is illustrated in Figure 2, in which the M_2 site is occupied by calcium in 8-fold coordination and in which the M_1 site is occupied by

Photomicrographs of various pyroxene minerals in thin sections (illuminated with polarized light). (Left) Augite phenocryst (large, individual, gray crystal) in basalt lava, showing characteristic basal octagonal form and square-segmentation cleavage (magnified about 18.5 X). (Centre) Titanaugite crystal (yellow) showing typical hourglass zoning (magnified about 13.2 X). (Right) Gabbro with two pyroxenes, a calcium-rich augite (blue-red and green) enclosed by a calcium-poor pigeonite crystal; clinohypersthene in thin lamellae has separated from the calcium-rich augite, and augite has separated from the pigeonite before it inverted to hypersthene (gray; magnified about 21.1 X).

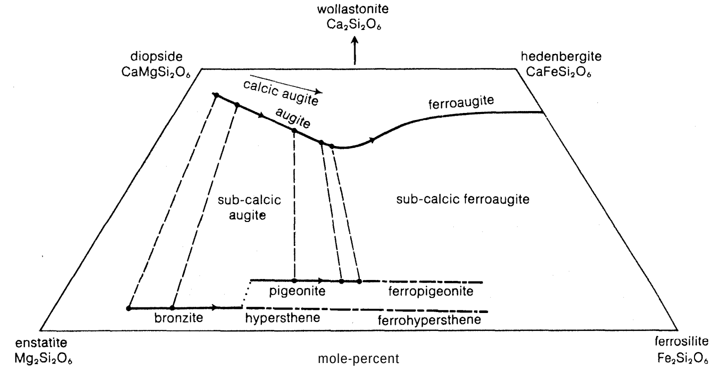
magnesium in 6-fold coordination. Hedenbergite would differ only by the presence of ferrous iron rather than magnesium in the M_1 site, and in the common augite both the M_1 and M_2 sites must be disordered between calcium, magnesium, and ferrous iron.

In the calcium-poor pyroxenes, the structural relations are more complex and lead to polymorphism. Magnesium silicate ($Mg_2Si_2O_6$) may be taken as an example. Three structural forms exist: clinoenstatite, rhombic enstatite, and protoenstatite. In these, successive tetrahedral slabs are related by glideplanes of symmetry parallel to (100), the glide component acting along either direction of the c-axis (see CRYSTALLOGRAPHY).

Chemical composition. The term common pyroxenes is applied to the great majority of minerals with compositions that can be expressed in terms of their calcium silicate ($Ca_2Si_2O_6$), magnesium silicate ($Mg_2Si_2O_6$), and iron silicate ($Fe_2Si_2O_6$) molecular contents. Compositions plotted on a triangular diagram show distinct pyroxene groupings that are of the greatest significance. No pyroxenes plot in that part of the diagram more calcic than the join (boundary line between phases) at $CaMgSi_2O_6$ and $CaFeSi_2O_6$ because of the structural prohibition of calcium from entering the M_1 sites. The common pyroxene quadrilateral is shown in Figure 3.

The pyroxene quadrilateral

The nomenclature of the common clinopyroxenes was once based on subdivision of the quadrilateral, but the rigidity of the nomenclature and the orientation of the boundary lines between each named type proved unsatisfactory. It is now known that relationships within and between the common pyroxenes simplify the diagrammatic representation of their compositional fields within the quadrilateral.



gι re 3: C(non pyr quadrilateral showing the compositional ranges f various py

Pyroxenes plotting close to or on the diopside–hedenbergite join are found only in metamorphosed calcium silicate rocks, for example by the reaction

$$\underset{\text{dolomite}}{CaMg(CO_3)_2} + \underset{\text{quartz}}{2SiO_2} \rightleftharpoons \underset{\text{diopside}}{CaMgSi_2O_6} + \underset{\text{carbon dioxide.}}{2CO_2}$$

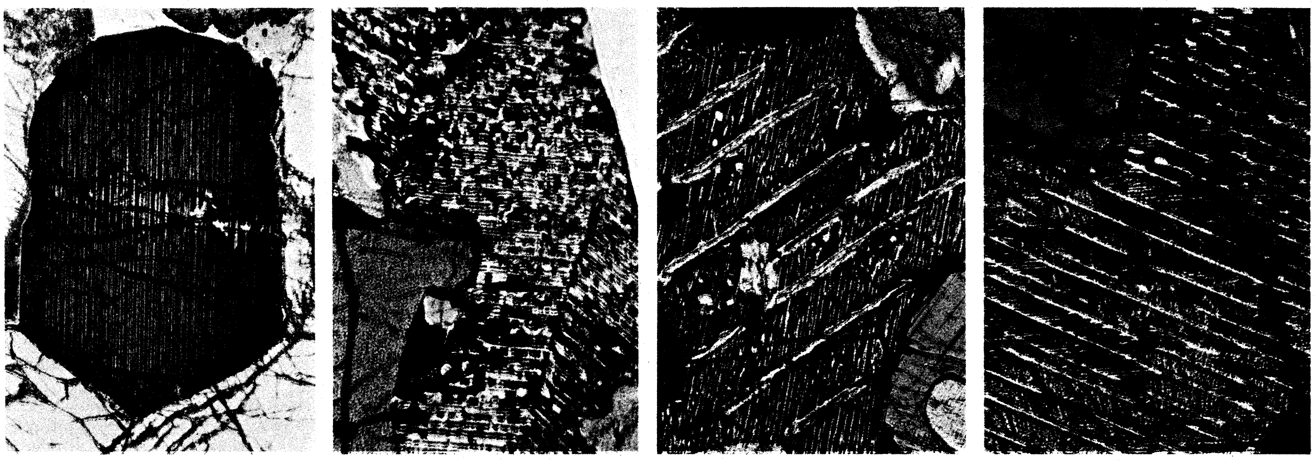
The calcic augites occur in alkali basalts and their derivatives and are usually richer in aluminum and titanium than the augites. The calcic augites do not have iron-rich variants because their parent magmas (molten silicate material from which igneous rocks crystallize upon cooling) generally produce liquids from which aegirine-augite and aegirine precipitate. The titanium-rich varieties are known as titanaugites and often exhibit hourglass zoning. The augites are the most common pyroxenes and show extensive magnesium–iron substitution to give the distinctive augite–ferroaugite trend line. Extreme fractionation of tholeiitic (olivine-poor) basalt magma is depicted by this trend of pyroxenes: diopsidic augite in ultramafic rocks (composed almost entirely of iron magnesium silicate), to augite in less mafic gabbroic rocks, to ferroaugite in intermediate, dioritic rocks (containing some quartz and sodium feldspar), and to ferrohedenbergite in acid, granitic rocks (rich in silica). The subcalcic augites and subcalcic ferroaugites occur as metastable phases (subject to further change under existing conditions) in the quickly cooled groundmass (fine-grained crystalline bulk) of lavas. The tholeiitic suite of differentiated rocks generally contain, in addition to a member of the augite series, a calcium-poor pyroxene with, approximately, either 5 percent (bronzite) or 10 percent (pigeonite) of calcium silicate. The ultramafic rocks usually contain a bronzite, the gabbroic rocks a pigeonite, the intermediate rocks a ferropigeonite, and the acid rocks have no calcium-poor pyroxene. Certain intermediate rocks, notably the andesite and dacite lavas, contain hypersthene or ferrohypersthene instead of a pigeonitic phase.

The enstatite–ferrosilite pyroxene series is not fully represented on the quadrilateral. The nomenclature, based on ferrosilite percentage, is: enstatite (0–10 percent), bronzite (10–30 percent), hypersthene (30–50 percent), ferrohypersthene (50–70 percent), eulite (70–90 percent), ferrosilite (90–100 percent).

Aluminum and other elements

The aluminum (Al) content of the common pyroxenes varies with temperature and pressure of crystallization, and, in cases in which two pyroxenes are present, it is higher in the calcium-rich phase. In ultramafic nodules from basalt, enstatites contain up to 5.5 percent (average about 1.5 percent in lava orthopyroxenes), and calcic augites contain about 6.5 percent alumina (Al_2O_3). Compared with coexisting olivines, pyroxenes show higher chromium and vanadium and lower nickel and cobalt contents. With fractionation, augites show depletion in chromium, vanadium, and nickel and slight enrichment in scandium. Coexisting calcium-rich and calcium-poor pyroxenes have a distribution of magnesium and iron between the phases that may ultimately be a valuable indicator of the pressure and temperature of formation. At present the distribution is too much influenced by other factors, including the oxidation state of the iron and aluminum content, to be dependable.

The less common pyroxenes have a more simple chemistry, which is expressed chiefly by the formulas in the Table. In aegirines the main replacement is sodium and ferric iron by calcium, magnesium, and ferrous iron to give aegirine augites, although varieties with up to 4 percent vanadium oxide and 5 percent manganese oxide have



Photomicrographs of various thin sections containing pyroxene minerals; all show separation within a mineral grain of distinct phases due to further cooling after the grain had solidified (illuminated by polarized light). (Far left) Bronzite crystal from an ultramafic rock; thin lamellae of a calcium-rich species, probably pigeonite, have separated from the bronzite, and the host (grayish) thus has a very low calcium content (magnified about 40 X). (Left) Twinned crystal of inverted pigeonite from a gabbro. Augite, seen as brightly coloured thin lamellae with herringbone texture because of the twinned relationship, has separated from the pigeonite; further cooling has caused the host, gray-coloured hypersthene, to change symmetry (invert; magnified about 22×). (Right) Inve[illegible] it r[illegible] a [illegible] e [illegible] ly cooled gabbro than that at left as a [illegible] l . the ugite lamellae are wider, and after inversion more augite has separated from the hypersthene host (magnified about 70.4 X). (Far right) Complex separation of augite from an inverted pigeonite (magnified about 70.4 X).

been reported. Ferroan johannsenite with about 13 percent iron oxide is transitional to hedenbergite. Omphacite (rich in sodium and aluminum) and fassaite (rich in aluminum and ferric iron) are otherwise of diopside composition.

PHASE RELATIONS AND STABILITY

Pyroxenes can be formed over a very wide range of temperatures, representing their stability in low-grade metamorphic rocks (subject to low temperatures and pressures), at the one extreme, and ultramafic nodules from upper-mantle sources, at the other. Diopside is formed under low carbon dioxide pressures at 300" C (57" F) from dolomite and silica and from a diopside melt at 1,391" *C* (2,536" F). The stability fields of pyroxenes are relatively larger at higher temperatures, however, and the more common phases are found in igneous and high-temperature metamorphic environments. Hydrothermal (referring to hot, water-rich fluids derived from magma) alteration usually produces amphibole or chlorite, but pyroxenes are generally resistant accessories in detrital sediments.

Pressure–temperature conditions

The pyroxene quadrilateral (Figure 3) has been studied extensively. Diopside (di) has no known polymorphs, and its pressure–temperature phase diagram is a simple melting curve: at low pressures the rate of change of temperature with pressure is 15° C (59° F) per kilobar (the bar is a pressure unit equal to 10^6 dynes per square centimetre). Enstatite (en) melts incongruently (accompanied by reaction with the liquid) at low pressures but congruently at about 2.3 kilobars. With respect to the di-en join at atmospheric pressure (Figure 4), reaction and crystallization result in two coexisting pyroxenes at temperatures below 1,400" C (2,550" F), calcium-rich and calcium-poor. The calcium-poor phase at solidus temperatures (the solidus is the locus of points on a phase diagram above which solid and liquid are in equilibrium and below which the system is entirely solid) is a protoenstatite solid solution (single crystalline phase that varies in composition within finite limits), and the calcium-rich phase is an augite solid solution. At subsolidus temperatures each phase exsolves (when solid solutions become unstable because of temperature change, the phases may separate out, or exsolve) the other phase and changes composition along the domed limbs of the curve. At about 1,100" C (2,000" F), the protophase inverts to a slightly more calcic, orthorhombic phase that then continues to exsolve diopside to 800" C (1,500" F) or lower. This bears general comparison with natural pyroxenes, except that the protoenstatite phase is rare. It inverts to clinoenstatite on quenching and ceases to be stable above about eight kilobars.

From F.R. Boyd and J.F. Schairer, "The System $MgSiO_3$-$CaMgSi_2O_6$," *Journal of Petrology*, Vol. 5, no. 2 (1964); Oxford University Press

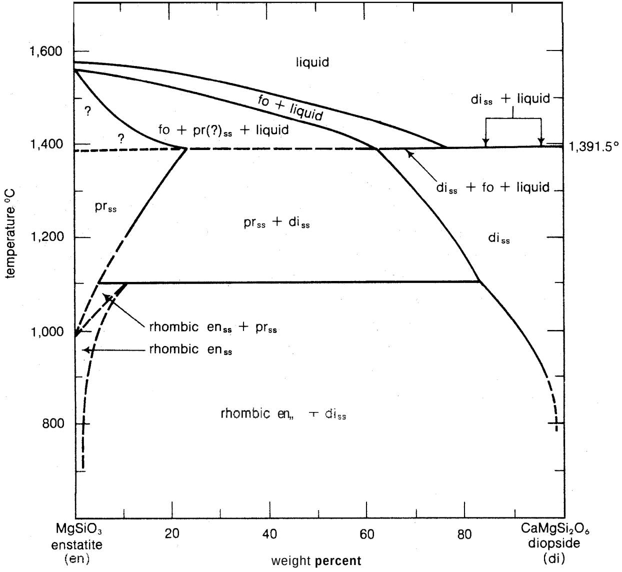

Figure 4: Equilibrium relations along the enstatite–diopside join. The phases of various mixtures of pure enstatite (en) and pure diopside (di) are shown as a function of temperature at atmospheric pressure. Other phases shown are protoenstatite (pr) and forsterite (fo), an olivine with the composition Mg_2SiO_4.

Pyroxenes in the hedenbergite (Hd)–ferrosilite (Fs) system are not stable at liquidus temperatures (above the liquidus temperature a system is completely liquid), the higher temperature equivalents being ferriferous wollastonite, fayalitic olivine, and a silica phase (see Figure 5). Ferrohedenbergite is stable below about 950" C (1,750" F), but ferrosilite is totally unstable at these low pressures. Pressure increases the stability field of hedenbergite, and at about 13 kilobars the iron wollastonite field is eliminated. At about 17 kilobars, ferrosilite is stable and melts congruently, although the high-temperature liquidus phase has a problematical pyroxene structure.

The diopside–enstatite and enstatite–ferrosilite phase relations would be simple solid solutions between each

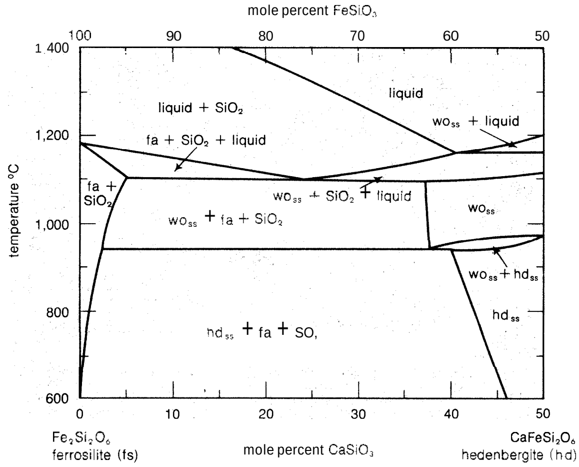

Figure 5: Equilibrium relations for the iron-rich pyroxenes along the ferrosilite–hedenbergite join. The phases of various mixtures of pure ferrosilite (fs) and pure hedenbergite (hd) are shown as a function of temperature at atmospheric pressure. Other phases, the result of the instability of pyroxenes at elevated temperatures, are iron-rich wollastonite (wo), the olivine fayalite (fa) with a composition of Fe_2SiO_4, and silica (SiO_2).

From D.H. Lindsley, G.M. Brown, and I.D. Muir, *Mineralogical Society of America* Special Paper *2* (1969)

end-member if it were not for the complexities shown on Figures 4 and 5. Natural pyroxene occurrences indicate the need for a restudy of the enstatite–ferrosilite system, of the effect of diopside on hedenbergite phase relations, and of compositional joins within the quadrilateral.

Confirmation by mineral synthesis

The broad natural relations shown in Figure 3 are confirmed by synthetic studies. Augite and bronzite coexistence, for example, results from the demonstrated instability of protopyroxene at moderate pressures and iron content. Inversion to clinoenstatite from protoenstatite occurs in a Papuan lava and in enstatite–chondrite meteorites. Pigeonite is stable at high pressures on the diopside–enstatite join but in nature is only found in the composition range shown on Figure 3, coexisting with augite. Inversion of pigeonite occurs in slowly cooled gabbros and dolerites unless they are iron-rich. The inversion product is orthorhombic hypersthene, with augite exsolution lamellae (thin layers) that indicate the previous monoclinic structure. Exsolution at 1,000" C and inversion at 980" *C* have been shown by experimental studies at zero pressure. The cessation of the calcium-poor pyroxene trend (Figure 3) is explained by ferrosilite instability, the end point of the calcium-rich trend coincides with the minimum for Wo,, + Hd,, shown on Figure 5, and the absence of iron wollastonites in all but low-pressure environments is also confirmed.

The occurrence of Tschermak's molecule

Aluminous pyroxenes contain the so-called Tschermak's molecule ($CaAl_2SiO_6$), which alone is stable above 1,150" C (2,100" F) and 11 kilobars. This molecule and the magnesium aluminum silicate molecule ($MgAl_2SiO_6$) are molecular expressions of the aluminum that can enter pyroxene structures at high pressure. In magnesium silicate ($MgSiO_3$), the alumina (Al_2O_3) solubility increases from 2.5 percent at atmospheric pressure to 14–19 percent at 20 kilobars, but it decreases at higher pressures. Diopside, however, can contain 12–15 percent Al_2O_3 at atmospheric pressure. Ferric diopsides contain ferri-Tschermak's molecule ($CaFe_2SiO_6$) produced, with andradite garnet and quartz, by oxidation of augites. More sodium in the magma would lead to formation of aegirine (acmite), which melts incongruently to hematite + magnetite + liquid up to 45 kilobars and from low to high oxygen pressures. Experiments at 40 kilobars suggest complete solid solubility between acmite and jadeite. Jadeite (from albite + nepheline) is only stable above about 17 kilobars (900" C [1,650° F]), and jadeite + quartz (from albite) is stable above about 25 kilobars at similar temperatures. Omphacite is a jadeite–diopside solid solution with a fairly wide pressure-staoility range if viewed in isolation from other phases. At 30 kilobars, it splits into jadeitic and diopsidic phases at about 1,450" C (2,640" F). Spodumene is the high-pressure member of three polymorphs with lithium aluminum silicate compositions ($LiAl\ Si_2\ O_6$). At 10 kilobars and 900" C (1,650" F), it converts to a form called *β*-eucryptite, so that its low-pressure pegmatite environment must imply crystallization well below 900" *C*.

Pythagoreanism

The philosophical school and religious brotherhood known as Pythagoreanism is believed to have been founded by Pythagoras of Samos, who settled in Croton in southern Italy about 525 BC.

GENERAL FEATURES OF PYTHAGOREANISM

The character of the original Pythagoreanism is controversial, and the conglomeration of disparate features that it displayed is intrinsically confusing. Its fame rests, however, on some very influential ideas, not always correctly understood, that have been ascribed to it since antiquity. These ideas include those of (1) the metaphysic of number and the conception that reality, including music and astronomy, is, at its deepest level, mathematical in nature; (2) the use of philosophy as a means of spiritual purification; (3) the heavenly destiny of the soul and the possibility of its rising to union with the divine; (4) the appeal to certain symbols, sometimes mystical, such as the *tetraktys,* the golden section, and the harmony of the spheres (to be discussed below); (5) the Pythagorean theorem; and (6) the demand that members of the order shall observe a strict loyalty and secrecy.

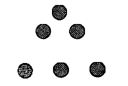

Figure 1: The *Tetraktys* (see text).

By laying stress on certain inner experiences and intuitive truths revealed only to the initiated, Pythagoreanism seems to have represented a soul-directed subjectivism alien to the mainstream of Pre-Socratic Greek thought centring on the Ionian coast of Asia Minor (Thales, Anaximander, Anaxagoras, and others), which was preoccupied with determining what the basic cosmic substance is.

In contrast with such Ionian naturalism, Pythagoreanism was akin to trends seen in mystery religions and emotional movements, such as Orphism, which often claimed to achieve through intoxication a spiritual insight into the divine origin and nature of the soul. Yet there are also aspects of it that appear to have owed much to the more sober, "Homeric" philosophy of the Ionians. The Pythagoreans, for example, displayed an interest in metaphysics (the nature of Being), as did their naturalistic predecessors, though they claimed to find its key in mathematical form rather than in any substance. They accepted the essentially Ionian doctrines that the world is composed of opposites (wet–dry, hot–cold, etc.) and generated from something unlimited; but they added the idea of the imposition of limit upon the unlimited and the sense of a musical harmony in the universe. Again, like the Ionians, they devoted themselves to astronomical and geometrical speculation. Combining, as it does, a rationalistic theory of number with a mystic numerology and a speculative cosmology with a theory of the deeper, more enigmatic reaches of the soul, Pythagoreanism interweaves Rationalism and irrationalism more inseparably than does any other movement in ancient Greek thought (see PHILOSOPHY, HISTORY OF WESTERN).

MAJOR CONCERNS AND TEACHINGS

The problem of describing Pythagoreanism is complicated by the fact that the surviving picture is far from complete, being based chiefly on a small number of fragments from the time before Plato and on various discussions in authors who wrote much later—most of whom were either Aristotelians or Neoplatonists (see below *History of Pythagoreanism*). In spite of the historical uncertainties, however, that have plagued searching scholars, the contribution of Pythagoreanism to Western culture has been significant and therefore justifies the effort, however inadequate, to depict what its teachings may have been. Moreover, the heterogeneousness of Pythagorean doctrines has been well documented ever since Heracleitus, a classic early-5th-century Greek philosopher who, scoffing at Pythagoras' wide-ranging knowledge, said that it "does not teach one to have intelligence." There probably never existed a strictly uniform system of Pythagorean philosophy and religious beliefs, even if the school did have a certain internal organization. Pythagoras appears to have taught by pregnant, cryptic *akousmata* ("something heard) or *symbola*. His pupils handed these on, formed them partly into *Hieroi Logoi* ("Sacred Discourses"), of which different versions were current from the 4th century on, and interpreted them according to their convictions.

Significance of belief in transmigration of souls

Religion and ethics. The belief in the transmigration of souls provided a basis for the Pythagorean way of life. Some Pythagoreans deduced from this belief the principle of "the kinship of all beings," the ethical implications of which were later stressed in 4th-century speculation. Pythagoras himself seems to have claimed a semidivine status in close association with the superior god Apollo; he believed that he was able to remember his earlier incarnations and, hence, to know more than others knew. Recent research has emphasized shamanistic traits deriving from the ecstatic cult practices of Thracian medicine men in the early Pythagorean outlook. The rules for the religious life that Pythagoras taught were largely ritualistic: refrain from speaking about the holy, wear white clothes, observe sexual purity, do not touch beans, and so forth. He seems also to have taught purification of the soul by means of music and mental activity (later called philosophy) in order to reach higher incarnations. "To be like your Master" and so "to come nearer to the gods" was the challenge that he imposed on his pupils. Salvation, and perhaps ultimate union with the divine cosmos through the study of the cosmic order, became one of the leading ideas in his school.

The advanced ethics and political theories sometimes ascribed to Pythagoreanism may to some extent reflect ideas later developed in the circle of Archytas, the leading 4th-century Pythagorean. But a picture current among the Peripatetics (the school founded by Aristotle) of Pythagoras as the educator of the Greeks, who publicly preached a gospel of humanity, is clearly anachronistic. Several of the Peripatetic writers, Aristoxenus, Dicaearchus, and Timaeus, seem to have interpreted some principles—properly laid down only for esoteric use in the brotherhood—as though these applied to all mankind: the internal loyalty, modesty, self-discipline, piety, and abstinence required by the secret doctrinal system; the higher view of womanhood reflected in the admission of women to the school; a certain community of property; and perhaps the drawing of a parallelism between the macrocosm (the universe) and the microcosm (man), in which (for instance) the Pythagorean idea that the cosmos is an organism was applied to the state, which should thus mix monarchy, oligarchy, and democracy into a harmonic whole—these were all universalized.

Metaphysics and number theory. According to Aristotle, number speculation is the most characteristic feature of Pythagoreanism. Things "are" number, or "resemble" number. To many Pythagoreans this concept meant that things are measurable and commensurable or proportional in terms of number—an idea of considerable significance for Western civilization. But there were also attempts to arrange a certain minimum number of pebbles so as to represent the shape of a thing—as, for instance, stars in a constellation that seem to represent an animal. For the Pythagoreans even abstracted things "have" their number: "justice" is associated with the number four and with a square, "marriage" with the number five, and so on. The psychological associations at work here have not been clarified.

The tetraktys

The harmony of the cosmos. The sacred decad in particular has a cosmic significance in Pythagoreanism: its mystical name, *tetraktys* (meaning approximately "fourness"), implies $1 + 2 + 3 + 4 = 10$; but it can also be thought of as a "perfect triangle," as in Figure 1.

Speculation on number and proportion led to an intuitive feeling of the *harmonia* ("fitting together") of the *kosmos* ("the beautiful order of things"); and the application of the *tetraktys* to the theory of music (see below *Music)* revealed a hidden order in the range of sound. Pythagoras may have referred, vaguely, to the "music of the heavens," which he alone seemed able to hear; and later Pythagoreans seem to have assumed that the distances of the heavenly bodies from the earth somehow correspond to musical intervals—a theory that, under the influence of Platonic conceptions, resulted in the famous idea of the "harmony of the spheres." Though number to the early Pythagoreans was still a kind of cosmic matter, like the water or air proposed by the Ionians, their stress upon numerical proportions, harmony, and order comprised a decisive step toward a metaphysic in which form is the basic reality.

The doctrine of opposites. From the Ionians, the Pythagoreans adopted the idea of cosmic opposites, which they—perhaps secondarily—applied to their number speculation. The principal pair of opposites is the limit and the unlimited; the limit (or limiting), represented by the odd (3,5,7, . . .), is an active force effecting order, harmony, "cosmos," in the unlimited, represented by the even. All kinds of opposites somehow "fit together" within the cosmos, as they do, microcosmically, in an individual man and in the Pythagorean society. There was also a Pythagorean "table of ten opposites," to which Aristotle has referred—limit–unlimited, odd–even, one–many, right–left, male–female, rest–motion, straight–curved, light–darkness, good–evil, and square–oblong. The arrangement of this table reflects a dualistic conception, which was apparently not original with the school, however, or accepted by all of its members.

The Pythagorean number metaphysic was also reflected in its cosmology. The unit (1), being the starting point of the number series and its principle of construction, is not itself strictly a number; for, to be a number is to be even or odd, whereas, in the Pythagorean view, "one" is seen as *both* even and odd. This ambivalence applies, similarly, to the total universe, conceived as the One. There was also a cosmogonical theory (of cosmic origins) that explained the generation of numbers and number-things from the limiting-odd and the unlimited-even—a theory that, by stages unknown to scholars, was ultimately incorporated into Plato's philosophy in his doctrine of the derivation of sensed realities from mathematical principles (see PLATONISM AND NEOPLATONISM: *Greek Platonism front Aristotle through Middle Platonism, its nature and history).*

Mathematics and science. Pythagorean thought was scientific as well as metaphysical and included specific developments in arithmetic and geometry, in the science of musical tones and harmonies, and in astronomy.

Arithmetic. Early Pythagorean achievements in mathematics are unclear and largely disputable, and the following is, therefore, a compromise between the widely divergent views of modern scholars.

Use of the *gnōmones*

In the speculation on odd and even numbers, the early Pythagoreans used so-called *gnōmones* (Greek: "carpenter's squares"). Judging from Aristotle's account, gnomon numbers, represented by dots or pebbles, were arranged in the manner shown in Figure 2. If a series of odd numbers is put around the unit as gnomons, they always produce squares; thus, the members of the series 4, 9, 16, 25, . . . are "square" numbers. If even numbers are depicted in a similar way, the resulting figures (which offer infinite variations) represent "oblong" numbers, such as those of the series 2, 6, 12, 20. . . . On the other hand, a triangle represented by three dots (as in the upper part of the tetraktys) can be extended by a series of natural numbers to form the "triangular" numbers 6, 10 (the tetraktys), 15, 21. . . . This procedure, which was, so far, Pythagorean, led later, perhaps in the Platonic Academy, to a speculation on "polygonal" numbers.

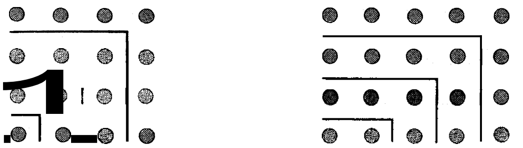

Figure 2: Gnomonsof Pythagorean numbertheory (see text).

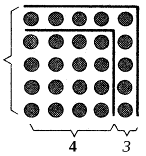
Probably the square numbers of the gnomons were early associated with the Pythagorean theorem (likely to have been used in practice in Greece, however, before Pythagoras), which holds that for a right triangle a square drawn on the hypotenuse is equal in area to the sum of the squares drawn on its sides; in the gnomons it can easily be seen, in the case of a 3,4,5–triangle for example (see Figure 3), that the addition of a square gnomon number to a square makes a new square: $3^2 + 4^2 = 5^2$, and this gives a method for finding two square numbers the sum of which is also a square.



Fiaure 3: Gnomon for Pythagorean theorem. The matked off "carpenter's square" —comprising 3 groups of 3 dots each (3 X 3)—thus represents 3^2, which when added to 4^2 yields 5^2 (<he total gnomon).

The problem of irrational numbers

Some 5th-century Pythagoreans seem to have been puzzled by apparent arithmetical anomalies: the mutual relationships of triangular and square numbers; the anomalous properties of the regular pentagon; the fact that the length of the diagonal of a square is incommensurable with its sides—*i.e.*, that no fraction composed of integers can express this ratio exactly (the resulting decimal is thus defined as irrational); and the irrationality of the mathematical proportions in musical scales. The discovery of such irrationality was disquieting because it had fatal consequences for the naïve view that the universe is expressible in whole numbers; the Pythagorean Hippasus is said to have been expelled from the brotherhood, according to some sources even drowned, because he made a point of the irrationality.

In the 4th century, Pythagorizing mathematicians made a significant advance in the theory of irrational numbers, such as the-square-root-of-it ($\sqrt{n}$), it being any rational number, when they developed a method for finding progressive approximations to $\sqrt{2}$ by forming sets of so-called diagonal numbers.

Geometry. In geometry, the Pythagoreans cannot be credited with any proofs in the Euclidean sense. They were evidently concerned, however, with some speculation on geometrical figures, as in the case of the Pythagorean theorem, and the concept that the point, line, triangle, and tetrahedron correspond to the elements of the tetraktys, since they are determined by one, two, three, and four points, respectively. They possibly knew practical methods of constructing the five regular solids, but the theoretical basis for such constructions was given by non-Pythagoreans in the 4th century.

It is notable that the properties of the circle seem not to have interested the early Pythagoreans. But perhaps the tradition that Pythagoras himself discovered that the sum of the three angles of any triangle is equal to two right angles may be trusted. The idea of geometric proportions is probably Pythagorean in origin; but the so-called golden section—which divides a line at a point such that the smaller part is to the greater as the greater is to the whole—is hardly an early Pythagorean contribution. Some advance in geometry was made later, by 4th-century Pythagoreans; *e.g.,* Archytas offered an interesting solution to the problem of the duplication of the cube—in which a cube twice the volume of a given cube is constructed—by an essentially geometrical construction in three dimensions; and the conception of geometry as a "flow" of points into lines, of lines into surfaces, and so on, may have been contributed by Archytas; but on the whole the achievements of non-Pythagorean mathematicians were in fact more conspicuous than those of the Pythagoreans.

Mathematical ratios of tones

Music. The achievements of the early Pythagoreans in musical theory are somewhat less controversial. The scientific approach to music, in which musical intervals are expressed as numerical proportions, originated with them, as did also the more specific idea of harmonic "means." At an early date they discovered empirically that the basic intervals of Greek music include the elements of the tetraktys, since they have the proportions 1:2 (octave), 3:2 (fifth), and 4:3 (fourth). The discovery could have been made, for instance, in pipes or flutes or stringed instruments: the tone of a plucked string held at its middle is an octave higher than that of the whole string; the tone of a string held at the ⅔ point is a fifth higher; and that of one held at the ¾ point is a fourth higher. Moreover, they noticed that the subtraction of intervals is accomplished by dividing these ratios by one another. In the course of the 5th century they calculated the intervals for the usual diatonic scale, the tone being represented by 9:8 (fifth minus fourth); *i.e.,* $3/2 \div 4/3$, and the semitone by 256:243 (fourth minus two tones); *i.e.,* $4/3 \div (9/8 \times 9/8)$. Archytas made some modification to this doctrine and also worked out the relationships of the notes in the chromatic (12-tone) scale and the enharmonic scale (involving such minute differences as that between A flat and G sharp, which on a piano are played by the same key).

Astronomy. In their cosmological views the earliest Pythagoreans probably differed little from their Ionian predecessors. They made a point of studying the stellar heavens; but—with the possible exception of the theory of musical intervals in the cosmos—no new contributions to astronomy can be ascribed to them with any degree of probability. Late in the 5th century, or possibly in the 4th century, a Pythagorean boldly abandoned the geocentric view and posited a cosmological model in which the Earth, Sun, and stars circle about an (unseen) central fire—a view traditionally attributed to the 5th-century Pythagorean Philolaus of Croton (see PHYSICAL SCIENCES, HISTORY OF).

HISTORY OF PYTHAGOREANISM

Literary sources, especially Aristotelian

The life of Pythagoras and the origins of Pythagoreanism appear only dimly through a thick veil of legend and semihistorical tradition. The literary sources for the teachings of the Pythagoreans present extremely complicated problems. Special difficulties arise from the oral and esoteric transmission of the early doctrines, the profuse accumulation of tendentious legends, and confusion caused by the split in the school in the 5th century BC. In the 4th century, Plato's inclination toward Pythagoreanism created a tendency—manifest already in the middle of the century in the works of his pupils—to interpret Platonic concepts as originally Pythagorean. But the radical skepticism as to the reliability of the sources shown by some modern scholars has on the whole been abandoned in recent research. It now seems possible to extract bits of reliable evidence from a wide range of ancient authors, such as Porphyry and Iamblichus (see below Neo-Pythagoreanism).

Most of these literary sources hark back ultimately to the environment of Plato and Aristotle; and here the importance of one of Aristotle's students has become obvious, viz., the musicologist and philosopher Aristoxenus, who in spite of his bias possessed firsthand information independent of the point of view of Plato's Academy. The role played by Dicaearchus, another of Aristotle's pupils, and by the Sicilian historian Timaeus, of the early 3rd century BC, is less clear. Recently, the reliability of Aristotle's account of Pythagoreanism has also been emphasized against the doubts that had been expressed by some modern scholars; but Aristotle's sources, in turn, hardly lead farther back than to the late 5th century (perhaps to Philolaus; see below Two Pythagorean sects). In addition, there are scattered hints in various early authors and in some not very substantial remains of 4th-century Pythagorean literature. The mosaic of reconstruction thus has to be to some extent subjective.

Four chief periods

Early Pythagoreanism. Within the ancient Pythagorean movement four chief periods can be distinguished: early Pythagoreanism, dating from the late 6th century BC and extending to about 400 BC; 4th-century Pythagoreanism; the Hellenistic trends; and Neo-Pythagoreanism, a revival that occurred in the mid-1st century AD and lasted for two and a half centuries.

Background. The background of Pythagoreanism is complex, but two main groups of sources can be distinguished. The Ionian philosophers (Thales, Anaximander, Anaximenes, and others) provided Pythagoras with the problem of a single cosmic principle, the doctrine of opposites, and whatever reflections of Oriental mathematics there are in Pythagoreanism; and from the technicians of his birthplace, the Isle of Samos, he learned to understand the importance of number, measuring, and proportions. Popular cults and beliefs current in the 6th century and reflected in Orphism introduced him to occultism, ritualism, and the doctrine of individual immortality. In view of the shamanistic traits of Pythagoreanism, reminiscent of Thracian cults, it is interesting to note that Pythagoras seems to have had a Thracian slave.

Pythagorean communities. The school apparently founded by Pythagoras at Croton in southern Italy seems to have been primarily a religious brotherhood centred around Pythagoras and the cults of Apollo and of the Muses, ancient patron goddesses of poetry and culture. It became perhaps successively institutionalized and received different classes of esoteric members and exoteric sympathizers. The rigorism of the ritual and ethical observances demanded of the members is unparalleled in early Greece; in addition to the rules of life mentioned above, it is fairly well-attested that secrecy and a long silence during the novitiate were required. The exoteric associates, however, were politically active and established a Crotonian hegemony in southern Italy. About 500 BC a coup by a rival party caused Pythagoras to take refuge in Metapontum, where he died.

During the early 5th century, Pythagorean communities existed in many southern Italian cities, a fact that led to some doctrinal differentiation and diffusion. In the course of time the politics of the Pythagorean parties became decidedly antidemocratic. About the middle of the century a violent democratic revolution swept over southern Italy; many Pythagoreans were killed, and only a few escaped, among them Lysis of Tarentum and Philolaus of Croton, who went to Greece and formed small Pythagorean circles in Thebes and Phlious.

Two Pythagorean sects. Little is known about Pythagorean activity during the latter part of the 5th century. The differentiation of the school into two main sects, later called akousrnatikoi (Greek: akousma, "something heard," viz., the esoteric teachings) and *mathēmatikoi* (Greek: *mathēmatikos,* "scientific"), may have occurred at that time. The acousmatics devoted themselves to the observance of rituals and rules and to the interpretation of the sayings of the master; the "mathematics" were concerned with the scientific aspects of Pythagoreanism. Philolaus, who was rather a mathematic, probably published a summary of Pythagorean philosophy and science in the late 5th century.

Archytas and his school

Fourth-century Pythagoreanism. In the first half of the 4th century, Tarentum, in southern Italy, rose into considerable significance. Under the political and spiritual leadership of the mathematic Archytas, a friend of Plato, Tarentum became a new centre of Pythagoreanism, from which acousmatics—so-called Pythagorists who did not sympathize with Archytas—went out travelling as mendicant ascetics all around the Greek-speaking world. The acousmatics seem to have preserved some early Pythagorean Hieroi Logoi and ritual practices. Archytas himself, on the other hand, concentrated on scientific problems, and the organization of his Pythagorean brotherhood was evidently less rigorous than that of the early school. After the 380s there was a give-and-take between the school of Archytas and the Academy of Plato, a relationship that makes it almost impossible to disentangle the original achievements of Archytas from joint involvements (but see above, Geometiy and Music).

The Hellenistic Age. Whereas the school of Archytas apparently sank into inactivity after the death of its founder (probably after 350 BC), the Academics of the next generation continued "Pythagorizing" Platonic doctrines, such as that of the supreme One, the indefinite dyad (a metaphysical principle), and the tripartite soul (see PLATONISM AND NEOPLATONISM). At the same time, various Peripatetics of the school of Aristotle, including Aristoxenus, collected Pythagorean legends and applied contemporary ethical notions to them. In the Hellenistic Age, the Academic and Peripatetic views gave rise to a rather fanciful antiquarian literature on Pythagoreanism. There also appeared a large and yet more heterogeneous mass of apocryphal writings falsely attributed to different Pythagoreans, as if attempts were being made to revive the school. The texts fathered on Archytas display Academic and Peripatetic philosophies mixed with some notions that were originally Pythagorean. Other texts were fathered on Pythagoras himself or on his immediate pupils, imagined or real. Some show, for instance, that Pythagoreanism had become confused with Orphism; others suggest that Pythagoras was considered a magician and an astrologist; there are also indications of Pythagoras "the athlete" and "the Dorian nationalist." But the anonymous authors of this pseudo-Pythagorean literature did not succeed in re-establishing the school, and the "Pythagorean" congregations formed in early imperial Rome seem to have had little in common with original Pythagoreanism; they were ritualistic sects that adopted, eclectically, various occult practices.

Amalgamation with Neoplatonism

Neo-Pythagoreanism. With the ascetic sage Apollonius of Tyana, about the middle of the 1st century AD, a distinct Neo-Pythagorean trend appeared. Apollonius studied the Pythagorean legends of the previous centuries, created and propagated the ideal of a Pythagorean life—of occult wisdom, purity, universal tolerance, and approximation to the divine—and felt himself to be a reincarnation of Pythagoras. Through the activities of Neo-Pythagorean Platonists, such as Moderatus of Gades, a pagan trinitarian, and the arithmetician Nicomachus of Gerasa, both of the 1st century AD, and, in the 2nd or 3rd century, Numenius of Apamea, forerunner of Plotinus (an epoch-making elaborator of Platonism), Neo-Pythagoreanism gradually became a part of the expression of Platonism known as Neoplatonism; and it did so without having achieved a scholastic system of its own. The founder of a Syrian school of Neoplatonism, Iamblichus, a pupil of Porphyry (who in turn had been a pupil of Plotinus), thought of himself as a Pythagorean sage and about AD 300 wrote the last great synthesis of Pythagoreanisrn, in which most of the disparate post-classical traditions are reflected. It is characteristic of the Neo-Pythagoreans that they were chiefly interested in the Pythagorean way of life and in the pseudoscience of number mysticism. On a more popular level, Pythagoras and Archytas were remembered as magicians. Moreover, it has been suggested that Pythagorean legends also influenced the Christian monastic tradition.

Medieval and modern trends. In the Middle Ages the popular conception of Pythagoras the magician was combined with that of Pythagoras "the father of the quadrivium"; *i.e.*, of the more specialized liberal arts of the curriculum. From the Italian Renaissance onward, some "Pythagorean" ideas, such as the tetrad, the golden section, and harmonic proportions, became applied to aesthetics. To many Humanists, moreover, Pythagoras was the father of the exact sciences. In the early 16th century, Nicolaus Copernicus, who developed the view that the Earth revolves around the Sun, considered his system to be essentially Pythagorean or "Philolaic," and Galileo was called a Pythagorean. The 17th-century Rationalist G.W. Leibniz appears to have been the last great philosopher and scientist who felt himself to be in the Pythagorean tradition.

It is doubtful whether advanced modern philosophy has ever drawn from sources thought to be distinctly Pythagorean. Yet Platonic–Neoplatonic notions, such as the mathematical conception of reality or the philosopher's union with the universe and various mystical beliefs are still likely to be stamped as Pythagorean. Even today uncritical admiration of Pythagoreanism is common.

EVALUATION

The history of the projection of Pythagoreanism into subsequent thought indicates how fertile some of its core concepts were. Plato is here the great catalyst; but it is possible to perceive behind him, however dimly, a series of Pythagorean ideas of paramount potential significance: the combination of religious esoterism (or exclusivism) with the germs of a new philosophy of mind, present in the belief in the progress of the soul toward the actualization of its divine nature and toward knowledge; stress upon harmony and order, and upon limit as the good; the primacy of form, proportion, and numerical expression; and in ethics, an emphasis upon such virtues as friendship and modesty. The fact that Pythagoras, to later ages, also became alternatively a Dorian nationalist, a sportsman, an educator of the people, or a great magician is a more curious consequence of the productivity of his teaching.

BIBLIOGRAPHY

Fragments and texts: The collection of the fragments in HERMANN DIELS and WALTHER KRANZ, *Die Fragmente der Vorsokratiker,* 6th ed., vol. 1 (1951), is insufficient; additions are given in MARIA TIMPANARO CARDINI (ed.), *Pitagorici: Testimonianze e frammenti,* 3 vol. (1958–64); and in CORNELIA J. DE VOGEL, *Pythagoras and Early Pythagoreanism* (1966). For the pseudo-Pythagoreans, see HOLGER THESLEFF (ed.), *The Pythagorean Texts of the Hellenistic Period* (1965).

Early Pythagoreanism: The best comprehensive introduction to Pythagoreanism is the long chapter "Pythagoras and the Pythagoreans," in W.K.C. GUTHRIE, *A History of Greek Philosophy,* vol. 1, pp. 146–340 (1962). Somewhat different approaches have been taken by DE VOGEL (*op. cit.*); and JAMES A. PHILIP, *Pythagoras and Early Pythagorearzism* (1966), works that demand more active criticism by the reader. Fairly full references to the discussion of Pythagoreanism up to 1960 are in WALTER BURKERT, *Weisheit und Wissenschaft: Studien zu Pythagoras, Philolaos, und Platon* (1962; Eng. trans., *Lore and Science in Ancient Pythagoreanism,* 1972), a highly technical and at times rather overcritical work. Among later technical discussions, likely to become influential, are the articles "Pythagoras" and "Pythagoreer" in *Pauly-Wissowa Realencyclopadie,* vol. 47, (1963), and suppl. vol. 10 (1965)--of the contributors, KURT VON FRITZ and H. DORRIE arrive at less controversial conclusions than B.L. VAN DER WAERDEN.

Hellenistic Pythagoreanism: HOLGER THESLEFF, *An Introduction to the Pythagorean Writings of the Hellenistic Period* (1961); additions and corrections in *Entretiens Fondation Hardt,* vol. 18 (1972).

Neo-Pythagoreanism: PHILIP MERLAN, *From Platonism to Neoplatonism* (1953).

For up-to-date bibliographical accession, see *L'Année philologique* (annual), under the subject heading "Pythagorica" and the various Pythagoreans.

Quarantine and Isolation

The words quarantine and isolation, which by popular usage can be employed almost interchangeably in reference to disease control, in the present article are used in the following technical senses: Quarantine is the detention or restraint of human beings or other creatures that may have come into contact with communicable disease until it is deemed certain that they have escaped infection, while isolation is the separation of an infected individual from the healthy until he is unable to transmit the disease.

Early practices with respect to leprosy and the plague

History of quarantine and isolation. The earliest recognition that diseases might be communicable led to extreme measures designed to isolate infected persons or communities. Fear of leprosy, a slowly progressive mutilating disease, caused wide adoption of the control measures set out in Leviticus 13, namely, isolation of the infected and the cleansing or burning of his garments. The leper, until only recently, was considered an outcast, and no healthy person would dare have any communication with him. Against acute, highly fatal diseases like bubonic plague, which spread rapidly throughout populations, attempts were made by healthy communities to prevent entry of goods and persons from infected communities; in the 7th century AD, for example, armed guards were stationed between plague-stricken Provence and the diocese of Cahors. Over a thousand years later, in 1720, when Marseilles was suffering a severe epidemic of the plague, a ring of sentries was placed around the city to prevent any person's escaping. "Cordons sanitaire" of this kind were probably an ineffective means of control.

In the 14th century the growth of maritime trade and the recognition that plague was introduced by ships returning from the Levant led to the adoption of quarantine in Venice. It was decreed that ships were to be isolated for a limited period to allow for the manifestation of the disease and to dissipate the infection brought by persons and goods. Originally the period was 30 days, *trentina,* but this was later extended to 40 days, *quarantina.* The choice of this period is said to be based on the period that Christ and Moses spent in isolation in the desert. In 1423 Venice set up its first lazaretto, or quarantine station, on an island near the city. The Venetian system became the model for other European countries and the basis for widespread quarantine control for several centuries.

In the 16th century the system was extended by the introduction of bills of health, a form of certification that the last port of call was free from disease; a clean bill, with the visa of the consul of the country .of arrival, entitled the ship to free pratique (use of the port) without quarantine. Quarantine was later extended to other diseases besides plague, notably yellow fever, with the growth of American trade, and cholera, which was particularly associated with the pilgrimages to Mecca.

By the mid-19th century the practice of quarantine had become a considerable nuisance. The periods of quarantine were arbitrary and variable from country to country, and there were instances of perverse and bureaucratic application of the quarantine regulations. The disinfection of letters and rummaging of papers could be an excuse for political espionage, and the opportunities for bribery and corruption were frequently exploited. Great discomfort and delay was caused to travellers; the prison reformer John Howard had, in 1786, deliberately sailed from Smyrna to Venice in a ship with a foul bill of health so that he could gain firsthand experience of lazarettos; his account (*An Account of the Principal Lazarettos in Europe* [1789]) presents a depressing picture.

First international sanitary conference

General dissatisfaction with quarantine practice led to the convening of the first international sanitary conference in Paris in 1851. The arguments were conducted at two levels. Commercially, the conflict was between the countries with considerable vested interests in quarantine and the major maritime nations, which favoured its abolition; medically, the opposition was between the "contagionists," who believed that diseases like cholera and plague are transmitted from person to person, and the "miasmatists," who thought that they are caused by infected atmosphere and that the remedy is sanitation, not quarantine. Despite these differences, agreement was reached on some important general principles for the standardization of quarantine procedures. Since the convention and regulations were not generally ratified, there was little immediate impact from it.

In the next fifty years a succession of sanitary conferences, with better understanding of the epidemiology of communicable disease, reached some agreement on the maximum permissible measures of control and on the removal of the most irksome restrictions of quarantine practice, but the accord reached by the 11th conference, at Paris in 1903, was the first really effective measure to be signed. Out of it came in 1907, the Office International d'Hygiène Publique ("International Office of Public Health"), the forerunner of the World Health Organization. (The forerunner of the Pan American Sanitary Bureau had been established five years earlier, in 1902).

Present practices. Today, isolation of persons is practiced much less rigidly or extensively than formerly in the control of communicable disease. It is clearly appropriate, and adopted, in dangerous diseases spread directly from person to person, such as smallpox or typhoid. It is recognized, however, that isolation may fail for a variety of reasons—it depends, for example, on complete and immediate recognition of infective persons, which is rarely achieved even for those with open signs of disease. It is ineffective in diseases that are transmitted by an intermediate carrier—*e.g.*, the mosquito in yellow fever and malaria. In plague, isolation is important to prevent man-to-man spread but would not have any effect on the main route of infection—by bites of the rat flea. It is inappropriate to isolate human cases of a disease, such as brucellosis, that is usually acquired by contact with infected farm animals or their products. Even for diseases in which it may protect individuals, isolation will often have little effect on the general epidemic; this may be, as in measles, because infectivity precedes the appearance of the characteristic feature, the rash, by a few days, or, as in polio virus infections, because a number of persons are carriers, harbouring the disease agent without discernible illness. The difficulty of recognizing potentially infective persons often makes isolation impracticable even in situations in which it could be appropriate.

Current use of quarantine

Quarantine is much modified in modern practice because of the better understanding of how communicable disease is transmitted. In its purest form it is applied to animals, as in the control of rabies; recent experience in Great Britain has revealed difficulties because dogs have developed rabies after a quarantine period of six months, generally accepted as a maximum reasonable incubation period. In man it is now more usual to apply *surveillance* of contacts, with, possibly, daily reporting to a doctor to get prompt recognition of illness but without restricting movement; such a policy, coupled with other control measures, is now accepted even in such diseases as smallpox. In some instances modified quarantine is imposed; adult contacts of typhoid should be excluded from food handling until repeated bacteriological examination of feces and urine has shown them to be free of the disease; susceptible children exposed to measles have sometimes been excluded from school, but the practice was already declining even before the widespread use of measles vaccines. Quarantine and exclusion of plants and of plant products are still widely practiced in accordance with international agreements (see DISEASES OF ANIMALS; DISEASES OF PLANTS).

BIBLIOGRAPHY. WORLD HEALTH ORGANIZATION, *International Sanitary Regulations,* 3rd annotated ed. (1966), lists the provisions designed to combine the minimum interference with world traffic with the maximum security against international spread of the six quarantinable diseases: plague, cholera, yellow fever, smallpox, typhus, and relapsing fever. These regulations have been superseded in part by the *International Health Regulations,* adopted by the 22nd World Health Assembly, 1969. These new regulations apply to cholera, plague, smallpox, and yellow fever, but not to typhus and relapsing fever.

AMERICAN PUBLIC HEALTH ASSOCIATION, *Control of Communicable Disease in Man,* 10th ed. (1965), a widely used reference work on most diseases of public health importance, including those occurring outside the Western Hemisphere; N.M. GOODMAN, *International Health Organizations and Their Work* (1952), a good summary of the history of quarantine and its influence on the development of international health work; C.E.A. WINSLOW, *The Conquest of Epidemic Disease* (1943), a wide-ranging and scholarly historical account; H. ZINSSER, *Rats, Lice and History* (1935), a classic history of typhus and plague; G. SMITH, *Plague on Us* (1941), a popular account of the epidemiology of communicable disease.

(J.Kn.)

Quasi-stellar Sources

Quasi-stellar sources (also often called quasi-stellar objects, quasars, or QSO's) form a class of astronomical objects with starlike point images that show large shifts to the red of the lines in their optical spectra. (A spectrum is the band of colour formed when light passed through a slit is then broken up instrumentally into its constituent wavelengths and is a continuous and overlapping series of images of the slit; dark or bright lines in a spectrum give clues to the chemical composition of the object and also to its temperature and other physical conditions.) No final agreement has been reached regarding the name of these objects and in this article they will be referred to as QSO's. As existing distance estimates are not fully reliable, the amount of light and in many cases radio energy released is not finally known either. QSO's could be among the intrinsically brightest objects in the sky; or the energy release might be more moderate if they were relatively near objects rather than among the most distant as was at first thought.

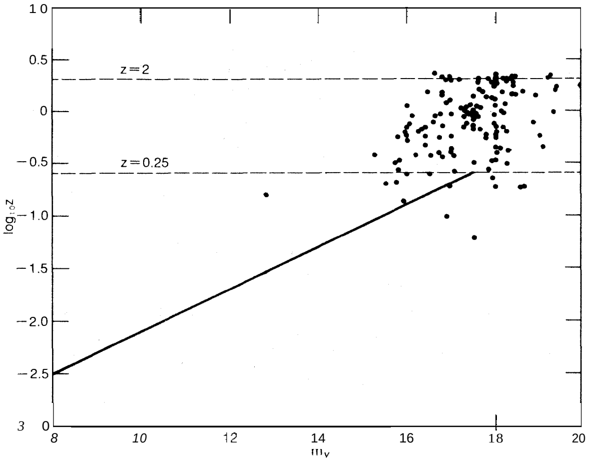
Discovery. The first QSO's were discovered by radio astronomers in 1960. Until then all radio sources outside the Galaxy that had been identified with optical objects had been found to have their origin in external galaxies. Accurate radio positions for three such radio sources, designated in the third Cambridge radio source catalog (3C) as 3C 48, 3C 196, 3C 286, led to the discovery of starlike objects, at those positions. The object 3C 48 was studied extensively by optical astronomers, but its line spectrum could not be understood. In 1962, a much brighter starlike object, 3C 273, was identified by the use of a radio telescope in Australia. The line spectrum of this optical object was finally identified as due to lines found in laboratory spectra in the ultraviolet and normally not visible in the spectrum of a star. The lines in the spectra of nearly all galaxies are shifted toward the red end of the spectrum; the red shift, discussed below, is defined as the observed wavelength minus the laboratory wavelength divided by the laboratory wavelength. The red shift for 3C 273 was 0.158. The red shift of 3C 48 was determined to be 0.367. Following this breakthrough, several quasi-stellar radio sources were identified and their red shifts measured.

In general, the red shifts turned out to be far larger than any that had been detected for ordinary galaxies. By 1965, at least one object with a red shift approximately equal to two had been discovered. The early—and possibly too quick—explanation was that the red shifts, like the red shifts of many galaxies, were due to expansion of the universe and would be proportional to their distance from the observer. It was therefore concluded that the quasi-stellar radio sources must be enormously far away and intrinsically much more luminous, up to 100 times brighter than the brightest galaxies. The fact that they emitted much more energy in the ultraviolet part of the spectrum than normal stars led to the conclusion that such objects might be found by optical survey methods alone. The search proved successful. By 1970 it had been shown that, down to the faintest objects that can be detected with the large telescopes, there are something like 200 quasi-stellar objects per square degree. If they are uniformly distributed, some 10,000,000 must exist, of the 22nd magnitude or brighter. (The visually brightest stars are of about magnitude −2. A difference of 5 magnitudes is equivalent to 100-fold difference in brightness, and the notation is such that the brighter object has the smaller magnitude.) Only a fraction of the QSO's known are radio sources.

Probable numbers of QSO's

Observed properties. *Emission-line red shifts.* By 1970 about 200 QSO's had been studied and their red shifts determined. The optical spectra in general show broad emission lines. (When the light from a hot incandescent gas is recorded directly, the lines in the spectrum are bright and are called emission lines; when the light from a hot source passes through a cooler region of the same gas before it is analyzed, some dark lines called absorption lines are formed at the same wavelengths.) The QSO lines are superposed on a continuous bright spectrum of light from the source, called a continuum, which has a nonthermal origin—that is, it is not simply due to radiation from a hot gas cloud. The optical emisson lines of the QSO's are mostly the strongest lines of some of the common elements. These include lines that would be produced in the laboratory at wavelengths of 2796 and 2803 angstroms by once-ionized magnesium (atoms with one electron missing); at 1548 and 1551 angstroms by three-times-ionized carbon; at 1909 angstroms by twice-ionized carbon; and the two strongest lines of the so-called Lyman series of hydrogen. None of these lines can be normally seen in the spectra of astronomical objects because their wavelengths, in the ultraviolet range, are absorbed by the Earth's atmosphere. In the QSO's the red shift moves them into the visible part of the spectrum. The range of the red shifts known at present is from approximately 0.06 to approximately 2.89. A plot of apparent brightness against red shifts (see the Figure) gives what is practically a scatter diagram; that is, there is very little correlation of optical brightness with red shift. The only striking feature appears to be the dearth of objects with red shifts larger than about 2.2. This cutoff is thought to be real, but the cutoff in apparent brightness—there are practically no QSO's identified that have apparent brightness less than magnitude 19.5—is due to the extreme difficulty in identifying or observing QSO's fainter than this.

From G.R. Burbidge and E.M. Burbidge. "A Progress Report," *Nature*, vol. 224



Plot of apparent brightness, m_V, in magnitudes against the logarithm of the red shift, *z*, for 136 QSO's. The line shows the relation between red shift and apparent brightness found for standard galaxies (see text).

Absorption-line red shifts. Since 1966 a considerable number of QSO's with absorption lines in addition to the emission lines in their spectra have been found. One QSO in which only absorption lines are seen has been found. In most of these it is found that the red shift values calculated from the emission and the absorption lines are about the same; there are several cases in which they differ by small amounts. Several have been found, however, to have many different values of the absorption red shifts, some much smaller than the emission red shifts; in one case seven have been identified. The QSO's with rich absorption-line spectra have large emission-line red shifts.

Flux variations and sizes. A general property of the QSO's studied so far is that they show time variations in the optical and radio energy flux; in the optical region, the energy flux is the brightness of the object measured in magnitudes. In some cases large changes amounting to factors of ten or more have taken place in less than a year's time. Measurable variations are known to occur on time scales as short as days. At the time that these variations were discovered, no other extragalactic objects were known to be variable, but later it was shown that the nuclei of some galaxies that are very similar in their radiating properties to the QSO's are also variable. From the time scale of the variation an upper limit to the size can be found, provided it is assumed that the radiating surface is not expanding relativistically—that is, at speeds approaching that of light. This limiting value is the time scale multiplied by the velocity of light. Thus, the sizes of the radiating regions are estimated to be no larger than light-years (10^{13} kilometres) or light-days (2.5 × 10^{10} kilometres). The blurring of the optical images caused by atmospheric effects means then that with optical telescopes on the surface of the Earth, man cannot measure the diameters of starlike objects to be less than about 0.5 seconds of arc. At quite modest distances in the universe this angular size corresponds to a linear size much bigger than light-years (*e.g.*, for a galaxy 30,000,000 light-years away, in the local Virgo cluster of galaxies, 0.5 seconds of arc will equal about 75 light-years). Radio astronomers can now measure angular sizes as small as 10^{-3} second of arc and have found that many QSO's and nuclei of galaxies that emit measurable radio-wavelength radiation contain very small nuclear emitting regions. For the nuclei of nearby galaxies, the sizes that are measured are compatible with the upper limits to the sizes set by the variations.

Size of QSO's

The radio variations are restricted to high frequencies (radio wavelengths less than about 20 centimetres) and are compatible with a model in which it is supposed that successive bursts of relativistic electrons expand outward from a central object. In general, no obvious pattern can be discerned in the optical variations though it is suspected that, in one or two QSO's, a component is periodic.

The nature of the red shift. Since the discovery of the QSO's there has been uncertainty concerning their distances. Though the simple explanation of the large red shifts were that they are due to the expansion of the universe, and that the objects are therefore exceedingly luminous and very distant, the discovery of the variable nature of the QSO's first led some workers to question this interpretation. The reasons why variations caused some doubts about the cosmological nature of the red shifts were in part intuitive—the sense that very distant objects 100 times more luminous than galaxies could not be so small that they could vary significantly in times as short as years or less. When translated to physical terms, these arguments led to the conclusion that there were severe difficulties in deriving self-consistent physical explanations for the phenomena if the distances were great, because the very high radiation density that must be present in the very small source must react strongly with its sources. If the QSO's are much closer than their red shifts would imply, their luminosities are much smaller, and the problem is much less severe. It is known also, however, that the nuclei of galaxies that are known to be close also vary, and the same problem, though in much milder form, arises.

Doppler red shifts

If the QSO's are much closer than the distance calculated from these red shifts, their large red shifts must be due to something other than the expansion of the universe alone. The only known mechanisms that could explain the red shifts are the Doppler effect or the presence of very strong gravitational fields. Any other explanation would be outside the laws of physics as they are now understood. Attempts to explain the red shifts by Doppler effect —*i.e.*, by arguing that the objects have all been thrown out of galaxies at very high speeds and are receding from the Galaxy so that large red shifts are seen (an object with a red shift of 2 must be receding with a velocity 80 percent that of light) have not been convincing. Since no blue shifts have been seen, there is no evidence that any objects are coming toward the Galaxy. It is known that large gravitational red shifts can arise if atomic transitions occur in regions in very strong gravitational fields, but no realistic models have been proposed on the assumption that the line spectra observed in the QSO's are produced in this way. Thus, without appealing to new effects altogether, theoretical arguments suggest that the red shifts are definitely cosmological in origin.

The distribution of the red shifts does give some indication that causes other than the expansion of the universe are at work. There is preliminary evidence of a sharp peak in the red shifts both of emission and of absorption lines at a value of 1.95. Like the scarcity of red-shift values above 2.2, the peak at 1.95 may have either a cosmological (caused by distance) or intrinsic origin. If position of the peak is a result of an intrinsic property of QSO's, then the width of the peak gives an indication of their distances. Specifically, the distance-caused component of their red shifts must be less than or about equal to 0.01; they must be closer than about 200,000,000 light-years (see Figure).

The problem is that there is no way of estimating distances of QSO's other than by assuming that the red shifts have an origin similar to that of the red shifts of galaxies that obey the Hubble expansion law; *i.e.*, the red shift is proportional to the distance from the observer. There is, however, no discemable Hnbble relation for the QSO's alone. Though this does not mean that their red shifts are not cosmological in origin, it does mean that there is at present no direct proof that the red shifts do have this origin. Apart from using the red shift, the only other known method that can be used to measure the distance of an extragalactic object is to establish that it is physically associated with another object whose distance is known. Attempts to measure distances of QSO's using this method have been tried. One QSO has recently been found to have the same red shift as an abnormal galaxy, and they both appear to lie in a cluster of faint galaxies. Three QSO's with large red shifts have been found to lie very close in angular measure to the centres of galaxies with very small red shifts. In each case the a priori probability that the QSO's are not associated with the galaxies is rather small. These latter results, however, have not been taken as strong evidence that the qso's are local. Investigations of the distribution of radio sources, some of which are identified with QSO's, in regions of the sky very close to nearby peculiar galaxies (galaxies with unusual. characteristics; see GALAXIES: EXTERNAL) have led to the conclusion that these radio sources and peculiar galaxies are physically associated. This evidence is not yet generally accepted as sufficient, and the result is not statistically sound.

It was suggested at an early stage that if the QSO's lie at cosmological distances, absorption features might be seen in the spectra because of absorption of some of the light by intergalactic gas lying in the light path between the solar system and the qso's. The discovery of such absorption would have established that the qso's lie at cosmological distances and would also have provided a method of investigating the intergalactic medium. The observations have shown, however, that no detectable continuous absorption caused by smoothly distributed neutral atomic hydrogen is present, meaning that either the density of this gas in intergalactic space is less than one atom per 10'' cubic centimetres — a fantastically low value — or else that the QSO's are local. A variety of spectroscopic and statistical arguments also suggest that the sharp absorption lines seen in some QSO spectra mentioned earlier arise in the objects and not in the intergalactic medium. Thus, this test also has failed.

At present it must be concluded that the distances of the QSO's are not known.

Physical models of QSO's. It is generally agreed that a QSO consists of an extremeiy small, very massive nucleus, with a total size of less than a light-year, which is surrounded by an extended halo of gas that is being excited by the energy radiated by the central object. The line spectra, both emission and absorption, arise in different parts of this cloud. The electron temperature, the temperature calculated from the physical condition of the electrons in the cloud, and electron densities in the gas are approximately 30,000" K, and approximately 100 to 1,000,000 electrons (and an equal number of protons) per cubic centimetre. Calculations show clearly that there is a widespread range of values in different QSO's. The composition of the gas regarding those elements that can be analyzed appears to be similar to that in gaseous nebulae in the Galaxy. The multiple absorption red shifts are probably to be associated with shells of gas that are moving at speeds ranging from about 1,000 kilometres per second to about 150.000 kilometres per second relative to the central object.

This central object emits radiation over a wide spectral range and the basic radiation mechanism is thought to be the synchrotron process; that is, radiation by relativistic electrons moving in magnetic fields that also occurs in artificial particle accelerators called synchrotrons. The intensity of the radiation varies as a power of the wavelength. A graph of this relationship, in many cases, steep-*ens* from the optical into the infrared region of the spectrum. The bulk of the power is radiated in the optical and the infrared regions. Scattering of the photons by electrons·— the Compton effect.—may be important in some situations.

Energy released by QSO's

It is generally agreed that the energy emitted by QSO's, by strong radio sources, and by galactic nuclei is gravitational energy and not thermonuclear in origin. It has been argued that it is generated in multiple supernova outbursts, each supernova collapsing and releasing a large amount of gravitational energy, or in collisions between stars, or in the gravitational collapse of a single supermassive star, or, related to this, that it is derived from the rotational energy of a supermassive star. The total energy released is determined by the luminosity (the total brightness) and the lifetime of the object. The luminosity is uncertain because it depends on the distance assumed. If the red shifts are cosmological in origin the luminosities are 10^{46}–10^{47} ergs per second, while if the objects are only at distances 100,000,000 light-years, the luminosities are 10^{42}–10^{43} ergs per second. The lifetimes in the luminous phase are estimated to be 10^{6}–10^{7} years, so that the total energy released lies in the range 10^{56}–10^{62} ergs or the rest-mass energy (the amount of energy equivalent. to a certain mass; mass and energy are sometimes interchangeable) corresponding to masses of from 100 to 10^{9} times the mass of the Sun. In the case of the strongly radiating radio galaxies, in which the distances are not in doubt, the total energy released is known to be 10^{60}–10^{62} ergs. Since according to general relativity only a few percent of the rest-mass energy is likely to be released even in the most favourable situations, it is clear that very large masses must be present in the very small volumes observed. Theoretical investigations of this problem have not led to any detailed acceptable theory. There are two basic problems: to understand how very large mass concentrations are produced and how they evolve, and then to understand the details of. the mechanisms by which a large part of the available energy is transformed into relativistic particles, which then radiate their energy via the synchrotron process and Compton scattering.

Violent activity in galaxies

It is now realized that the QSO phenomenon is closely related to violent activity that takes place over a wide range of power levels in the nuclear regions of many, and perhaps all, galaxies. This activity is manifested by the generation of nonthermal radio, infrared, and optical radiation; by the excitation of large masses of gas; and by the ejection of comparatively cool matter and relativistic plasma, a gas formed of electrically charged particles moving at speeds approaching that of light. The latter gives rise to nonthermal radio emission far from the centres of many galaxies. The nucleus of the Galaxy, of which the solar system is a part, shows some of these violent characteristics, as do many nearby galaxies, but the power level is low, so that they would remain undetected if they were at great distances. The fact that so many galaxies are known to behave in this way suggests that the phenonienon takes place fairly continuously over much of the life of a galaxy. An understanding of the sequence of events that leads to this situation will only come when it is understood how galaxies form and evolve, and this problem cannot be disentangled from cosmology. If the universe is evolving, and if the galaxies formed from diffuse matter at an early stage soon after a very dense beginning phase (a view that is taken by many), then it is necessary to understand how a very compact nucleus is formed through successive evolutionary stages going to higher and higher densities so that eventually gravitational energy release leads to the activity that is now seen. An alternative possibility advocated originally in another context by Sir James Hopwood Jeans in the 1920's, and later by some advocates of the steady-state (nonevolutionary) cosmology, is that the nuclei of galaxies are the places in which matter is being created, and that the activity in QSO's and in nuclei in general is a manifestation of this. The Soviet astronomer and academician V.A. Ambartsumian, who already proposed in 1958 that this type of activity would turn out to be of the greatest importance, has argued, within the framework of an evolving universe, that the violent activity is caused by small regions in the initial dense configuration in which expansion has been delayed by varying amounts.

Plainly the problems are of great significance since this area may be one in which astronomy will have a direct impact on fundamental physics, but no clear picture has emerged so far.

There is a clear continuity between the QSO phenomenon and the activity in the nuclei of galaxies. If it is accepted that the red shifts are all due to the expansion of the universe, the QSO's are some of the most energetic events of the type seen in galactic nuclei, and at a time in the past corresponding to red shifts of approximately two, the universe went through a phase at which there was much more activity than there is at present. If the QSO's are local objects, their energetic properties are no greater than those of many galactic nuclei, and the powerful radio galaxies are the most energetic manifestations of nuclear activity so far discovered. In this picture, however, the existence of large intrinsic red shifts must be related to the physics of the nuclei themselves.

(G.B.)

Quebec (Province)

One of the 10 provinces of Canada, Quebec is bounded on the north by Hudson Strait and Ungava Bay, on the east by Labrador, on the southeast by the Gulf of St. Lawrence and New Brunswick, on the south by the United States (Maine, New Hampshire, Vermont, and New York), and on the west by Ontario and Hudson Bay. Its 594,860 square miles (1,540,680 square kilometres) of land and water make it the largest Canadian province in area, while its more than 6,000,000 inhabitants make it the second most populous, after Ontario. Its capital, Quebec city, is the oldest city of Canada, and its metropolis, Montreal, is the largest city in Canada.

Historical and contemporary complexitiesof Quebec

To understand present-day Quebec, however, one must see the province against a background that goes back to the creation of the French colony in North America during the 16th century. Most observers would agree that the single most important theme in Quebec's history since the British acquisition of New France in 1763 has been the continuous attempt to achieve an accommodation between the numerically dominant French-speaking population and the economically dominant English-speaking one. Whatever changes in geographical size or political institutions have taken place in the province, life in Quebec has always been marked by a collective effort to maintain a distinct society. This characteristic in the second half of the 20th century was at the core of debates over the future of the federal structure of all Canada.

The present Province of Quebec was created in 1867, after being the colony of New France for over two centuries until it was ceded to Britain in 1763. Named the Province of Quebec between 1763 and 1791, it then became the Province of Lower Canada until 1841, and then the District of Canada East until 1867. During these earlier periods its geographical boundaries were changed arbitrarily, and only in the 20th century, with the reacquisition of the northern part of Quebec, did it acquire its present size. Even today, however, there are problems about the eastern boundaries, because no Quebec government has accepted a 1927 decision of the British Privy Council to award Labrador to Newfoundland.

Quebec's size and its boundaries are not the most important influences on its life. Profoundly marked by 18th-century wars between France and Britain over their North American territories and by difficulties between the two linguistic groups since 1763, the social, economic, and political institutions of Canada and of Quebec have been unable to solve these tensions. Because only in Quebec and at the level of the federal government are French and English on an equal footing as official languages, French-Canadians have felt that they are threatened as a minority group in Canada. In Quebec, where they comprise about 80 percent of the population, they maintain that the situation remains discriminatory. Control by the English minority in Quebec of most economic activities of the province has generally led to exclusion of the French-Canadians from opportunities of economic advancement.

Although men of goodwill on both sides have tried to find a lasting solution, the economic and social inequalities have created a growing nationalism among French-Canadians and a feeling among some of them that only the separation of Quebec from Canada can solve their problems. Events since the late 1960s have shown, however, that neither extreme nationalism nor separatism is yet accepted by the majority of those who live in Quebec. For information on related topics, see the articles CANADA and CANADA, HISTORY OF. Features of the province are covered in MONTREAL; QUEBEC (CITY); SAINT LAWRENCE RIVER; and SAINT LAWRENCE SEAWAY.

THE HISTORY OF QUEBEC

Antecedents of crisis. When in 1534 the French explorer Jacques Cartier landed at present-day Gaspé and took possession of the land in the name of the King of France, he brought with him the traditions of mercantile expansion of 16th-century Europe to this land where Indians and Eskimos had been living for some thousands of years. That some school books start the "real" history of Quebec with the founding of Quebec city by Samuel de Champlain in 1608 reflects the mercantilist attitudes of the 16th century. The debate among historians as to what comprises the real history of Quebec, however, is not limited to the question of who were the first occupants. Because the Province of Quebec as a political and geographical entity was created by the proclamation of 1763, the notion is sometimes also advanced that its real history should start with the capitulation of the French Army in 1760.

Problems of cultural and national identity

The various definitions given by historians are not simply semantic questions, for they contain diverse assumptions concerning the political identity of the Quebec government. For example, there is a political tradition among French-Canadians that the government of Quebec is also the government of the French-Canadian people, and, therefore, they are heir to what was New France. The 1966–67 ***Annuaire du Québec*** ***(Que'bec Yearbook)*** states this claim most clearly:

> Quebec is a state with limited responsibilities that belongs to the Canadian Federation as a province. It is also the national state of the French-Canadians and exercises its governmental prerogatives, in the areas of its responsibilities, on the majority of the heirs of those who colonized New France.

To this, some authors have replied that the territories covered by New France and those now included in the Province of Quebec cannot be equated. Although New France began with the founding of three cities—Quebec city in 1608, Trois-Rivières in 1616, and Montreal in 1642—it finally included territories that extended west in what is now the United States to the Ohio and Mississippi rivers. Even if the British government, by the Quebec Act of 1774, did in fact include practically all the territories of New France in the new Province of Quebec, this situation lasted only briefly.

Some English-speaking historians assert that the Quebec Act created what is now Quebec as well as the practice of trying to fuse British and French institutions in the new political entity. The new British colony was, thus, to be governed by a governor and a council, using British criminal law and French civil law. Whatever the British government intended, however, when the composition of Quebec's population gradually changed as a result of increasing English-speaking immigration, it became increasingly difficult to carry out a policy that could give satisfaction to both the English- and French-speaking groups. In 1775, the year the American Revolution broke out, Quebec city was besieged by American troops, and Montreal was occupied. When peace was restored in 1783, the Loyalists who had fled from the United States were settled west of Ottawa River, in what became the Province of Ontario. This was the beginning of the basic geographical dichotomy in Canada between French and English. In 1791, Canada was split into Lower Canada (Quebec) and Upper Canada (the future Ontario), roughly following the Ottawa River boundary.

Beginnings of ethnic inequities

Furthermore, although throughout the province the rural population remained overwhelmingly French, Montreal became the domain of the English merchants, who were bitterly anti-French. The metropolis of Canada was to have an English-speakmg majority until the middle of the 19th century, and, even after that, French-Canadians never achieved control of its economic life. In this way, the ethnic-economic stratification was maintained within the Province of Quebec. Discrimination existed between the two linguistic groups not only in economic, political, and religious activities but also in such other fields as education. Gradually, two different educational systems came into being. English-speaking McGill University was opened in 1821, but it was not until 1852 that the French-speaking Quebec Seminary, founded in 1668, became Laval University.

Continuing symptoms of internal malaise. During the first part of the 19th century, the causes for conflict between the two groups increased with the rapid growth of the English-speaking population in Canada. The English merchants of Montreal tried in 1822 to obtain an Act of Union that would have united Lower and Upper Canada and given them an English-speaking majority in the country as a whole. The reaction against this attempt among French-Canadians was strong and prepared the way for the 1837 rebellion. This rebellion, the first major manifestation of political nationalism among French-Canadians, was led by Louis-Joseph Papineau, whose Patriote Party became a centre for radical politics. After the rebellion was put down, the British government sent out the Earl of Durham to investigate; his report, published in 1839, offended French-Canadians by referring to them as a people without a history or culture and by characterizing the situation in Lower Canada as "a war between two races." The report also suggested the setting up of responsible government in Canada as a solution to the tensions between the two groups. In 1841 a new Act of Union joined the provinces of Upper and Lower Canada, and, in 1867, the British North American Act created the confederation of Canada by the federation of the four provinces of Nova Scotia, New Brunswick, Quebec, and Ontario.

From then on, French-Canadian nationalism became a permanent feature of Canadian as well as Quebec politics. Doctrines of papal supremacy over national authority introduced the idea of the religious mission of French-Canadians in North America. Under the leadership of such men as Henri Bourassa and the abbé Lionel Groulx, the province evolved its special vocation as the "political home" of French-Canadians, and the government of that province assumed special responsibility for the defense of French culture. This situation also resulted in the doctrine of provincial autonomy that was used by Prime Minister Maurice Duplessis during his various terms of office between 1936 and 1957.

French-Canadian nationalism also led to the "quiet revolution" of the Liberal government under Jean Lesage, who took office in 1960, and to the not-so-quiet revolution of a terrorist group known as the Front de Libération du Québec (FLQ), which was responsible for sporadic violence and the murder in 1970 of Quebec's labour minister, Pierre Laporte. The creation of the Parti Québecois in 1970 brought into being a new form of Quebec nationalism, one that is no longer strictly French-Canadian: it has English-speaking members as well as members of other ethnic groups, and its advocacy of separation from Canada is based on issues of economic and social development.

Revival of nationalism and separatism

THE NATURAL AND HUMAN LANDSCAPE

Quebec is a sort of "land's end," almost separated from the rest of Canada by Hudson Bay and Hudson Strait. For a number of years, provincial maps issued by the Quebec government have reflected the long-standing dispute by not showing the Labrador boundary, thus including the whole of the North Atlantic Coast down to the Gulf of St. Lawrence as part of the province.

Physical environment. ***Geographical regions.*** Quebec usually is divided into three major geographical areas that reflect its main geological structure: the Canadian Shield (aiso called the Laurentian Shield); the populated lowlands of the St. Lawrence Plain; and the Appalachians. The Canadian Shield covers 95 percent of Quebec, comprising the entire region north of the St. Lawrence Plain. Beginning at the foothills of the Laurentians, the oldest mountain range in the world, it runs northward to the Hudson Strait. The Shield is composed of three main subdivisions: the Laurentian Hills, covered with trees, have become a natural playground for summer and winter activities; the taiga, a region of stunted trees farther north; the tundra, in which a continuously frozen ground, or permafrost, allows no trees to grow and where summer enlivens only caribou moss and a few dwarf birches.

The fertile zone of Quebec and the most densely populated is the lowlands of the St. Lawrence Plain, while the Appalachian region is composed of hills and plateaus, more or less undulating and rising to the higher mountain ranges in the United States. This region includes the Eastern Townships (the area south of the St. Lawrence Plain) and the Gasp6 Peninsula.

Waters. The landscape of Quebec is laced with thousands of lakes and rivers: if the St. Lawrence is included, the freshwater area amounts to some 110,000 square miles. The St. Lawrence, which cuts across southern Quebec from west to east, is one of the world's greatest waterways. Among its tributary rivers are the Ottawa, the Saguenay, the Saint-Maurice, and the Manicouagan.

Climate. Quebec's climate is often extreme, sometimes severe. In Fort-Chimo, on Ungava Bay, the temperature ranges from an average of —11° F (—24" C) in January to 52" F (11° C) in July. In the south in Sherbrooke, it varies from a January average of 15° F (—9" C) to a July average of 68° F (20" C). Temperature changes may be as great as 30° F (17" C) in less than 24 hours. The period in which the snow remains on the ground differs from an average of 12 to 13 weeks on the Montreal plain to 23 weeks on the north coast of the St. Lawrence. The same variations exist for days without frost, Montreal having an average of 140 days without frost, the far north fewer than 80 days.

Patterns of settlement

Human imprints. For all practical purposes, the inhabited part of Quebec is limited to the St. Lawrence Plain and parts of the Appalachians and the Laurentian Hills. Over 80 percent of its population lives within an area 200 miles long and 60 miles wide, one of the highest concentrations in Canada. Almost 80 percent lived in towns in 1970, and fewer than 500,000 were classified as rural farmers; the balance of the population was scattered in forestry, fishing, mining, and other types of activity in small settlements. The historical movement of the population in Quebec has been from large numbers in scattered, diversified settlements to an increasing concentration in urban areas. The shortage of fertile land suitable for cultivation prevented the development of a truly agricultural economy. Contradicting some long-held beliefs, sociologists have advanced the idea that Quebec never developed a peasant society on European models.

The rural settlements that existed during and after the period of French control were limited to the shores of the St Lawrence, forming a continuous line between the urban centres of Montreal and Quebec city. Outside of Quebec city, Trois-Rivières, and Montreal, the land was divided into long, narrow, individual strips. A house was built at the end of each of these strips, on the side of the road that led to the towns, thereby forming a type of ribbon development. Rural Quebec had no village until the end of the 18th century, and most rural paiishes were created during the 19th. As each road became fully settled, a parallel road was opened further inland, a process that was repeated until the whole of the St Lawrence Plain was occupied This system cf colonization. in which houses were located equidistantly along a road, allowed for maximum density in settlement, but it was not suitable for agricultural activities.

The very rapid urbanization of the province in the 20th century did not imply, therefore, the breakdown of a traditional peasant society. Although relatively isolated rural and fishing settlements existed on the north coast of the St. Lawrence and mining and foresting settlements existed in the Laurentian Hills or in northern Quebec, these communities did not create any distinctive “folk” type of society that would have grven a dominant cultural orientation to French Canada. As research has shown, the rural mode of life remained within the general cultural norms of Quebec as a whole.

Until the 1940s, when industries dislodged agriculture from its economic dominance, most French Canadians lived in rural areas, receiving their income from mixed farming, forestry, fishing, poultry raising, livestock, and dairying. In the St. Lawrence Plain, the favourable soils and climatic conditions added a certain diversity of crops —tobacco in Joliette, sugar beets in the Richelieu Valley, and apples in the Montreal plain. The early-springtime collection of sap from the maple trees and the "sugaring-off" process is a pleasant feature of Quebec agriculture.

Importance of the Canadian Shield area

The future of Quebec is, however, now linked with the development of the Canadian Shield, which contain? one of the world's largest reserves of minerals. The first area to be developed in the 20th century was around the Noranda–Rouyn area, which is noted for copper, zinc, lead, gold, and silver. Continued demand for copper resulted in the opening up of new mines in Chibougamau. At present, the main attention is on Labrador, where large deposits of iron are located. Outside the shield. copper is mined at Murdochville in Gaspé, while the Eastern Townships supply nearly two-thirds of the Western world's output of asbestos.

Cheap waterpower, abundant raw materials, relatively iow labour cost,, and dense concentration of population in the St. Lawrence Plain have been the main factors behind the development of industries in Quebec. The process began with the building of textile mills in the Eastern Townships, but industry gradually was concentrated in the Greater Montreal area, in which today some 5,000 plant? account for 60 percent of Quebec'? manufacturing output. Montreal is a leading producer of aircraft, railway locomotives, leather footwear, and chemical and pharmaceutical products; other industries include flour milling, tobacco, biewing, and distillery. Montreal also has oil refineries that supply nearly one-third of the petroleum requirements of Canada.

Because of the present distribution of the population. Quebec can be presented as a dichotomy between Greatei Montreal, with more than 40 percent of the population, and the rest of the province. Although other large cities in the province include Quebec, Chicoutimi, Hull, and Trois-Rivières, this division represent3 the basic structure of Quebec society. In the rural backwaters, most of the population ekes out a meager living by cultivating relatively small farming lots and by cutting wood In the smaller cities and in Greater Montreal are to be found all the characteristics of modern industrial urban concentrations, with their pollution and their social pathology. The dichotomy is most evident when outlying areas of Quebec are compared with Montreal. The Gasp6 Peninsula, the poorest and least urbanized region, has over 240,000 inhabitants, but it is only about one-third urban. Nearly 20 percent of its population earns its living through agriculture. and, in the summer months, tourism becomes the major source of income for the population.

THE PEOPLE OF QUEBEC

The ethnic mélange. Because the distribution of the various ethnic groups is the single most important factoı m Quebec's social, economic, and political life, past and future trends must be taken into account. In the years of French colonization, from 1608 to 1750. only some 10,000 French came over to settle on the shores of the St. Lawrence. The approximately 60,000 persons who were "ceded" to Britain in 1763 were practically all Canadian born, and most of them traced their descent through several generations of habitants, the name given to those born in New France

Impact of changing birth and death rates

The high birth rate among habitants explains the growth of French Canada. Between 1700 and 1760, the average yearly rate of birth was between 54 to 62 per 1.000 inhabitants, while the death rate war relatively low for the time: between 24 and 40 per thousand. After 1763, this extremely rapid natural growth of the population cootinued, and from 1800 to 1850 the total number of French-Canadians increased from about 100,000 to 1,000,000.

The very favourable conditions for population growth ceased gradually to operate during the 19th century, however. for the fertile lands around the St. Lawrence were fully occupied, and increasing difficulties were encountered in maintaining satisfactory economic conditions for family life. French-Canadians began a migration to the United States and other parts of Canada that between 1840 and 1940 is said to have taken 1,000,000 persons from Quebec. Although efforts were made to open new rural areas in more northerly Quebec, the harsher conditions of life limited the new settlements. Trends were, in fact, away from rural settlements, and the new industries attracted an ever larger number into the towns. By the beginning of the 20th century, the birth rate had been reduced to about 38 per 1,000, while the death rate still hovered around 20 per thousand From then on, both figures declined rapidly, especially the death rate. In 1963 the birth rate was about 16 per 1,000, the lowest in Canada, and the death rate less than 7. By 1970 the birth rate had fallen to 15.3, bringing about what some authorities called a “crisis of the birth rate ”

As a result, the overall population distribution in Quebec is changing. Predictions made by demographers from the Université de Montréal suggest that by the year 3000 the oresent 68 percent of Montreal that is French-speaking may decline to 50 percent, while the overall French population in the province may drop to 70 percent. With nearly half of Quebec's population in the Greater Montreal area, what is happening there to population distribution is of considerable political importance The cosmopolitan character of Montreal makes it a “pluricultural” city, with a diversified population of persons of British origin (close to 12 percent in 1961), Italian (7 percent), German (1 percent), and many others (12 percent).

At a time when there are demands for change in the electoral map of Quebec so as to give better representation to the urban population, ethnic pluralism has become a decisive factor of Montreal politics and is gradually acquiring more importance in the Province of Quebec. The long-term trend in population change is making for an ever greater differentiation between Montreal and the rest of Quebec, so that most of the cultural legislation prepared by the Quebec government will become less and less acceptable for Montreal. This fact became evident when, at the end of 1971, a bill to reorganize the educational system of Montreal was withdrawn from the National Assembly of Quebec because of attacks on it from nationalistic French-Canadian groups and from other ethnic groups who, for diverse reasons, felt their linguistic rights threatened.

The Indian population of Quebec has grown to more than 25,000, distributed among 39 different reserves and

Northern coast of the Gasp6 Peninsula.

Indian communities. Some 3,300 Eskimos live in northern Quebec. Eskimo and Indian affairs in Canada are under federal jurisdiction, but, with the transfer of certain responsibilities to the province, a Direction Générale of northern Quebec has been created by the Quebec government to provide services for the Eskimo population. This creation has led to a debate between the federal and provincial governments as to their exact responsibilities in this matter.

Religion. Another distinctive characteristic of Quebec has been its religious homogeneity. During the period of New France, Catholicism was the official religion. After 1760, freedom of religious practice was authorized bv the British government. As the English population grew, so did Protestantism. Following the potato famine in Ireland in the mid-19th century that forced many Irish to migrate to Canada, the number of Catholics in Quebec also increased. Many marriages took place between the Irish and the French-Canadians, and today many persons in Quebec who have French as their mother tongue have Irish names. With the coming of such new immigrant groups as the Italians after World Wars I and II, the proportion of Catholics again increased and stood at 88 percent in 1961. For a long period, religion was a basic mode of differentiation among the various groups; today this is not so. Religion is no longer a major aspect of Quebec's political life.

Increasing proportion of non-French Catholics

Current immigration. During the 1960s, Quebec received about 20 percent of all immigrants entering Canada, some 30,000 each year; the largest group, about 5,000 a year, was from Italy. Immigrants from France were the second most important group, while immigrants from French-speaking countries made up between 25 to 30 percent of the yearly average for those years. The tendency, however, has been for the majority of immigrants to settle in Montreal, to choose English as their working language, and to send their children to English-speaking schools. To solve certain problems in social and linguistic integration, the Quebec government in 1968 created a Department of Immigration.

THE PROVINCIAL ECONOMY

The most distinctive feature of Quebec's economy is clearly shown by its present distribution of labour, which in 1967 was about 61 percent in tertiary, or service, industries; 30 percent in secondary, or manufacturing–processing, industries; and the balance in primary, or agricultural–extractive, industries. Although until recently Quebec was considered to have a mainly agricultural vocation, the occupational concentration that now exists in industrial and service activities shows that Quebec has followed the general trend of industrialization in Canada.

Quebec's economic growth, however, has done little to change the economic position of French-Canadians. Within the major corporations, banks, or branches of multi-national companies that operate in Quebec, few French-Canadians have risen to the top. Promotion has been very slow for them, even in the nationally owned Canadian National Railway or Air Canada, both of which have their headquarters in Montreal. This problem has provided an increasing point of contention in the province's social and political unrest.

Economic resources. Because of continuing difficulties in surveying the land, it is not yet known how extensive Quebec's natural resources are. What is known to exist is quite considerable, especially as far as mining is concerned. Between 1910 and 1970, mineral production increased 100 times in gross dollar value (not accounting for inflation). This rather spectacular development is due to the discovery of extremely large iron-ore deposits in northern Quebec. Geologists estimate that these deposits are among the largest in the world. Two new towns have been created in the north as a result, Schefferville and Gagnon, and a large port, Sept-fles, has been developed. The government of Quebec has created two corporations to survey resources and stimulate exploitation. Furthermore, since only a small part of Quebec's iron is processed in the province, it has created another corporation, the objective of which is to develop an integrated iron-and-steel industry in Quebec. Another major development has been the establishment of the General Investment Corporation. The aim of this corporation is not only to finance economic growth by acting as a broker in the amalgamation of small firms but also to lend money to start new industries.

Minerals, water-power, and forestry

Another of Quebec's major economic resources is electric power. With the nationalization of all electric power in Quebec in 1963, Hydro-Québec became the largest producer of electricity in Canada, its installed capacity representing over one-third of all electricity produced in Canada. Besides its more than 50 hydroelectric plants, Hydro-Québec has 17 thermal plants, and a nuclear plant opened near Trois-Rivières in 1971. With the government of Newfoundland, Hydro-Québec is engaged in developing the hydroelectric resources of Churchill Falls in Labrador. The James Bay project, under discussion in the early 1970s, will increase electric resources further. In February 1967, the Research Institute in Electricity, the first of its kind in the world, was created near Montreal, employing more than 200 research workers.

Forestry is the third great economic resource of Quebec, It is estimated that forests cover close to 400,000 square miles, of which some 221,000 are actually exploited, contributing about 25 percent of the gross industrial production. About two-thirds of the annual forest harvest is used by the more than 50 pulp and paper plants in Quebec, which employ more than 28,000 employees and produce nearly one-half of the Canadian and over one-tenth of the world's pulp and paper products.

Production sectors. The gross domestic product of Quebec is growing, but its rate of increase is less than that for Canada as a whole. A number of unfavourable factors affect Quebec's economy, and such areas as textiles were definitely in regression in the early 1970s, causing a high rate of unemployment. Slowdowns in investments have been reported for the pulp and paper industries, food and beverages, construction, and other related services. The per capita income has also lagged significantly behind that of Ontario, the other highly industrialized province.

Transportation. Quebec is fully integrated in the general transportation system of Canada and of North America. Except in northern Quebec, neither climate nor distance are serious problems. The major handicap in the development of transportation is the low population density of the regions outside the urban area of the St. Lawrence Valley and the restricted flow of goods and persons to the north. With nearly 57,000 miles of modern highways, 73 airports, more than 5,000 miles of railroads, and numerous ports on the St. Lawrence, however, transportation facilities play a paramount role in the growth of industries. Yet, with about 2,000,000 road vehicles, Quebec has a lower per capita ratio of vehicles than the Canadian average.

The transportation system is largely oriented on the basis of the geographic position of Montreal, the major crossroad for moving persons and goods in and out of Quebec, whether by road, water, or air. Nearly 30 international airlines serve Montreal. Montreal International Airport, in Dorval, ranks second only to Toronto's airport in flights and passengers. The inner air traffic for Quebec province is provided by two companies. Montreal is both a major ocean port and, by virtue of the St. Lawrence Seaway, which allows ships to travel a total of 2,300 miles from the North Atlantic to the ports of the Great Lakes, a major inland port as well.

The railway system of Quebec is practically restricted to the St. Lawrence Plain, with a few branch lines of the two major Canadian companies. Three privately owned railways transport iron ore from northern Quebec.

In urban transportation, the subway system in Montreal has 16 miles of track that supplement the Montreal Transportation Commission surface routes. Quebec has 25 other urban transportation services and more than 50 transportation companies carrying passengers to and from various towns.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. *Provincial level.* Quebec's administrative system, created by the British North American Act of 1867, can be defined as government through parliamentary democracy. An elected unicameral National Assembly is the equivalent of the parliamentary institutions of other Canadian provinces; its second chamber was abolished in 1968. A lieutenant governor represents the British monarch. The Executive Council, or Cabinet, of 23 ministers is headed by a prime minister who is responsible to the National Assembly for all legislation within provincial competence. The Executive Council has responsibility for preparing legislation for the National Assembly. Adoption is assured through the parliamentary principle that a prime minister and his Cabinet will remain in power as long as the prime minister is able to command a majority in parliament.

Legislative, executive, and judicial branches

An unusual characteristic of Quebec is its administration of justice. Although its Department of Justice, as in other Canadian provinces, has a dual responsibility for criminal and civil laws, the civil law of Quebec is different from that in the other Canadian provinces. It also has its own provincial police, La Sûreté Provinciale du Québec, who have taken over this responsibility from the federal Royal Canadian Mounted Police.

Politics. To elect the National Assembly for its four-year mandate, Quebec is divided into 108 electoral districts, each returning a representative on the basis of a majority vote. There is a universal franchise for all persons over the age of 18. The law limits electoral expenses, and the state pays a major part of each candidate's costs. An imbalance exists in the representation between rural and urban districts, a problem that was especially important in the 1970 election, when the Parti Québecois claimed that the present system was undemocratic. In that election, more than 80 percent of the 3,500,000 registered voters went to the polls. Since then, a parliamentary commission has been created to propose a new electoral map of Quebec.

Provincial–municipal interactions. The Quebec government long centralized the greater part of its administrative activities in Quebec city, but, to regionalize its responsibilities, 10 regional administrative centres were created in 1966. Certain difficulties have been encountered in developing this new administrative structure, however, because there are more than 1,600 municipalities in Quebec, each with its own form of local administration. Each municipality consists of a council and a mayor. The councils administer revenues, which come mainly from diverse local taxes as well as f om government grants. In defense of their autonomy, local governments have resisted the efforts of the provincial government to integrate them into some form of regional administration, even when the need for such coordination has become most urgent—as in the development of police, transport, and similar services for Greater Montreal. Although regional administration has been in existence for Greater Montreal since 1970, the conflicting claims of the separate municipalities present constant difficulties.

Revenues. Another problem of the provincial administration has been that of finding ways to increase revenues. In Canada, taxes are divided into the four levels of administration: federal, provincial, municipal, and school board. Quebec, unlike the other Canadian provinces, also levies direct taxes on personal and corporate incomes and on estates, which together represent about 50 percent of the total taxes paid in the province. Other sources of income are an 8 percent tax on retail sales, a provincial lottery, and a provincial monopoly on the sale of alcoholic beverages. Municipal corporations and school boards also impose real-estate taxes and some taxes on business and on the retail value of premises. All these sources of revenue have been insufficient, however, to finance the large-scale health, social, and educational investments that have been made by the Quebec government, and one of the main sources of conflict between the federal and the Quebec governments has been the redistribution of federal tax revenues.

Problems of revenues and social services

The social milieu. Social conditions in Quebec differ from those in the rest of Canada in a number of respects.

Services. Although sharing with the rest of Canada one of the world's highest standards of living, Quebec has a larger proportion of unemployed and persons on social security than the Canadian average. The cost of social aid is one of the highest among provincial governments in Canada. This situation is explained by the fact that age, health, level of education and training, and similar factors place a higher percentage of the population below the requirements of a modern industrialized society. The Quebec government began a large-scale re-evaluation of social assistance in the early 1970s and was trying to develop minimum-wage legislation. It also completely reorganized its health service and introduced universal medicare. These steps meant stretching resources to the limit, however, and serious difficulties were being encountered. Nationalist French-Canadians also point out that, because the basic resources in Quebec are in the hands of the English-speaking minority, the inequalities between the two linguistic groups cannot be solved until economic decisions are completely controlled by the Quebec government.

Thus the relation among economic development, social conditions, and educational level remains one of the basic causes of the political tension between French and English, on the one hand, and between the federal and the provincial governments, on the other. Although Quebec has transformed some of its institutions in order to meet the difficult demands of an industrial society, the changes are yet too recent to be able to determine whether they will improve the present situation permanently. The ethnic division of labour between French and English in Quebec, according to all the published research on the subject, shows no improvement, and the various reports published by the Royal Commission on Biculturalism and Bilingualism in Canada indicate that the goal of equality between the two ethnic groups is as distant as it was at the beginning of the 1960s.

Education. Nothing shows more clearly the complex nature of Quebec than its educational system. Organized originally along religious and linguistic lines and largely privately financed, it has become, for all practical purposes, a public system since 1964 under the provincial Department of Education. Larger sums are spent each year on education (in 1970–71 more than 30 percent of the province's expenditures). Although the religious dichotomy between Protestants and Catholics has been maintained, it is largely along linguistic lines that the separation continues. A major problem is the gradual growth in the number of English-speaking pupils, while, because of the low birth rate, the overall number of French-speaking pupils at the elementary level is decreasing. Some tension exists over the fact that, because of the law that permits parents to choose the language of education, increasing numbers of persons are choosing English.

Organized on the normal structure of pre-school, elementary, secondary, and college–university levels, the new system has created Collèges d'Éducation Général et Professionnel, which act as two-year pre-university-level institutions. There are three English-speaking and four French-speaking universities; of the latter, the Université du Québec is organized in three campuses, in Montreal, Trois-Rivitres, and Chicoutimi.

CULTURAL LIFE AND INSTITUTIONS

Ethnicity within the cultural milieu. In many ways, Quebec is a smaller plural society within the larger pluralism of Canada: that is to say, it is nearly as difficult to define the cultural identity of Quebec society as it is to define that of Canada as a whole. Although a minimum of overall cultural identity does exist in French-Canadian life in Quebec, there are also many cultural differences between its working class groups in east Montreal and similar working class groups in such smaller centres as Abitibi, Lac-Saint-Jean, Gaspé, or the Eastern Townships. Regional variations do exist, and they produce a sociocultural fragmentation that in part explains the differences in political votes, religious behaviour, and even the quality in the use of the French language. Furthermore, there are class–cultural differences among French-Canadians, a strong elitist tradition in French Canada explaining the high social status of such professions as medicine, law, and the clergy. Even the new middle class of French Canada, which has appeared since the development of urban industrial society, is more politically aggressive in Montreal than in Quebec city, for the obvious reason that in Montreal their socio-economic status is most difficult. Because of the cultural variations within Quebec, it is often difficult and sometimes impossible to obtain unanimity in political decisions that touch cultural or educational questions.

Ramifications of cultural pluralism

Governmental activities. To ensure that French-Canadians are not placed at too great a cultural disadvantage in their own society, the Quebec government has created a number of institutions that aim to foster cultural life. Foremost among these institutions is the Department of Culture, which is responsible for improving the quality of the language used and for stimulating cultural, literary, and other artistic activities. Created in 1961, it was the first of its kind in North America. It not only gives direct financial aid to such state cultural bodies as museums and helps more than 60 theatrical, ballet, and musical companies but it also has contributed for a number of years to book publishing and to public libraries for book buying. One of the major responsibilities of the department is to develop cultural links with other French-speaking countries, and, in 1965, a cultural entente was signed between Quebec and France that set up cultural- and educational-exchange programs. Another of its activities has been the development of regional cultural centres within Quebec to foster regional cultural life. Another institution created by the Quebec government in its efforts to stimulate French-language cultural development is Radio-Québec, founded in 1968 to develop cultural and educational programs. In 1969 its scope was broadened to take in television as well, and it was renamed Quebec Broadcasting Bureau.

The arts. Besides the official cultural institutions, Quebec possesses an extremely large number of private artistic organizations, ranging from theatre companies to film making. The most spectacular cultural development in Quebec, however, has been that of the ***chansonniers,*** who represent a cross between poets and songwriters. Their popularity, especially among the younger generation, arises from the fact that their songs reflect the present search for cultural and political identity. The *chansonniers* are involved frequently in political activites and are identified largely with the nationalist movement. Music and painting also share in this artistic revival, as does literature. In the area of book publishing, nearly 1,000 books a year are published in Quebec, in both English and French. This activity, together with 19 television stations, 73 radio stations, and 14 daily newspapers, gives an intense and varied cultural life to the province.

PROBLEMS AND PROSPECTS

When in 1967 Gen. Charles de Gaulle, the visiting president of France, made his controversial declaration "Vive le Quebec libre" ("Long live free Quebec") in Montreal, he marked the beginning of a new wave of rising separatist feeling in Quebec. Although an ever larger number of French-Canadians were attracted to extreme nationalism, this renewed wave did not create the required unanimity among Quebecers that was expected by separatists. On the contrary, not only did it sharpen the political differences between English and French and provoke most of the new immigrant groups in Quebec society to make a stand on the question of separatism, it also split French-Canadians into two opposing camps. The new urban, middle class French-Canadians, who form the majority of the population, became divided over separatism, and even the labour unions did not achieve unanimity on this question.

As the chaotic events of the early 1970s have shown, there is no present converging national interest between lower class and middle class French-Canadians. It would seem, therefore, that unless extensive social and economic deprivation among all classes develops in the future to create such a political unity, the present fragmentation among French-Canadians will continue. Although it would be premature to speak about a decline in the present wave of nationalism in Quebec, there is no doubt that a decline in separatism as a political choice has occurred. In many ways, the present social pluralism of Quebec society, with its division between Greater Montreal and the rest of the province, and the new class stratification that is to be found in the cities preclude any extreme solution acceptable to all groups. These facts do not mean absence of conflicts or even of violence, however, and in all probability the present difficulties will continue.

BIBLIOGRAPHY. An excellent short bibliography on historical and literary aspects of Quebec may be found in ***The Oxford Companion to Canadian History and Literature,*** pp. 679–687 (1967); while PHILIPPE GARIGUE, ***A Bibliographical Introduction to the Study of French Canada*** (1956) and ***Bibliographie dzt Québec, 1955–1965*** (1967), cover all areas. The best source of statistical and other basic information is the ***Qztebec Statistical Year-Book*** (issued annually since 1914). On geographical questions, see the chapter on Quebec in LUDGER BEAUREGARD, ***Le Canada*** (1970). No recent single study of Quebec presents the overall situation regarding Quebec's

unique status within the Canadian confederation. MASON WADE, *The French-Canadians, 1760–1945*, rev. ed. (1968), remains the best simple introduction in English. MARCEL RIOUX and YVES MARTIN, *French-Canadian Society* (1964); and *Facets of French Canada*, prepared by the Association Canadienne des Éducateurs de Langue Française (1967), are both collections of essays on social issues. On the recent political events, large documentation has yet to be analyzed properly. Among them the following may be consulted: RAMSAY COOK (comp.), *French Canadian Nationalism* (1969); PIERRE ELLIOTT TRUDEAU, *Le Fédéralisme et la Société Canadienne-Française* (1967; Eng. trans., *Federalism and the French Canadians*, 1968); RENE LEVESQUE, *Option Quebec* (1968); and GERARD PELLETIER, *The October Crisis* (1971).

(P.Ga.)

Quebec (City)

The oldest city of its nation and one of the most picturesque on the North American continent, Quebec (French Québec) is the capital of the province of Quebec and, to its residents, the spiritual capital of French Canada. The thick stone walls of its Citadel, topped by the guns of an earlier day, lie astride Cape Diamond, which rises precipitously for 333 feet (101 metres) out of the north bank of the St. Lawrence River. This "Gibraltar of America" was built to protect the water entrance to New France, at the point where the river suddenly widens on its eastward course to the Gulf of St. Lawrence and the Atlantic Ocean. The name Quebec is derived from an Algonkin Indian word meaning "narrowing of the river," a phenomenon noticed by the explorer Jacques Cartier when he sailed in from the Atlantic in 1535.

European atmosphere

Quebec is often referred to as the most European of cities in the Americas. Among the elements contributing to its distinctive character are its old wards cut through by narrow, winding streets, the architecture of its houses, an overall atmosphere redolent of a bygone France, its relics from the past, and its slow rhythm of life—all existing alongside the institutions of a modern metropolis. The Quebecois, almost 95 percent of them of French ancestry, are a people proud of their past and of the authentic cultural life that has been retained. Vast amounts of money are spent annually on the preservation and restoration of the old city, while, elsewhere within the city limits, demolition is constant for the widening of streets and the construction of other aspects of modern commercial and domestic life.

Present-day Quebec is a major inland seaport open to ocean navigation throughout the year. It is also the centre of provincial administration, the commercial hub of eastern Quebec province, and an industrial city with rail, highway, air, water, and electronic connections to the nation and the world. Its landscape and life tumble across the hills from Cape Diamond to the tablelands around the confluence of the Saint-Charles and St. Lawrence rivers, from the governmental and cultural centres of the upper city to the commercial centres and slums in the lower city. Amid its geographical complexity and in its sometimes jarring juxtapositions of centuries, Quebec is both a contemporary city growing vertically and a living museum of man's aspirations to re-create the forms of his civilization in a wilderness. (For information on related topics, see QUEBEC; CANADA; CANADA, HISTORY OF.)

History. The origins of Quebec coincide with the discovery of Canada. Jacques Cartier, the first European to sail up the St. Lawrence River in search of the Northwest Passage to the Orient, landed at the Stadacona settlement of the Huron Indians on September 7, 1535. Chief Donnacona welcomed him favourably. After a hard winter encampment at Cap-Rouge, on the St. Lawrence, during which illness killed many of his men, Cartier returned to France in the spring with Chief Donnacona and five Hurons. Donnacona never returned.

In 1608 Samuel de Champlain revived Cartier's colonial plan, installing the first permanent base in Canada at Quebec. At the foot of Cape Diamond, he built a combination dwelling place, store, and fortress. From here he undertook several expeditions to the interior and made alliances with the Indians he found in the area.

French foundations

The first economic activity of the settlement was the fur trade, but Champlain understood that this alone would not assure the survival of his young settlement. The land had to be tilled, and the Indians had to be "civilized." In 1615 the first missionaries, the Récollets, reached Quebec, followed by the Jesuits in 1625. The first settler, a French apothecary named Louis Hébert, landed in 1617 and built a small house atop Cape Diamond.

In 1628 Quebec was exposed to a long blockade by a British expedition and surrendered in 1629. Though 36 settlers had confidence in the future and remained, Champlain returned to France until 1632, when the Treaty of Saint-Germain-en-Laye returned Quebec to France. The colony was then able to develop rapidly and on more solid bases. Quebec, a colony of men, greeted the return of its Jesuit missionaries and welcomed its first nuns. In 1639 Madame de la Peltrie and two other Ursulines opened the first school, and three Hospitalières established the first hospital. With the arrival of Monsignor François-Xavier de Montmorency de Laval in 1659, Quebec became the first episcopal seat in North America. Laval founded the first professional school and, in 1663, the Quebec Seminary.

During the following years, the first efforts at industrialization emerged. Jean Talon opened the first brewery and set up the leather and hosiery industries. He also encouraged the wood trade and stimulated shipbuilding. New settlers and a regiment of soldiers sent to fight the threatening Iroquois swelled the population of Quebec to about 500; yet it was smaller than that of Montreal, its sister city, 150 miles up the St. Lawrence.

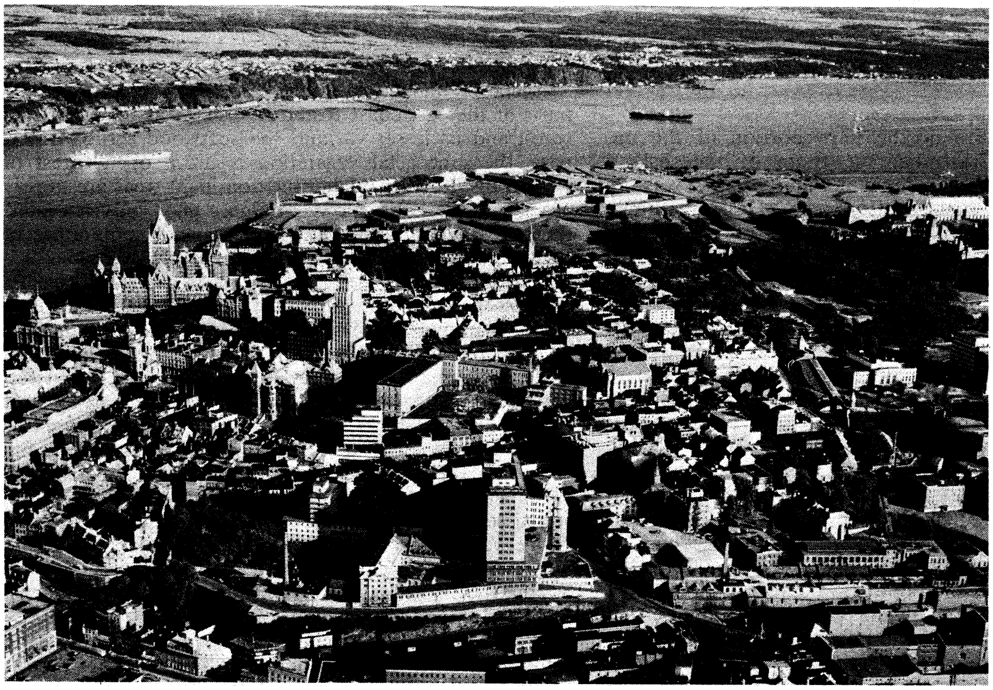
At the same time, the English colonies of America were growing rapidly, and America was beginning to experience the old European rivalries between France and England. A confrontation was inevitable. In October 1690 the fleet of Sir William Phipps attempted to take Quebec but was beaten back by its governor, the comte de Frontenac. Having lost 400 men, Phipps sailed back to Boston. In 1711 a second attempt to take the city also failed when a British armada crashed on the reefs of the St. Lawrence before reaching Quebec.

The traditional enemy came back, however, during the summer of 1759. The expedition included 76 warships, 150 transports, 13,500 sailors, and 9,000 soldiers. It submitted the city to a violent bombardment, but the colony held out. Unable to take it by front, the English troops moved around it; and, on the morning of September 13, they deployed on the heights of the hill to the west of the fortified enclosure. The marquis de Montcalm accepted the battle. Fifteen minutes later the French troops were in full flight. James Wolfe, the English commander, was killed in action, and Montcalm died of his wounds. The city fell on September 18 and finally was surrendered to England by the Treaty of Paris in 1763. A new life under an English governor began for the nearly 8,000 inhabitants of Quebec. In 1775–76, during the American Revolution, the Americans, under Richard Montgomery and Benedict Arnold, failed in an attempt to take the city.

British capture and acquisition

In 1791, after the creation of the provinces of Upper and Lower Canada, Quebec was designated as the capital of Lower Canada, now the province of Quebec. It was incorporated in 1832 and was given its actual charter in 1840. In 1864 Quebec was the seat of the conference of British North American colonies to plan the confederation of Canada. In 1917, during World War I, the city suffered from violent riots in protest over the decision of the Canadian government to enforce military conscription. During World War II, Pres. Franklin D. Roosevelt of the United States and British prime minister Winston Churchill twice met in the Citadel to plan the invasion of Normandy.

The contemporary city. The upper city is built on top of Cape Diamond, the lower city beneath it, most of it lying at the bottom of the cliff and on the foothills of the Laurentides, in the valley of the Saint-Charles. The lower city, by far the largest and most populous, includes the principal commercial centre and densely populated wards with their poverty zones and industrial sections. The upper city is the heart of the artistic and cultural life, of



Quebec city, overlooking the St. Lawrence River. In the background are Chateau Frontenac (left), the Citadel on Cape Diamond (centre), and the Plains of Abraham (right).

provincial and municipal administration, and of the more affluent residential quarters.

Points of interest. Quebec presents many points of attraction for the many thousands of tourists who visit it annually. The best known is the Dufferin Terrace, crowned by the impressive Château Frontenac, a hotel behind which rises the Citadel. From the terrace are visible the Heights of Lévis on the south shore, Île d'Orléans, which divides the St. Lawrence into two branches, and, beyond, the coast of Beaupré, backed by the peaks of the Laurentides. The largest park is the Plains of Abraham, the site of the great battle of 1759. It is located on Cape Diamond, alongside the river, and extends from the west bounds of the city to the bottom of the Citadel walls. A promenade hung on the slope of the rock joins the park with the terrace. Many other parks with various monuments are scattered throughout the city.

The principal relics of the past are religious, many dating from the 17th century. On the Place Royale stands the modest church of Notre-Dame des Victoires (1688). Other old buildings include the Ursuline monastery, the seminary, the Anglican cathedral (the first of that confession in Canada), and the Catholic basilica, where many of the bishops of Quebec are buried.

The Quebecois. Quebec is the nerve centre of an urban agglomeration of almost 500,000 persons, most of them Canadian born and of French ancestry. Slightly more than 5 percent are of other descent, the largest group being Irish. The vast majority are Roman Catholics and French speaking. Most of the English-speaking population is bilingual and descended from old Quebec families and, as a consequence, blends readily into the city's general life.

The port of Quebec

Economic life. The service industries provide jobs for about 80 percent of the working population. Another large group includes provincial, municipal, and federal employees, including those in schools and hospitals. Some 500 manufacturing plants in the Greater Quebec area employ about 25,000 people. This aspect of industrial life is strongly influenced by the port, where each year more than 7,000,000 tons of goods are handled. In order of importance, the major fabrication industries are newsprint, grain milling, cigarettes, garments, and shipbuilding. Factories are situated largely in the vicinity of the port and along the Saint-Charles. The port is 35,000 feet long, and the harbour has a depth varying between 35 and 50 feet at high tide, allowing the accommodation of vessels of up to 50,000 tons. About 1,000,000 visitors a year yield an annual tourism income of $45,000,000.

Government. The administration of Quebec lies in the hands of a municipal council consisting of a mayor and 15 councillors from various districts, each elected for four-year terms. Every citizen 18 years of age and older is entitled to vote. There is also an executive committee presided over by the mayor and responsible to the municipal council. Since 1970 Quebec has been the seat of the Quebec urban community, a body coordinating services for the 23 municipalities within the metropolitan area. It is responsible for all the land valuation, the promotion of industry and tourism, and regional management and long-range planning. The governing body consists of the mayors of the 23 municipalities and an executive council.

Education and community activity. A system of dual school boards——ne for Catholics, one for Protestants—is maintained, with the Catholic schools outnumbering the Protestant schools by 68 to 3. Instruction is carried on in French and English, respectively.

Quebec's cultural life is concentrated on Université Laval and its affiliated teaching institutions. Prior to the early 1960s, higher education was the privilege of a small elite, but since then numerous reforms and financial grants have opened it to students from all social classes. Night courses reach a large adult population, while summer sessions in French attract persons from around the Western Hemisphere.

The concert hall and small theatre of the Grand Théâtre, opened in 1971, became a focus of Quebec's artistic life. The modern building is decorated with a mural by the sculptor Jordi Bonet, a work that caused considerable controversy. Many museums and libraries are available among the public and private institutions. Sports are exceedingly popular, especially hockey, baseball, racing, golf, and skiing in the many centres in the Laurentides only a few miles from the city. The Mont Sainte-Anne centre has been the scene of world-cup skiing tournaments. Among the principal local events are the three-week-long winter carnival ending on the night of Mardi Gras and the Provincial Exhibition of late August.

Queensland

Comprising the entire northeastern portion of the nation-continent of Australia, the State of Queensland reaches well north of the Tropic of Capricorn and was the first successful settlement of European peoples within a tropical climate. The 1,000 miles (1,600 kilometres) of its eastern coastal region are separated by the northern reaches of Australia's Great Dividing Range from the vast inland plains. Extending for 1,250 miles off this coast is the Great Barrier Reef, one of the most remarkable coral formations in the world.

Queensland's 667,000 square miles (1,730,000 square kilometres) make up nearly one-quarter of all Australia and nearly one-third of the occupied part of the continent. It is bounded on the north and east by the Pacific Ocean, on the south by New South Wales, on the southwest by South Australia, and on the west by the Northern Territory. Although Brisbane, the capital, contains slightly less than one-half of the 1,800,000 residents of the state, smaller but sizable cities, especially along the coast, have dispersed the population across a larger area than in any other state of the commonwealth. Settled originally on the basis of the grazing potentiality of its great grasslands, Queensland in the 1970s was becoming increasingly diversified in its economy, a significant part of which lay in the allure of its tropical resorts. (For information on related topics, see the articles AUSTRALIA, COMMONWEALTH OF; AUSTRALIA, HISTORY OF; AUSTRALIA; AUSTRALIAN ABORIGINAL CULTURES; and GREAT BARRIER REEF.)

THE NATURAL AND HUMAN LANDSCAPE

Physical environment. ***Surface features.*** The inland two-thirds of Queensland comprises a vast plain, broken in a few places by low ranges and hills, whereas the eastern (coastal) third is hilly, occasionally mountainous, with wide valleys and plains between the ranges. The Great Dividing Range runs the entire length of the state, separating east-flowing from west-flowing rivers. In South Queensland it lies close to the coast, and peaks reach to 4,500 feet; but it becomes a low range 250 miles inland at the Tropic of Capricorn, and again nears the coast in North Queensland. Between the Dividing Range and the coast are many other ranges, more conspicuous than the Divide in Central and North Queensland, where the state's highest peak is Bartle Frere, at 5,287 feet (1,611 metres).

Mountains, rivers, and soils

The rivers of Inland Queensland flow only after heavy rains, when they flood widely across the flat plains. In the arid southwest, the rivers branch into thousands of distributaries, and big floods are followed by lush growth of clover and other herbage in what is known as Channel Country. Most coastal rivers are also intermittent in flow and shallow, navigable only in the tidal reaches.

Most coastal soils have low fertility, though occasional alluvial and other richer soils occur. Large areas of rich black, gray, and gray-brown soils are found inland, forming the basis for one of the greatest natural grasslands of the world. The Great Artesian Basin underlying the plains provides water for livestock.

Climate. The rainfall of Queensland ranges from 180 inches (4,500 millimetres) a year on the wettest part of the northeastern coast to five inches (125 millimetres) in the southwest. All Queensland receives more summer rain than winter rain, but the latter is important in the southeast, in which large areas of wheat and other winter crops are grown. Rainfall decreases in quantity as one moves inland, where droughts are frequent.

Queensland's summer temperatures are warm to hot, humid on the coast but usually dry inland. Winters are mild and sunny, with frosts occasional on the southern coast and frequent inland. Average maximum summer temperatures, registered in January for the southern coast, the northern coast, and the central inland area, are about 85" F (29" C), 88° F (31" C), and 100" F (38° C), respectively; comparable winter minimums in July are 49" F (9° C), 63" F (17" C), and 45" F (7" C). Humidities are greatest in the north, lowest inland.

Vegetation and animal life. The wetter or more fertile parts of the east coast foster several areas of dense rain forest and its lesser variant, the softwood scrub. Otherwise, the subcoastal vegetation is more open forest of eucalyptus. Further inland, the dominant trees are mostly acacia species—brigalow, mulga, and gidyea—interspersed with large grassy plains and with some areas of desert spinifex, a spiny grass growing in clumps.

Tropical rain forests and exotic animals

Queensland has a great variety of animals—50 species of marsupials, 400 of birds, and 1,600 of fish. Two egg-laying mammals, or monotremes, are the spiny anteater and the platypus. Marsupials range from the large red and gray kangaroos to koala bears, opossums, cuscusses, and marsupial mice. Birds include the flightless emu of the plains, great flocks of coloured parrots, and songbirds of the forests. Fish include the freshwater Queensland lungfish, eating and gamefish, and beautiful reef fish.

Human imprints. ***Traditional regions.*** The strong regional sentiment within Queensland arises from the size of the populated areas, some 1,000 miles from south to north, 800 miles east to west. The main regions are South Queensland, Central Queensland, North Queensland, and Inland Queensland.

South Queensland extends north to Bundaberg and some 200 miles inland, including the Darling Downs farming subregion. Some 1,300,000 of Queensland's 1,800,000 inhabitants live in South Queensland. Rockhampton, Central Queensland's largest city, is the outlet and commercial centre for the beef cattle and wool produced in its hinterland. In recent years this region's vast coalfields have been developed, and a very large alumina-refinery has been built at Gladstone.

North Queensland is identified with sugarcane, producing about three-quarters of Australia's crop. Subregions are Mackay and the Atherton (Atherton Tableland). Townsville serves as the commercial centre for the pastoral hinterland and has a copper refinery nearby. Coalfields lie inland from Mackay and Bowen. Inland Queensland is the great pastoral area of the state. Popularly called the West, it has an identity overriding its 900-mile spread and is sharply different from the coast.

Patterns of settlement. Almost all of Queensland has been occupied by pastoralists for 80 to 100 years, but large areas of the state are little changed from the original landscape. In western Queensland, the flocks of sheep and herds of cattle mainly graze the natural grasslands, the interspersed belts of trees providing only light grazing. In southern Inland Queensland the mulga is a useful drought reserve, since the leaves are edible by livestock. It is cut or rolled down for this purpose, and it regenerates.

Nearer the coast, some large areas of open eucalyptus forest have been "ringbarked," a process that kills the trees and allows grass to grow. A large belt of brigalow timber, an acacia looking much like an eucalyptus, in the 20-to-30-inch-rainfall belt of Central and South Queensland has been partially cleared for farming and grazing in recent years, since the presence of brigalow indicates good soils.

In the crop-growing and dairying region of the southeast and on the sugar-growing north coast, timber has been completely cleared from the better soils, mainly river alluviums and basalt areas. Elsewhere, much original timber remains, and there are many national parks and hardwood forests.

Farm holdings and township patterns

The outstanding feature of land settlement in Queensland is the large size of the grazing holdings and farms. Most of the western grazing country is held in leasehold from the crown, and some 2,000 pastoral holdings average over 100,000 acres in area. On the better grassed country the holdings are 15,000 to 25,000 acres, carrying 5,000 to 10,000 sheep. In the grain-farming areas much of the land is freehold, and most farms are between 600 and 3,000 acres in size. Large holdings, with a high degree of mechanization and a small labour force, suit the rather unreliable rainfall pattern of Inland Queensland.

In the coastal sugar areas, farms range from 50 to 100 acres and are highly mechanized.

The large holdings in rural Queensland have produced a sparse pattern of villages, or townships. In the far west and in the rougher rangy areas of the subcoastal belt, the grazing properties, or stations, are very large, employing six to 20 people and carrying more supplies than a village store. Hence, townships often lie as far apart as 30 to 100 miles.

The last decade has seen a decrease of population in most of western Queensland. In the agricultural areas containing mainly single-family farms, the small towns are closer, about 10 miles apart; but with the improvement of roads and vehicles some small towns are disappearing, and towns of more than 1,000 people and lying 40 to 60 miles apart are serving the rural areas.

Queensland has a more decentralized population than any other state. Apart from Brisbane, with more than 750,000 persons, there are five cities with more than 40,000 and five others with more than 20,000. The development of ports and commercial centres along the Queensland coast and the growth of the sugarcane industry are in large part responsible for this widespread settlement.

THE PEOPLE OF QUEENSLAND

Ethnic groups. Nearly 90 percent of Queensland's population is Australian born, and, as in other states, it is predominantly of English, Scottish, or Irish ancestry. Important minorities came from Germany in the 19th century and from Italy after 1920, the latter frequently becoming cane farmers in North Queensland. After 1947, a wider range of European immigrants arrived from The Netherlands, West Germany, and southern and eastern Europe, as well as some from the United States.

The assimilation of Europeans has been rapid once some fluency in spoken English is achieved, and religion has not proven to be a barrier. The assimilation of the Australian Aboriginal, on the other hand, has been slower. Persons having more than 50 percent Aboriginal blood total about 30,000, including some Torres Strait Islanders, who are Papuan in ancestry. Efforts are being made to give the Aboriginal children the same range of job training as other Queenslanders.

Contemporary ***demography.*** Queensland's present-day birth and death rates are close to the Australian average. The annual birth rate is 21 per 1,000 persons, the death rate nine per 1,000. Throughout its history, Queensland's birth rate has been significantly higher than the Australian average, reflecting a more rural population. The margin has narrowed in recent years with increasing urbanization.

Scourge of tropical diseases in the 19th century

From 1860 to 1890 the death rate was substantially higher than the Australian average. During this period, Queensland's future was threatened by tropical diseases brought in by troops from India, by Chinese miners, and by South Pacific islanders. Almost every tropical disease was introduced, and Queensland seemed likely to suffer the same fate as previous European attempts to settle in the tropics. Intense and continued effort by the medical profession and the Queensland health services, however, progressively wiped out the diseases. Australia's policy of restricted immigration was strongly influenced by Queensland's experience of unrestricted immigration, and after about 1890 the state was developed almost entirely by European labour.

The number of rural workers has declined since 1965, with increasing mechanization of farming and the abandonment of some small farms and dairy farms. These trends have far more than offset the increased population in those few rural areas that still are expanding, notably the brigalow lands.

Although Queensland is the most decentralized of Australia's states, the trend toward increased urbanization is strong. Brisbane's population as a percentage of Queensland's increased from about 39 in 1961 to 45 in 1971. The development of Queensland's great mineral resources, contributing to the growth of mining towns and ports, is both a decentralizing and urbanizing force.

THE STATE'S ECONOMY

Queensland's economic pattern is similar to that of the other states, but its manufacturing is less developed than that of New South Wales and Victoria in such areas as steel, chemicals, and transport equipment. It is more developed in the production of certain minerals, in tropical crops, and in extensive cattle raising.

Components. ***Employment patterns.*** Some 580,000 Queenslanders were employed at the end of 1971, excluding employees in agriculture and private domestic service. The largest groups were in manufacturing, commerce and finance, and professional and personal services. Seasonal unemployment is more noticeable in Queensland than in other states, mainly because of the seasonal nature of sugar harvesting and cattle slaughtering and the decline in construction work in the wet months from December to April. Unemployment ranges from about 1 percent of the work force in the busiest months to 3 percent in the slackest.

Agriculture. The original attraction of Queensland is the great natural grasslands of its interior. The grasslands remain the state's largest single resource, even with the growth of manufacturing, mineral exploitation, and agriculture.

Domination of agriculture by livestock

Wool production is almost all of the fine-textured merino variety. Beef cattle are tending to replace sheep in some areas and already have replaced many dairy cattle. Some of the best croplands in Queensland are fully developed: for sugar production on the coast and for grains on the subcoastal Darling Downs. Other crops include peanuts, tobacco, cotton, and many tropical and temperate-climate fruits and vegetables. Queensland has a greater area of land suitable for further development than any other state, especially brigalow and similar lands suitable for beef grazing and summer grain crops.

Manufacturing. Queensland's manufacturing and processing industries now exceed the output of the rural industries in their contribution to the state's income. Brisbane, which employs more than 60 percent of the factory workers, has by far the greatest range of manufacturers. Elsewhere in the state, most manufacture comprises the processing of such primary products as sugarcane, meat, timber, and alumina and various base metals, as well as in industry supplying local needs—printing, baking, vehicle repair, and the like.

Mining. The most spectacular development in Queensland in the late 1960s was in minerals, including alumina and coal. The value of overseas exports of these rose fourfold between 1966–67 and 1970–71. The great bauxite field at Weipa on Cape York Peninsula exports bauxite overseas and supplies the big alumina refinery at Gladstone. The Mt. Isa mines in the northwest greatly expanded their production of copper and of silver, lead, and zinc. Several large coal mines for the export market have been opened up in the hinterland of the central coast. Natural gas from the Roma field supplies Brisbane, and there is a small oilfield at Moonie.

Tourism. A major Queensland industry, the tourist facilities of the state are serving a rapidly increasing number of Australian and overseas visitors attracted by the mild, sunny winters and moderate summers. Prime attractions include the surfing beaches and the Great Barrier Reef islands, as well as the rain-forested national parks and tours of the eastern coast. The surfing beaches are in South Queensland. Gold Coast, 20 miles of beaches near the southern border, is built on the tourist and holiday industry. It has some 70,000 permanent residents and accommodations for 120,000 annual visitors.

Federal and local services

Role of government. The state government in Queensland regulates those parts of the economy not under federal control and provides directly some services, especially railways, main roads, education, health services, police and law, some forestry and irrigation, and some housing. Operating under state legislation, local authorities provide minor roads, some bus services, water supply, drainage and sanitary services, and town planning. Statutory bodies provide electricity, harbours, slaughterhouses, and marketing of some primary produce.

State industrial awards (wages and hours fixed by the state-appointed arbitration authority) cover some 65 percent of the employees in Queensland, a larger percentage than other states. Notable among employee unions is the large Australian Workers Union, covering shearing, grazing, canefarm, and mill employees and construction workers.

Transportation. Queensland developed as a series of ports, with railways tapping the inland, but now coastal shipping is used only for heavy cargoes such as steel and sugar. Brisbane is the largest receiving port, while Gladstone (alumina and coal) and Weipa (bauxite) are the largest shipping ports. Some 6,000 miles of railway operate throughout the state. Closure of some branch lines in agricultural areas has occurred; but two new railways have been built for coal exports, and other lines have been improved. Air services are important in Queensland, especially in getting about the large area of the inland.

A steadily improving road network links all parts of the state, but maintenance of unpaved roads is costly and difficult with heavy summer rainfall. A paved road reaches Cairns and is partly constructed to the main inland towns. Paved beef roads have been built to get fat cattle to railheads from the southwestern Channel Country and the northwest.

Brisbane is the only city with serious traffic congestion, and a 2.5-year program of freeway construction is under way. Most provincial cities also have planned similar but less extensive systems.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. The state government follows the usual British pattern of a legislature, an executive, and a judiciary. Queensland is the only state with a unicameral parliament, the upper house having voted itself out of existence in 1922. Local authorities are established under the Local Government Acts; they are elected through adult franchise, and voting is compulsory. Unlike the situation in other state capitals, most of the metropolitan area of Brisbane is controlled by a single city council. Public justice is vested in the Supreme Court and district courts and, for civil jurisdiction, in lower courts as well. The Supreme Court holds periodical sittings in centres throughout the state.

The Australian Labour Party controlled the state for two long periods, 1915–29 and 1932–57. Since 1957 a coalition of the Country and Liberal parties has governed, and Queensland is the only state in which the Country Party is the major partner in the coalition.

The social milieu. Social and economic divisions are even less marked in Queensland than in the rest of Australia, which itself makes up the world's largest area of uniform language, social customs, and standards of living.

Education. About 80 percent of primary school children attend state-government schools, and the rest are in schools run by religious and other bodies. About 75 percent of secondary school children also attend state high schools. Education is compulsory between ages six and 15.

Private schools receive governmental subsidies, as well as grants for libraries and science laboratories. Correspondence schools always have been important to the remote parts of the state, and more than 10,000 children, including apprentices, are educated in this way. Regular school assessments of pupils are made, and university-admission examinations are held.

Universities are located in Brisbane and Townsville and institutes of technology in Brisbane, Toowoomba, and Rockhampton. An agricultural college, a conservatory of music, and some 20 technical colleges complete the state's offerings in higher education.

Health and housing. Queensland is the only state with a public hospital system that provides free wards as well as the usual subsidised private wards that charge fees. Some 150 public hospitals treat 230,000 patients and 40,000 maternity cases each year. Among the medical-research institutes is the Radium Institute, which successfully deals with skin cancers, a high-incidence affliction in Queensland. The Flying Doctor Service, which commenced in Queensland in 1928, now makes over 400 flights a year to remote farms or settlements, especially in the inland region.

Prevalence of single-family homes

Some 17,000 dwelling units a year are built in Queensland, of which 14,000 are separate houses. With a warm climate and ample hardwoods, relatively cheap timber houses have been the most common type in Queensland. Older houses often were erected on timber piles to give room below the house for laundry, automobiles, etc. and to keep houses airy and free from termites. The trend in recent years is to build low-set houses, as in other states, and brick or brick veneer is now very common.

CULTURAL LIFE AND INSTITUTIONS

A feature of recent cultural development in Queensland is the greater opportunity now enjoyed by people in the nonmetropolitan areas. A network of radio stations, both governmental and commercial, extends over the whole state, except in the most remote areas, which must depend on shortwave transmissions of national programs. Television also covers most of the state. Several companies sponsored by the Arts Council make continuous tours of music, ballet, and theatre into the provincial cities and inland country centres and schools, covering a far greater rural area than is done in any other state. Provincial newspapers are strong in Queensland, and the larger daily papers carry international news.

Local participation in press, radio, television, theatre, and vocal, orchestral, and band music is growing in provincial and rural Queensland, as is the time spent on the arts in school courses. At a higher level, the new James Cook University at Townsville offers arts courses at both undergraduate and graduate levels.

Thus, the earlier isolation and lack of cultural opportunities of rural dwellers in Queensland is, to an extent, being overcome. The state government has established a Cultural Activities section in the Department of Education to advise and coordinate cultural work and to help remote areas. In the early 1970s more than 125 bodies were receiving government grants, and a number of cultural centres were set up and vacation courses held.

Brisbane, with a population 10 times that of any provincial city, is naturally the strongest cultural centre. It has a history of good performance in orchestral music, and the Queensland Symphony Orchestra, though small, is accorded high rank. There is an excellent junior orchestra as well. Vocal music also has been strong, especially in the city of Ipswich, where many Welsh coal miners settled. In theatre, Brisbane is notable for its number of little theatres, run for many years by competent amateurs and now receiving financial aid; some groups have become professional companies. Several new theatres have been built recently, and playwriting has shown strength in Queensland. Brisbane also has many privately owned art galleries, in addition to the state art gallery and museum, and interest in the visual arts has been increased by leading Australian painters working in Queensland at various times. On the more popular level, annual competitions of fence painting are held in Brisbane and elsewhere, which attract many entries, and there are competitions for works of sculpture. The state Public Library, with its associated Oxley Memorial Library of specifically Queensland items, is in Brisbane. Libraries are maintained by 86 of Queensland's 131 local governments, some having several branches.

Popular culture shows little that is distinctively Queensland in origin. One widely enjoyed form of popular culture, however, is the appreciation of the many miles of unspoiled landscapes and shorelines within the state. This is reflected back in the popularity of separate houses that offer outdoor living amid trees and gardens.

PROSPECTS

Queensland, long regarded by Australians as "the state of the future," achieved full and early development only on the great inland grasslands. There and nearer the coast, beef cattle, fodder crops, and grains are now the major expanding industry. The present rapid mineral expansion is based on enormous deposits of high-grade coal and bauxite and on the refining of alumina. The tourist industry is strong and growing, especially on the surfing beaches and islands near the Barrier Reef. The early handicap of great distances has become the asset of great stretches of unspoiled landscape with a well-decentralized population. Manufacturing is expanding, particularly in Brisbane, the population of which faces most of the current urban problems, although not acutely and with a degree of subtropical relaxation.

Quintilian

The author of a treatise in Latin called *Institutio oratoria* ("The Training of an Orator"), Marcus Fabius Quintilianus was an experienced and successful teacher whose work embodies the best educational thought of late antiquity. The core of the *Institutio* is a treatise on the systematic study of oratory (rhetoric), and Quintilian's discussions of the minute technicalities of his subject properly belong to an age in which the primary aim of education was to produce skilled public speakers. But his general observations on education are of permanent value. He advises the teacher to apply different teaching methods according to the different characters and abilities of his pupils; he believes that the young should enjoy their studies and knows the value of play and recreation; he warns against the danger of discouraging a pupil by undue severity; he makes an effective criticism of the practice of corporal punishment; he depicts the schoolmaster as taking the place of a parent. "Pupils," he writes, "if rightly instructed regard their teacher with affection and respect. And it is scarcely possible to say how much more willingly we imitate those we like."

Quintilian was born *c.* AD 35 at Calagurris (modern Calahorra) in northern Spain. He was probably educated in Rome, where he afterward received some practical training from the leading orator of the day, Domitius Afer, and then practiced for a time as an advocate in the law courts. He left for his native Spain sometime after 57 but returned to Rome in 68 and began to teach rhetoric, combining this with advocacy in the law courts. Under the emperor Vespasian (ruled 69–79) he became the first teacher to receive a state salary for teaching Latin rhetoric, and he also held his position as Rome's leading teacher under the emperors Titus and Domitian, retiring probably in 88. Toward the end of Domitian's reign (81–96) he was entrusted with the education of the Emperor's two heirs (his grandnephews); and through the good agency of the boys' father, Flavius Clemens, he was given the honorary title of consul (*ornamenta consularia*). His own death, which probably took place soon after Domitian's assassination in 96, was preceded by that of his young wife and two sons.

The systematic study of oratory

His great work, the *Institutio ouatoria,* in 12 books, was published shortly before the end of his life. He believed that the entire educational process, from infancy onward, was relevant to his major theme of training an orator. In book I he therefore dealt with the stages of education before a boy entered the school of rhetoric itself, to which he came in book II. These first two books contain his general observations on educational principles and are notable for their good sense and insight into human nature. Books III to XI are basically concerned with the five traditional "departments" of rhetoric: invention, arrangement, style, memory, and delivery. He also deals with the nature, value, origin, and function of rhetoric, and with the different types of oratory, giving far more attention to forensic oratory (that used in legal proceedings) than to other types. During his general discussion of invention he also considers the successive, formal parts of a speech, including a lively chapter on the art of arousing laughter. Book X contains a famous and much-praised survey of Greek and Latin authors, recommended to the young orator for study. Sometimes Quintilian agrees with the generally held opinion of a writer, but he is often independent in his judgments, especially when discussing Latin authors. Book XII deals with the ideal orator in action, after his training is completed: his character, the rules that he must follow in pleading a case, the style of his eloquence, and when he should retire.

Quintilian's concept of a good orator

The *Institutio* was the fruit of Quintilian's wide practical experience as a teacher. His purpose, he wrote, was not to invent new theories of rhetoric but to judge between existing ones, and this he did with great thoroughness and discrimination, rejecting anything he considered absurd and always conscious that theoretical knowledge alone is of little use without experience and good judgment. The *Institutio* is further distinguished by its emphasis on morality, for Quintilian's aim was to mold the student's character as well as to develop his mind. His central idea was that a good orator must first and foremost be a good citizen; eloquence serves the public good and must therefore be fused with virtuous living. At the same time, he wished to produce a thoroughly professional, competent, and successful public speaker. His own experience of the law courts gave him a practical outlook that many other teachers lacked, and indeed he found much to criticize in contemporary teaching, which encouraged a superficial cleverness of style (in this connection he particularly regretted the influence of the early-1st-century writer and statesman Seneca the Younger). While admitting that stylish tricks gave an immediate effect, he felt they were of no great help to the orator in the realities of public advocacy at law. He attacked the "corrupt style," as he called it, and advocated a return to the more severe standards and older traditions upheld by Cicero (106–43 BC). Although he praised Cicero highly, he did not recommend students slavishly to imitate his style, recognizing that the needs of his own day were quite different. He did, however, appear to see a bright future for oratory, oblivious to the fact that his ideal—the orator-statesman of old who had influenced for good the policies of states and cities—could not exist in times when there was no longer any political freedom.

Declamations attributed to Quintilian

Two collections of declamations attributed to Quintilian have also survived: the *Declamationes majores* (longer declamations) are generally considered to be spurious; the *Declamationes minores* (shorter declamations) may possibly be a version of Quintilian's oral teaching, recorded by one of his pupils. A speech that he is known to have published early in life and a work called *De causis corruptae eloquentiae* ("Reasons for the Decline of Oratory") have not survived. The text of his *Institutio* was rediscovered by a Florentine, Poggio Bracciolini, who, in 1416, came across a filthy but complete copy of it in an old tower at St. Gall, Switzerland, while he was on a diplomatic mission there. Its emphasis on the dual importance of moral and intellectual training was very appealing to the 15th and 16th centuries' Humanist conception of education. Although its direct influence diminished after the 17th century, along with a general decline in respect for the authority of classical antiquity, the modern view of education as all-round character training to equip a student for life follows in a direct line from the theories of this 1st-century Roman.

BIBLIOGRAPHY. The best text of Quintilian is that edited by M. WINTERBOTTOM (Oxford Classical Texts, 2 vol., 1970). There is an English translation by H.E. BUTLER (with text) in the Loeb Classical Library, 4 vol. (1921–22). G.L. SPALDING'S edition with Latin commentary, 6 vol. (1798–1834; vol. 6, index by E. BONNELL), is still useful. Three individual books have been edited with full commentary and introductions: book I by F.H. COLSON (1924); book X by W. PETERSON (1892; 2nd ed., 1939); and book XII by R.G. AUSTIN (1948). See GEORGE KENNEDY, *Quintilian* (1969).

Qur'ān

The Qur'ān (Arabic "reading," "recitation"; often spelled Koran), the holy book of Islām, regarded by believers as the true word of God, was revealed to the Prophet Muhammad and collected in book form after his death. It is accepted as the earthly reproduction of an uncreated and eternal heavenly original, according to the general view referred to in the Qurʾān itself as "the well-preserved tablet" (al-awh *al-maḥfūẓ;* Qurʾān 75:22). The word *qurʾān* is derived from the verb qara'a "to read," "to recite," but there is probably also some connection with Syriac *qeryānā*, "reading," used for the scriptural lessons in the Syrian Church. In the Qurʾān itself the word is not used with reference to the book as a whole but only as a term for separate revelations or for the divine revelation in general. The Qurʾān is held in high esteem as the ultimate authority in all matters legal and religious and is generally regarded as infallible in all respects. Its Arabic language is thought to be unsurpassed in purity and beauty and to represent the highest ideal of style. To imitate the style of the Qur'Bn is a sacrilege.

FORM AND CONTENT

Division into chapters and verses

Form. In length the Qur'Bn is approximately comparable with the New Testament. For purposes of recitation during the holy month of Ramadan it is divided into 30 "portions" (juz', plural *ajzāʾ*), one for each day of the month. Its main division, however, is into 114 chapters, called *sūrah*s, of very unequal length. With the exception of the first *sūrah*, the so-called *fātiḥah* ("opening" of the book), which is a short prayer, the *sūrah*s are arranged roughly according to length, siirah 2 being the longest and the last two or three the shortest. Because the longest *sūrah*s generally derive from the latter part of Muhammad's activity, the consequence of this arrangement is that the oldest *sūrah*s are generally to be found toward the end of the book and the youngest generally appear at its beginning.

In the accepted version now in use, each siirah has a heading containing the following elements: (1) a title, which is usually derived from some conspicuous word in the siirah, such as "The Cow," "The Bee," "The Poets," but usually not indicating the contents of the whole chapter; (2) the *basmalah*; *i.e*., the formula "In the name of God, the Merciful, the Compassionate"; (3) an indication of whether the siirah was revealed at Mecca or at Medina and of the number of its verses; and finally (4) in some cases one or more detached letters; *e.g.*, *tāʾ* sin, *tāʾ* sin mim, or alif *lām mīm*, the meaning of which has not been satisfactorily explained, though it is thought that they might stand for abbreviated words, indicate certain collections of siirahs, or have a magical significance.

The verses in the Qurʾān are called ayah (plural *āyāt*, literally "signs") and vary considerably in length. The shortest verses generally occur in the earliest *sūrah*s, in which the style of Muhammad's revelation comes very close to the rhymed prose (*sajʿ*) used by the *kāhin*s, or soothsayers, of his time. As the verses get progressively longer and more circumstantial, the rhymes come farther and farther apart. There is also a change of linguistic style: the earlier *sūrah*s are characterized by short sentences, vivid expressions, and poetic force; and the later ones become more and more detailed, complicated and, at times, rather prosaic in outlook and language. As a result, it is sometimes difficult to decide whether or not a rhyme is intended to indicate the end of a verse; and consequently, there are variations in the numbering of verses (*e.g.*, between the European editions long used by Western scholars and the official Egyptian edition that has now replaced them in most scholarly works).

The Qurʾan generally appears as the speech of God, who mostly speaks in the first person plural ("we"). When the prophet Muhammad is speaking to his compatriots, his words are introduced by the command, "Say," thus emphasizing that he is speaking on divine injunction only. At times the form is also dramatic, bringing in objections by Muhammad's opponents and answering thern by counter-arguments. Narrative passages are mostly brief. Stories of prophets and biblical persons are often alluded to as though they are known to the audience. The stress is not on the narrative but on its didactic uses.

Hetero-geneous style

On closer analysis very few of the siirahs turn out to be uniform in style or content. The longest text dealing with one subject is *sūrah* 12, which retells the story of Joseph, adding to the biblical account a great many legendary details, most of which seem to be drawn from Jewish sources. Otherwise the longer *sūrah*s are composed of several brief sections dealing with a variety of topics. Thus the Qurʾān often gives the impression of having been produced by a rather haphazard method of composition, an impression that is further heightened by the fact that certain favourite phrases such as "but God is forgiving, compassionate," "God is knowing, wise," "most of them know nothing" often have little or no connection with the immediate context and seem to have been added in order to produce a needed rhyme.

It is often emphasized that Muhammad brought to his people "an Arabic Qurʾān"; *i.e.*, a book in the Arabs' own language comparable to the holy books of Judaism and Chtistianity. Also the vocabulary of the Qur'Bn is overwhelmingly of Arabic origin, but there are, nevertheless, loan words, mostly from Hebrew and Syriac, bearing witness to Muhammad's debt to Judaism and Christianity. These loan words are primarily technical terms such as injil, "gospel" (Greek evangelion); *taurāt*, "the law, or Torah" of Judaism; *Iblīs*, "the devil" (Greek diabolos); or translations or adaptations of theological terms such as *amanā*, "to believe" (Hebrew or Aramaic); *salāt*, "prayer" (probably Syriac). Such explanations are usually regarded with suspicion by Muslims, since orthodox doctrine is that the language of the Qurʾān is the purest Arabic.

Content. It is difficult to classify the contents of the Qurʾān. If the material is arranged chronologically, certain patterns appear since the predominant interest is different in various periods.

God: His nature *and* design for creation. The earliest siirahs concentrate on God as the creator of the world, whose beneficence should arouse the gratitude of mankind and who recompenses or punishes man according to his attitudes toward him. References to the sudden advent of the last judgment and descriptions of the bliss of paradise and the torment of hell complete the picture. Strangely enough, there is no reference to the oneness of God in these early chapters. According to one tradition, on one occasion Muhammad even acknowledged the relative authority of three goddesses, al-Lāt, Manāt, and al-ʿUzzā, but later on abolished the passage in which this reference occurred. There are also a few allusions to the ritual of prayer.

Tradition of previous prophets

Later *sūrah*s place much emphasis on the doctrine that there is but one God, while the other gods of the Arabs are said to be only powerless idols. The references to the last judgment, to paradise and hell are fewer and shorter. On the other hand, there are many polemic utterances: against the idolaters, against those who are ungrateful and do not believe in Muhammad's message. In this connection there are several references to previous prophets, who bad warned their people but were met with disbelief, and thus catastrophe befell the unfaithful. These prophets serve as examples; their lack of success also reflects the experience of Muhammad, and it is implied that the outcome would be similar in his case as well. One implication of this is that Muhammad is one in a long series of prophets who have been sent by God to warn their peoples against the imminent judgment, or, to be more exact, the last and final link in the chain of prophets with a divine message, much in the same way as Mani (3rd century AD Iranian reformer of Zoroastrianism who advocated that matter is evil) regarded himself as the last in the row of revealers of divine truth. It is to be noted that some of the prophets referred to are biblical persons (Noah, Moses, Abraham, Jesus), while others seem to be derived from native Arabic traditions (Hūd, Ṣāliḥ). Major Christian and Jewish figures are common; there is frequent mention of Mary, Zacharias, and John the Baptist, as well as of David, Solomon, Job, and Jonah.

Toward the end of Muhammad's activity in Mecca the earlier mentioned change in style occurs: the verses grow longer, poetic, and often elliptic language is exchanged for a much calmer and prosaic style. Several parables occur in this period; *e.g.*, the rain reviving vegetation is used to illustrate God's resurrecting the dead; the story of seafarers who are surprised by a strong wind and pray to God for help but then forget him as soon as they are saved exemplifies the fickleness of human nature. Verses from earlier revelations are often repeated with additional elaboration. The power of God and the wonders and wisdom of creation are the themes that are elaborated upon. The descriptive element is less pronounced in the eschatological passages (about the end of time); the emphasis is on the fact of intervention by the Lord of Justice. The references to earlier prophets are further developed but Jesus is mentioned less frequently. The oneness of God is emphasized more than ever, and it is emphasized that false gods will not be able to help their worshippers on the day of judgment. In addition to God's omniscience, the problem of his omnipotence then comes to the fore.

Human destiny. Man's destiny is entirely in God's hand, even faith and disbelief are dependent on his will. "They would not believe unless God willed (Qur'Bn 6:111). There is no freedom of will, nor is the Prophet to blame for disbelief, for in the last recourse the decision rests with God in his eternal predestination. But other passages fail to press the point and appear to leave man some freedom to listen to the Prophet's preaching and make his own choice for good or for evil. Muhammad's role as a warning prophet is emphasized. In this connection the references to the row of earlier prophets are elaborated and systematized. It is emphasized that Muhammad's preaching confirms earlier revelation. Abraham appears as the founder of Arabian monotheism. In a way Muhammad is his successor, and there are obvious efforts to establish relations with the Jewish tradition.

Eihical and ritual guidance. In this period there is some interest in ethical commandments. The duty of almsgiving is inculcated—as for ritual practices only prayer seems to be mentioned. On the other hand certain rules concerning forbidden food appear.

In the siirahs revealed at Medina the abovementioned stylistic development is continued. The practical interests of the new Muslim community come into focus. Several revelations deal with various episodes in Muhammad's military operations, encouraging the brave and faithful and blaming the hesitant. Ritual and legal prescriptions are common and detailed. Questions concerning the organization of the community are dealt with, rules of conduct in intercourse with the Prophet are given, laws of matrimony and inheritance and the ritual practices of fasting and pilgrimage are regulated, and so forth. The hostility of the Jews is met by accusations that they have altered the scriptures and abandoned the religion of Abraham, the founder of the *Kaʿbah* (a cube-shaped Muslim holy place in Mecca).

The revelation of the various portions of the Qur’ān met the needs and answered the questions of each period. Sometimes, it even dealt with the personal affairs of Muhammad and his contemporaries. There is no doubt of the Prophet's sincere conviction that he had received the word of God on every occasion.

ORIGINS OF QUR’AN

Revelation of the Qur'Bn to the Prophet

According to Muslims. According to Muslim tradition the Qur'Bn was revealed to Muhammad in separate pieces over some 20 years. On such occasions, Muhammad, it is said, was in a kind of trance or ecstasy, during which the revelations were brought to him by the angel Gabriel. On his return to normal consciousness he recited the words of revelation to those present. There are many traditions about the occasions on which a certain siirah or part of a shrah was revealed. Thus the revelation of the Qur’ān is connected with events in the life of the Prophet. Even the traditional recension (version) of the Qur'iin itself classifies the shrahs as Meccan or Medinan.

Obviously, many people learned the words of the revelation by heart, but there are also traditions that, at the time of their revelation, Muhammad had them written down on "pieces of paper, stones, palm-leaves, shoulder-blades, ribs, and bits of leather," *i.e.,* whatever writing-material there was at hand. It is believed that the Prophet indicated to the scribes the context in which a certain passage should be placed.

Establishment of an authoritative text

After the Prophet's death, and especially after the battle of Yamāmah (633), in which a great number of those who knew the Qur'Bn by heart had fallen, fear arose that the knowledge of the Qur'Bn might disappear. So it was decided to collect the revelations from all available written sources and, as Muslim tradition has it, "from the hearts [*i.e.,* memories] of people." A companion of the Prophet, Zayd ibn Thābit, is said to have copied on sheets whatever he could find and to have handed it over to the caliph 'Umar. After ʿUmar’s death the collection was left in the care of his daughter Ḥafṣah. Other copies of the Qur’ān appear to have been written later, and different versions were used in different parts of the Muslim empire. So that there would be no doubt about the correct reading of the Qur'Bn, the caliph ʿUthmān (644–656) is reported to have commissioned Zayd ibn Thābit and some other learned men to revise the Qur'iin using the "sheets" of Ḥafṣah, comparing them with whatever material was at hand, and consulting those who knew the Qur'Bn by heart. It was decided that in case of doubt about the pronunciation, the dialect of Quraysh, the Prophet's tribe, was to be given preference. Thus an authoritative text of the Qur'Bn (now known as the ʿUthmānic recension) was established.

These traditions may have been reworked and changed to some extent to suit certain dogmatic theories concerning the Qur’ān, but in the main they reflect historical truth. It is obvious that the description of the method of revelation has been somewhat simplified. The Qur’ān itself states (42:50–52) that God spoke to Muhammad "by suggestion, or from behind a veil, or by sending a messenger to suggest what he pleases." The first term (Arabic *waḥy*) denotes a "suggestion" or "inspiration" of the kind that is well known by many poets; the Qur'Bn also uses a term meaning "it was sent down." The second term seems to suggest some kind of imaginative locution without any accompanying vision. Only the third expression alludes to an angel but without mentioning the name of Gabriel.

According to orientalists. The chronology of the *sū*rahs is a much debated problem. The existing traditions concerning the occasions for the revelation of certain passages cannot always be controlled and may or may not be reliable. European scholars have applied the criteria of style and contents to establish the relative order of the shrahs or parts of *sūrahs*. From the time when Theodor Noldeke published his *History* of the *Qur’ān* (1860), it has been common to arrange the *sūrahs* in four groups, deriving from three subsequent periods at Mecca and from Medina. The above exposition of the content of the Qur'Bn roughly follows this arrangement.

In the Muslim view, Muhammad received every word of the Qur'Bn directly from God. The Qur'Bn describes, and indignantly rejects, accusations that the Prophet had reproduced things that he had drawn from other sources.

Question of influence of oral traditions on text

Western scholars who have analyzed the contents of the various revelations have shown that much of the narrative material concerning biblical persons and events is not derived from the Bible, but from later Christian and, above all, from Jewish sources (*e.g.,* Midrash). Other motifs, such as the idea of the impending judgment and the descriptions of paradise agree with standard topics in the missionary preaching of the contemporary Syriac church fathers. The dependence need not, however, be of a literary kind, but might be due to influence from oral traditions.

It would appear that learning the words of the revelation by heart was the normal way of preserving them, and that only on special occasions were the words written down immediately. The existence of various early collections of Qur’ānic material seems to be a warranted fact, although their nature and contents cannot be determined. Some of the siirahs beginning with separate letters (*al-fawātiḥ*)—certain consonant combinations detached from the main text (mentioned above)—occur together in the present Qur'iin and in the order of decreasing length in such a way as to suggest that they once formed separate collections. The establishment of a vulgate recension (a standard version) was not sufficient to secure the uniform and correct leading of the Qur'Bn in all details. The Arabic script was incomplete; several consonants were easy to confuse, and there was no way of indicating the vowels to differentiate the variety of possible meanings inherent in a particular combination of consonants. To assure the correct recitation, therefore, it was necessary to know the text more or less by heart. In this way, differing variant readings arose, warranted by this or that "reader" of the Qur'Bn. The recorded variations, however, turned out to be remarkably few, and though no complete listing of the textual variants exists, it can safely be said that the textual tradition of the Qur'Bn is much firmer and more uniform than that of the New Testament. The Arabic script was gradually improved. Diacritical signs were introduced to distinguish the letters that were similar in form, and long vowels were indicated by the letters *alif* (for *ā*), *wāw* (for *ū*), and yd (for **i**). It is known that this vowel system was still disputed at the beginning of the 9th century. The special vowel signs placed above or beneath the letters were added in a different colour and did not count as part of the text itself.

Interpretations. The "readers" (qurrd', singular *qārī'*) were the specialists of the text of the Qur'ān. They were at the same time philologians, and it was to a great extent from their dealings with the language of the Qur'Bn that the science of Arabic grammar grew. Two schools developed, one at Baṣra (in present-day Iraq), which was especially interested in systematizing and ordering the material to set up the rules governing the language, and a rival one at Kiifa (also in Iraq), which took more interest in the exceptional. It was theorized that several variant readings could be accepted only if they were based on the ʿUthmānic recension (version). It was also important that a reading be based on the authority of some renowned reader.

There was also theological speculation as to the true nature of the Qur'Bn. In the discussions initiated by the Mu'tazilites (lit. "those who stand apart"; a group that sought to introduce principles from Greek rationalism into Islāmic thought) the question of the eternity of the Qur'Bn (*i.e.,* of its heavenly prototype) was one of the main points. The Muʿtazilites, who wanted to avoid everything that might encroach upon the oneness of God, denied the doctrine that the Qur'an was uncreated and eternal, because this would mean that something else besides the God of eternity would exist eternally and thus create an eternal and irreconcilable "dualism." Consequently they asserted that the Qur'Bn was created by God. This doctrine, however, was rejected by orthodox Islām. In popular belief, the reverence for the Qur'Bn is often directed toward the visible book or parts of it. Oaths are taken on it, passages are copied for magical purposes.

Qur'Bnic exegesis

In these and other doctrinal disputes the parties sought support for their opinions in the sayings of the Qur'ān, since it was considered as the ultimate authority in all legal and religious questions. The correct interpretation of the Qur'Bn became the object of a special branch of learning, the so-called tafsir, or Qur'Bnic exegesis. All kinds of resources were utilized in order to elucidate the meaning of a Qur'Bnic passage. Traditions concerning the circumstances surrounding the revelation of certain passages or containing interpretative utterances of the Prophet that had been transmitted orally were recorded and collected, together with other traditions deriving from and concerning the Prophet (Hadith). At times, in order to provide authority for a certain theory, traditions were simply invented. Any interpretation of a Qur'ānic passage that could not be supported by a Hadith was originally rejected. The results of the study of grammar and lexicography were also utilized; examples from contemporary poetry were often quoted in order to elucidate the grammatical structure or the lexical meaning of a passage. Thus, work on the Qur'Bn, whose ultimate goal was the correct understanding and application of its teachings, went hand in hand with the development of Arabic grammar and lexicography.

Two works are especially renowned in the field of tafsir, namely the commentary of aṭ-Ṭabarī (839–923), a huge encyclopaedic collection that sums up everything that had been done so far in the field, and the *Kashshāf* of Zamakhshari (1075–1143), which has gained almost canonical reputation, though its author was a Mu'tazilite and began his work with the words, "Praise be to God who created the Qur'Bn." A handy commentary of Bayḍāwī (d. *c.* 1280), which is often quoted as authoritative, is merely an abridged revision of the latter work.

The theological schools of medieval Islām all sought to support their doctrines with the aid of Qur'Bnic exegesis, and each of them produced their own commentaries. There are also examples of allegorical interpretation (ta'wil) especially in Ṣūfī (Islāmic mystical) literature, in which the doctrines of mysticism are found to be hidden behind the literal sense of the Qur'Bnic word.

Qur'Bnic exegesis gained new significance with the appearance of modernism toward the end of the 19th century. The modernists, who sought to revive Islām from its degradation and to reconcile it with what they found valuable in Western scientific traditions, set up the principle of returning to the pure and uncorrupted Islām of the "ancestors." As a consequence, the interpretation of the oldest and original source of Islām was regarded as imperative, and attempts were made to establish the principles necessary for a correct understanding of the Qur'Bn. Traditional exegesis was accused of having introduced Israelite legends and false traditions that had nothing to do with the original teachings of the Prophet. On the other hand, the authority of the Qur'Bn was never called in question.

Modern commentaries

Muhammad 'Abduh, the founder of modernism in Egypt, for several years published exegetical lectures in the journal al-Mandr; and they were later published in book form by his Syrian disciple Rashīd Riḍā. In them he accepts the Qur'Bn as the literally inspired word of God, in which there can be nothing false or antiquated, and tries to show that the results of modern science and many modern views are already present in the Qur'Bn. This is often achieved by twisted interpretations, reading modern ideas into the words of the Qur'Bn. For instance, the *jinn* (genii) of *sūrah* 2:176 that cause disease are interpreted as "microbes," and the words in 2:250, "How often a little company has overcome a numerous company; and God is with those who endure," is taken to refer to ideas reminiscent of Darwin's theory of the struggle for life and the survival of the fittest. Allegorical interpretation is also used when it can serve the purpose of the author. Other modernistic interpreters of the Qur'Bn have continued along the same lines. The Qur'Bn is, however, left untouched by criticism; as the infallible word of God it cannot have been influenced by the circumstances under which it was revealed, it can contain no mistake, and it cannot be superseded by any new discovery.

The latest development, though, has brought some new ideas to the fore. In an Urdu commentary on the Qur'Bn, which has in part been made available in English, Maulana Abul Kalam Azad (1888–1958), an Indian Muslim scholar (minister of education of the Republic of India at the time of his death), develops some new principles for the interpretation of the Qur'Bn. He argues that it is necessary to interpret the Qur'Bn against the background of its environment; therefore it is necessary to study the cultures and the languages of ancient Arabia and other Semitic peoples. Study of the historical circumstances in which the Qur'Bn came into being is said to facilitate the understanding of what it meant to those who received the revelation.

Scholars have no doubt, however, that something new is entering the field of Qur'Bnic exegesis. D. Rahbar, in his study The God *of* Justice (1960), argues that in order to elucidate a passage in the Qur'Bn one should quote traditional exegesis and medieval dogmatics and, above all, use other Qur'Bnic passages for comparison, letting one passage throw light on another. Though such ideas are looked upon with suspicion by orthodox Muslims and are fervently rejected by most Muslim leaders, they may indicate the inception of a more historical view of the

Qur'ān, one that tries to distinguish between central religious ideas and those outward things that are dependent on the historical environment.

TRANSLATIONS

The Qur'ān was revealed to Muhammad as "an Arabic book" or an Arabic reading (*qur'ān*), to provide the Arabs with a holy book in their own language, comparable with the Scriptures of Judaism and Christianity. As has been noted, the language of the Qur'ān is regarded as surpassing everything that can be written in Arabic. The Qur'Pn itself is a miracle and cannot be imitated by man.

As a consequence of this, it is regarded as unfitting to translate the Qur'ān. In countries in which other languages are spoken, the Qur'ān is still recited in Arabic. There exist Muslim translations of the Qur'Pn; *e.g.*, into Turkish, Urdu, and English (the latter during the Aḥmadiyah movement founded in 1889 by Mirza Ghulam Aḥmad in the Punjab region of India), but on principle these are regarded as paraphrases. not as translations that can be used for ritual purposes.

The Qur'Pn was first printed in Arabic at Rome by Pagninus Brixiensis (1530), but the edition was never circulated. A. Hinckelmann published an Arabic text at Hamburg in 1694. Since then several European editions have appeared; one of the best was that of G. Fliigel (1834), the first critical edition, often reprinted. It is from this edition that Western scholars have usually quoted the Qur'ān. Several editions are today printed in Muslim countries, and an official Egyptian edition is gaining more and more ground among Western scholars.

First critical edition

The first Latin translation was made in 1143 at the request of an abbot of the monastery of Cluny and was published at Basle in 1543 by Theodor Bibliander and afterward rendered into Italian, German, and Dutch. The first French translation was by A. du Ryer (1647); it was translated into English by Alexander Ross (1649–88). G. Sale's English translation first appeared in 1734 and has passed through many new editions. It has become something of a classic and can still be useful in many respects. A translation by J.M. Rodwell, with the *sūrah*s arranged in chronological order, appeared in 1861. E.H. Palmer's translation was published in Sacred Books of the East in 1880. Bell's translation "with a critical rearrangement of the sūrahs" (1937–39) tries to analyze the *sūrah*s into their smallest units and show how these were joined together to form the present Qur'Pn. The translation (1955) of A.J. Arberry, distinguished British scholar of Islām, is well known for its literary qualities, and is highly esteemed, especially by Muslims, for its rendering of Qur'ānic style.

The Qur'ān has also been translated into most other European languages. Special mention should be made of R. Blachère's French translation (1949–50) because of its rather detailed notes, and of R. Paret's German rendering (1962), which is very accurate and makes extensive use of parallel passages within the Qur'ān itself, but is rather dry in its style.

BIBLIOGRAPHY. The basic work is T. NOLDEKE, *Geschichte des Qorans* (1860), *2nd* ed. by F. SCHWALLY (1919–38). Less comprehensive but more modern are R. BELL, *Introduction to the Qur'an* (1953); and R. BLACHERE, *Introduction au Coran* (1947). The history of Qur'ānic interpretation is set forth in I. GOLDZIHER, *Die Richtungen der islamischen Koranauslegung (1920).* It should be supplemented by J.M.S. BALJON, *Modern Muslim Koran Interpretation, 1880-1960* (1961, reprinted 1968). A. JEFFERY, The *Qur'ān as Scripture* (1952), deals with the Qur'ān's view of its own function.

(H.R.)

Rabelais, François

A Franciscan priest as well as an eminent physician, François Rabelais is noted primarily as the author of the comic masterpiece *Gargantua and Pantagruel.* The four novels composing this work are outstanding for their rich use of Renaissance French and for their comedy—ranging from gross burlesque to profound satire—covering the major intellectual and moral preoccupations of the day: legal, medical, political, religious, philosophical. The novels exploit popular legends, farces, and romances, as well as classical and Italian material, but were written, at least in part, for a court public and a learned one. The adjective Rabelaisian applied to scatological humour is misleading; Rabelais uses scatology aesthetically, not gratuitously, for comic condemnation. His creative exuberance, colourful and wide-ranging vocabulary, and literary variety continue to ensure his popularity.

Cliche Musees Nationaux, Paris

Rabelais, oil painting by an unknown artist, 17th century. In the Musée National de Versailles et des Trianons.

Early life. Details of Rabelais's life are sparse and difficult to interpret. He was probably born about 1483 (some believe *c.* 1494, though this is less likely), the son of Antoine Rabelais, a rich Touraine landowner and a prominent lawyer who deputized for the *lieutenant-général* of Poitou in 1527. After apparently studying law, Rabelais became a Franciscan novice at La Baumette (1510?) and later moved to the Puy-Saint-Martin convent at Fontenay-le-Comte in Poitou. By 1521 (perhaps much earlier) he had taken holy orders, a step that presupposes serious scholastic studies in the Franciscan tradition, particularly of John Duns Scotus and St. Bonaventura. The eminent French Hellenist Guillaume Budé, in a letter to a mutual friend, praised Rabelais's legal learning and his mastery of Greek and Latin. At Fontenay-le-Comte, Rabelais frequented legal Humanists, including Amaury Bouchard and André Tiraqueau, a friendship that survived a quarrel between the two concerning the dignity of women. In 1524 Rabelais wrote a eulogistic poem in Greek that Tiraqueau prefixed to some editions of *De legibus connubialibus.* Rabelais's *Tiers Livre* (1546) makes use of legal erudition borrowed from Tiraqueau's *De Nobilitate,* a work he must have consulted in manuscript, as it was not published until much later. The prologue to Rabelais's *Quart Livre* (1552) was to contain a eulogy of Tiraqueau, though it is possible that this friendship had cooled and that Tiraqueau supported the banning of the *Tiers Livre.*

Friendship with leading Humanists

Rabelais was closely associated with Pierre Amy, a liberal Franciscan Humanist of international repute. In 1524 the Greek books of both scholars were temporarily confiscated by superiors of their convent, because Greek was suspect to the hyperorthodox as an "heretical" language: it opened up the original New Testament and encouraged the study of Greek Fathers of the Church, such as Origen and Clement of Alexandria. Both scholars may have been temporarily imprisoned in their convent. Rabelais then obtained an indult (a special privilege) from Pope Clement VII and was removed to the Benedictine house of Saint-Pierre-de-Maillezais, the prior of which was his bishop, Geoffroy d'Estissac. He never liked his new order, however, and later satirized the Benedictines in the person of Frère Jean, though he passed lightly over Franciscan shortcomings. His only known works of this period are a (lost) Latin translation of the first book of Herodotus and of a dialogue of Lucian (also lost), a French poem addressed to Jean Bouchet (an orthodox poet and historian), and the Greek eulogy of Tiraqueau.

Rabelais studied medicine, probably under the aegis of the Benedictines in their Hôtel Saint-Denis in Paris. In 1530 he broke his vows—though later in his *Supplicatio pro apostasia* ("Supplication for Apostasy") he claimed to have worn the habit of a secular priest and to have regularly celebrated mass. He studied medicine at Montpellier, probably with the support of his patron, Geoffroy d'Estissac. Graduating within weeks, he lectured on the works of distinguished ancient Greek physicians, publishing his own editions of Hippocrates' *Aphorisms* and Galen's *Ars parva* in 1532. As a doctor he placed great reliance on classical authority, siding with the Platonic school of Hippocrates but also following Galen (when not opposed to Hippocrates) and Avicenna (980–1037), the Persian philosopher and physician.

During this period an unknown widow bore him two children (François and Junie), who were given their father's name and were eventually legitimated by Pope Paul IV in 1540. A third child, Théodule, was recognized by Rabelais but died in infancy.

First novels. ***Pantagruel.*** After apparently practicing medicine briefly in Narbonne, Rabelais was appointed physician to the hospital of Lyons, the Hôtel-Dieu, in 1532. In the same year he edited the medical letters of Giovanni Manardi, a contemporary Italian physician, as well as a Latin will that later proved to be a fabrication. On November 30 he wrote an enthusiastic letter to Erasmus, the leading Humanist of the time. It was during this period that he discovered his true talent. Fired by the success of an anonymous popular chapbook, *Les Grandes et inestimables cronicques du grant et e'norme géant Gargantua,* he published, pseudonymously, his first novel, *Pantagruel* (now usually read second). *Pantagruel* is slighter in length and intellectual depth than his later novels, but nothing of this quality had been seen before in French in any similar genre. Rabelais displayed his delight in words, his profound sense of the comedy of language itself, his mastery of comic situation, monologue, dialogue, and action, and his genius as a storyteller who was able to create a world of fantasy out of words alone. Within the framework of a mock-heroic, chivalrous romance, he laughed at many types of sophistry, including legal obscurantism and hermeticism, which he nevertheless preferred to the Scholasticism of the Sorbonne. One chapter stands out for its sustained seriousness, praising the divine gift of fertile matrimony, a compensation for death caused by Adam's fall. Rabelais maintains that the Christian father, having enjoyed the privilege to beget legitimate heirs, must educate his sons to become mirrors of his own body and soul conjoined. The work borrows openly from Sir Thomas More's *Utopia* in its reference to the war between Pantagruel's country, Utopia, and the Dipsodes but gaily preaches a semi-Lutheran doctrine—that nobody but God and his angels may spread the gospel by force. *Pantagruel* is memorable as the book in which Pantagruel's companion, Panurge, a cunning and witty rogue, first appears.

The genius of *Pantagruel*

This successful novel was followed in 1532 by the *Pantagrueline Prognostication,* a parody of the almanacs, astrological predictions that exercised a growing hold on the Renaissance mind, particularly after the great conjunction of planets in 1524. As a doctor, Rabelais could (and did) compose almanacs and prognostications. He disbelieved in "judicial" (essentially fortune-telling) astrology, however, and joined forces with authors who, in the name of divine Providence, attacked judicial astrology. His satirical form here owes much to German Latin models but surpasses them in quality. Suddenly, in 1534, Rabelais left the Hôtel-Dieu to travel to Rome with the bishop of Paris, Jean du Bellay. He returned to Lyons in May of that year and published an edition of Bartolomeo Marliani's description of Rome, *Topographia antiquae Romae.* He returned to the Hôtel-Dieu but left it precipitately in February 1535, perhaps because of the persecution following the Affaire des Placards (October 1534), an incident of the Reformation in which France was placarded with posters that openly attacked the "idolatry" of the mass. Even Catholic evangelicals, who sought truth in religion through recourse to scriptural authority, were accused of "Lutheranism" and were forced to flee.

Gargarztua. *Gargantua* belongs to this period. The second edition is dated 1535; the first edition lacks the title page in the only known copy; it probably also dates from 1535, though many believe it was first published in 1534. This masterpiece was, in part, designed to support royalist causes espoused by Jean du Bellay, who had been created cardinal, essentially by King Francis I, in May 1535. The King, the Cardinal, and his brother Guillaume du Bellay, seigneur de Langey, were in contact with the German theologian Philip Melanchthon, hoping to win his support for an ecumenical effort to end the Lutheran schism and to counter-reform the church in France. Meanwhile, diehard Scholastic theologians of the Sorbonne, such as Noel Beda, were kept in prison. *Gargantua* advances these causes, preaching steadfastness in face of persecution but condemning the persecution itself. The Sorbonne is mocked, evangelism propagated. In *Gargantua,* Rabelais continues to exploit the romances mock-heroically, telling of the birth, education, and prowesses of the giant Gargantua, Pantagruel's father. Much of the satire—for example, mockery of the ignorant trivialization of the mystical cult of emblems and of erroneous theories of heraldry—is calculated to delight the court; much also aims at delighting the learned reader—for example, he sides with Humanist lawyers against legal traditionalists and doctors who accepted 11-month, or even 13-month, pregnancies. Old-fashioned Scholastic pedagogy is ridiculed and contrasted with the Humanist ideal of the Christian prince, widely learned in art, science, and crafts, and skilled in knightly warfare. In politics, Rabelais champions appeasement against bellicosity, though he insists that the Christian prince should, as God's agent, follow unsuccessful appeasement with military might. The war between Gargantua and his neighbour, the "biliously choleric" Picrochole, is partly a private satire of an enemy of Rabelais's father, partly a mocking of Charles V, the Holy Roman emperor, and the imperial design of world conquest. Gargantua commands the operations, but some of the exploits are carried out by Frère Jean (the Benedictine). Lean, lecherous, dirty, and ignorant, Frère Jean is a "true monk if ever there was one, since the world started to monk," but he is redeemed by jollity and active virtue; for his fellow monks are timorous and idle, delighting in those "vain repetitions" of prayers that Christ condemned. Gargantua's last major episode centres around the erection of the Abbey of Thélème, a monastic institution that rejects poverty, celibacy, and obedience in the name of self-discipline. It welcomes wealth and the wellborn, praises the aristocratic life, rejoices in good marriages. Probably as an afterthought, it is also a refuge for persecuted evangelicals.

Themes of *Gargantua*

After *Gargantua,* Rabelais published nothing new for 11 years, though he prudently expurgated his two works of overbold religious opinions. He continued as physician to Cardinal Jean and his powerful brother Guillaume. After leaving the Hôtel-Dieu in February 1535, he eventually accompanied the Cardinal to Rome. There he regularized his position by making a "supplication" for his "apostasy" (*i.e.,* his unauthorized departure from the Benedictine monastery), arranging to enter the Cardinal's Benedictine convent at Saint-Maur-les-Fossés. The convent was secularized six months later, and he became a secular priest, authorized to exercise his medical profession.

In 1537 he joined Budé, Clément Marot, and others in a famous banquet celebrating the release from prison of a fellow Humanist, Étienne Dolet. Rabelais may later have quarrelled with Dolet, who pirated his works without the expurgations. In May of that year he was awarded the doctorate of medicine of Montpellier and subsequently dissected at least two corpses, a fairly rare practice at that time. At Montpellier he delivered, with considerable success, a course of lectures on Hippocrates' *Prognostics.*

He was at Aigues-Mortes in July 1538 when Charles V met Francis I, but his movements are obscure until he followed Guillaume du Bellay to the Piedmont, visiting Turin and Ferrara. Late in 1542 Guillaume set out for Lyons but died in January 1543, in the presence of Rabelais and other doctors, before he reached his destination. Rabelais twice alludes in his works to this important event. He believed that God sent special portents and that Guillaume was granted on his deathbed the gift of prophecy.

Condemnation of the novels

Guillaume's death meant the loss of a hero and the loss of a patron. The same year Geoffroy d'Estissac died as well, and Rabelais's novels were condemned by the Sorbonne and the Parlement of Paris, Rabelais sought protection from the King's sister Margaret, queen of Navarre, dedicating to her his ***Tiers Livre*** (1546). Despite its royal *privilège* (*i.e.*, license to print), the book was immediately condemned for heresy by the Sorbonne, and Rabelais fled to Metz (an imperial city), remaining there until 1547. As counsellor to the city, he earned 120 livres a year but wrote, pleading desperate poverty, to Cardinal Jean:

> If you do not have pity on me, I know not what I should do, other than put myself into service with someone over here . . . with harm and evident loss to my studies. It is not possible to live more frugally than I do.

Later work. ***Tiers Livre.*** The ***Tiers Livre*** is Rabelais's most profound work. Pantagruel has now deepened into a Stoico-Christian inerrant sage; Panurge, a lover of self and deluded by the devil, is now an adept at making black seem white. Panurge hesitates: Should he marry? Will he be cuckolded, beaten, robbed by his wife? He consults numerous prognostications, both good Platonic ones and less reputable ones favoured by such authorities as H.C. Agrippa and Girolamo Cardano—all to no effect because of his self-love. His ideas of human sexuality are "erroneous" Galenic ones, not "sound" Hippocratic ones. He consults a good theologian, a Platonic doctor, and a Skeptic philosopher approved of by the learned giants, but his problem is not treated by the "foolish" Bridoye, a judge who—like Roman law in cases of extreme perplexity—trusted in Providence and decided cases by casting lots. Panurge trusts in no one, least of all in himself. It is therefore decided to consult the oracle of the Dive Bouteille (Sacred Bottle), and the travellers set out for the temple. With Bridoye the novel deepens into a paradoxical defense of Christian "folly," owing something to Erasmus' ***Praise of Folly*** but more to St. Paul as Rabelais understood him. The ***Tiers Livre*** was condemned probably for its mockery of penance, its subordination of canon law to civil law in matrimonial matters—Rabelais denied the validity of marriages contracted without parental consent—and for its threat of civil intervention into monastic affairs. The work ends enigmatically with a mock eulogy (a highly appreciated genre) in which hemp is eulogized for its myriad uses, thus artistically balancing Panurge's perverse eulogy on debts at the beginning of the book.

Quart Livre. From 1547 onward, Rabelais found protection again as physician to Cardinal Jean and accompanied him to Rome via Turin, Ferrara, and Bologna. Passing through Lyons, he gave his printer his incomplete ***Quart Livre,*** which, as printed in 1548, finishes in the middle of a sentence. It contains some of his most delightful comic storytelling but also defends a "synergistic" theology (*i.e.*, men must "work together" with grace for salvation). In Rome he sent to the Cardinal de Guise a description of the "Sciomachie" ("Simulated Battle") organized by Cardinal Jean and his allies to celebrate thk birth of Louis of Orléans, second son of Henry II of France. He published the account in 1549 on his return to Lyons with his patron, whom he tended in an illness at Saint-Maur-les-Fossés.

In January 1551 Cardinal Jean presented him with two benefices at Meudon and Jambet, though Rabelais never officiated or resided there. In 1552, during the height of the Gallican crisis, when France nearly broke with Rome over the dispute on the monarch's jurisdictional rights within the French church, he published—with a new prologue—the full ***Quart Livre,*** his longest book. A wealth of both serious and comic writing, it propagates synergism against Calvinistic predestinationalism, mocks bloodthirsty bishops, dismisses the Council of Trent as a non-Catholic council of nitwits, and champions a "syncretistic" Christianity (a welding together of the best of ancient wisdom and scriptural Christianity). This Christian classicism is symbolized by Plutarch's dying Pan, which Rabelais saw as an allusion to the crucified Good Shepherd, the Christian All.

Views on theology

This work, too, was designed to please a Gallican court and is proudly and aggressively dedicated to the liberal Cardinal Odet de Châtillon. Despite its royal *privilège*, it, too, was condemned by the Sorbonne and banned by Parlement on March 1, 1552; the Gallican crisis had passed. On January 9, 1553, Rabelais resigned his benefices. Rumour had it—probably without foundation—that he was in prison. He died in 1553 (probably on April 9) and was buried in Saint-Paul-des-Champs, Paris.

In 1562 appeared in Lyons the *Isle sonante,* allegedly by Rabelais. It was expanded in 1564 into the so-called ***Cinquiesme et dernier livre.*** The work is partly satirical, partly an allegory; the Dive Bouteille—the ostensible quest of the ***Quart Livre—is*** consulted, and the heroes receive the oraculous advice: "drink" (symbolizing wisdom?). The work cannot be by Rabelais as it stands. Some scholars believe it to be based on his (lost) drafts; others deny it any authenticity whatsoever.

Influence and reputation. Rabelais was connected with some of the great scholars of his age (Budé, Tiraqueau) and with great and powerful political figures (Margaret of Navarre, Guillaume du Bellay) and was consistently protected—though not always effectively—by high-ranking liberal ecclesiastics (Bishop Geoffroy d'Estissac, Cardinal Jean du Bellay, Cardinal Odet de Châtillon). His works are those of a man who had studied several subjects in depth, including scholastic and biblical theology, medicine, and, above all, the law. His reputation for profound Humanist learning was a secure one in his lifetime. Despite his religious irregularities, the Franciscans considered him as a writer of their order. Rabelais's works were placed on the "Index of Forbidden Books" by the Council of Trent and tended to be interpreted in an increasingly Protestant sense when published—as for a long time they could only be—outside France. They have had an enormous influence not only on later French writers, such as Voltaire, Balzac, and Chateaubriand, but also on writers as diverse as Sterne, Swift, Trollope, and Charles Kingsley.

MAJOR WORKS

Gargantua and Pantagruel comprises: ***Pantagruel*** (full title, ***Pantagruel. Les horribles et espoventables faictz et prouesses du très renommd Pantagruel, roy des Dipsodes, filz du grand gdant Gargantua, composez nouvellement par Maistre Alcofrybas Nasier;*** published 1532, forms book ii); ***Gargantua*** (full title, ***La vie inestimable du grand Gargantua, pbre de Pantagruel, jadis compose'e par I'abstracteur de quinte essence;*** 1535, forms book i); ***Tiers Livre*** (full title, ***Tiers Livre des faictz et dictz héroïques du noble Pantagruel, composez par M. Franç. Rabelais, docteur en medicine et calloïer des isles Hières***; 1546); ***Quart Livre*** (full title, ***Le Quart Livre des faictz et dictz hdroiques du noble Pantagruel;*** complete, 1552); ***Le Cinquiesme et dernier livre*** (full title, ***Le Cinquiesme et dernier livre des faicts et dicts héroïques du bon Pantagruel, compose'e par M. François Rabelais, docteur en medicine;*** 1564). Also ***Pantagrueline Prognostication*** (1532).

BIBLIOGRAPHY. P.P. PLAN, ***Bibliographie rabelaisienne: les éditions de Rabelais de 1532 à 1711*** (1904, reprinted 1965); A. TCHEMERZINE, ***Les dditions anciennes de Rabelais, 1532–1742*** (1933); J. PORCHER, ***Exposition organisée à l'occasion du quatribme centenaire de la publicatiorz de Pantagruel*** (1933); J. BOULENGER, ***Oeuvres completes de Rabelais,*** pp. 997–1018 (1955). For further bibliography of studies, see the "Textes littéraires français" editions cited below as well as the following principal periodicals devoted to Rabelaisian scholarship: ***Revue des Etudes rabelaisiennes*** (1903–12); ***Revue du seizibme siècle*** (1913–33); ***Bibliothèque d'Humanisme et Renaissance*** (1934–); ***Etudes rabelaisiennes*** (1956–); and the ***Bulletin des amis de Rabelais et de la Devinière*** (1960–).

Editions: The standard edition is ***Les Oeuvres de Rabelais,*** ed. by ABEL LEFRANC ***et al.*** (1913– ; up to part of ***Le Quart Livre*** published). This edition, however, needs correcting and supplementing by editions of individual works (especially those in the "Textes littéraires français" Series: ***Pantagruel,***

ed. by VERDUN L. SAULNIER, 2nd ed. *(1965); Gargantua,* ed. by RUTH CALDER and M.A. SCREECH *(1970); Le Tiers livre,* ed. by M.A. SCREECH *(1964)*; *Le Quart livre,* ed. by ROBERT MARICHAL *(1947).* Also, for lesser works, *Oeuvres de Rabelais,* ed. by CHARLES MARTY-LAVAUX, *6* vol. *(1870–1903);* and *Oeuvres complètes,* ed. by PIERRE JOURDA, *2* vol. *(1962).*

English translations: The most colourful, though not the most reliable, translation is that of SIR THOMAS URQUHART and PIERRE MOTTEUX, available in "Everyman Classics," ed. by D.B. WYNDHAM LEWIS *(1929,* reprinted *1966).* Very useful are the incomplete translation of W.F. SMITH *(1893,* reprinted *1934);* and J.M. COHEN'S translation *(1955,* reprinted *1970).* See also SAMUEL PUTNAM, *The Portable Rabelais (1946)* and *The Essential Rabelais (1968).*

Biography and criticism: Especially useful for his life are JEAN PLATTARD, *Vie de François Rabelais (1928)* and *François Rabelais (1932);* and SAULNIER'S "Chronologie" in his introduction to *Pantagruel Club du meilleur livre (1962). (Sources)*: JEAN PLATTARD, *L'Invention et la composition dans l'oeuvre de Rabelais* (1909), needs supplementing with aid of more modern editions of "Textes littéraires français." *(Intellectual context)*: M.A. SCREECH, *The Rabelaisian Marriage: Aspects of Rabelais's Religion, Ethics and Comic Philosophy (1958)* and *L'Evangélisme de Rabelais (1959)*; A.J. KRAILSHEIMER, *Rabelais and the Franciscans (1963).* For a Marxist interpretation of Rabelais, see MIKHAIL BAKHTIN, *Rabelais and His World (1968;* orig. pub. in Russian, *1965).*

(M.A.S.)

Races of Mankind

The term race as applied to man has been variously used —by politicians, military leaders, philologists, human biologists, demographers, and historians. Some "races" constitute language groups, often of peoples whose only kinship is that they speak a common language. Such was the original meaning of the so-called Aryan race. Some "races" are simply hypothetical, invented to embrace present distributions of such genetic (hereditary) characteristics as stature or hair colour; *e.g.*, the Nordics. (The word Nordic also has been given a political meaning, referring, despite their differences in physical characteristics, to peoples in Northern Europe.) The term has been variously applied to national or cultural groupings, as in the days when English writers referred to an "Irish race" and to a "Scottish race." The word also has been applied to human groups inferred to have existed on the basis of archaeological discoveries; the "Etruscan race" is an example. Various religious groups who may or may not have common ancestry sometimes are called races— the "Jewish race." By extension of biblical thinking and in honour of Shem, son of Noah, a "Semitic race" was conceived in an effort to describe people who spoke Semitic tongues, some of whom may have learned their language more recently than others.

All of those uses of the term race are separate and distinct from its biological meaning in classification (taxonomy). Just as the term race is often too broadly applied to the entire species of man (as in the "human race"), particular race names invented to explain distributions of grossly observable physical characteristics of human populations are not biologically meaningful. Thus, the early meaning of "Negro race," once used to describe all people with dark skins whatever their ancestry, has been abandoned. The term Negro now is restricted to black people of African ancestry (*i.e.*, African Negroes); it excludes the "blacks" of Australia, the dark-skinned peoples of Southern India or Fiji, and some of the darkest skinned American Indians as well.

Biological basis of races

Today, races are defined neither as hypothetical umbrellas to cover people who share superficial similarities, nor as linguistic, political, or social groupings; nor are they defined from inferences concerning prebiblical human origins. Instead, they are biological races: breeding or mating populations of people (or groups of breeding populations). They are distinguished or classified in terms of genetically transmitted differences. They are studied (in terms of their hereditary origins and their biological relationships with other such races) for evidences of ongoing evolution and of continuing genetic change. Such studies help explain the origin and persistence of genetically determined diseases and serve to explore their long-term influence. For races that have been long resident in their present locations, research sheds light on the long-term genetic effects of such environmental factors as temperature and climate, and of food type, source, and availability. For races that have been formed in the recent and historical past, the investigations can reveal the proportion of different groups that entered into genetic admixture. For particular groups with common racial ancestry that have moved from their original locations, evidences of genetic change also interest researchers. As people moved from equatorial Africa into the temperate zones, there was an expectable decrease in the frequency of genetic adaptations to heat and moisture. Changes in genetic composition may well be expected among people who have moved from northern Europe to the warmer areas of the American Southwest, Hawaii, New Zealand, and Australia.

RACES: SUBGROUPS WITHIN A SPECIES

All living mankind constitutes a single biological species (Homo *sapiens)* within a larger grouping or genus (Homo). Within the human species, Homo *sapiens,* a large number of populations may be differentiated genetically through readily observable characteristics (*e.g.*, skin, hair, and face and body proportions) and through less obvious but more distinctive biological traits, such as blood type. These biological groupings within species are commonly called races, in man as well as in other living forms.

Some biological descriptions refer to human "stocks," one intention for this being to avoid political overtones. Other writers have favoured the word division in lieu of race, again apparently to escape what may be perceived as offensive connotations. Other references to these human groupings include: "strains" (without implying the equivalent of purebred strains of laboratory animals); "varieties" (although the specific botanical meaning does not apply to human races as ordinarily constituted); or "ethnic group," sometimes limited to cultural or political groupings (*e.g.*, Macedonians, Croats, Magyars, or Slovenes) and at other times used with exactly the same biological meaning as race.

Reproductive isolation

Geographical races. Naturally occurring (*i.e.*, produced by natural, usually geographical separation of human groups) races of the human species are by no means identical in number of members or degree of genetic differentiation. There are small groupings of a few hundred to a few thousand individuals, some slightly and only recently isolated in the reproductive sense from adjacent people. Other equally small groups may have been mating apart from the rest of mankind for centuries, or even for thousands of years. Members of some human races number in the hundreds of millions (as the peoples of modern Europe) or in the thousands of millions (as in Asia). The present populations of Tristan da Cunha and Pitcairn and Norfolk islands, long-isolated and only recently rediscovered, were formed by mutinous European sailors and "natives" of adjacent areas. Other natural populations are descended from slaves who were isolated reproductively from their ancestral group and from the peoples with whom they came to live. There are people of mixed (hybrid) recent origin (as in the U.S. coastal Carolinas), contrasted with such populations as the Aboriginal Australians who show evidence of a 25,000-year genetic separation from the rest of mankind.

It is both useful and meaningful to identify the very large human groupings that often correspond to continents or other major geographic areas as "geographical races," a term extensively used with other life forms. Such geographical races are numerically large, containing within them smaller groups of reproductive isolates (breeding populations). The reasons for the large groups' geographic delineation are usually clear. The Indians of the Americas were reproductively separated from the peoples of other geographic regions for many thousands of years. Thus, they have come to differ genetically from the rest of mankind, and even from those Asians from whom they stemmed. The Aboriginal peoples of Australia similarly constitute a geographically defined group of local races (see below) separated from the rest of the world until little more than a century ago, except for slight contact in the Cape York region, Though the Hawaiians are presumably of remote geographic origin, their historical spread over the broad range of the Pacific Ocean is consistently supported by their legends, by their genealogical records, and by genetic studies conducted over an expanse of thousands of miles of islands.

All in all, there are not many geographical races. In Africa (with due regard to scientific disagreement about the degree of historical separation between the Bushmen and Hottentot of South Africa and the remaining peoples south of the Equator), there seem to have been at most only two ancient African geographical races; some say only one. There is reason to argue for a continuity between pre-Columbian America and Asia, whence the earliest Americans manifestly came, yet most modern racial classifications separate American Indians from Asians on the basis of firm genetic evidence. There are some groups (such as the Ainu people of northern Japan) of puzzling status; they, and such groups as some of the "pygmies" of the Philippines. specific native groups of Thailand, and the Miao people of China, may be valid geographical races (though each is numerically small). As currently viewed, a listing of nine or ten geographical races encompasses about 99 percent of mankind.

Local races. Except for people including the Ainu and the Miao (and perhaps such groups as the Bushmen) whose classification is not entirely resolved, most geographical races include numerous local breeding populations. While such local races may have few members, others number hundreds of millions. Local populations (local races, usually with distinctive languages) dotted pre-Columbian America; there were hundreds in North America alone. One need only list the names of the Algonkin and the Cocopa, the Blackfoot and Cree, the Salish and Mandan, the Penobscot and the Seminole, the Zuni and the Navajo, and the Hopi, the Papago, and the Pima to realize how many local races of American Indians there weie and in many cases continue to be.

Sizes of local breeding populations

In other parts of the world, where high population densities have not built up, local races are also apparent, as in many parts of Africa. History provides a picture of ancient local races in much of the European continent, with numerous local groupings in the British Isles cataloged and categorized by Julius Caesar. In the course of the last two millennia, however, local races in Europe seem to have become less easily defined, except along such broad lines as Northwest European, Alpine, and Eastern Mediterranean. Marked average differences in many hereditary traits over the regions from northern to southern Europe may be plotted like lines on a weather map, interrupted by enclaves of genetically distinct peoples. The Basques of Spain and the Lapps of Scandinavia represent old enclaves. Gypsies, who stem from India, are spread across Europe; their language is still of Indian origin. There are also groups of people of Middle Eastern origin in modern Europe. Such local races are the ones most easily identified and studied; they constitute population units that display continuing evolutionary change.

It is the local population or local race that either expands or contracts its numbers relative to the geographical race as a whole that most readily provides material for the study of racial origin and contacts, and of genetic intermixture (see GENETICS, HUMAN).

Microraces and smaller units. For much of the world, local races exist as reproductively isolated, culturally distinct, and genetically differentiated breeding populations. Indeed, barriers to gene flow (interbreeding) are prerequisites for the continuing existence of these populations. Culture and geography together tend to maintain such hereditary differences over time; thus, social or caste prohibitions on interbreeding serve to maintain local races in India. Elsewhere, religious regulations have maintained many local races for millennia. Rivers were efficient barriers to interbreeding in older days, and oceans remain major barriers to intermarriage. As populations have grown, however, as in Europe, geographical distance itself has become less of a barrier. Where once there was a 40-mile (64-kilometre) distance between hamlets, there are now often continuous zones of human habitation; with roads, bridges, canals, and trains, distance alone does not have the isolating influence it once had.

Yet sheer density of population is itself a restriction on gene flow and on the distance over which human mating is likely to occur. A boy is less likely to venture far afield for marriage when there are thousands of "girls next door" within the same apartment block in which he lives. Under such circumstances, the human male has but the same effective mating range as the mosquito. Thus, even in heavily settled locations, genetic differentiation continues in its course. In a long-established city such as Tokyo genetic differences occur from district to district; this also holds for Rome and London and every other large city studied. Some of these differences clearly represent older residence patterns of breeding that support the continuance of localized groups of people (microraces) long genetically distinct (as in the Limehouse district of London or in certain of the ghetto districts of Rome). In moving from one coast of England to the other, there are found systematic genetic differences, some related to earlier settlements and cultural patterns, still others apparently reflecting later differential directions of selection. The distribution of blood group O in England alone provides a fascinating pattern of such differences, as does the frequency of another blood group (Diego) in related American Indian groups, or the occurrence of hereditary sickle-cell anemia in parts of Africa. Such local patterns draw attention to microgeographical differentiation among many living organisms; thus, the term microgeographical races has been applied to fruit flies and simplified as microraces when speaking of man.

Causes of gent-flow restrictions

ASSOCIATIONS WITH RACE

Adaptations to environment. Local genetic adaptations may well be expected for races long occupying the same habitat, accustomed to a distinctive way of life, and used to a particular climate. Many studies demonstrate genetic heat adaptation in people living in the tropics and among those accustomed to the burning desert. Other studies reveal cold adaptation, as is found among the Eskimo, who have evolved a metabolic response for body heat maintenance under conditions of extreme cold. There is also evidence of selective genetic adaptation to moderate cold and night cold only, as among Australian Aboriginals and other desert groups. These people are exposed only occasionally during the day and commonly at night to temperatures not much below freezing. Since their food economy does not afford a caloric surplus for body heat maintenance, specific hereditary adaptations (*e.g.*, in body size) seem to have emerged by natural selection (see EVOLUTION).

One might expect more sweat glands per square unit of skin surface in peoples whose ancestors were long exposed to tropical heat, as an adaptation through genetic mechanisms that favour evaporative cooling of the body. By contrast, a minimum ratio of skin surface to body size is expected within breeding populations long exposed to Arctic cold; by minimizing surface (including the length of arms and legs), heat loss is reduced and more of the tissues are kept close to the waim body core. Evidence of just such genetic adaptations to cold, heat, humidity, and dryness have been found through systematic research. Careful study is required because, in addition to heredity, variable levels of nutrition may also affect body size or even fatness. Populations that are chronically exposed to specific diseases may evolve protective genetic adaptations; for example, the so-called sickle-cell trait is associated with resistance to malaria.

There is difficulty in sepaiating behavioral differences attributable to child-rearing practices and cultural expectations from those differences having a genetic basis, even within the same racial group (see HUMAN BEHAVIOUR, INNATE FACTORS IN: Genetically Mediated Group Differences). It is only when research turns from such behavioral attributes as intelligence or emotional stability to consider specific disorders of metabolism or neural development that clear differences between races on a genetic basis are found.

Language, culture, and behaviour. It used to be conjectured that languages were originally coloured by hereditary configurations of the mouth, teeth, and tongue of their earliest speakers. Research, however, has failed to relate the characteristics of any spoken language to the genetically transmitted facial configurations of its speakers. English, for instance, seems to be no better learned by children of English ancestry than by those of German, Italian, Egyptian, Ethiopian, or Pakistani derivation. Spoken language is learned rather than passed on through genes.

Historical locations of the major races of man.

Gestures are typical of some groups, as may be seen in a Middle Eastern bazaar, but do not necessarily depend on a genetic basis. Postures are characteristic of some racial groups, and may have some basis in differences in bodily structure and functions, but they, too, are largely due to learning. Ways of expressing or suppressing emotion are learned in a cultural matrix, as American-born citizens of Japanese, or Italian origin discover when they visit the villages and cities from which their grandparents came.

Cultural versus genetic basis of behaviour

In theory, the distinctive characteristics of any culture could have been determined by the genetic makeup of its founders. Most people, however, are long removed from their ancestral cultures, which are themselves the products of social change. Once the most warlike people of Europe, the French expanded to northern and eastern Europe and as far south as Egypt. At one time the Spanish were widely feared for their military skills and threatened an invasion of England. The old Turkish Empire included part of Europe, the Middle East, and North Africa; and ancient Rome covered much of Europe, building still-famous baths in England (in the city of Bath) and farming North Africa. Yet, the imperial tendencies of all these cultures have now sharply waned.

In the face of such historical changes, it is difficult specifically to associate any of the races of man with enduring skills, abilities, gestures, or with warlike or pacifistic proclivities on any presumed genetic basis. Nor is it likely that cruelty, playfulness, mathematical or musical skill, engineering ability, or mercantile accomplishment have a genetic basis unique to any particular race of people.

Teeming and populous Tokyo now outdoes New York City, especially in subway rush hours and in the department stores on Sunday. Parisians now travel to London for less fettered play. In the United States Southwest a conservative voting record has replaced a once-adventurous pioneer spirit. Once relaxed Honolulu grows increas-

ingly frenetic, and in Mexico City taxicab drivers simply do not behave as if they believe in the old ethos of *mañana.* With this kind of evidence it is difficult to support the notion that a characteristic way of life is simply an expression of the genetic makeup of the people.

OLD AND NEW "HALLMARKS" OF RACE

Old hallmarks of race. *Colour.* For centuries, geographical races and local races were identified by the most obvious physical differences, chief among them the colour of eyes, skin, and hair. From such observations came the simple notion of a few groupings based on the apparent colour of the skin alone: "black" men, "white" men, "yellow" men, and "red" men. Apparent skin colour is deceptive, however; it may be from dirt, grease, or mineral pigments (*e.g.*, ochre); it may be affected by exposure to sunlight and maintained with maximum tanning, as among the modern economic aristocracies of European origin on the beaches of Hawaii and North Africa. Moreover, all intrinsically dark skins do not necessarily have a common genetic origin; indeed, the people with the most skin pigment (melanin) in the unexposed areas of their skin come from quite unrelated parts of the world.

Suntanned "white" men

Hair form. In the 19th century, attempts were made to create racial classifications based on the form of the hair: straight, curly, woolly. To some extent these classifications have validity. Straight black hair of relatively wide diameter at the shaft is common among people of Asian origin, and the extreme of a spiral-tuft form of head hair is found in Africa south of the Equator, especially among Bushmen. Hair form, however, is affected by modes of hairdressing, and there is great individual variability in unmodified hair form within groups in many pads of the world. At any rate, no modern racial classifications are based on hair form done.

Anthropometry. The development of the technique of anthropometry (human bodily measurement) in the 19th century brought other approaches to the identification of races. Various groups of "pygmies" were identified by their extremely short stature. The proportions of leg and torso (trunk) was a distinguishing mark of short-legged groups such as the Eskimo and Southern Asians and long-legged peoples such as the Nilotes (a number of African tribes).

Head measurements (craniometry) showed distinctively round-headed (brachycephalic) populations like those of central Europe and long-headed (dolichocephalic) populations such as those typical of northern Europe. Cranial and facial bone measurements helped to distinguish differences in living people and in skeletons alike and clarified such features as the broad faces and jutting jaw angles of northern Asians and the broad-faced, narrower heads of some American Indian groups.

Body measurements do reflect a genetic component, but they only can be used with caution, since they are also affected by nutrition. Better nourished people tend to grow larger in many dimensions, because they have more fat and because proper diet enables them to build more muscle and bone. Most body dimensions are attributable both to the interaction of a number of genes and to the effects of nutrition and, thus, are used less than formerly in racial comparisons. In regions in which the nutrition of the population is relatively uniform, however, body measurement (anthropometry) can be useful in comparing genetically isolated subgroups.

Other features. Certain observations of eyelid and nose form, lip thickness, and even proportions of the fingers and toes are less subject to the objections on body dimensions. The form of the upper eyelid (the so-called mongoloid, or epicanthal, fold) often is diagnostic of Asian origins. Thickness and turning out (eversion) of the lips are notably great in some parts of Africa. Noses tend to be narrow in northern Europe and Tibet and wide in parts of Africa, New Guinea, and Fiji. But observations of characteristics with complex genetic bases have lost favour to simply inherited (single-gene) traits that can be studied more precisely.

The role of blood groups

New hallmarks of race. ***Blood traits.*** The classic human blood groups are examples of traits produced in the individual by the action of a single set of genes in the set of chromosomes (the majority of genetically determined features of the individual come about through the interaction of many gene sets). Because it is known how blood groups A, B, and O are inherited, the frequencies of their genes in any human population can be calculated from the results of blood tests. For blood group B, the gene frequency is close to zero among American Indians and Australian Aborigines and occurs in as many as 40 percent of the people in parts of Africa and Asia. Frequencies of another blood group, called M, range from zero to nearly 100 percent in different parts of the world; other blood groups have a tendency to show ranges nearly as wide.

Blood factors other than blood groups include abnormal red pigments, such as hemoglobin S, (the variant hemoglobin that is the cause of sickle-cell anemia), which is rare in most parts of the world but found in as many as half the local residents in some parts of Africa. Inherited blood factors include blood substances called haptoglobins and tranferrins and deficiency of a red-cell enzyme called glucose-6-phosphate dehydrogenase. Dozens of additional properties of red blood cells and of other blood fractions have become known through widespread medical use of blood transfusions (see BLOOD GROUPS).

Other genetic traits. Besides blood fractions and blood groups, there are genetically determined differences in the excretion of amino acids (protein components) via the urine; for example, there is a tendency to excrete high levels of β-amino-isobutyric acid among many people of Asian origin. There is a widespread, genetically determined deficiency in lactase (an enzyme that helps digest milk sugar), and there are simply inherited differences in earwax type: dry-flaky versus sticky-moist. With dozens of simply inherited traits available for study, far less reliance is being placed on once-popular body measurements, proportions, or descriptions of obvious physical differences.

METHODS OF RESEARCH

When a modern anthropologist or human geneticist studies a newly discovered subgroup of people or restudies one already known, he does not start from the very beginning. He is likely to have previously available statistical data that delineate the effective geographical and breeding limits of his group; he commonly knows their geographical race and, in most cases, their local race. He frequently has clues from earlier studies about what traits to study; for example, selected blood groups, abnormal hemoglobins, transferrins, haptoglobins, or β-amino-isobutyric acid, lactase deficiency, or earwax may already have been investigated.

Tracing evidence of admixture

In studying a group of people of largely African origin in Brazil, he may concentrate on a few blood groups and hemoglobin S. For a community of American Indians he may choose to study p-amino-isobutyric acid excretion and earwax. In New Guinea he may make dental casts (to study tooth size) and test for abnormal hemoglobins. Among so-called black people in the United States he may be interested in evidence of admixture with Europeans and American Indians; or he may want to relate an Indian tribe or "nation" to their origins in Mexico, the United States, or Canada. No group of human beings is now studied as if nothing were known about them.

Problems and approaches. In a group of related microraces or local races, the problem may be to investigate malarial selection, of particular social and economic concern in such places as the Middle East and Indonesia. The task may be to relate body size to climate or rainfall, to determine the frequency of resistance to smallpox infection, or to explain a high local occurrence of red–green colour blindness. Such research may be used to guide international relief organizations. Evidence of lactase deficiency, for instance, might reveal that members of a given microrace would have difficulty in digesting of milk products.

Some approaches to race research are purely classificatory (taxonomic), designed to place one group in relation to others; or the task may be historical, to trace origins. The goal may be to measure genetic change or to study disease susceptibility and other racial differences in terms of nutrition and climate. Each problem requires its own set of approaches, typically going well beyond the simple question of classification alone.

An anthropologist may be interested in the size and form of teeth; a geneticist may be concerned with the structure of different chromosomes; a human biologist may direct attention to the typical sequence of maturation within a group; a radiologist may measure skeletal density or investigate the order of appearance of centres of bone formation (ossification) in infants. Another approach may be to ascertain genetic influences on fat metabolism, perhaps to understand what makes fat-plugged blood vessels and deaths from heart disease so rare in a given microrace. The problem may be to study congenital (birth) defects such as cleft palate. While races ordinarily are studied with other ends in mind, the results still may add information bearing on simple classification; thus, research on blood factors casts new light on the taxonomic position of the Ainu, and measurements of Y-(male) chromosomes in blood-cell cultures clarified the genetic affinities between Jews and Arabs.

Identifying degree of admixture

The study of race mixture. All human populations are of mixed origin. The problem of research is to discover when and with whom. The people called black in the United States typically provide firm evidence of substantial admixture with European genes over the last two centuries; but information is lacking about their ancestral admixtures in Africa before American enslavement. Study of blood groups and other monogenic (single-gene) traits permits the estimation of the degree of admixture in any population of recent origin. People socially identified as blacks from Detroit, Oakland, Calif., or West Texas average close to 73 percent African genes and 27 percent European genes. For mixed populations of greater antiquity, such estimates are complicated by evolutionary changes that tend to obscure initial proportions.

People of English origin are provided with documented evidence of mixture with Vikings, Romans, occasional Spaniards, Irish, Scots, Welsh, and Bretons (among other Frenchmen). Among the "purest" (genetically isolated) North Americans, in a most restricted, recent sense, are those with ancestral Welsh surnames (Jones, Lewis, and Owens'), selected Pueblo Indian groups, and some more lately arrived Armenian communities.

Admixture with contiguous groups has been a human accomplishment through the ages—Israelites with Philistines, Egyptians with Sudanese, Aztecs with Toltecs, and Hindus with Dravidians. Mating with more remote groups was accelerated by such social movements as the romanization of North Africa, the Near East, and Europe; the spread of Bantu speakers southward in Africa; and the wide conquests of the Mongol troops of Genghis Khan. Through such avenues many Europeans came to incorporate African and Asian genetic elements; *e.g.*, the Mongol eye fold is discernible among Poles and Hungarians. With the development of sea transport, more far-flung intercontinental genetic mixing led to newer populations with immediate ancestors from even more geographical races; *e.g.*, the so-called triple hybrids (African, American Indian, and European) of the Carolinas in the United States.

It was once held that human "hybrids" or "half-breeds" such as Eurasians or Afroindians would be biologically inferior to the parental stocks. Contemporary studies of such groups indicate no systematic decreases in fertility or longevity; neither do they fully confirm contrary claims of "hybrid vigour." Admixture nevertheless does tend to dilute the pool of deleterious genes and favours the production of new genetic combinations upon which natural selection operates. The effect is to increase genetic variability and the rate of human evolutionary change.

MODERN MEASURES OF RACE

Little-used particular traits

Measures now used in the study of races are primarily those of factors that are genetically and simply determined, such as single-gene traits. While genetically complex differences as in the size and shape of the teeth can also be measured, their utility is limited by ignorance of their exact mode of inheritance. Thus, wisdom teeth never develop (third molar agenesis) among an exceptionally high proportion of Eskimo and in many Asians. While, by contrast, third molar agenesis is exceptionally rare in Australia, New Guinea, and in some parts of Africa. This genetically complex trait, however, is relatively little used in making racial comparisons. There are simply inherited skeletal traits, such as presence of a broad middle segment of the fifth, or little, finger (brachymesophalangia-5), that are common in some populations and extremely rare in others. Fusion of two of the wristbones occurs in up to 6 percent of individuals in some parts of Africa but in only the merest fraction of the populations of Europe or Asia. Such skeletal differences readily can be studied with X-rays but are not so easily detected in field studies through ordinary visual inspection. Significant racial differences in the size and thickness of the walls of longer bones also require X-rays for their measurement.

Single-gene traits. The greatest amount of information on simply inherited traits bearing on race has come from the study of the blood and from biochemical analysis of the urine. While the components of the blood are no more informative than are those of muscle or viscera, many millions of people throughout the world have had their blood typed, producing an accumulation of information on blood differences, their inheritance, and their geographic distribution. In similar fashion, modern medical interest in metabolic abnormalities ("biochemical lesions"), often diagnosed by measuring amounts of different amino acids in the urine, has revealed various biochemical polymorphisms (a variety of forms or types) that characterize families of close relatives, microraces, local races, and, in some cases, geographical races as well.

Some findings about race have been by-products of other kinds of study. It was discovered almost by accident that a chemical called phenylthiocarbamide tastes bitter to some people but seems tasteless to others. Only later did physical anthropologists and human geneticists discover that some racial groups are remarkably "taste-blind" to phenylthiocarbamide. Population differences in colour blindness were discovered in the course of routine, large-scale visual examinations for military purposes; ability to distinguish red from green can be urgently important to an infantryman, a submarine commander, and the driver of a military truck. Earwax polymorphism (dry-flaky and moist-sticky) was long known in Japan; this observation led European and African geneticists, who had assumed all earwax was sticky, to discover the polymorphism in their own lands.

Medical Disorders. Initial medical concern with abnormal hemoglobins led to the observation that sickle-cell anemia appears to be limited to people of African origin and that a disorder known as thalassemia (literally "sea blood") is apparently distinctive of people with Mediterranean ancestry. Discovery of genetically determined deficiency of the enzyme glucose-6-phosphate dehydrogenase (G6PD, noted above) came about when new antimalarial drugs were introduced after World War II and occasionally caused dangerous side effects in persons of African and Middle Eastern origin. Ancient Egyptians and Greeks knew about some people who got sick when they ate common broad beans (fava beans). The geographical limits of this genetically determined disorder (favism) seem clear, but the details of its inheritance have not yet been unravelled. It appears to be related to G6PD deficiency disease.

Disorders of genetic origin

Medical disorders of genetic origin are of importance in making racial comparisons only when they are common enough to permit comparison of one group with another. Geographical sleuthing has led to the realization that relatively high gene frequencies for the sickle-cell trait (because of hemoglobin S), various thalassemias, G6PD deficiency, and, apparently, favism, all tend to be found in places in which there is a particular kind of malaria (falciparum malaria). The abnormal hemoglobin S or the G6PD red-cell enzyme deficiency apparently makes for red blood cells that are relatively unsuitable for the reproduction of the malarial parasite. Thus, the individual can be said to gain protection against malaria at the cost of suffering another disorder. Microraces with high gene frequencies for disorders that are rare elsewhere may be indicative of local disease adaptation, perhaps fighting an infectious disease with one of genetic origin.

Blood groups and subtypes. Within the ABO blood-classification system, B is the least common of the three blood groups the world around. Absent among genetically isolated American Indians and lacking in isolated Australian Aborigines, B is relatively common in eastern Asia, India, and Africa; it is only a minor blood group in Europe, the observed frequency rarely exceeding 12 percent. Apparently, Australia became isolated reproductively from the rest of the world before B became frequent elsewhere. Most investigators assume either that the east Asian ancestors of American Indians crossed into the North American Arctic before blood group B had become established in Asia or that, having had it once, they lost blood group B in the process of evolution.

So-called Rh blood subtypes, first discovered in rhesus monkeys and later in people, leaped to medical importance in Europe when incompatibility between the Rh types of the mother and her unborn baby was found to damage or kill the fetus. The troublesome Rh-negative gene (r) is relatively common in Europe (especially among the Basques of Spain) but less frequent elsewhere; thus, its frequency can be used as one measure of European admixture in populations that once lacked it. Rare or absent in the rest of the world, R_o (another distinctive gene in the Rh series) is relatively common in Africa. Thus, the occurrence of R_o can provide a measure of the gene flow into the mixed population of Brazil or out from the "black" people of the port of Puerto Barrios in Guatemala. By its relative frequency, R_o serves as one measure of "white" admixture among American "black" groups.

M–N series in racial comparisons

Other blood groups often used in racial comparisons include the M–N series. Since the frequencies of M and N are about equal in most parts of Europe, they do little to characterize local differences there. Japanese and Britons both have M and N, so the frequencies also fail to distinguish adequately between the English village of Stoke Poges and the city of Kyoto, Japan. Since M is virtually missing in Aboriginal Australia and rare in the other lands of the Pacific Ocean, and since N is absent or nearly so in the Indians of the Americas, M and N have great value in comparing Pacific populations, in postulating their origins, and in assessing European or African admixture in various American groups.

Within the Diego blood group, the Diego positive gene (Di") is especially common among people of Asian origin. It also has been detected among people of Polish origin in the United States, perhaps as a residue of the Mongol invasions of Europe. Yet Di^a cannot be used to compare people within groups that lack the gene, nor is the question of origins easily resolved simply by comparing those who have it in the highest frequency. Not every genetically determined set of traits has equal value in comparing, differentiating, or searching for the origins of each race. Great differences within the same geographical race point to local selective factors and considerable blood-group diversity. Even within small and related villages, investigators do not use the same list of genetically determined traits for every set of people studied.

Abnormal hemoglobins. When present on only one of a person's chromosomes, the gene that generates abnormal hemoglobin S merely leads to sickle-shaped red blood cells (sickle trait) without making him ill. When the individual inherits a double dose (one gene on each of a pair of chromosomes), he rarely reaches reproductive age, dying first of severe sickle-cell disease (anemia).

As first detected, the sickling gene occurred in people from parts of Africa where methods of agriculture led to stagnant, standing water that gave malarial mosquitoes a chance to breed heavily. Thus, among people of the Western world the frequency of hemoglobin S indicates African origins, while the relative frequency of S in different African populations provides estimates of past malarial selection. The sickle-cell gene in modern, slave-owning Saudi Arabia presumably was introduced long ago by slaves of African origin but seems to have been maintained in oasis villages there by malarial selection. The gene is also known from Indonesia, where malaria is widespread; apparently, sickling is maintained and even increases wherever malarial selection is active.

The pattern for the thalassemias

Much the same holds for thalassemia minor (a single dose of the offending gene) and thalassemia major (a double dose). In the thalassemias the abnormal hemoglobin is a poor carrier of oxygen; the sufferer needs blood transfusions from time to time if he is to grow and live effectively. But the disorder is not without compensations; the oxygen-deficient blood cells provide the malaria parasite a relatively poor home, one that may be less hospitable than the sickle cells. Once thought to be restricted to the Middle East, thalassemia is found in a broad band aroucd the tropics, where malaria has been a problem for years. Absence of the abnormal thalassemia hemoglobins in some populations that were originally Mediterranean has been attributed to generations of genetic adaptation to nonmalarial regions. Jews of western Europe (Ashkenazim) seem to have lost whatever thalassemic genes their ancestors may have had 2,000 years ago. Spanish-Portuguese-North African Jews (Sephardim) in the United States appear to have lost the thalassemic gene a few hundred years after their forefathers came to North America. Thus, the abnormal hemoglobins provide evidence of racial origins that supports the record of history.

In similar fashion, the frequency of G6PD enzyme deficiency repeats the story. When one lacks this red-cell enzyme, the malarial parasite finds the blood cells poor places for development. People from Middle Eastern regions where malaria is prevalent have the highest frequency of G6PD deficiency; in some Kurdistani villages the gene frequency rises to a phenomenal 60 percent. In the United States the deficiency characterizes people who come from malarial areas of that country or who are relatively recent arrivals from the Middle East and North Africa. People whose ancestors left those Mediterranean regions thousands of years ago to live free of malaria no longer have the abnormal gene.

Since gene frequencies change with time, the presence or absence of a gene does not always confirm or disprove ancient relationships. If hemoglobin S can become frequent in Africa after the introduction of agricultural methods that favour mosquitoes, and if G6PD deficiency can disappear in people of Mediterranean origin, then such problems as posed by the absence of blood group B in American Indians seem less puzzling. It is likely that ancestral Indians came to the Americas with blood group B and then subsequent generations lost it, still retaining the Diego blood group, the high level of β-amino-isobutyric acid excretion, and many other traits found among modern Asians.

Metabolic factors. While some people excrete much β-amino-isobutyric acid (BAIB), the urine of most people shows very little of this substance even when all share the same diet. Genetically determined (BAIB) polymorphism and any metabolic advantages it may provide are incompletely understood. Nevertheless, people who do show high levels of BAIB excretion are Asians and American Indians. If the trait is assumed to have come from Asia, it is an unexpected finding that many Indian groups living nearest to Asia (theoretically of more recent arrival) seem to excrete less BAIB than those living in South America.

Lactase deficiency and its world distribution

Lactase deficiency is even more common in the Orient than is the BAIB trait. After drinking about eight ounces of cow's milk, people with lactase deficiency are likely to suffer abdominal cramps and diarrhea. This disorder of lactose metabolism is also very common among individuals of African origin and, indeed, in much of the world except Europe. The European geographical race is statistically unusual in tending to maintain high intestinal lactase levels into adulthood. That race has the highest proportion of people who can drink milk in great quantities without distress even when they are grown up.

Other diseases and congenital defects. Through continuing natural selection (favouring some genes and eliminating yet others), the frequency of genetically related diseases differs from race to race. A form of mental deficiency that arises from an inherited enzyme disorder (phenylketonuria) is far less common in Africa and Asia, for instance, than it is in Europe. Jews from near Vilnius, U.S.S.R., tend to a relatively high frequency of Tay-Sachs disease (progressive blindness and mental defect in infants); people from England are particularly prone to develop a bone disorder called Paget's disease; and congenital hip dislocations are especially common in American Indians from the Southwest.

Certain types of cleft palate are remarkably common among Japanese, while abnormal narrowing of the body's largest artery (the aorta) is far less frequent in Americans of African origin than in their fellow citizens of other origins. Minor wristbone (carpal) fusions are 15 times more common in people of African ancestry than in Mexican-Americans, who in turn show broad middle segments of the fifth finger 10 times more frequently than Afro-Americans. Women of African origin are comparatively unlikely to suffer the spontaneous fractures and low-back pains that come from adult bone losses (osteoporosis); yet men of African origin who are military pilots are unusually prone to suffer ejection-seat fractures of the lower lumbar vertebrae. Skin cancer is far more frequent among light-skinned, freckled Texans than it is in East Texans of African origin. Painfully impacted wisdom teeth (third molars) are most common among Asians and Europeans who are genetically delayed in third-molar development.

Symptoms of genetically related disorders often are manifested onlv under direct environmental influences. The headaches of what has come to be called the "Chinese-restaurant syndrome" are found to appear among people who have inherited a tendency to react deleteriously to monosodium glutamate, a flavour-enhancing product used by many Chinese cooks. An inherited inability to tolerate milk sugar usually is of little consequence unless the person drinks more than half a pint of milk at a time. Wheat-gluten sensitivity may produce no distress among people who subsist on rice or barley, but in Italy it may cause major discomfort and debilitation because the diet there includes pasta products (*e.g.*, macaroni), which are made of high-gluten wheat. Even a genetically related disease such as diabetes may diminish as a medical problem among populations that eat little carbohydrate (sugar, starch) and take most of their calories from protein foods such as meat and fish. Clearly, many genetically determined differences between races are "diseases" only under specific circumstances.

THE EVER-CHANGING RACES

Ongoing evolution. Human races drift genetically, resembling the shifting sands of a desert. They all are in a continuing state of change; new genes are readily introduced from the outside, since all races of *Homo sapiens* are interfertile. Explorers, military men, and others contribute their genes to populations they visit; conquerors still bring home the new genes of their captives or war brides. Maya Indian genes were introduced into Spain and other American Indian genes to England; genes from Japan, Korea, Vietnam, and Germany have been mixing on a large scale with those from the United States since World War II.

The role of explorers and conquerors

In a relatively short time, chance events (*e.g.*, in the selection of mates) can serve to build up the frequency of rare genes in particular populations, as among Polish Jews from the vicinity of Vilnius or French Canadians in the St. Lawrence Seaway region. Apparently lost by Ashkenazic Jews of Europe, the gene for G6PD deficiency has gained at a phenomenal rate among Jews from Iran and Kurdistan. The genes for a disorder called familial Mediterranean fever are so restricted to the eastern Mediterranean that their changes document local evolutionary change. Essentially, evolution is a change in gene frequency.

The distribution of the sickle-cell gene attests to recent changes in gene frequency; for example, there is evidence of its gradual elimination in North America over the last 150 years. Studies of religious isolates such as the Mennonites (*e.g.*, Amish and Hutterites) reveal differences that reflect local ongoing evolution. American Indians of the Southwest evidence many genetically related disorders that must be comparatively recent in their present gene frequencies.

Within a small group of a thousand or so mating pairs, genetic differences may be the simple result of chance sampling effects on pairing (*i.e.*, genetic drift), the group perhaps even arising as a distinctive race on that basis. Some individual families do especially well reproductively and have hundreds of offspring in a matter of generations. Other families tend to die out; for example, compare the relatively small number of people named Holmes today with those called Adams. In some societies polygamy may raise rare genes to numerical importance; men who live on to father several generations of progeny affect small populations by the sheer numbers of descendants who bear their genes.

The ingredients of population evolution

Ongoing evolution at the population level thus is a product of chance, geography, and natural selection. It also is affected by religion and local attitudes toward reproduction; *e.g.*, depending on whether such attitudes support a norm of large or small families. Between populations, the rate of human evolution may be a question of technological advancement, of the availability of food, or of major medical advances that reduce the number of deaths. As countries develop improved food technology, more effective food distribution, immunization, and other medical care, their populations tend to increase, thereby changing the genetic makeup of the world's population.

The future of races. In the last 200 years, many small and some once-large racial groupings have disappeared as distinct populations. The once-numerous Tasmanians are gone but not quite forgotten; the last officially recorded "full-blooded" Tasmanian died in 1876. Aleuts, natives of the Aleutian Islands, have declined to less than 8 percent of their former numbers. The Carib Indians who met Columbus are gone entirely (as a distinct racial group) from Caribbean lands. Indians of New York state are memorialized more by place names than by living people. Where now are the Picts and the Celts; or the Germanic tribes that Caesar cataloged; or the people of the Greek city-states; and where are the traditional ten tribes of Israel?

Many of these groups live on only in the sense that their distinctive genes were added to and survive among the larger groups that eventually encompassed them. Penobscot Indian genes are scattered throughout Maine, and those of ancient Norse invaders are spread over the map of England. In parts of New Hampshire, Hessian genes from the German mercenaries of the American Revolution live on; and in Rhode Island, some French genes still survive from Count de Rochambeau's troops who stayed there for about a year before they helped defeat the British at Yorktown. Other microraces and local races exist today as part of newly formed hybrid groups.

New races emerge, as in Hawaii and in South Africa; in South America the populations include varying proportions of genes from that continent, from southern and northern Europe, from Africa, and (in some regions) from India, too. Gene flow in the United States once was largely from the European population into that of African origin, up to 25 percent in American "blacks" in the North and West. More recently, gene flow in the other direction has also taken place, as individuals have "crossed over," or as African genes have entered the nominally European populations in the United States and Canada from Cuba, Puerto Rico, and Jamaica. Gene flow from the United States into Japan since 1946 has been countered by gene flow from Japan; thus, in the 1970s there were nearly a quarter of a million "hybrid" children in the U.S. whose mothers came from Japan, China, Korea, Taiwan, and Vietnam. Groups without some infusion of genes from half a world away are few indeed.

Continuous gene flow

Some gene pools have been quite eradicated from the human species, while other gene pools live on in newly named populations. The genetic makeup in all developed nations is changing as the result of the breaking up of isolates, of incorporation of new genes, and of new directions in natural selection. Genes from Pakistan and India are now spreading across the English countryside. Some long-isolated gene pools from North Africa and the Yemen are now becoming part of the Israeli genetic complex.

New races are forming as the results of history, geography, and political alliances, and as the results of bridges and oil companies and mining camps and military activities. The genetic makeup of existing races is changing because of improved medical care, ditch drainage, and the elimination of insects that carry disease. The same processes that created the Pitcairn Islanders in the 1790s continue at work, as jet transports erase some barriers to gene flow and as political units build still others. The races of the next century will include some that do not exist now, while some of the local races and microraces of the 1970s will be missing.

RACE AND SOCIETY

Race, intelligence, and behaviour. There is some small evidence that infants from different races do differ in reactivity, rates of skeletal maturation, and optimum birthweight. Beyond this, the possible existence of true racial differences in behaviour and intelligence becomes difficult to establish. Peoples long characterized as "stolid," "unimaginative," "childish," or "cruel" tend to become very different when they emigrate, when their economic status changes, or when they live in rapidly changing environments. Once misjudged by some Westerners to be innate imitators of other cultures, the Japanese nation has shown technological and scientific progress to such a creative degree as to disprove this belief. Pacifistic European Jews have become tough warriors since they took root in modern Israel; the once-warlike Navajo Indians have been peaceful since the 1880s, and the sexually repressed England of the 1930s has become more and more uninhibited since 1950.

The problem of race and intelligence is extraordinarily complicated simply because "intelligence" as conventionally measured is not a stable trait in the way blood group B, blue eyes, or extra cusps on teeth are. Measured intelligence changes with emotional state, with parental encouragement, with motivation, and with disillusion. If an intelligence test is constructed for use with city dwellers, then rural children may tend to fare poorly with it. If Aboriginal boys and girls in primitive Australian surroundings are tested in ways that demand literacy, knowledge of science, and a large vocabulary, they fail to do well regardless of their talent.

Social deprivation and malnutrition

Childhood social deprivation and juvenile malnutrition may also affect intelligence test scores; the test taker is also penalized if he comes from a cultural tradition that takes a dim view of competition. For these and other reasons, the problem of race and intelligence remains unsolved. While so-called racial groups may differ markedly in measured test performance, it is not known how the differences reflect variations in prenatal care, social experience, family structure, and way of life (see INTELLIGENCE, DISTRIBUTION OF: *Group differences* in intelligence).

Racism. In the record of human history, races (however defined) generally have met in conflict, in the course of empire building, and in forays for captives or slaves. Victor and vanquished built and nourished mutual dislikes. In the United States, immigrants imported as cheap labour were initially disliked as economic rivals by earlier residents and, in turn, came to resent later migrants. Chinese and Japanese labourers and their children suffered especially in the U.S. West; on the East Coast newly arrived Irish families were perceived as a threat to the wage structure in mills and shops. Africans, first imported into the United States as slaves, early showed such spirit and talent that alarmed slaveholders sought theoretical justification for the continuance of slavery, establishing laws against slave education, even forbidding mere literacy to Africans. Italians moved to the United States as labourers, and Jews from central Europe and Russia went there to face old, transplanted European prejudices. After World War II, the arrival of Pakistanis and West Indian nationals in England recapitulated problems earlier encountered by many groups in the United States. By the 1970s restrictive laws against immigration had been passed in England.

Racism in its simplest form is dislike of any people lumped together as a microrace, local race, or geographical race. It results in attempts to limit economic opportunity, to preserve status, to deny equal protection under law, and to maintain cheap labour. Racism is most likely to arise between groups that show obvious physical or linguistic differences or who are distinguished by various levels of education. Reverse racism occurs when members of previously underprivileged races achieve political and economic strength and proceed to discriminate against others.

After World War II and the American occupation of Japan, negative sentiments in the United States abated to the extent that Japanese-Americans became highly respected citizens in the very regions where they were earlier most despied. Puerto Ricans became more generally accepted in that country over the last generation or so. Modem Israeli military successes have stimulated respect for Jews by other Europeans, but rising anti-Jewish feelings have been reported among Americans of African origin. Recently, some Eskimos have balked at hiring technical advisers of European ancestry, tribal Navajo have condemned "Anglo" advisers of European ancestry, and Latin Americans of mixed origin (Chicanos) have refused to deal with agricultural experts of so-called "white" cultural background.

Racism tends to persist most readily when there are obvious physical differences among groups; *e.g.*, "white"–"black" differences in Australia and South Africa and the distinctions in bodily traits between Hindus and other residents in Guinea and the Caribbean region. Racism based on differences in language and behaviour tends to disappear more readily as cultural communality is attained; as later immigrations threaten older, established groups, however, they may provide new directions for fear and dislike.

When changing sentiments alter directions of dislike, those previously discriminated against may newly become racist if their social and economic gains are threatened, or if their group problems tempt them to seek easily identified "enemies" as a substitute for working toward social betterment.

Rachmaninoff, Sergey

Sergey Vasilyevich Rachmaninoff was the most popular Russian composer of the 20th century, a gifted conductor, and possibly the most formidable pianist of his time. He was the last great proponent of the tradition of Russian Romanticism.

Early life. Rachmaninoff was born on April 2, 1873, at Oneg, an estate belonging to his grandparents, near Lake Ilmen in the Novgorod district. His father was a retired army officer and his mother the daughter of a general. As a matter of family tradition, he was destined to become an army officer until his father lost the entire family fortune through risky financial ventures and deserted the family. Sensing his abilities, young Sergey's cousin Aleksandr Siloti, a well-known concert pianist and conductor, suggested sending him to the noted teacher and pianist Nikolay Zverev in Moscow for his piano studies. It is to Zverev's strict disciplinarian treatment of the boy that musical history owes one of the great piano virtuosos of this century. For his general education and theoretical subjects in music, Sergey became a pupil at the Moscow Conservatory.

Rachmaninoff.
Bassano and Vandyk, Elliott and Fry

At the age of 19 he was graduated from the conservatory, winning a gold medal for his one-act opera *Aleko* (after Pushkin's poem "The Gypsies"). But his fame and popularity, both as composer and concert pianist, were launched by two compositions: the *Prelude in C Sharp Minor,* played for the first time in public on Sept. 26, 1892, and his *Concerto No.* 2 *in C Minor,* which had its first performance in Moscow on Oct. 27, 1901. The former piece, although it first brought Rachmaninoff to public attention, was to haunt him throughout his life: the prelude was constantly requested by his concert audiences. The concerto, his first major success, revived his hopes after a trying period of inactivity.

Failure of First Symphony

In his youth, Rachmaninoff's passionate nature was not sustained by the will and equilibrium he later developed, and he was subject to emotional crises over the success or failure of his works as well as in his personal relationships. Self-doubt and uncertainty carried him into deep depressions, one of the most severe of which followed the failure, on its first performance (March 1897), of his *Symphony No. 1 in D Minor*. The symphony was poorly performed, the critics condemned it. (Ironically, this was the work that, following Rachmaninoff's death, was acclaimed by many musicologists as his greatest contribution to symphonic literature as well as his most original composition.) During this period, also brooding over an unhappy love affair, he was taken to a psychiatrist, Nikolay Dahl, who is often credited with having restored the young composer's self-confidence, thus enabling him to write the *Second Piano Concerto* (which is dedicated to Dahl).

The association with Dahl seemed to have an even greater influence on Rachmaninoff's personal life than on his music: about this time he married his cousin Natalie Satin. The writing of the *Second Piano Concerto* marked the resumption of his creative activity, and it was soon followed by a number of shorter works. The concerto is studded with such melodic themes that it has become his most popular longer work.

Major creative activity. At the time of the Revolution of 1905, Rachmaninoff was a conductor at the Bolshoi Theatre. Although more of an observer than a person politically involved in the revolution, he went with his family, in November 1906, to live in Dresden. There he wrote three of his major scores: the *Symphony No. 2 in E Minor* (1907), the symphonic poem *The Isle of the Dead* (1909), and the *Concerto No. 3 in D Minor* (1909). The last was composed especially for his first concert tour of the United States, highlighting his much-acclaimed pianistic debut on Nov. 28, 1909, with the New York Symphony under Walter Damrosch. Probably the composer's best unified longer work, the *Third Piano Concerto* requires great virtuosity from the pianist; its last movement is a bravura section as dazzling as any in the literature. In Philadelphia and Chicago he appeared with equal success in the role of conductor, interpreting his own newest symphonic compositions. Of these, the *Second Symphony* is the most significant: although it displays Rachmaninoff's usual propensity for lapsing into familiar romantic conventions, it is a work of deep emotion and haunting thematic material. While touring, he was invited to become permanent conductor of the Boston Symphony, but he declined the offer and returned to Russia in February 1910.

Place in
Russian
music

It was at that time and during musical feuds in Moscow between several divisions in the large family of Russian composers that Rachmaninoff's compositions were clearly classified and his place in Russian music defined. On the one hand there were the adherents to the St. Petersburg group of the "Mighty Five" (Balakirev, Borodin, Cui, Mussorgsky, and Rimsky-Korsakov), and on the other there were the more conservative followers of Tchaikovsky, Anton Rubinstein, and Taneyev. Another, smaller, group was composed of enthusiasts of Alexander Scriabin's music. Of these three factions, Rachmaninoff belonged unmistakably to the Tchaikovsky group. His lyricism, devoid of any particular innovation, is especially evident in the large number of songs he composed, even more than in his piano compositions.

Rachmaninoff's music, although mostly written in the 20th century, remains firmly entrenched in the 19th-century musical idiom. He was, in effect, the final expression of the tradition embodied by Tchaikovsky—a melodist of Romantic dimensions still writing in an era of explosive change and experimentation.

The one notable composition of Rachmaninoff's second period of residence in Moscow was his choral symphony *The Bells,* based on Konstantin Dmitriyevich Balmont's Russian translation of Poe's poem. Although it became a staple of the symphonic repertory, partly because of its scoring for chorus and soloists, the work displays considerable ingenuity in the coupling of choral and orchestral resources to produce striking imitative and textural effects.

Exile in
the U.S.

After the Revolution of 1917, Rachmaninoff went into his second self-imposed exile—this time taking his family to the U.S., where he made his home for the rest of his life. For the next 25 years he lived in an English-speaking country, yet never mastered its language nor thoroughly acclimatized himself. With his family and a small circle of friends, he lived a rather isolated life. He missed Russia and the Russian people—the sounding board for his music, as he said. And this alienation had a devastating effect on his formerly prolific creative ability. He produced little of real originality, but rewrote some of his earlier work. Indeed, he devoted himself almost entirely to concertizing the U.S. and Europe, a field in which he had few peers. His only substantial works from this period are the *Symphony No. 3 in A Minor* (1936), another expression of sombre, Slavic melancholy, and the *Rhapsody on a Theme by Paganini* for piano and orchestra (1934), a set of variations on a Paganini violin caprice. The *Rhapsody* has vied with the *Second Concerto* as the composer's most often-played work.

In the midst of one of his concert tours, Rachmaninoff was taken to his home in Beverly Hills, California, where he died on March 28,1943.

Of his compositions, the *Second* and *Third Piano Concerti,* as well as the *Rhapsody,* still remain in the concert repertory and may continue to do so. His symphonies, his vocal works, and his solo piano pieces have declined somewhat in their appeal, yet the general charm of his work and his unique performances retain for him an honourable position in the history of music.

MAJOR WORKS

Orchestral works

SYMPHONIES: *No. 1 in D Minor,* op. 13, 1895; *No. 2 in E Minor,* op. 27, 1907; *No. 3 in A Minor,* op. 44, 1936.

PIANO CONCERTOS: *No. 1 in F Sharp Minor,* op. 1, 1890–91, rev. 1917; *No. 2 in C Minor,* op. 18, 1901; *No. 3 in D Minor,* op. 30, 1909; *No. 4 in G Minor,* op. 40, 1927.

MISCELLANEOUS: *The Rock,* op. 7, 1893 (for orchestra); *Capriccio on Gypsy Themes,* op. 12, 1894 (for orchestra); *The Island of Death,* op. 29, 1909 (symphonic poem based on picture of Böcklin); *Rhapsody on a Theme of Paganini,* op. 43, 1934 (for piano and orchestra); *Symphonic Dances,* op. 45, 1941 (for full orchestra).

Chamber music

Trio Elegiaque in D Minor, op. 9, 1893 (for piano, violin, and cello); *Sonata for Cello and Piano in C Minor,* op. 19, 1901.

Piano music

SOLO PIANO: *Five Pieces for Piano,* op. 3, 1892 (including the *Prelude in C-Sharp Minor*), *Six Moments Musicaux,* op. 16, 1896; *Variations on a Theme of Chopin,* op. 22, 1903; *Nine Etudes-Tableaux,* op. 39, 1916–17; *Variations on a Theme of Corelli,* op. 42, 1932; preludes, études, and sonatas.

TWO PIANOS: *Suite No. 1,* op. 5, 1893; *Suite No. 2,* op. 17, 1901.

Vocal Music

OPERAS: *The Miser Knight,* op. 24, 1904; *Francesca da Rimini,* op. 25, 1904.

SONGS: Approximately 72 songs composed between 1893 and 1916.

MISCELLANEOUS: *Liturgy of St. John Chrysostomus,* op. 31, 1910, (for mixed choir); *The Bells,* op. 35, 1913 (choral symphony); *Vesper Mass,* op. 37, 1915; *Three Russian Folksongs,* op. 41, 1928.

BIBLIOGRAPHY. The central collection of Rachmaninoff papers, holograph scores, and autograph letters in the U.S. is the Rachmaninoff Archive at the Library of Congress. The Rachmaninoff Room at the State Central Museum of Musical Culture, Moscow, also holds autograph papers, letters, scores, and a complete catalogue of works. Rachmaninoff's letters have been collected and published in Russian, *Письма* ("Letters"), ed. by Z. APETIANZ (1955). This collection includes all previously published letters and some newly published ones. *Rachmaninoff's Recollections Told to Oskar von Riesemann,* trans. from the German by D. RUTHERFORD (1934), are reminiscences by the composer about his life and work. One of the few interviews with Rachmaninoff published in English, "Some Critical Moments in My Career," appears in the June 1, 1930 issue of *The Musical Times* (London). SERGEI BERTENSSON and JAY LEYDA, *Sergei Rachmaninoff: A Lifetime in Music* (1956), is a comprehensive biography whose preparation was assisted by Sophia Satina, the composer's cousin and sister-in-law, containing letters previously unpublished in English, a complete list of works in order of composition, and a discography. Other important biographical studies are VICTOR SEROFF, *Rachmaninoff* (1950), a sympathetic biography containing letters and a complete list of compositions; and WATSON LYLE, *Rachmaninoff:A Biography* (1939), which includes portraits, a list of works in order of composition, and a critical survey of recordings. JOHN CULSHAW, *Sergei Rachmaninov* (1949), contains a biographical outline, an extensive discussion and critical analysis of the music, a complete list of works, and a discography. A contemporary evaluation of Rachmaninoff may be found in M. MONTAGU-NATHAN, *Contemporary Russian Composers* (1917).

(V.I.S.)

Racine, Jean

Racine gave supreme form to what has come to be called the "classical" French tragedy of the 17th century; he was among the greatest French poets in any genre; and in modern eyes he was the only French playwright ever to catch the authentic note (however it is defined) of tragedy. He was also the first French writer born without rank or money to die a courtier, a noble, and a man of means and influence.

Early life. Born in 1639, of a provincial family of modest excise or legal officials at La Ferté-Milon, some 40 miles northeast of Paris, Racine was left motherless at the age of one, fatherless and penniless at three. When he was nine his paternal grandmother became a widow

Racine, oil painting by an unknown artist, 17th century. In the Musée National de Versailles et des Trianons.
Giraudon

and took him with her to the convent of Port-Royal des Champs in the Chevreuse Valley, near Paris. There she took vows, joining a daughter and a sister both of whom were nuns, and another sister, Mme Vitart, who lived with her family near the convent.

Influence of Jansenism on Racine

This was Racine's first stroke of fortune. Around this community lived a handful of distinguished scholars and enlightened teachers who had retired to live lives of austere seclusion under the influence of Jansenism, a theological tendency in Catholicism condemned by Rome in 1642 and 1656, of which they were the champions. Three of them, during a temporary dispersal, had found shelter at La Ferté with Mme Vitart. Their famous Petites Écoles were carefully taught groups of from 10 to 20 boys, never totalling more than 50 in all. Racine, admitted free in consideration of the Vitart connection, gained from them a knowledge of Latin, literary taste, and more Greek than any other pure man of letters of his day; he also learned something of their sombre theology of original sin and grace; and it was among aristocratic former pupils that he later found his first patrons. In 1653–54 he was in a college of similar spirit in Beauvais, after which he returned to Port-Royal for further study at the Petites Ecoles. In 1656 the schools were closed by royal command, but Racine stayed, for this was his only home. He is said to have continued his Greek reading in the woods; he also imitated slightly outdated models of descriptive verse in the immature but interesting Promenades *de* Port-Royal.

After a year of law studies in Paris (1658), the young man found employment with his grandmother's nephew Nicolas Vitart, steward of Charles Honoré d'Albert, duc de Luynes. In 1661 Racine's mother's family took an interest in him again; alarmed at his worldly associations in Paris, they sent him down to the cathedral of Uzès, in Languedoc, where an uncle was vicar general and might get him an ecclesiastical living. He spent about two years there, studying and noting the violent temperaments and feuds of this still-Huguenot region, but his uncle's ambitions for him bore no immediate fruit.

Back in Paris he followed his own bent and plunged into a career of authorship. His only literary associate of merit, as yet, was the future fabulist Jean de La Fontaine. Drama was at this time the best road to success, but this meant defying his Jansenist kinsfolk and teachers, who were ahead of general Catholic opinion in condemning the stage and all connected with it. He was told in 1663 to keep away from Port-Royal unless he reformed. In 1666, after his first dramatic success, he counterattacked bitterly with a brilliant anonymous open letter (Lettre *à l'auteur des 'Hérésies imaginaires'*) to his old master Pierre Nicole, who had recently written (with no reference to Racine) that a novelist or playwright was a public poisoner.

Mature life and works. Racine's career as an increasingly successful poet-playwright ran from 1664 to 1677, coinciding with the brilliant early years of Louis XIV's reign. Even before Uzès he had obtained a little notice by publishing an ode on the King's marriage (1660); another ode on a royal attack of measles (1663) brought him a small gratuity, the first of a great many. His letters of exile from the south speak of one rejected and one abandoned play (there may have been a third). On his return he somehow met Molière, the great comic poet and actor-manager, who accepted, perhaps even commissioned, his first tragedy, La *Thébaïde* ou *les frères ennemis*, produced with mediocre success in 1664. Alexandre, the year after, was as superficial and fashionable in its use of the themes of love and glory as La The'bai'de had been archaic in its gloom and violence. Alexandre did very well, but Racine, apparently dissatisfied with Molikre's relatively natural acting style, surreptitiously took the script to the oldest of the three permanent theatres then in Paris, the Hôtel de Bourgogne, which actually put it on while it was having its sixth performance with Molière. The latter took offense and dropped Racine, who gave all the rest of his commercial plays to the Hôtel de Bourgogne. Molikre's star actress, Du Parc, followed Racine and became his mistress. Hers was the title role in *Andromaque* (first performed 1667), in which Racine found what was to be his most appreciated (though not his only) theme: the tragic folly and blindness of passionate love. As poetry, the play was far superior to any competitor. In the neat efficiency of its dramatic mechanics it was a model—if anything, too clever. Its sometimes antiheroic moral realism disturbed some devotees of the idealistic tradition of romance, but in spite of critical cavils it was a sensational triumph.

Collaboration with Molière

Breach with Corneille

There followed Racine's only comedy, the three-act Les Plaideurs (1668; *The* Litigants) a slight but witty adaptation of The Wasps—far removed from the original, but no one else in the century would have thought of borrowing from Aristophanes at all. Then came the sombre *Britannicus* (1669) and the touching *Bérénice* (1670), both set in imperial Rome. The first was the occasion of an open breach with Pierre Corneille, the declining idol of an older generation of playgoers, who attended the first night and was openly hostile. *Bérénice* was based on the same historical episode as a play of Corneille produced almost simultaneously with it. (Such competitions were quite normal: Racine's *Thébaïde* seems to have been a counterblast to a tragedy put on by the Hôtel de Bourgogne, and *Iphigénie* and *Phèdre*, later on, both encountered rivals with the same titles and subjects.) One or both playwrights had some idea of what the other was writing, to judge by the texts. Corneille's play was not a failure, but Racine's was another triumph. He had shown up, by a deliberate contrast, his rival's weakness: the complexity of motives and interests that Corneille at this time was weaving into each of his plots. The point was pressed home in the prefaces to both Britannicus and *Bérénice*.

Not that this plea for "simplicity of action" was Racine's last word. Still trying new directions as he never ceased to do, he made his next subject, *Bajazet* (1672), from almost contemporary Turkish history, full of intrigue and danger. Mithridate (1673) confronts an aging Asiatic despot·with a Greek heroine. *Iphigénie,* first produced in 1674 in the outdoor setting of a great royal fête at Versailles, is an adaptation of *Iphigenia* at *Aulis* by Euripides, but with a love plot and a happy ending; *Phèdre* (1677) was to use the same Greek poet even more successfully.

Literary triumph

Iphigknie had a public run of extraordinary length and brought its author, at 35, to the apex of his first, literary, career. Racine was now head of his profession and powerfully patronized: official backing had won him membership in the Académie Française, the officially recognized body that arbitrated French literature and language, in 1672; in 1674 he obtained a sinecure conferring nobility, a treasurership of France. The man who had been in debt and without prospects in 1662 had been putting aside his savings in careful investments since 1669 and, for an author, was well off. The year 1676 saw a collective edition of all Racine's work to date, with the waspish polemical passages removed from the prefaces; the new or recast versions consciously built up the image of the scholar-poet.

Phèdre was the last, most profound, and most poetic of the tragedies for the Paris stage; the heroine suffers equally from her incestuous passion and her sense of degradation. Coming as it does before Racine's decisive break with the theatre, the play has often been thought to reflect the author's remorseful return to the principles of his youth.

Retirement from the theatre. Within eight months of the premiere of *Phèdre*, the great playwright had cut all links with the commercial stage, married a pious, unintellectual young woman of 24 or 25 (a connection by marriage of the Vitarts), and accepted—with his friend the critic and satirist Nicolas Boileau—the high honour of writing the official history of the reign.

Racine's motives

There will always be debate about Racine's motives for this sudden retirement. It was said that his present mistress, the actress Champmeslé, had played him false (but she was notoriously promiscuous, anyway). It is true that *Phèdre* had been challenged for a short time by a rival play, and Racine, with Boileau, had been implicated in an ugly episode as supposed authors of scurrilous sonnets against Philippe Mancini, duc de Nevers, supporter of the other playwright, Jacques Pradon—but these were passing clouds. Racine spoke later of having turned away from a life of sinful dissipation, and ttie son who wrote his life gives a radical conversion as the sole cause of the retirement. Some modern scholars suggest that, with *Phèdre*, Racine had said all it was in him to say; or that he had shocked himself by this powerful picture of a world where the gods could be evil.

Most attribute at least some part to ambition and the desire for security. It must be remembered that, although he had made sacrifices to embrace a career in letters, he had always courted patronage, and that art had far less dignity in his society than it has since acquired. The new post, proffered through the influence of the King's favourite, Mme de Montespan, was an unexpected honour and a surprisingly well-paid one; socially and financially it would have been hard to refuse; humanly, perhaps impossible. The stage, too, was more and more frowned upon in religious circles, and the author of *Phèdre* himself was to express the same views in his last years.

He remained a man of letters; as such he was already a classic (and as irritably jealous as ever of his reputation). He went on revising new editions of his plays (1687 and 1697), which in book form seemed less blameworthy than on the stage. "The scandals of his past life," as his deathbed testament calls them, had resulted from his playwright's life, and ceased with it. His only known love affairs were with his two leading actresses, whom he coached in their roles. The first, with Mlle du Parc, it is true, seems to have been a passionate one. The affair ended with her death, which may have been caused by an abortion; but accusations to this effect against Racine by a disreputable character, in the course of a criminal inquiry into poisonings and black masses in 1679–80, were never followed up. (One tradition says that she had earlier borne Racine a daughter, who died in childhood).

After 1677 his calling and way of life were irreproachably respectable. His wife presented him with two sons and five daughters, one of whom took the veil just before his death and one just after. He was a strict and solicitous father.

He renewed contact with Port-Royal and showed some courage in exerting his influence to help it. Not that he renounced the world: he had to be near the King, whose numerous campaigns he followed in order to report them; his pen was at the command of the King, Mme de Montespan, and later Mme de Maintenon, the King's morganatic wife. His social talents made him acceptable at court, so much that the envious accused him of hypocrisy. New honours arrived: he became a gentleman of the bedchamber in 1690, a second and more indubitable title of nobility than the treasurership, and one that was made hereditary by a new grant in 1693. All these had been—quite exceptionally—free gifts of the King; not so the secretaryship he purchased (for unknown reasons) in 1696. That post, and a tax levied on it in 1698, upset his hitherto flourishing finances and proved in the end that he could not afford the social eminence he had earned.

Last two plays

Racine's last two plays were commissioned by Mme de Maintenon for her school for daughters of impoverished nobles at Saint-Cyr. The preface of *Esther* (1689) explains that the plan for an improving dialogue with sung interludes was an unhoped-for chance to revive two features of Greek drama—the chorus and the religious inspiration. (Another model, not mentioned, was the opera.) *Esther* was a brilliant court occasion. The play's three acts, something of a nursery tale in comparison with the passion and subtlety of Racine's earlier dramatic actions, are redeemed by the poetry of the choruses. *Athalie* (1691), which for uncertain reasons never had a public performance in Racine's lifetime, has five acts with choruses, and, though different, equals most or all of the rest.

Racine died of an abscess (which may have been a cancer) on the liver on April 21, 1699, after 18 months of notably stricter austerity. He was buried at his own request in the Port-Royal graveyard. When Port-Royal was destroyed by royal decree (1710), his body was reinterred at Saint-Étienne-du-Mont.

MAJOR WORKS

PLAYS: *La Thébaïde ou les frbres ennemis* (1664); *Alexandre le Grand* (1666); *Andromaque* (1668); *Les Plaideurs* (1669); *Britannicus* (1670); *Bérénice* (1671); *Bajazet* (1672); *Mithridate* (1673); *Iphige'nie* (1675); *Phèdre* (1677); *Esther* (1689); *Athalie* (1691).

VERSE: "Cantiques spirituels" (1694).

PROSE: *Abrégé de l'histoire de Port-Royal* (1767).

TRANSLATIONS: The plays were rapidly translated into Dutch. Ten English stage versions apepared, 1675–1723, but differences of national taste made them grossly unfaithful: E. SMITH, *Phaedra and Hippolytus* (1707) and A. PHILIPS, *The Distrest Mother* (after *Andromaque*, 1712) had successes that now appear undeserved. SCHILLER's German *Phadra* (1805), is admired. The great obstacle in modern English is the absence of an accepted equivalent poetic style. KENNETH MUIR has translated *Five Plays* (1960); J. CAIRNCROSS, *Phaedra and Other plays* (1963) and *Andromache and Other plays* (1967); s. SOLOMON, the *Complete Plays,* 2 vol. (1967–68). See also R.C. KNIGHT, *Phèdre* (1971).

BIBLIOGRAPHY. The works are adequately cataloged in the standard editions. No manuscripts survive of the principal works. The correspondence is interesting for the early years, abundant for the married life; but almost every letter from the years of commercial playwriting has been destroyed. Most of the rest, with private papers and annotated books, was presented by Racine's son to what is now the Bibliothèque Nationale, Paris. See also E.E. WILLIAMS, *Racine depuis* 1885, *essai de bibliographie raisonnée* (1940).

The only critical edition complete with biographical material, still consulted though superseded in much of its detail, is the *Œuvres*, ed. by P. MESNARD, 8 vol. (1865–73). The "Pléiade" edition, by R PICARD, 2 vol. (1950–52), gives accurate text, good critical introductions, and many of Racine's notes. The Garnier edition (1960) and "l'Intégrale" (ed. by P. CLARAC, 1962—without variants), may be commended.

Racine's life has been treated exhaustively and definitively in its external and material aspects by R. PICARD, *La Carrière de Jean Racine* (1956). The *Me'moires* of L. Racine, who was not seven at his father's death (in Mesnard and Picard editions) are conscious whitewashing. See also G. BRERETON, *Jean Racine:* A *Critical Biography* (1951), balanced and sympathetic; FRANCOIS MAURIAC, *La Vie de Jean Racine* (1928), a religious interpretation; and R. JASINSKI, *Vers le vrai Racine,* 2 vol. (1958).

For historically-based academic criticism, see O. DE MOURGUES, *Racine, or, The Triumph of Relevance* (1967); J.C. LAPP, *Aspects of Racinian Tragedy* (1955); and R.C. KNIGHT (ed.), *Racine* (1969). Modern critical tendencies are represented, with moderation, by J.D. HUBERT, *Essai d'exégèse racinienne: les secrets témoins* (1956), a thematic study of images; and much more extremely by French *néo-critiques* —L. GOLDMANN, *Le Dieu cache': etude sur la vision tragique dans les Pense'es de Pascal et dans le théâtre de Racine* (1955; Eng. trans., *The Hidden God: A Study of Tragic Vision in the Pense'es of Pascal and the Tragedies of Racine,* 1964), structuralist and Marxist; R. BARTHES, *Sur Racine* (1963; Eng. trans., *On Racine,* 1964), structuralist and Freudian; and c. MAURON, *L'Inconscient dans l'œuvre et la vie de Racine* (1957), Freudian psychocriticism.

(R.C.K.)

Racism

Racism is the theory or idea that there is a causal link between inherited physical traits and certain traits of personality, intellect, or culture and, combined with it, the notion that some races are inherently superior to others. The term racism has no necessary relation to biological or anthropological definitions of race, a subdivision of a species (see RACES OF MANKIND). Racist ideas are often indiscriminately extended to apply to such nonbiological and nonracial groupings as religious sects, nations, linguistic groups, and ethnic or cultural groups. As one authority has noted, "Racism is quite different from a mere acceptance or scientific and objective study of the fact of race and the fact of the present inequality of human groups." (J. Comas, "Racial Myths," in The Race Question *in* Modern Science, UNESCO, 1956, pp. 52–3.)

(Racialism is an older term, more or less synonymous with racism, the latter now being more common. Some recent writers have attempted a division in their meanings —applying *racism* to the theory or doctrine and *racialism* to the practice of discrimination and prejudice.)

DEFINITION OF RACIAL TERMS

Racial and ethnic criteria. Race, in the sense relevant to racism, refers to a human group that defines itself or is defined by others as culturally different by virtue of innate and immutable physical characteristics. Thus, under racism a race is defined socially but on the basis of physical characteristics. Such physical characteristics have no inherent significance, but only such significance as is socially attributed to them in a given society. If a group in a given society is defined in terms of its skin colour, its hair texture, its facial features, its body build, and so on, then it is a "race," in racist terms. Presumably, if a group were socially defined in terms of sharing a common language, a common set of religious beliefs, or some other cultural characteristic—without physical considerations—then it would be an "ethnic group." In the case of both race and ethnic group, the defining criterion is relative to a given society, and the same person or group may be differently defined in different societies. Thus a black North American may be a "Negro" in his own country but a "Yankee" in Mexico. The first label is racial, the second ethnic or cultural.

In practice, the distinction between a "race" and an "ethnic group" is not always clear-cut, and many groups are socially defined in terms of both physical and cultural criteria. Jews, for instance. have frequently been regarded as both a racial and a cultural group. In such equivocal cases, it is necessary to try to determine which criterion is paramount. In Nazi Germany, Jews were primarily regarded as a race, whereas in the Middle East they are more an ethnic group. In any case, the phenomena of prejudice and discrimination that are commonly linked with differences between human groups are not markedly different whether one deals with a race or with an ethnic group. The one essential distinction is that culturally based groups generally tend to be more open and flexible in composition than physically based ones. One can convert to another faith or learn another language, whereas what one can do to one's physical appearance is decidedly limited. It should be remembered, however, that ancestry can mark a person in racist terms even though he may outwardly have no distinguishing physical trait. "Aryans" in Nazi Germany, for instance, were summarily reclassified as "Jews" when search into their ancestry discovered a Jewish forebear, and "whites" in South Africa have been similarly reclassified as "coloureds" after investigation had revealed a non-European ancestor.

Ethnocentrism and racism. Parallel to the problem of distinguishing between race and ethnic group is the problem of distinguishing between racism and ethnocentrism. Presumably, the distinction is that in ethnocentrism the alleged inferiority, disabilities, and negative traits of the outgroup are thought to be culturally determined (and only culturally determined), whereas in racism there is a belief that the disabilities are inborn. In practice, however, the cause of the alleged disability is not always made explicit, and it is not always easy to distinguish between racism and ethnocentrism. This is the case, for example, with anti-Semitism, which sometimes takes a cultural emphasis and sometimes a racial one. Ethnocentrism is in reality a much more widespread phenomenon than racism. Indeed, it may be said to be almost universal. Members of nearly all the world's cultures regard their own way of life as superior to that of even closely related neighbours. The exceptions to the universality of ethnocentrism are some of the societies, often small nonliterate ones, that have been conquered by more powerful ones and reduced to the status of a subject people. In some cases, after many years of oppression, some peoples have accepted their conqueror's derogatory views of themselves and flattering view of their masters. Under slavery, great numbers of American blacks, for instance, were psychologically conditioned to consider themselves inherently inferior. Unlike ethnocentrism, racism is far from universal. In fact, as a fully explicit theory of the biological causation of cultural behaviour, it is the exception rather than the rule. Ethnocentrism and racism are not mutually exclusive, of course: racist societies are almost invariably ethnocentric as well; people often feel superior to others on both racial and cultural grounds. Nevertheless, many highly ethnocentric societies are not racist.

Ethnocentric and racial aspects of anti-Semitism

DISCRIMINATION AND PREJUDICE

The term racial discrimination denotes all forms of differential behaviour based on race. The most notable form of racial discrimination is, of course, physical segregation by race, but there are many others, such as rules of etiquette defining forms of address between racial "superiors" and "inferiors," or choice of friends or spouses. Racial endogamy (that is, marrying within one's own racial group) is frequently required and almost always preferred in racially stratified societies. *Commensality* rules (rules determining with whom one may or may not eat) are also a very common manifestation of racial discrimination. The term racial discrimination, then, always refers to behaviour and indeed to social behaviour.

A second aspect of racism is racial prejudice. Prejudice is a psychological phenomenon; it is defined as an attitude, usually emotional, acquired without, or prior to, adequate evidence or experience. It can be favourable or unfavourable and can develop in a person through suggestion, belief, or emulation. Racial prejudice consists of negative attitudes directed in blanket fashion against socially defined races (not necessarily coincident with biologically defined races).

Although it is important to distinguish between the psychological and social aspects of racism—that is, between discrimination and prejudice—it is equally essential to understand that the two are inextricably related. Prejudice against a certain category of persons could not develop in the minds of individuals unless their society had already set groups apart and subjected some of them to discrimination. Conversely, it is difficult to conceive of a society in which a system of discrimination could exist in the absence of widespread prejudice among members of the discriminating group. Discrimination and prejudice are mutually reinforcing. Prejudice is a rationalization for discrimination, and discrimination often brings forth in the victims those behaviour patterns that seem to validate the prejudice. A white bigot, for example, can easily rationalize the existence of inferior schools for blacks if he believes that blacks are not capable of benefitting from equal schooling. The same bigot, when he compares the competence of graduates of the inferior black schools and white schools, will find confirmation for his belief that blacks are intellectually inferior.

Reinforcing roles of discrimination and prejudice

If there were always a one-to-one relationship between discrimination and prejudice, the distinction would serve no useful purpose. However, this is not the case. There are wide differences in individual prejudice, tolerance, and open-mindedness within a given society. One finds relatively open-minded or unprejudiced persons who live in virulently racist societies and pathological bigots who live in nonracist societies. It is in such cases that one can expect to find discrepancies between the level of prejudice and discrimination. The open-minded white person who lives in South Africa, for example, finds it practically impossible not to be racially discriminatory in his behaviour. The law compels him to be so; and even if he chooses to go to jail in protest, he will be sent to a superior white jail. The reciprocal is also true. The bigot who lives in a nonracist society will often hide his prejudice and refrain from open acts of discrimination. In both cases, the person conforms to social norms in his outward behaviour; that is, he behaves in a manner consistent with the behaviour of the majority but inconsistent with his own attitudes.

A number of studies have demonstrated, however, that such situations are transitory for most people because they are so difficult to live with. Open-minded persons tend to become prejudiced after moving to a racist environment, or at least to become more prejudiced than they would otherwise have been; conversely, prejudiced persons become more tolerant in a nonracist society. These changes in attitudes can be quite rapid. taking no more than a few days or weeks, and changes in behaviour can be nearly instantaneous. Generally, however, there is an appreciable time lag between change in behaviour and change in attitudes, and it is this lag that makes the imperfect correspondence between discrimination and prejudice.

THE HISTORY OF RACISM

In nearly all the world's societies, men have apparently developed pride in the cultural accomplishments of their own groups and a corresponding derogation of those of their neighbours. Notably, however, the idea that certain groups of people are superior to others because of their genetic makeup does not appear to have been widespread. Where it now exists, it is mostly an outgrowth of the rationalizations of slavery and colonial expansion in the vast territories dominated by European settlers.

Non-European racism. Some scholars have argued that the Hindu caste system originated in a physical difference between the conquering Aryans and the conquered Dravidians. The top three caste levels, or *varṇa*—Brahmin, Kṣatriya, and Vaiśya—were in all probability recruited from the ranks of the Aryans, whereas the fourth *varṇa*, the Śūdra—as well as the "untouchables" who fall outside the scope of the four *varṇa*—were perhaps originally composed mostly of Dravidians. The word *varṇa* means "colour," even though the colours traditionally associated with the *varṇas* show no relation to skin pigmentation. It is true that in Hindu culture, the colour dualism of white and black has associations with good and evil as it does in the Judeo-Christian tradition, but the link with skin pigmentation is not established. In modern India, there is a weak association between light skin and high caste, and perhaps a slight overrepresentation of lower castes among the darker skinned southern Indians, but skin colour in India is anything but a reliable index of social status. Kṛṣṇa, the most cherished character in the Hindu mythology, is often represented as a darkly handsome young man frolicking with a bevy of fair girls. Many Indians express a marked aesthetic preference for light skin, especially in women, but, on balance, the evidence that the Indian caste system is racial in origin and that India is or was a racist society is unconvincing. The basic caste dichotomy between "once-born" and "twice-born" was probably related to the *cultural* distinction between Aryan conquerors and Dravidian conquered. The latter were probably darker skinned than the former, but it is not established that this physical distinction was the socially significant one.

Skin colour and Hindu caste

Middle Eastern racial attituties. The Bible, one of the oldest sets of written documents in the Judeo-Christian tradition, contains no positive suggestion that the ancient Semites were racists. The ambiguous reference in the Song of Solomon ("I am dark, but comely, O daughters of Jerusalem, like the tents of Kedar, like the curtains of Solomon. Do not gaze at me because I am swarthy, because the sun has scorched me. My mother's sons were angry with me, they made me keeper of the vineyard;") might be interpreted as expressing a prejudice against blackness. Several other passages in the Bible, notably the curse of Noah on Canaan in Gen. 9:22–27, have been interpreted by later racists in a racial light, but in themselves they do not necessarily suggest anything of the kind, and, on balance, the evidence is negative.

The same is true of the Qur'ān and the Islamic tradition in which religious conversion has always been the test of membership in the ingroup. Although it is true that black Africa was the source of many of the slaves in Muslim countries and that, to this day, in some Arab countries a dark skin is a presumptive sign of slave descent and hence of low social status, none of the Muslim countries ever developed a racial caste system. Since the spread of Islam across the Sahara in the early 11th century, it has become by far the most important religion in black as well as in white Africa, and by now approximately one-fifth of the world's and one-half of Africa's Muslims are black. From medieval times, black African kings went on pilgrimage to Mecca with thousands of their subjects and were well received, and Arab writers on black Africa reveal no racism in their writings. They often express admiration for the black Muslim kingdoms that they encountered, and whatever negative value judgments they make are religious or moralistic in nature (such as the disapproval of the nakedness of women). Even the devastation brought about by the Arab slave trade in East Africa in the middle of the 19th century does not appear to have been rationalized on racial terms as European slavery was.

East Asian views of race. Chinese and Japanese cultures have traditionally been conscious of physical differences, especially from an aesthetic point of view, but neither society ever developed a racial caste structure. Even in pre-Tokugawa Japan, where there existed a fairly rigid "estate" system similar to that of medieval Europe, the distinctions were apparently not racial, and the Eta caste—an outcast, "untouchable" group that still exists today—is not physically distinguishable (even though one theory, popular in Japan, holds that the ancestors of the Eta were anciently Korean war prisoners and slaves). In any event, both Chinese and Japanese express a sometimes marked aesthetic dislike for physical types that are at variance with their own well-established canons of beauty. A 16th-century Chinese mandarin, for example, likened the hairiness of Portuguese sailors to that of monkeys and pronounced the Portuguese totally lacking in the social graces of civilized life, though surprisingly clever and capable of learning. Many Japanese find black skin and other Negroid characteristics unattractive and, since the recent wave of American influence, appear to have adopted some Western canons of beauty, as witnessed by the eyelid operations undergone by some women. The generally inferior status of Koreans in Japan seems to be based more on socioeconomic and cultural than on racial criteria; and the distinctive-looking Ainu minority on Hokkaido Island do not appear to be the target of racial prejudice. Thus, despite narcissistic canons of physical beauty and highly ethnocentric judgments of other cultures, East Asian civilizations do not exhibit what might properly be called racism.

Racism in nonliterate societies. The evidence from the world's many nonliterate societies is fragmentary on the topic of interethnic and interracial relations. There are, however, a few documented cases of indigenous systems of racism not attributable to contact with Western societies. One of the most notable cases is that of the traditional kingdoms of Rwanda and Burundi in the interlacustrine area of central Africa. Until the overthrow of the *ancien régime* shortly after independence in 1961, the population was stratified into three racial castes. The tall, semitic looking Tutsi constituted some 15 percent of the population and, as pastoralist conquerors, ruled over the Hutu horticulturalists. The Hutu, of average stature and distinctly Negroid in physical appearance, constituted a servile peasantry of approximately 80 to 85 percent of the population. At the bottom of the hierarchy was a small group (approximately 1 percent of the total) of pygmoid Twa. The close relation between physical stature and social status made for a truly racist system. The Tutsi claim to superiority was based to a considerable extent on their physical characteristics.

Development of racism in Europe. Far and away the most widespread, enduring, and virulent form of racism and the costliest in terms of human suffering has been that which developed in western Europe and its colonial extensions in Africa, Asia, Australia, and the Western Hemisphere. Western racism is of relatively recent origin. None of the main waves of influence on European civilization seems to have brought racism with it. In ancient Greece and Rome, the status criteria were cultural and not racial. The barbarian was the person who spoke another language. Slavery was a juridical and economic condition unrelated to racial or ethnic origin. The statuses of patrician or plebeian, patron or client, slave or freeman, citizen or noncitizen were all based on strictly nonracial criteria. Although Roman literature is often quite ethnocentric in its judgment of barbarians, differences in physical appearance are generally mentioned neutrally as interesting *exotica.* A number of black Africans must have reached Rome in the last centuries of the empire, and blacks appear on frescoes in a number of Roman sites in Europe and North Africa, but there is no evidence that they were regarded as inherently inferior.

In the Middle Ages, the religious criterion of membership in the ingroup became paramount. Anti-Semitism was clearly religious and not racial in nature and continued so through the Renaissance, the Reformation, and the Wars of Religion of the 16th and 17th centuries. The important thing was whether one was Christian, Moor, or Jew, Catholic or Protestant. Even at the height of religious persecution during the Spanish Inquisition and the Thirty Years' War, acceptance was typically granted in return for a simple public profession of faith. "Race," in any case, was irrelevant.

The anti-Semitic wave that swept Germany in the 1930s and ended in the crematoria of the death camps in the 1940s will hopefully remain the most heinous manifestation of racism in human history. Although Nazi anti-Semitism grew out of a long tradition of religious intolerance in Europe and more especially of victimization of Jews in eastern and central Europe, Hitler's theory of the master race gave it a hitherto unknown genocidal virulence.

Racism in European colonies. Even when Europeans first came into more extensive and direct contact with large numbers of dark-skinned peoples, as a result of their colonial expansion starting in the late 15th century, racism took some time to develop.

The Spanish record. The Spanish conquest of the New World was more than averagely brutal, and the economic exploitation of the Indians was thorough; but the Spanish crown quickly settled the issue of the Indians' humanity by declaring that they did have souls worthy of salvation and that they should not be enslaved. It is true that in the Spanish colonies of the Americas, there developed a caste system that was at least partly racial: a fundamental distinction was made between an Indian, a *mestizo* (or mixed-blood), and a Spaniard; but an equally important difference was made between a Spaniard born in Spain and a criollo, a Spaniard born in the colonies. Initially, the Spaniards expressed wonder and admiration for the accomplishments of the Indian civilizations that they destroyed. This did not prevent them from condemning what they regarded as barbarism and idolatry, but there is no suggestion that the Spaniards regarded the Indians as genetically inferior when they first met them. Only after the Indians had been reduced by epidemics, wars, tribute exactions, and countless acts of brutality to the status of an impoverished servile peasantry did negative stereotypes about them develop. The Spanish colonial caste system established in the 16th century was continuously undermined by a dual process of hispanization and miscegenation, which blurred both cultural and racial distinctions between groups. By the time that the criollos gained their independence from Spain in the second decade of the 19th century, the caste system had lost its social significance except in the countries that, like Guatemala, Peru, and Bolivia, were still predominantly Indian.

Today, racism, though not totally absent in Spanish America, is certainly much less prevalent than in other parts of the continent. Cultural criteria are far more important than physical ones in most of Spanish America, even in the heavily Indian countries. In some Latin American countries, the term *mestizo* no longer generally denotes a person of mixed Spanish-Indian descent but instead often designates a person who speaks Spanish as his mother tongue even though he may be of pure Indian ancestry. Many derogatory stereotypes about Indians do continue to exist, and in the heavily Indian countries, Indians continue to be subjected to various forms of social discrimination; but, by and large, an Indian ceases to be regarded as such when he becomes hispanicized in his language, customs, and religion. Racism, as such, is minimal.

Muted racism in Spanish America

Portugal in Africa and Brazil. The Portuguese case is somewhat different from the Spanish one. In Africa, the initial contacts between Portuguese and Africans were relatively free of racism and relatively peaceful and friendly, except in east Africa, where Portugal came in conflict with Arabs and Persians. There is, for example, a record of a friendly correspondence between the kings of Portugal and Kongo and of an exchange of ambassadors. Starting in the middle of the 16th century, these auspicious beginnings were increasingly compromised by Portuguese military incursions, the sacking of cities, and incessant demands for slaves for the Brazilian plantations. Brazil soon became, with the West Indies and the Southern English colonies of North America, one of the world's three major consumers of black slave labour, and it remained so until the middle of the 19th century. Generally, the Portuguese claim that its colonialism in Africa has been nonracial is correct, at least by comparison with the British, Belgian, and Dutch. This is not to say that the Portuguese regime in Africa has been any less oppressive and exploitative than the regimes of the other colonial powers, but whereas the latter have frequently applied racial tests of discrimination, the Portuguese have been ethnocentric rather than racist.

Complex race relations in Brazil

In Brazil, race relations are quite complex and vary greatly from one region to another. Brazil's reputation as a "racial paradise" appears to most observers to be undeserved; on the whole there is considerably more racism in Brazil than in Spanish America, though much less than in the United States. Consciousness of physical differences is highly developed, and Brazilians use a complex racial nomenclature to describe a score or more of combinations of facial features, hair texture, and skin pigmentation resulting from the intermixture of Afro-, Euro-, and Indo-Brazilians. Certain stereotypes are attached to these physical types as well as an order of aesthetic preference, but the very complexity of the nomenclature itself has made impossible the establishment of any system of racial castes, and members of the same family may frequently fall into different "racial" categories. Thus, Brazil might be described as a highly racially conscious country but without a rigid system of racial castes and without well-defined forms of racial discrimination. Such discrimination as exists is usually a subtle combination of racial, ethnic, and social-class factors, with race frequently not the most important one.

The French experience. The French, like the Portuguese and Spaniards, tended to be more ethnocentric than racist in their colonial policy of "assimilation," but in practice, like the Portuguese, they failed to assimilate more than a tiny minority of their African subjects. Consequently, except for a few black professionals and intellectuals who were totally integrated in French society, French colonial policy was not all that different in practice from that of more avowedly racist powers. It should also be noted that in Algeria, where there was a European settler population of over 1,000,000, the French exhibited considerable racism vis-à-vis the Arabs.

Dutch and English colonies. The Netherlands and Great Britain were responsible for the growth of the most racist colonial societies that the world has ever known—namely, South Africa, the United States, and Australia. In Australia, racism has taken the form of discrimination against the aboriginal population and the exclusion of immigrants of non-European stock. In the United States, virtual genocide against the Indian groups was accompanied by the institutionalization of a slave plantation system and, after 1865, of racial segregation and discrimination against the "emancipated" Afro-Americans. In addition, a number of states adopted racially discriminatory laws against other nonwhite groups, notably Asians, in the field of immigration, marriage, and political rights. As late as World War II, tens of thousands of American citizens were interned for several years in camps, solely on the basis of their Japanese ancestry.

The South African policy of apartheid has become a byword for racial discrimination and, next to the Nazi policy of genocide against Jews, represents the most extreme and systematic form of racism practiced in a modern society. The white government of South Africa is attempting to create four rigid colour-castes (Europeans, Asians, Africans, and Coloureds), to segregate them physically, and to perpetuate the economic and political privileges of the white minority at the expense of 80 percent of the population. In theory, apartheid aims to establish a "separate but equal" system, but in practice the indefinite maintenance of white supremacy is clearly the objective. Countless laws limit the nonwhite South Africans' rights to travel, own and occupy land, hold meetings, seek work, attend universities, enter public places, marry, vote, and indeed be present almost any place without the consent of the white authorities.

IDEAS ABOUT THE CAUSES OF RACIAL PREJUDICE AND DISCRIMINATION

"Scientific" support in 19th century

As a well-developed theory, racism is a fairly recent phenomenon, even in Western history. The 18th century was predominantly environmentalist in its outlook; the science of that day tended to attribute social behaviour either to climatic and geographical environment or to sociocultural factors. Racism as a widely accepted "scientific" theory of behaviour did not appear until the 19th century, which was the age of racism par excellence. Although Charles Darwin himself was not a racist, his theory of biological evolution was extended to social evolution, giving birth to the theory of social Darwinism. Mankind was regarded as having achieved various levels of evolution, culminating in the white-European civilization. These stages of evolution were thought to be related to the innate genetic capabilities of the various peoples of the world. By the second half of the 19th century, racism was accepted as fact by the vast majority of Western scientists, and various forms of it were popularized through the writings of Joseph-Arthur, comte de Gobineau, Houston Stuart Chamberlain, Rudyard Kipling, Alfred Rosenberg, and Adolf Hitler.

By the 1930s the intellectual climate had swung clearly away from racism, and racism had lost its apparent scientific respectability. The social sciences began to adhere to a strict theory of the social determination of human behaviour, to the nearly complete exclusion of biological or physical-environmental factors. Man was held to be almost entirely a product of his culture, and each culture was to be evaluated in its own terms. This cultural relativism was popularized by such anthropologists as Ruth Benedict and Margaret Mead, and the study of race relations became distinctly antiracist in orientation. Gordon Allport, Otto Klineberg, Roger Bastide, Gunnar Myrdal, and E. Franklin Frazier, to name but a few of the prominent scholars active in the 1930s and 1940s, all took the position that such "racial" differences as are found between human groups are attributable to the differential social environments in which they find themselves and not to any intrinsic physical properties.

Most recently the pendulum is once more swinging away from the extreme social environmentalism and cultural relativism that dominated the social sciences until the 1950s. Genetic and biological factors in human behaviour and aptitudes are once again becoming accepted as having at least some importance, although the crude racism, evolutionism, and social Darwinism of the 19th century seem to be permanently discredited.

As a rule, complex social phenomena like racism cannot be explained in terms of a single causal factor. Causation is not only multiple but also often reciprocal, in the sense that *A* generally is a cause of B and B in turn frequently is a cause of *A*. This is clearly what happens in the relation between discrimination and prejudice. Each is a cause of the other, and this vicious circle is often difficult to break. The reciprocal causation between discrimination and prejudice illustrates the interplay between psychological and sociocultural variables, and both approaches are essential to a comprehensive understanding of race relations.

"Their own fault" theory

Specious popular *theories*. Numerous theories on the causes of racism have been advanced, some patently false, others partly true; at the present stage of knowledge, only an eclectic but selective acceptance of several of the theories can give a comprehensive view of the phenomenon. Perhaps one of the commonest popular theories to account for prejudice and discrimination (both racial and ethnic) is that it is "their own fault." The theory advanced by most dominant groups in racially or ethnically stratified societies is that the allegedly reprehensible behaviour and qualities of the outgroup causes discrimination and prejudice in the ingroup. This theory, even when it is not made explicit, is often implied in the very definition of the situation as the "Negro problem," the "Jewish problem," the "Asian problem," and so on. It should be clear that such an approach is a *symptom* of racism or ethnocentrism and not an explanation thereof.

Another unviable theory of the cause of racism is that there is an innate or instinctive repulsion between groups of people who look different. Experiments on young infants have shown that infants could easily be conditioned to scream with fear when a white rabbit entered a room and, conversely, to pet snakes. There seem to be no innate dislikes of any animals in man, much less of relatively minor differences in appearance between members of the same species. If this is true, then there is no intrinsic relation between racism and the sheer presence of physical differences. Physical differences are one of the important conditions facilitating the development of racism once it is there, but they are not a cause of racism. Differences in physical appearance are simply visual stimuli to which prejudices may or may not become attached.

Psychological theories. Several psychological theories about the causes of racial and ethnic prejudice have linked the phenomenon with certain personality traits or with certain responses to social situations. The "frustration-aggression" theory holds that frustration frequently leads to aggression and that this aggression becomes "displaced" onto scapegoats that are quite unrelated to the source of the frustration. Outgroups are frequently blamed for one's frustrations and failures, and this displacement of aggression is often accompanied by "projection^{w}—that is, by the attribution to others of one's own undesirable or unavowed traits. Although a number of experiments have shown that experimentally induced frustration can lead to displaced hostility against outgroups, the theory does little to explain why certain persons are more apt to displace their hostility than others and why certain groups are chosen as scapegoats. It also fails to account for the fact that highly privileged groups can be as strongly prejudiced as groups that have suffered much frustration.

The "authoritarian personality" approach holds that persons who exhibit certain attitudes and personality traits such as respect for power, submission toward superiors, aggression toward subordinates, lack of self-insight, superstitiousness, and contempt for weakness are predisposed to be generally prejudiced against all ethnic and racial outgroups. Numerous studies have shown some relation between these factors, at least in Protestant. Anglo-Saxon cultures, but the theory does not easily account for great differences in levels of prejudice between groups of people who show substantially the same amount of "authoritarianism." Two matched groups of American whites, one Southern, one Northern, for example, showed nearly identical levels of authoritarianism, but widely discrepant levels of anti-Negro prejudice.

The relation between personality traits and prejudice seems to vary considerably depending on the social climate. Thus, in societies in which racial discrimination is the norm, as in South Africa, even persons who show little authoritarianism will typically be prejudiced. (This has been referred to as "conformity prejudice" to distinguish such attitudes from the more psychopathological forms of bigotry.) It may also be that, in societies that do not openly condone discrimination, the authoritarian personality is more apt than other personalities to be a bigot. Thus, although attempts to apply this psychological theory at the societal level—as, for example, by explaining the rise of Nazism through the authoritarian structure of the German family—are at best unconvincing, the theory seems able to account for individual differences in levels of prejudice within the same cultural group.

Economic influences. Social scientists have stressed a number of social variables that may be causally linked with prejudice and discrimination. Economic factors are of unquestioned importance. Marxian writers have interpreted racism as a rationalization for slavery and colonialism and also as a means of splitting the working class along colour lines and of deflecting attention from the central reality of class conflict to the ancillary problem of "race." It is certainly no accident that racism flourished at the time of the second great wave of European colonial expansion and the scramble for Africa, and the ideology of colonialism and the white man's burden was often expressed in racist terms. It is also true that racism provided ideological justification for slavery. But slavery antedates the development of racism in Western societies, and some slave societies, notably those of Latin America, have been much less racist than those of English or Dutch origin in North America, the Caribbean, and South Africa.

Non-Marxian writers have stressed the importance of other economic factors, such as competition for jobs, as problems aggravating interethnic or interracial conflicts. Racial segregation in urban ghettos and its resultant conflicts have been linked with the pattern of absentee landlordism in slums and the control of the housing market by realtors and investors. In blatantly discriminatory societies like South Africa the link between racist legislation and the economic interests and privileges of the white minority is obvious. A common form of economic determinism in racial and ethnic relations is the "middleman syndrome." A number of scattered minorities, often of alien origin, are subjected to much the same syndrome of prejudice. Indians in east and South Africa, Lebanese in west Africa, Chinese in Southeast Asia, and Jews in various countries, insofar as they have concentrated in retail trade and middle-level white-collar occupations, have often been the victims of an "anti-Semitic" type of prejudice, being accused of clannishness, rapaciousness, underhandedness, dishonesty, stinginess, and exploitation of the indigenous majority. These stereotypes are due in part to the envy felt toward an alien minority whose living standard is often above the average in the host country.

Minority
middleman
as bias
target

Relations of production—that is, the economic and class position of the constituent racial or ethnic groups within a society—are always of crucial importance in determining the type of relations that exist between these groups. Equally important and closely related to the relations of production are the relations of power between groups. For example, a multiracial society in which a minority exerts a clear domination over a majority, such as is characteristic of colonial regimes, makes for a type of race relations different from that of an ostensibly democratic society such as the United States, where a majority discriminates against a minority. An agrarian, patriarchal state such as characterized the slave regimes of the Western Hemisphere or the Boer republics in the 19th century makes for a type of race relations different from that of a highly urbanized and industrialized country like modern South Africa. The techniques of racial domination, for example, are radically different in a slave plantation and in an urban ghetto. Relations of power determine the legal structure of the society, and many studies have demonstrated the importance of legislation in changing a society either in a more egalitarian direction, as in the United States since the 1940s, or in a more racist one as in South Africa under apartheid.

Religion's role in racism. Religion has also been shown to be related to the amount of prejudice and discrimination. There is an undeniable difference between the more racially tolerant Catholic countries of Europe and their colonial extensions and the more racist Protestant countries. The Catholic Church has frequently taken a more universalistic position and rejected racism, whereas many Protestant denominations, especially the more fundamentalistic and puritanical ones, have often interpreted the Scriptures in a racist fashion. The role of the Dutch Reformed churches in South Africa in supporting apartheid as the will of God is well known, and Protestant Fundamentalism in the United States has sometimes also been deeply racist.

Demographic influences. Numerous racial studies have stressed the importance of demographic and ecological factors in intergroup relations. The demographic ratios between groups, the number of distinguishable groups, and the geographical concentration of these groups within a country all affect the system of intergroup relations. Thus situations in which the dominant group is a majority are different from those in which it is a small minority, and different again from those in which two groups of nearly equal size maintain a competitive balance of power. It also matters whether groups are evenly spread throughout a country or heavily concentrated in a given province or packed in urban ghettos. And the balance of power of course varies according to whether there are two, three, four, or many groups.

Social and cultural factors. The degree of cultural differences between groups is also a relevant factor. Ethnic or racial prejudice is often exacerbated by barriers of language or customs. Acute racial conflicts, however, can also exist between groups that are culturally nearly identical—as between white and black Americans.

Situations of rapid change are often marked by an intensification of racial and ethnic conflicts because one aspect of change is frequently an alteration in the traditional relations between groups. Such changes are commonly perceived as a collective threat, and this makes for outbursts of conflict. The rapid immigration of racially distinctive groups, as in post-World War II Britain, is a case in point. The rapid influx of a hitherto rural group into urban areas can have the same effect, as shown in the urbanization of Afro-Americans in the last few decades.

Conflict
from
sudden
social
change

International conflict can have domestic repercussions in intergroup relations, as witnessed by the wave of anti-Japanese racism in the United States during World War II or by the wave of anti-Algerian feelings in France during the Algerian war of independence.

The complex interplay of these numerous social and psychological factors on racial and ethnic relations makes predictions and generalizations hazardous. No single factor ever accounts for more than a fraction of the phenomenon to be explained, and the relative importance of various factors is often difficult to establish.

THE EFFECTS OF RACIAL DISCRIMINATION

The consequences of racial discrimination are as diverse as its causes. It is useful to distinguish here between psychological and social effects and between those effects on the group that discriminates, on the group that is discriminated against, and on the society at large.

Effects on victims. There is little doubt that psychologically racism is harmful to its victims. The most profound effect of racism associated with situations of extreme degradation (such as is found under slavery or in concentration camps or in racist states like South Africa) is the acceptance by the oppressed group of the dominant group's definition of the situation. This is the phenomenon of self-hatred found, for example, in cases of Jewish anti-Semitism or in the acceptance by blacks of white aesthetic criteria such as the desirability of having straight hair or a light skin. Self-hatred is often accompanied by neurotic symptoms of apathy, anxiety, and depression or by forms of self-destructive escapist reactions such as alcoholism or drug-addiction or, in extreme cases, by paranoid, schizophrenic, or manic-depressive psychoses. In such situations of extreme degradation then, the oppressed group frequently reacts in an "intropunitive" fashion; that is, it turns its frustrations inwardly against the self or the ingroup at large. At the social level, this intropunitiveness takes the form of predatory crimes by an organized underground against the oppressed group. Racial ghettos in the U.S. and South Africa, for example, have very high rates of crimes committed by blacks against other blacks, a phenomenon that is encouraged by the disinterest of the police in providing adequate protection.

Turning against the dominant group

When victimized groups do not accept their inferior status or when conditions improve to such a degree that they regain self-respect and conceive of the possibility of changing the status quo, frustration turns outward as hostility and aggression against the dominant group. Paradoxical as it seems, situations of open racial conflict, like other forms of revolution, are generally associated with periods of both relative and absolute improvement in the position of the subjugated groups. Hostility toward the dominant group may take many forms, ranging from nonviolent passive resistance to apolitical crime and politically inspired guerrilla warfare. The search for an identity independent of the dominant group's definition of the situation is often only a preliminary step to concerted political action, frequently violent, to try to overthrow the existing racial order. Group cohesiveness and political militancy replace apathy and self-hatred.

Effects on the dominant group. From the perspective of the dominant group, the effects of racism are more mixed. Psychologically, racism warps the personality of the oppressor as it does that of the oppressed, though probably in a less devastating way. Racially prejudiced persons living in highly racist societies can behave "normally" in situations not involving race; yet racism, by erecting an irrelevant and artificial barrier between people, strains relations and distorts social perception in the dominant group. Social consequences of racism for the dominant group can vary widely. Generally, in colonial-type situations in which the dominant group is a minority and has entrenched itself in an economically and politically privileged position, the benefits it derives from racism can be considerable. Thus the artificially high standard of living of the white South African population probably can only be maintained by the elaborate apparatus of racial laws limiting the freedom of movement, organization, and employment of the nonwhite majority. Some of those material benefits for the whites are diverted to the maintenance of the repressive apparatus; however, the economic balance remains positive for the whites, even though the total economic cost of segregation for the society as a whole is quite high.

In situations in which the dominant group is in large majority, as in the United States and Australia, the economic benefits of racial discrimination to the dominant group as a whole tend to be much more marginal and are often overshadowed by the costs in conflict, violence, and lost productivity. There are also situations in which the economic effects of racism may be opposite for different segments of the racially dominant group; in the antebellum South, for example, slavery benefitted the slave- and land-owning aristocracy but not the white yeomen and workers.

If one attempts to assess the overall effects of racism on an entire society, one must conclude that they are negative insofar as racism erects an artificial barrier to the full use of talents and often generates destructive conflicts.

THE REDUCTION OF RACIAL DISCRIMINATION AND FUTURE PROSPECTS

How discrimination is practiced. In practical terms. situations of racial discrimination and conflict may be reduced to three broad types:

Segregationist or apartheid societies. In societies like South Africa or Rhodesia, it is clearly in the collective interests of the racially dominant group (typically a minority) to maintain the status quo. The reduction of racial discrimination in such cases can come about through a drastic change in the power structure (as it did in the U.S. South as a result of the Civil War) or it can come about in evolutionary fashion (as it did in colonies ruled by Great Britain); but, in any case, the new ruling group no longer feels the need to defend its interests by maintaining a racial caste system.

Pluralistic societies. Those societies in which several racial groups, none of them clearly dominant, compete for power and economic resources (as in some parts of Africa and Asia) probably offer the widest range of alternatives for the reduction of racial tensions. Racial and cultural assimilation may reduce differences and blur old lines of cleavage. Or a more amicable modus vivendi may develop from changes in government policy, the spread of a broader nationalist ideology, or changes in the economic and political structure making for a more democratic society. When conflicts escalate to chronic violence and civil war, political partition and emigration are other possibilities for reducing tensions.

Societies publicly committed to ending racial discrimination. In some societies, as in Australia and the United States, official government policy is often against racial discrimination and has to contend both with the inertia of conservative opinion from the dominant group and the "revolution of rising expectations" from the hitherto subordinated group.

Ways of reducing racial bias and inequities. There seem to be two basic approaches to the alleviation of racial tensions in this third type of society, assuming an official desire to do so. One is to attack racial prejudice by educating the public. There is abundant evidence that people's attitudes can be changed by propaganda and that behavioral changes follow changes in attitudes; but there is also evidence that as a method to bring about rapid social change in a conservative population, this approach is relatively expensive and ineffective. In terms of practical consequences, it may be more important to reduce racial discrimination than racial prejudice, and, hence, it follows that the strategy of attacking discrimination is frequently more directly effective.

Dilemma of means and ends

Legislation is undoubtedly one of the main ways of destroying racial discrimination, provided it is followed by forceful implementation. This often entails a dilemma of means and ends: the achievement of a more democratic society may imply the use of force against a majority—a policy that democratically elected governments are naturally loath to adopt. Consequently, attempts to outlaw various aspects of racial discrimination (for example, in housing and employment) have frequently failed to bring about the rapid change that was intended because of a lack of determined implementation. The delays in school integration in the United States can be considered a case in point. By contrast, integration in the U.S. armed services has been more rapid and thorough, largely because it was done autocratically.

At the economic level, it is clear that the profit system of production helps to perpetuate disabilities for racial minorities. High returns on slum property, for example, are one of the factors making for the persistence of racial ghettos in the United States. Racial discrimination in housing creates an artificial scarcity of housing for blacks, who are thus forced to pay higher rents than their white counterparts. This makes for high returns on investments in the black areas that, because of high population density and municipal neglect, quickly become slums. Other economic systems, such as the "consumer credit," are also known to discriminate against the poor and thus to affect racial minorities disproportionately. Reforms in the economy might be effective in reducing racial discrimination, but the realistic prospect of such reforms in the United States is limited.

In the last analysis, the most effective way of reducing racial discrimination may be militancy on the part of the groups that are discriminated against. When such groups are large enough to affect the outcome of elections and when the political system is democratic enough to give the voters some real alternatives, political action can be effective within the constitutional framework. When such conditions are lacking, political action ranging from civil disobedience to guerrilla warfare has been known to bring about important changes.

Rackets

Rackets (racquets) and squash rackets are games played with a ball and a strung racket in an enclosed court, all four walls of which are used in play. Rackets, the older game, is played with a hard ball; whereas squash, or squash rackets, is played with a soft ball on a smaller court.

History. It was once a common notion that rackets originated in the debtors' section of Fleet Prison in England early in the 19th century. Charles Dickens in his novel *The Pickwick Papers* (1836–37) describes a court in which the inmates whiled away their time. The game might, however, and more accurately, be said to be an outgrowth of the ball games of the ancient Greeks and Romans. It has features in common with palone, pelota, and other Basque games. Historians of real tennis (court tennis) have traced the origin of rackets to the wall of a real tennis court, and Robert W. Henderson, in his researches into the antiquity of athletic games, found mention of rackets (in the singular form, racket, as then used) as early as 1529 in *The Complaint of Schir David Lindesay*. Most now place the origin of rackets in real tennis, quoting J.R. Atkins' opinion in *The Book of Racquets* (1872) that "both games (rackets and real tennis) have so much in common that it is impossible to separate them historically; for practical purposes we must regard them as identical."

In its beginnings, rackets was played in rather formless fashion without set rules. In Fleet Prison the game was well established by the middle of the 18th century, and in the new Fleet of 1782 it achieved such popularity that its fame spread to taverns and other public houses. Robert Mackey, an inmate of Fleet, is listed as the first "world" champion or at least as the first claimant of the title in 1820.

It was with its introduction into Harrow School in 1822 that rackets achieved respectability and was enclosed within four walls. The first roofed-in structure is believed to have been a court built at Woolwich by the Royal Artillery in the 1840s. The building of old Prince's Club in London in 1853 is regarded as marking the beginning of a new era in which rackets became the game of the clubs, military services, and universities.

Rackets flourished in the 1860s and 1870s. Earlier than this it had been introduced into Canada and the United States, and it spread to India, Malta, and Argentina. Queen's Club was opened in London in 1887 and became the headquarters of the game. The next year the Amateur Championships were started there and the Amateur Doubles began in 1890. The rules of the game were drawn up for the first time in 1890 by tennis historian Julian Marshall and rackets authority Major Spens. The Tennis, Rackets and Fives Association was formed in 1907 to govern the sport. During and following World War I, private courts closed and rackets play declined. The expense of building courts and playing the game and the rising popularity of squash rackets brought about a great reduction in the number of rackets players, except in the public schools. Nevertheless, the game continued to be played. In 1928 a British team travelled to the United States to inaugurate the International Racquets Cup matches, which still continue from time to time.

Rackets champions

The world rackets championship, which is decided by a challenge match, has been dominated by English players, although India and the United States have also produced outstanding players. Peter Latham, an English professional, is generally rated the greatest of rackets players. (Professionals, in rackets and squash rackets, are players who are paid to teach the games.) Latham was world champion from 1887 to 1902, when he resigned, and was also a great player of real tennis. The foremost English amateurs have included Sir William Hart-Dyke, the first amateur to hold the world championship (1862); and Geoffrey Atkins, world champion from 1954 to 1970, who excelled Latham's record of reigning for 15 years. Atkins is rated by some as the greatest of all amateurs.

Squash rackets. Squash rackets, often called squash, is believed to have originated around the middle of the 19th century at Harrow School. Students unable to get into the rackets court took their exercise hitting an india-rubber ball, which squashed when hit against a wall. Toward the end of the century, "almost every boarding school had its miniature racket court in which a game with a soft, india-rubber ball is played," wrote E.O. Pleydell-Bouverie in the Badminton Library, a British series on sports published in 1890. In the 1890s private courts were built and, after the turn of the century, club courts appeared at Bath, Queen's, and the Marylebone Cricket Club.

It was not until after World War I that squash rackets caught on, and in the 1920s the game spread rapidly, becoming more popular than its parent game rackets. Many courts were built in clubs, schools and colleges, and privately. Rules were formulated, the English national association was organized, and dimensions of the court were established, along with regulations in regard to the ball and racket. Many competitions were inaugurated: the Professional Championship in 1920, the Amateur Championship for men and women in 1922, and the Open Championship in 1930. International competition with the United States began with the sending of a team to America in 1924, and a member of the team, Captain Gerald Robarts, won the U.S. crown. Competition between the two countries, however, has been hampered by differences in the ball, the court, and methods of scoring. In 1933 the Wolfe-Noel Cup was put up for an international women's series with the United States.

In the United States the game played in the early years was actually squash tennis, using a lawn tennis ball and tennis racket. Around 1915 a soft, india-rubber ball and the racket with a small, circular head and long, slender handle were adopted instead. Only in Philadelphia was squash rackets the original game. Squash tennis has disappeared from most cities and continues to have a following only in New York.

From England the game spread throughout the Empire —to Canada, India, Australia, and South Africa. In the late 1920s King Prajahipek said to a newspaper correspondent in Bangkok, "Squash is nothing less than a Godsend to a country like Siam." Today squash is played in some 40 countries, including France, Germany, Denmark, Sweden, Belgium, The Netherlands, Egypt, Mexico, Pakistan, India, Thailand, Hong Kong, Kenya, and New Zealand. An International Squash Rackets Federation promotes the game and coordinates tours and championships between nations.

Outstanding squash players have included F.D. Amr Bey, an Egyptian amateur who won several British open titles in the 1930s; the Khans of Pakistan, a family of professionals who dominated open play in the 1950s and 1960s; and Janet Morgan, English women's champion from 1950 to 1959, winner of U.S. and Australian titles, and member of Britain's Wolfe-Noel team from 1949 to 1959.

Rackets. No dimensions are specified for the rackets themselves, which are made of ash and average 76 cm (27 in.) long and 255 g (9 oz) in weight. The head, strung with catgut, is usually 178–203 mm (7 or 8 in.) in diameter. The ball, which has a renewable covering of adhesive tape, is 2.54 cm (1 in.) in diameter and weighs 28.35 g (1 oz).

The court. Most courts are about 18 m (60 ft.) long by 9 m (30 ft.) wide and accommodate both the singles and doubles (four-handed) games. Courts have four walls. The roof, where skylights or other lighting is placed, is out-of-bounds for play; in India courts were left unroofed. The cement floor and walls must be perfectly smooth and very hard since the faster the ball travels the better the game. Front and side walls are about 9 m (30 ft.) high, the back wall being about half that height with a spectators' gallery and marker's, or scorer's, box above it. The court is entered by a door in the centre of and flush with the back wall. On the front wall is fixed a wooden board, the upper edge of which, 0.68 m (27 in.) from the floor, constitutes the play line; 2.93 m (9 ft 7½ in.) from the floor a second line called the cut line or service line is marked. On the floor, 10.92 m (35 ft 10 in.) from the front wall and parallel to it, the short line runs from wall to wall. From the centre of the short line to the centre of the back wall, the fault line divides the back court into two rectangular service courts. Against the side walls and separated from the service courts by the short line are the service boxes.

*The **game.*** Rackets may be played by two persons (singles) or four persons playing two against two (doubles). The players must return the ball either before it reaches the ground or on its first bound so that it strikes the front wall above the play line (or service line in the case of a serve) and returns into the court and continue to do so alternately (either player of each in doubles) until one player fails to make a valid return and loses the stroke. The ball must not go out of court (into the gallery or roof of the court) or touch the players' clothing or person. Hard, low hitting close along the side wall is the essence of the game, with cutting, volleying, half-volleying, drop shots, and angled shots also in the repertory. In the four-handed game (doubles) one of each set of partners takes the right-hand side of the court and his partner the left. The game consists of 15 points, called aces. Points can be scored only by the hand-in (the player, or side, having the service), and the hand-out (side receiving service) must therefore win a stroke or strokes to obtain service before he or they can score an ace. In doubles each of the partners serves in turn, and both must be ousted before their opponents obtain the service. In the first exchange of each game, however, only one partner of each side has service.

Serving the ball

The server, with at least one foot inside the service box, serves the ball as in tennis, but directly to the front wall above the service line so that it rebounds and hits the floor within the service court on the opposite side, permissibly striking the side wall, back wall, or both before or after touching the floor. The serve is a fault if the ball (1) strikes the front wall below the service line; (2) touches the floor on the first bounce in front of the short line; or (3) first touches the floor in the wrong court. If the receiving player chooses to take a faulty first serve, play proceeds as if the serve had been good; otherwise the server must serve again; if he serves a second fault he loses his service to his partner or opponent, as the case may be. A serve that makes the ball strike the board or the floor before reaching the front wall or that sends it out of court counts the same as two consecutive faults: it costs the server his innings. In the United States and Canada only one serve is permitted.

If the player receiving service succeeds in returning the serve, the rally proceeds. If he fails in the rally (or in receiving service), the server scores a point and the side that first scores 15 points wins the game. When, however, the scores reaches 13–all, the receiving side may, before the next serve is delivered, declare that he elects to set the game either to 5 or 3, making the game 18 or 16 points, whichever he prefers; and similarly when the score stands at 14–all, he may set the game to 3 (game 17).

"Lets"

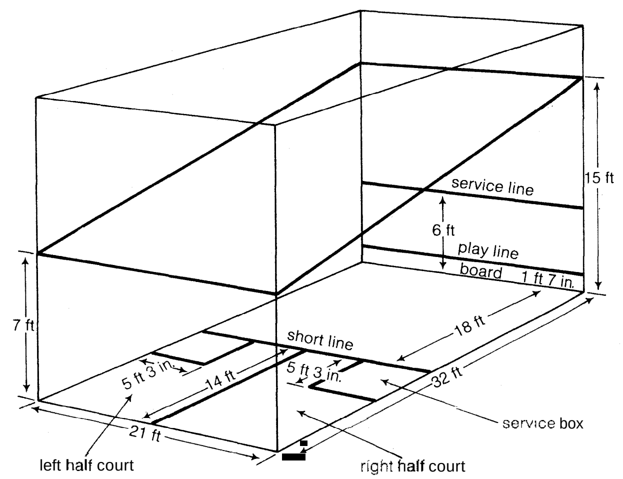
It is the player's first duty to give the opponent full room for his stroke, but it is not always easy and sometimes, especially in doubles, absolutely impossible not to obstruct him. The rules, therefore, carefully provide for "lets." When in matches a let is claimed by any one of the players and allowed by the referee, the service or rally counts for nothing and the server serves again from the same service box.

The server in possession at the end of a game continues to serve in the new game, subject as before to the rule limiting the first innings of a doubles game to a single hand. The usual number of games in matches is five for singles and seven for doubles. In matches where there is a referee, there is an appeal to him from the marker's decision but no appeal is allowed if a foot fault is called.

Squash rackets. Squash is played on the same principle as rackets. The rules are in most particulars similar, but the scoring is different. In England, hand-in only can win the point. A game consists of 9 points; if, however, the score becomes 8–all, hand-out has the option of a set to two—making the game 10 points. In the United States a game consists of 15 points, and a point is scored for each rally irrespective of which player is serving; at 13–all, hand-out may set to 5 points (game 18), to 3 points (game 16), or no set (game 15). In doubles games as played in the U.S. and Canada, a rubber consists of the best three out of five games.

The squash racket is similar to that used in the game of rackets, but the handle is shorter, and the U.S. racket is heavier than the British. The ball is of rubber or rubber and butyl composition. The ball used in the U.S. is larger and faster than that used in England.

The court. The standard British court has four walls, which are of wood or composition, and can either be covered or uncovered. The dimensions and markings of the British court are shown in the accompanying diagram.



British squash racquets court

The board, or telltale, is a strip of sheet metal or other resonant material that produces a clearly different sound when the part of the front wall "out-of-play" is hit. The standard U.S. court is considerably narrower than the English, being 5.6 m (18 ft 6 in.) wide, and some other dimensions are also slightly different. Doubles courts are 13.7 m (45 ft) by 7.6 m (25 ft).

Squash tennis. Squash tennis is played in the same court as squash rackets. There are minor differences in the line markings, such as the "out" line on the back wall being two feet lower than for squash rackets. Players use a lawn-tennis racket, an inch shorter in the handle, and a green, pressurized ball, similar to but slightly smaller than the lawn-tennis ball. Scoring is the same as in American squash rackets. Points were scored only by the server until a change in 1954 allowed hand-out to score as well.

Squash tennis makes fewer demands than squash rackets on the legs in pursuing the ball, but puts a greater premium on agility and quickness of foot and reflexes in turning and spinning. The ball caroms off the front, side, and back walls in dizzying action. It is so volatile that it may rebound from the front wall to the back wall and again to the front wall. Squash rackets is largely a game of wrist and touch, as well as of the arm. The squash tennis stroke is more comparable to the free-swinging lawn-tennis drive. The volley—returning the ball before it touches the floor—is important in both squash games.

Radar

Radar is an electronic system that uses radio waves to detect objects invisible to the unaided eye because of distance, darkness, or cloud cover. Radar can, as well, determine the position of an object, its distance from the observing station, and, if the object is moving, its speed and direction of travel. The word radar is an acronym derived from the phrase radio detection and ranging. Although developed as a wartime device to detect enemy airplanes, radar has many nonmilitary applications. The equipment used for radar is called a radar set, radar system, or simply a radar.

BASIC PRINCIPALS

Echoes and targets. When radio waves radiated from a transmitting antenna are interrupted by any object such as a ship, airplane, or even a mountain, part of the energy is reflected back to the receiver. The reflection is called an echo, and the reflecting object is called a target. Echoes from desired targets are referred to as target signals or simply signals, whereas echoes from masses that make it difficult to detect the wanted signals are called clutter.

Target distance

The distance to a target is determined by the time required for the radio wave to travel from a transmitter to the target and back to a receiver. The calculation is possible because radio waves travel at a known speed, that of light, which for purposes of approximation may be taken as 1,000 feet (300 metres) per microsecond (millionth of a second).

Pulse modulation. If the transmitter were operating continuously, reflected signals, or echoes, would arrive continuously, and it would be impossible to associate a certain part of the echo with a specific part of the transmitted signal. The signal must therefore be labelled. One method of doing this is to emit the radar signal in short, high-power bursts or pulses; this method is called pulse modulation. The echoes then return as short pulses. If conditions are arranged so that the transmitter is off (not transmitting) during reception of a pulse, the received signal can be associated with a specific transmitted pulse. Radar using pulse modulation, referred to as pulse radar, was the first type used and is still the most common.

Since a pulse radar's transmitter and receiver are operating at different times, a single antenna system can be used for both. The antenna is connected to the transmitter during the short transmission pulse and is then switched to the receiver during the interval between pulses; this is accomplished with a device called a duplexer.

From Gershon J Wheeler, *Radar Fundamentals* (1967) Prentice-Hall

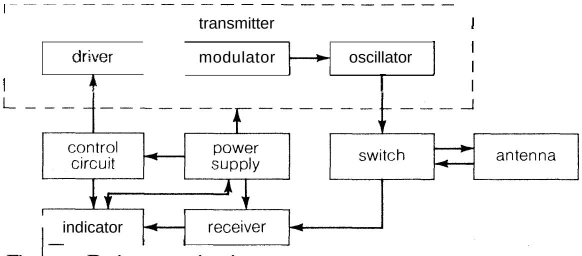

Figure 1: Basic radar circuit.

A block diagram of a basic radar circuit is shown in Figure 1. During transmission, a short pulse of radio-frequency energy is fed from the transmitter to the antenna. After the pulse has been transmitted, the antenna is switched to the receiver to detect echoes. The detected echo signal is fed to the indicator, which is usually some form of visual display, such as a cathode-ray (television) tube, that enables the operator to measure the time intervals that occur between the transmitted pulse and the reception of its echo.

Since the output tube is actually operating only a fraction of the time, pulsing the transmitter permits it to provide higher peak power than would be possible if it were operating continuously. Figure 2 shows two successive transmitted pulses, each lasting a time designated by the Greek letter tau (τ). The height of the pulse (P_P) indicates the power level.

Power output and duty cycle. Operating continuously with the same total energy, a transmitter would radiate a much lower peak power signal. The power level would be the average of the energy in the pulse taken over the entire interval up to the following pulse. This is called the average power (P_A), indicated by the dotted line in the figure. The average power is limited by the ability of the circuits to dissipate the heat produced.

If the pulse repetition frequency (or repetition rate) is designated f_r (in pulses per second), then the interval in seconds between pulses is the reciprocal of this, or $1/f_r$, as shown in Figure 2. For example, if the repetition rate is 2,000 per second, the pulse interval is 1/2,000 of a second, or 500 microseconds. The product of pulse width times the repetition frequency is called the duty cycle (τ f,) and is defined as the proportion of the total time that a device operates. Thus, if a radio transmitter has a 10 percent duty cycle, it transmits 10 percent of the time and is silent 90 percent of the time. The average power is equal to the product of the peak power and the duty cycle.

From Gershon J. Wheeler, *Radar Fundamentals* (1967); Prentice-Hall

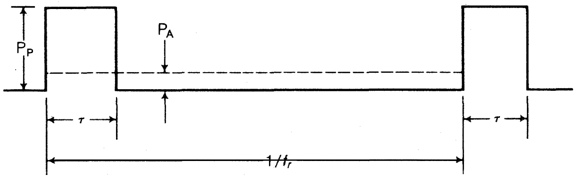

Figure 2: Pulse envelope (see text).

With a repetition rate of 2,000 pulses per second, the pulses are 500 microseconds apart. If echoes are received 100 microseconds after each pulse, they could be caused by a target 100 microseconds away or by one 600 microseconds away. Assuming approximately 12 microseconds per mile, this means that the target could be about eight miles (13 kilometres) or 50 miles (80 kilometres) away. To overcome this ambiguity, the repetition frequency must be so chosen that echoes from all detectable targets for one pulse will appear before the next pulse is emitted. Thus, if it is known that no target exists beyond 25 miles (40 kilometres) or if receiver sensitivity does not permit detection beyond this point, then a pulse interval of 300 microseconds is acceptable. If on the other hand targets as far as 50 miles away may be detected, then the pulse interval must exceed 600 microseconds.

Choosing the repetition frequency

Radar frequencies. A radar transmitter emits radio waves of a given frequency, measured in hertz, or cycles per second; this is called the carrier frequency of the transmitter. Choice of the carrier frequency is influenced by available transmitting equipment, power and range desired, and spreading (propagation) characteristics of radio waves at different frequencies. Most radars operate in the microu ave region of the electromagnetic spectrum; *i.e.*, between 1,000 and 35,000 megahertz (1,000,000,000 and 35,000,000,000 cycles per second). During World War II, for security reasons, radar frequencies were given code designations. Some of these codes are still in use today. The frequencies near 10,000 megahertz are called X-band; near 3,000 megahertz, S-band; near 1,000 megahertz, L-band; and near 6,000 megahertz, C-band. The band limits are not clearly defined, so that 2,000 megahertz. for example, may be called high L or low S band.

Doppler shift. When a target is moving toward or away from the transmitter, the frequency of the received echo differs from that of the transmitted carrier. This change in frequency is called the Doppler shift and is positive (an increase in frequency) for a target approaching and negative (decrease in frequency) for a receding target. The amount of frequency change depends upon the speed at which the target is approaching or receding from the transmitter. By careful measurement of the change in frequency, it is possible to determine both the speed and direction of a target.

THE DEVELOPMENT OF RADAR

Radar cannot be attributed to a single inventor or even to an identifiable group of inventors. Its basic concepts have been understood as long as those of electromagnetic waves.

Early history. The first patent for a radar-like system was granted in several countries in 1904 to a German engineer named Christian Hiilsmeyer. Evolving from the search for a means of detecting radio waves from ships, his system worked, was demonstrated to the German Navy, but was never accepted. Technical limitations made his system ineffective at ranges exceeding one mile.

The principles used in Hulsmeyer's system were actually known much earlier through the experimental work of the English physicist Michael Faraday and the mathematical investigations of the Scottish physicist James Clerk Maxwell, who predicted the existence of radio waves and formulated the electromagnetic theory of light. The German physicist Heinrich Hertz tested Maxwell's theories experimentally and in 1886 succeeded in proving the existence of radio waves. He also proved that radio waves were similar to light waves and could be reflected from solid objects.

Contributions of Faraday and Maxwell

The use of a radio echo for detection was frequently mentioned in sceintific literature after Hertz's demonstration of radio-wave reflections; but the idea was not seriously considered until 1922, when the Italian engineer Gugiieimo Marconi presented a paper on radio detection, and the United States Naval Research Laboratory tested his idea experimentally. Using a five-metre continuous-wave (nonpulsed) radar with a separate receiver and transmitter, the researchers were able to detect a wooden ship passing between the receiver and transmitter. This type of radar is now called a bistatic continuous-wave radar, differentiated from monostatic continuous-wave radar, which positions both transmitter and receiver at the same site.

Pulse modulation as a means of measuring distance or range was first developed in the U.S. in 1925. Using a pulse technique to measure the height of the ionized layer of air high above the earth, called the ionosphere, this pulse-ranging method became the standard for ionospheric investigations all over the world. It was not, however, applied to radar for several years.

Developments before World War II. Radar research and development was conducted during the 1930s in Great Britain, France, Germany, and the U.S. An early development of radar for practical use took place in the United States in 1930, when a researcher working on direction-finding equipment noticed that the received signal increased whenever an airplane passed between the transmitter and receiver of his experimental apparatus. The Naval Research Laboratory followed up this lead and by 1932 could detect aircraft as far as 50 miles from the transmitter.

Bistatic continuous-wave radar could detect the presence of a target but not its location. Since pulse radar promised a solution to this problem, scientists began development work early in 1934 and, after many failures, produced a workable radar in April 1936. The range of this device was 2½ miles (4 kilometres); it used a five-microsecond pulse at a frequency of 28.3 megahertz. By the end of 1936 a range of 7 miles (11 kilometres) had been achieved, and by 1938 an anti-aircraft fire-control radar had been placed in operation.

By 1939, the United States had lost what lead it might have had to European countries more imminently threatened with war.

Though work in France originally had been aimed at nonmilitary applications, military development came first in Britain, Germany, and, as has been clear, the United States. The first French radar was an iceberg detector for ships, used aboard the ocean liner "Normandie." As war became imminent and radar work in France shifted toward aircraft detection, a bistatic continuous-wave system was developed at the National Radio Laboratories, and in 1939 the French began work on pulse radar.

In Germany, development of a ship detection system began early in the 1930s; work on aircraft detection was soon added; and by 1939, a system called Freya, for early warning of approaching aircraft, was in production. A ship detection system followed. By mid-1940, the Germans were using a 600-megahertz radar system (called Wiirzburg) that provided position information with sufficient accuracy to direct effective anti-aircraft fire, outperforming the radars in use in other countries at that time.

Early British radar

Radar development did not begin in Great Britain until the mid-1930s, after which, with strong financial support from the government, it proceeded at a rapid pace. By September 1935, ranges greater than 40 miles (64 kilometres) were achieved, and by 1938 a chain of radar stations was operational.

Though these ground-based chain radars could detect enemy aircraft, they were not sufficiently accurate to guide British fighter planes to a successful interception. Consequently, the British worked to develop a successful airborne aircraft-intercept radar, to be installed in fighter planes and capable of detecting surface vessels and even submarines. Special radars, designated as air-to-surface-vessel radars, were later developed with an improved capability for detecting surface vessels.

Developments during World War II. When a radar transmitter scans the sky, its radio signal can be compared to the light beam of a searchlight. Obviously, if a radar beam is too wide, it will not locate objects very precisely. Development work during this period was thus aimed at narrowing the radar beam.

For several reasons, investigators concluded that the most logical approach to narrowing radar beams was to employ high transmitter frequencies, preferably those in the microwave range; but these were not available, since no one knew how to build them. In 1939 the klystron, a type of microwave signal generator, became available for use in microwave receivers. Its power output was too low, however, for employment in a transmitter. In 1940, the highest power output achievable was about one watt.

In England, a breakthrough occurred in 1939 with the development of the multicavity magnetron, able to produce about 20,000 watts of power at 3,000 megahertz, a tremendous advance over the klystron. Modern radar was born with this tube, because it made microwave radar practical for the first time. The development of the magnetron and the fact that high-power microwave did indeed exist were both closely guarded secrets in England for more than a year.

In the U.S., important advances were also taking place. Early in November 1940, a group of U.S. scientists began work on military radar. Their first experiments were set up on a roof, with antennas pointed toward buildings on the Boston skyline; and on January 4, 1941, the first aircraft interception radar, using two parabolic (dish-shaped) antennas, detected the buildings and a month later detected and tracked an airplane. In March 1941, an experimental aircraft intercept radar installed in an aircraft flying over water detected a ship clearly and unmistakably; and the design of that radar became the basis of World War II systems for detecting surface vessels from the air, aircraft from a ship, and ground-based harbour defense. By May 1941, a radar set had been developed that tracked planes automatically; this was the ancestor of highly successful gunlaying radars of World War II.

Another program, aircraft navigation, also began early in 1941. Basic techniques were worked out before the end of the year. The name Loran (an acronym for long range navigation) was adopted for this system (see NAVIGATION).

Early in the war, the British had developed an airborne S-band (3,000 megahertz) radar for bombing, called the H2S. Later, U.S. and British laboratories cooperated in developing the H2X, an X-band (10,000 megahertz) bombing radar, whose shorter wavelength (three centimetres for the H2X versus ten centimetres for the H2S) permitted sharper beams and consequently more accurate bombing. After further cooperation with the U.S., the British developed gunlaying radars that surpassed the German Wiirzburg radars; these were placed in operation in 1944.

German radar

Although Germany had entered the war with superior long-wave radars such as the Freya and the Wiirzburg systems, the German high command, placing heavy emphasis on rocketry, reduced expenditures for radar development. In response to Allied air attacks, a hastily developed aircraft-interception set, called Lichtenstein, was developed. Thousands of Freyas, Wiirzburgs, and Lichtensteins were deployed and helped maintain German radar superiority until 1943. When the Allies began using microwave radars, they quickly gained supremacy. In February 1943, the Germans downed a British plane carrying an H2S radar and learned for the first time that the Allies were using microwave radar. Germany immediately set up a laboratory to develop magnetrons and microwave radar. In December 1943, a U.S. bomber carrying an H2X crashed in The Netherlands and Germany shifted its efforts to make an X-band radar similar to the H2X recovered from the crashed bomber. Before the end of the war, the Germans did succeed in building microwave radars, but these came too late to affect the war's outcome.

Japan, Italy, and Russia also worked on radar during the war, but in general their efforts lagged behind those of the U.S., Great Britain, and Germany. Work in Italy and Russia was minimal, with no original development. Japan began working on pulse radar in 1940, but the radars they deployed during the war were versions of the Wiirzburg system that had been shipped to them from Germany or versions of U.S. sets captured in battle.

Applications in World War II. The original purpose of radar was aircraft warning. Large ground-based installations detected approaching enemy bombers in sufficient time to enable fighter planes to engage them. Britain's chain radar played a major role in the Battle of Britain, detecting German planes even as they massed for flight on the continent. British fighter planes could thus be strategically placed in the air by the time the bombers arrived. Even though greatly outnumbered, the Royal Air Force repelled the German planes.

During daylight bombing raids, the British frequently observed their fighter plane and the enemy bomber simultaneously on the radar indicator. They developed the technique of directing their fighter plane from the ground to a position behind and close to the bomber; this enabled the fighter pilot to see and intercept the enemy. Called ground control of interception, the technique worked well during daytime raids but was almost impossible at night. When the Germans realized this, they began nightly bombing runs at the end of 1940. The British responded with aircraft-interceptor radar, which they placed in their fighter planes. Now a fighter pilot was directed by ground control to a point about a mile behind the enemy bomber, where he could see the enemy on the screen of his radar. Final interception was accomplished by use of radar, rather than by visual sighting. The first British aircraft-interceptor sets operated at 200 megahertz, and though not highly accurate, they helped keep the nighttime raids in check. By early 1943, microwave aircraft-interceptor radars were operational, and the Nazis stopped nighttime bombing raids completelv.

Like the Americans, the British modified their aircraft-interceptor radars to locate surface vessels and direct fire from ships against enemy vessels. Airborne surface-vessel detectors worked effectively, since a ship on the open sea cannot manoeuvre out of range of the bomber once it has been located. As the state of the art progressed, the airborne surface-vessel detection sets were reduced in size and weight, an important consideration in the design of an airborne package, and were able to pinpoint the location of a target more accurately. Though the improved accuracy was not necessary for airborne surface-vessel detection, it did make the radar practical for many other applications. The first sets designed specifically for airborne surface-vessel detection were flown early in 1942.

First U.S. Army radar

The first radar sets used by the U.S. Army were gun-layers that determined the direction and range of enemy planes at night, so that searchlights and then anti-aircraft guns could be directed at them. Fire-control radars, an outgrowth of the gunlayer sets, made it possible to direct guns, rather than searchlights, by synchronizing their direction with that of the radar antenna. Gunlayer sets were not accurate for fire control, however, because the radar beam was too wide, and not until the advent of microwave radar did fire-control radars become practical. The most effective fire-control set, the SCR-584, measured the angular position of a target plane with an accuracy of less than three minutes of arc and the range within 0.1 percent. It was also the first radar with automatic tracking; once pointed at a target, it could be locked on that target and made to follow it automatically.

The SCR-584 was also used for close control of aircraft from the ground. Since a friendly aircraft's position could be accurately determined by the device, radar operators were able to direct the pilots on missions, other than that of aircraft interception. Small bombers, for example, could be directed to an exact position over a target and instructed when to release their bombs, even under conditions of darkness or overcast. A special application of close control involves leading a pilot to a safe landing when weather conditions make the landing field invisible. An accurate short-range set, called ground-controlled approach radar, was developed for this purpose and first placed in operation in Europe early in 1945.

Since the trace on a radar screen does not differentiate between friendly and enemy planes, an additional means of identification is required. The British devised a system for use by the Allies throughout the war. All friendly planes carried a device called a transponder, which was simply a radar transmitter that responded only when triggered by a signal from the inquiring radar set. The signal from the transponder was coded to keep enemy planes from transmitting signals to foil identification. If an airplane showed a response to the inquiry, it was known to be friendly. But pilots occasionally forgot to turn on their transponders and the transponders sometimes failed to operate. In addition, when many planes were in the air, signals returning to the inquiring radar could not be associated with specific aircraft. Consequently, this identification system failed in air operations, though it was used successfully to identify friendly surface vessels. Rapid identification of aircraft is still an unsolved problem, especially when several are in view at one time.

Beacon devices

The transponder used in the identification system is one of a class of devices called beacons. A beacon is a transmitter triggered by a signal arriving from another transmitter. The main radar transmits a signal that is received by the beacon; the signal that returns is not a simple echo but a much stronger signal originating from the transmitter in the beacon. Thus, the beacon signal can be easily detected and separated from weaker echoes. Beacon bombing systems were developed by Great Britain and the United States to pinpoint the position of a bomber with great accuracy. In the first British system, called Oboe, the bomber carried the beacon. Two separate ground stations queried the beacon, and the exact position of the bomber was determined by triangulation, a method of determining position that involves the use of trigonometry (see NAVIGATION). Radio signals transmitted to the bomber from the two stations directed the pilot on his course and indicated when to release bombs. This system could handle only one bomber at a time and had a usable range of about 250 miles (400 kilometres).

A later British system, called H, used many ground-based beacons and an inquiring radar on each bomber. It could handle many bombers simultaneously. The U.S. developed a similar system called Shoran.

Though the extreme accuracy of Oboe, H, or Shoran was not needed for guiding a plane between airfields on a friendly mission, some sort of navigational device was desirable. Long-range systems using pulsed radar were eventually developed in both England and the United States, designated, respectively, as Gee and loran.

Until 1943 radar was used primarily for defense. With the introduction of the H2S radar, the Allies were armed with an offensive tool. The Royal Air Force used it in combination with Oboe to direct nightly bombing raids against Germany, while the U.S. Air Force used it in combination with Shoran for daylight raids. When the more accurate H2X was developed, it was installed in 12 planes for tests. Beginning in November 1943, the 12 planes made daily bombing raids against Germany for five months, permitting the Allied ground forces to advance without interruption.

In 1944 a microwave early-warning radar was placed in operation to monitor the invasion of Normandy. During the landing, the microwave early-warning system directed the fighting against the Nazi defenses, keeping track of landing ships and friendly bomber planes. Equipped with H2X radars, the bombers wiped out the enemy defenses. In 1944, the Germans began firing long-range V-1 rockets against London. Detected by microwave early warning, many were shot down. In November 1944, the Germans switched to the much faster V-2 rockets; these could be reliably followed only with the microwave early-warning radars, which tracked them in flight and determined the launching sites from their trajectories.

From the standpoint of offense, the three most important radars in the European conflict were the H2X, airborne bombing systems, microwave early warning, and the SCR-584 fire-control system. Improved versions of these were used in the Pacific theatre in what were almost routine bombings. The Japanese Navy was destroyed in battles in which pilots directed their bombs entirely by ıadar.

Developments after World War II. When World War II ended in 1945, military radar research and development work was drastically reduced in all countries. With the lifticg of military security after the war, however, scientists began experimenting with radar as a research tool. In 1946, the U.S. Army Signal Corps successfully detected radar echoes from the moon with a modified radar set. Though the experiment had little practical application at the time, it marked the beginning of the study of radar astronomy. Subsequently, radar signals were reflected off Venus (1958) and the Sun (1959) and their echoes detected. The techniques developed in radar astronomy proved valuable in tracking man-made satellites in space a few years later.

Non-military applications

Civilian, or nonmilitary, applications of radar increased as soon as the security ban was removed. Radar as a navigational aid and for collision avoidance became a standard accessory on ships and planes. Harbour surveillance sets now guide ships when visibility is poor.

Radar on planes detect storms and help pilots to avoid bad weather and a phenomenon known as clear-air turbulence. A familiar police application is radar that determines the speed of a moving automobile. Operating on the Doppler principle, this radar determines the speed of the car by the shift in frequency of the reflected signal. In general, radars for civilian use involve new applications rather than new developments or techniques.

When the U.S.S.R. tested an atomic bomb in 1949, the U.S. began to consider air defense an urgent problem again. Radar was reactivated, and contracts for radar development, design, and manufacture were given to companies with radar capabilities. During the Korean War, the U.S. found that its old radars were not effective against the new high-speed planes; new equipment and techniques were required. In the elapsed time between viewing and relaying information by radio, planes could move great distances at the new high speeds, and the relative positions would be changed.

It was obvious that radar and computer techniques had to be combined to permit automatic interception. Development of the airborne interceptor radar subsequently advanced to a point at which a computer could control the aiming and firing of guns aboard the plane.

In the United States and Canada, ground radars of advanced design were stationed across the country to detect planes approaching from any direction. Signals from these radars were transmitted to control computers that had been given information about the flight plans of all friendly aircraft. The computers determined which friendly planes should be assigned to particular missions and performed the ground-controlled intercept function. In addition, aircraft batteries and other ground installations received directions from the system, and ground-based missiles were brought under automatic control.

Early warning has always been a most important consideration, and with the higher speed of jets, the warning has to be even earlier to be useful.

To this end the United States has constructed distant early-warning stations across the northern portion of North America; this system is called the DEW line. These radars presumably would detect any supersonic plane coming toward North America on a polar route. In addition, man-made islands supporting early-warning radars were constructed on the Atlantic continental shelf of the United States.

DEW stations

When the intercontinental ballistic missile became a threat, it was recognized that the DEW line could not supply information on approaching missiles soon enough, because missiles fly at speeds several times faster than the fastest jet plane. To counter this threat, a ballistic missile early-warning system was developed, consisting of three powerful radar installations—in England, Alaska, and Greenland. The first such radar, in Thule Greenland, was the largest and most powerful set in existence at that time. It had four antennas, each more than 300 feet (90 metres) wide and transmitters that generated millions of watts of peak power. It could detect a missile at 3,000 miles (4,800 kilometres), and its computers could almost instantaneously determine the missile's trajectory, target, and time of arrival. Since missile speeds approach 200 miles (320 kilometres) a minute, the radar could provide at least 15 minutes' warning of an approaching intercontinental ballistic missile.

At the other end of the scale, the military found many applications for small radars. Sets that could be carried on a man's back were developed to detect moving tanks or trucks at short distances up to three miles (five kilometres). Working on the Doppler principle, these radars translate the movement of the vehicle into a sound signal. Smaller sets capable of detecting a man crawling at distances up to 100 yards (90 metres) were built into soldiers' helmets.

An unusual airborne radar with military and civilian applications involves a radar-equipped plane flying a fixed course with a small antenna directed downward. The echoes received are detected and recorded on film, which is developed and fed to a computer. In effect, the computer assembles all the echoes and analyzes them as if they had been received by a huge antenna the length of the plane's flight. The result is a picture of the terrain with almost photographic clarity, even though the area may have been hidden by clouds or darkness during the flight.

The advances in radar since 1950 were made possible by a number of new developments. Although the Doppler principle was well known before World War II, radars making use of it were not developed until after the war. By detecting the frequency shift caused by a moving target, the target's echo could be separated from echoes arising from fixed ground masses (clutter). This resulted in moving-target-indicator radars in which a moving plane or other object could be detected in the presence of ground clutter. Later sets, both continuous-wave and pulsed, were developed to extract the Doppler shift as useful information so that the speed of the target could be determined. Moving-target-indicator radar was made possible by the invention of the high-powered klystron amplifier, which was more stable than the magnetron as a source of microwave power.

The development of more sensitive receivers also advanced the capabilities of radar. Low-noise-amplifier devices extended the range of the radar system by permitting the detection of weaker signals. Though these amplifiers were not originally invented for radar, they were quickly adopted by radar-system designers.

The capabilities of radar were further enhanced by advanced methods of information processing. While a radar antenna is pointing at a target, the transmitter emits a series of pulses in succession (pulse train), rather than a single pulse. A succession of echoes is received, one for each pulse in the train. If the energy in an echo is below the noise level of the receiver, it will not be detected by an ordinary receiver. Through a process called signal integration, however, these weak signals can be added together by a computer and "heard" by the receiver. Signal integration thus greatly increases the range of a radar set.

The pulse train

Early radar frequencies extended into the ultrahigh frequency (300–3,000 megahertz) range. Microwave radar was desirable but seemingly unattainable because of the lack of a suitable transmitter. When the magnetron became available, radar moved into the microwave region (3,000–300,000 megahertz) and remained there throughout World War II. With the advent of the ballistic missile threat, high power became an overriding consideration for early-warning radars. Since higher power was technically feasible at lower frequencies, radar began to move back to the ultrahigh frequency range. Ultrahigh frequency antennas were much larger than microwave antennas, however; had to be fixed in place; and could not be rotated. To fit the situation in which scanning was required, the antenna system was made to consist of an array of several hundred or even thousands of small antennas. The signals at the several antennas were varied electronically, thus controlling the direction of the transmitted beam. This type of antenna system is called a phased array or an electronically steerable array.

RADAR PERFORMANCE CONSIDERATIONS

Range. The range of a radar—that is, the maximum distance at which a target can be detected—depends on the sensitivity of the radar receiver, the peak power transmitted, the size of the antenna, and the size of the target. Power must be multiplied by 16 in order to double the range. Antenna area, on the other hand, need only be multiplied by four to double the range. Increasing the frequency by a factor of four will also double the range, other things being equal.

Radar cross section. The radar cross section of a target is equivalent to an area that would intercept the transmitted signal and reflect uniformly in all directions an amount which produces the returned echo. The actual area of the target is usually greater than its radar cross section, because some power is absorbed. In fact, in designing countermeasures against radar, one approach involves the possible use of absorbent materials to reduce the radar cross section. In special cases, however, a target may be designed to have a radar cross section larger than its physical area.

The radar cross section of a target is not constant with frequency. In general, there are three ranges of interest. In the first, the target dimensions are small compared to the radar wavelength. This is called the Rayleigh region, after Lord Rayleigh, the British mathematician and physicist who first studied scattering of electromagnetic radiation from small objects (Rayleigh scattering). In the next region, the target dimensions are approximately equal to the wavelength. This is called the resonance region. The third, or optical, region is that in which the target dimensions are much greater than the radar wavelength.

Principal ranges of the cross section

These scattering principles are important when it is necessary to choose a frequency to pick out or see through a specific target. For example, if it is desired to detect planes flying during rainstorms, a frequency should be chosen such that the dimensions of the raindrops are very small compared to the radar wavelength. On the other hand, for weather radars it is important to get strong reflections from rain. In that event the frequency should be chosen so that the dimensions of the drops lie in the resonant region.

Resolution. Range is measured by the time interval between the transmitted pulse and the received echo.

If two targets are in the same direction but at different distances, two separate echoes will be received. These will arrive at different times; each arrival will indicate the range of a specific target. In order to separate the two returns, however, it is necessary for the second echo to arrive after the first one has ended. A wide transmitted pulse will produce a wide return pulse. Hence, the narrower the transmitted pulse, the closer together the two targets can be and still be distinguished from each other (resolved). The smallest distance that can be discriminated is called the range resolution of the radar. Targets closer together than this minimum distance appear as one large target.

The direction of a target is usually specified in terms of two angles — azimuth and elevation. Azimuth is the angle in the horizontal plane between a fixed reference direction and the direction of the target. The reference direction may be a compass direction such as north, or it may be the direction in which the search radar is moving (for example, on a ship or airplane). The angle of elevation is the angle above the horizontal.

Angles of direction

As a radar antenna scans, its beam moves across a volume of space. When a target is intercepted, the reflection returns in microseconds, during which time the antenna movement has been infinitesimal. Consequently, when a target signal is detected, it may be assumed to lie in the direction in which the antenna is pointing. Measuring the angle of arrival of a target signal consists essentially of noting the direction in which the antenna is pointing when the target is acquired.

If two targets are at about the same range but at slightly different angles, they can be separated if they are more than a beam width (the angular width of the transmitted radar beam) apart. If they are closer than this, echoes from both will return simultaneously from a single pulse and will appear in the receiver as one signal. The angular resolution of the radar, then, is the beam width.

Doppler. The Doppler shift or Doppler frequency, is the change of frequency in the returned signal from a target having a component of motion toward or away from the radar.

If the returned signal is at a different frequency from the transmitted signal, the target must be moving radially. The amount of this shift (called the Doppler frequency) can be measured, and the velocity of the target can thus be determined. The radial velocity of the target is the rate at which the range of the target is changing, and it is usually referred to as the range rate of the target.

The measurement of Doppler frequency as well as range and angle makes it possible to pick out a moving target from larger, stationary masses. For example, the echo of a plane flying close to a mountain may be completely obscured by the echo from the mountain, but the plane's echo will be changed in frequency. A radar using Doppler can detect the plane easily.

Losses. The achievable range of a practical radar system is always much smaller than the theoretical value because of losses (attenuation) in the system. These include losses that result from passing a signal through the transmission lines and components in the system, which may be equivalent to reducing transmitter power by as much as 50 percent.

Operator loss is a measure of the efficiency of the human operator, who may miss a weak signal when tired or make errors when rushed. Propagation loss occurs between the radar and the target and is caused by weather, reflections from the ground, refraction (atmospheric bending), and other kinds of interference.

Propagation effects. Radar signals have many properties similar to those of light waves. In general, signals travel in straight lines but may be reflected or bent by refraction. Signals are also affected by moisture in the atmosphere and other meteorological phenomena.

If either the radar or the target is near the earth, the earth could be within the antenna beam width when the radar antenna is pointing directly at the target. Part of the transmitted signal hitting the earth may be reflected toward the target. The target is thus illuminated by two signals, the direct beam and the reflected beam. If the two beams arrive thus at the target out of phase (out of step) they cancel each other, and no radiation reaches the target. The target then remains undetected even if within the normal range of the radar. On the other hand, if the two beams reach the target in phase (in step), the target will be illuminated by a stronger signal and will then reflect a stronger echo toward the radar. This permits detection of targets normally beyond the maximum range of the radar.

Atmospheric effects

Although radar waves travel in straight lines in free space, close to the earth they may be bent or refracted by variations in the density of the atmosphere. Since a target will then appear to be displaced from its true position, it is necessary to correct observations to take into account the effects of refraction. Because of this bending of radar signals, it is also possible to see objects below the horizon.

It is sometimes possible for a layer of warm air to occur above a layer of cool air in the atmosphere, an abnormal condition. This temperature inversion changes the index of refraction (amount of bending) enough that signals may follow the curvature of the earth for great distances, far beyond the radar horizon. This phenomenon is called superrefraction or anomalous propagation.

All forms of precipitation adversely affect radar signals. The increased moisture causes loss by absorption. In addition, unwanted echoes from the precipitation, called weather clutter, may mask signals from a wanted target. By careful selection of frequency, it is possible to minimize the effects of weather clutter, where unwanted, or to maximize the reflections, where desired, to detect the presence of storms.

Displays. In practically all radars used through World War II and in many present-day radars, the presence of a target was indicated by some sort of visual display on the face of a cathode-ray tube, similar to the picture tube in a television set. The cathode-ray tube and its associated circuitry are simply called a scope an abbreviated form of oscilloscope.

There are many different types of visual displays possible on the face of the cathode-ray tube. The simplest, called an A-scope presentation, is shown in Figure 3A.

From Gershon J. Wheeler, *Radar Fundamentals* (1967); Prentice-Hall

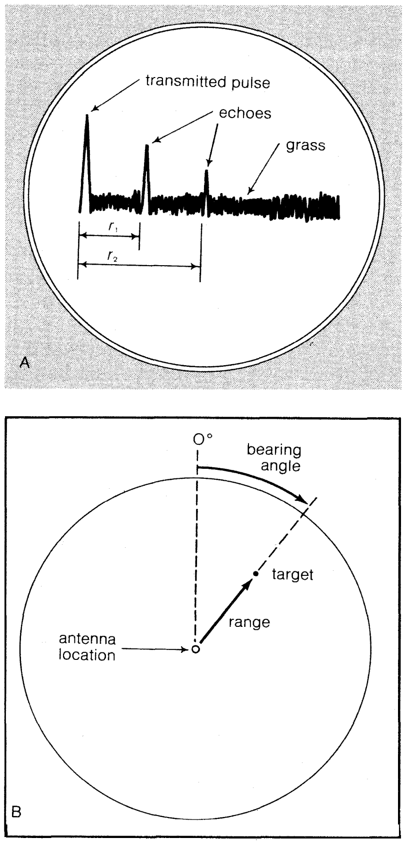

Figure 3: (A) A-scope presentation. (B) **Plan position indicator (PPI) presentation (see text).**

The horizontal distance across the face is calibrated in range, and the vertical displacement is the amplitude of the received echo. Each sweep begins when a pulse is transmitted and is indicated on the cathode-ray tube by a large inverted V or spot of light, called a pip, caused by a small part of the transmitted signal leading into the receiver. Echoes appear as pips along the horizontal line. The range, or distance, of a target producing the echo can be determined directly from the horizontal calibration. In Figure 3A two echoes are shown, one at a range r_1 and a weaker one at a range r_2. The horizontal sweep is not a sharp line but a constantly shifting pattern of short vertical lines caused by random noise in the receiver. This is called grass, possibly because in most of the early cathode-ray tubes the indications on the tube face were green.

There is no indication of direction of target on an A-scope. The operator knows that a target is in the direction the antenna is pointing. He can get this information by looking at the antenna or at some meter which indicates the antenna direction. Other types of displays were tried to present both range and direction simultaneously. On a B-scope presentation, azimuth is plotted horizontally and range vertically. The C-scope shows elevation vertically and azimuth horizontally. The B- and C-scopes were rarely used and were soon superseded by the plan position indicator display.

The plan position indicator, shown in Figure 3B, depicts the range and angular position of all targets seen by the radar as its antenna scans through a complete circle. A radial line sweeping from the centre to the perimeter is the equivalent of the base line in the A-scope. A target appears as a dot, and its range is indicated by the distance of the dot from the centre of the cathode-ray tube. As the antenna rotates, the radial line rotates on the face of the scope in synchronism, so that any targets that appear are always indicated in the proper relative directions. A point on the circumference is chosen as a reference. The face of the scope is specially treated so that images persist for about one revolution of the antenna. The result is a virtual map of the area being scanned. Moving targets can be detected by noting displacements of their echoes on successive sweeps.

Cathode-ray tube displays are not used in all applications. For example, in a small radar built inside a soldier's helmet, the echo is displayed as a sound in the earphones connected to the radar. If the soldier turns his head until the sound is maximum, he will then be facing approximately in the direction of the target. The pitch of the sound is related to the Doppler signal and thus gives some indication of the radial speed of the target.

The plan position indicator was used successfully during World War II, but its drawbacks became apparent toward the end of the war. In operation, the radar operator observed the plan position indicator and directed positioning of planes or guns and even firing times. With increasing target speeds, however, this method proved too slow for most practical operations, and computers had to be added.

Although computers are important components of most modern radars, there are still some applications in which the plan position indicator is used. At airports, for example, many planes may approach simultaneously at comparatively slow speeds. Nothing surpasses the plan position indicator for presenting a picture of all the planes in the area and their relative positions.

Countermeasures. During World War II both sides recognized the importance of developing countermeasures to render enemy radars ineffectual. As new techniques for jamming or deluding enemy radars were discovered, counter-countermeasures were developed, and radar warfare became a battle of wits.

Jamming
and
deluding

Jamming was a moderately successful, early technique of radar countermeasure that consisted of transmitting signals at the frequency of the enemy radar, so that his radar receiver was saturated or blocked and could not detect target signals. The flaw in jamming was that the enemy knew his radar was being jammed and could take evasive action by changing frequency. The object then was to discover the new frequency and jam that. In the early days of the war, radar frequencies could not be changed easily, and thus jamming was a successful countermeasure until better radars were developed.

One of the simplest, and yet most effective, methods of deluding radars consisted of dropping strips of aluminum foil from planes during raids to produce false echoes. Maximum return from the foil strips occurs when they are cut to a length of a half-wavelength. The Allies dropped long strips cut to a half-wavelength at the low frequency of the German radars while the Germans dropped short strips to yield false echoes for the microwave radars used by the Allies. On a full-scale bombing raid, the Royal Air Force dispensed enough aluminum foil to equal the weight of three bombers. The aluminum foil dispensed was called window by the British, chaff by the Americans, and *Dueppel* by the Germans.

More sophisticated countermeasures were developed after World War II, some of which are still secret. Absorbent materials were developed to coat friendly vehicles and thus absorb enemy radar signals and minimize reflections. Coatings of this material are used on military missiles to reduce their radar reflectivity and make the missiles more difficult to detect. In another technique the enemy radar beam is detected by the friendly vehicle, which, after a short delay, transmits a signal at the same frequency. The enemy radar then receives a signal much later than it should have from the particular target, and thus the range seems greater than it really is.

In all countermeasure systems it is important to know the frequency of the enemy radar. If a radar is to be jammed, signals must be set at the proper frequency. Aluminum strips must be cut to the proper length. Delayed signals must be transmitted at the received frequency. A large part of the radar countermeasure effort is spent in determining these frequencies.

RADAR EQUIPMENT

Continuous-wave radar. If a radar transmits continuously, the continuous echo cannot be associated with a specific part of the transmitted wave. Thus it is impossible to derive range information from a simple continuous-wave radar. This equipment can, however, derive speed information from the Doppler shift by measuring the shift in frequency of the reflected signal.

A simple continuous-wave radar is shown in Figure 4.

From Gershon J. Wheeler, *Radar Fundamentals* (1967); Prentce-Hall

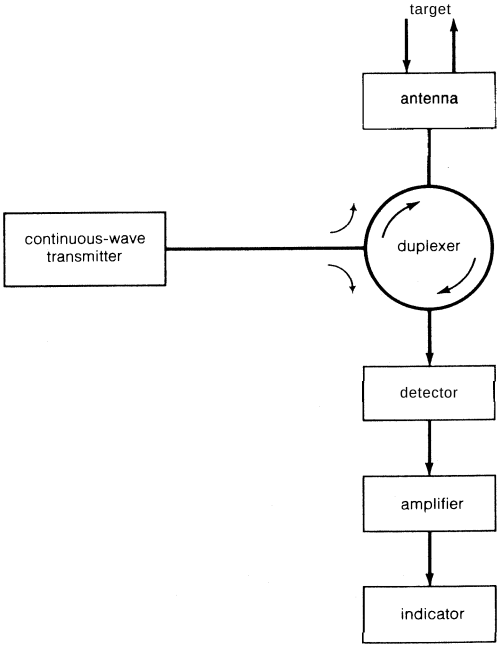

Figure 4: Continuous-wave radar (see text).

A signal transmitted at a given frequency is coupled to the antenna through the duplexer (a device which permits use of the same antenna for transmitting and receiving) and radiated into space. When the transmitted radiation is interrupted by a target moving radially, the reflected signal will be changed in frequency by the Doppler shift.

Though simple continuous-wave radar cannot furnish range information, it can be made to do so if each portion of the transmitted radiation is tagged so that it can be recognized on reception. One method of tagging the signal is to change the frequency continuously. When an echo is received, its frequency will be different from that of the signal leaving the transmitter at that time; if the rate of change of frequency is known, the difference in frequency will be an indication of the range; this is frequency-modulated radar.

Pulsed-Doppler radar. When early pulse radars were used with a plan position indicator for display, it was not necessary to use the Doppler shift to know that a target was moving. With each revolution of the antenna, a moving target would appear slightly displaced from its last position, and an experienced operator could learn to pick out the moving targets on the plan position indicator and ignore the fixed targets. When the moving target was very close to a large land mass, however, the large echo from the land mass completely masked the echo from the relatively small moving target. Experienced pilots soon learned this and tried to fly as close as possible to hills to avoid detection by enemy radar.

Radially moving targets produce Doppler shifts; fixed targets do not. Since the phase difference (the amount the two waves are out of step) between a reference signal and the echo is constant for a fixed target but is continuously changing for a radially moving target, there are differences in echoes from fixed or moving targets; and a radar has been developed to exploit these differences so that moving targets can be detected even in the presence of large land masses. Called moving-target-indication radar> this equipment can detect a moving target in the presence of clutter hundreds of times as strong.

Sometimes a target is moving at such a speed that its echoes are indistinguishable from those from fixed targets. Such a speed is called a blind speed, and various approaches have been made toward solving the problem. A possible solution is to increase the pulse-repetition frequency so that the blind speed is greater than the velocities of the targets of interest. Another approach is a staggered pulse-repetition frequency, in which each alternate pulse is delayed by a small amount, alternately producing two different interpulse intervals. A speed that is blind for one of the intervals will usually not be blind for the second.

Transmitter components. The heart of the transmitter, the high-powered device that produces the electromagnetic radiation, is one of the most expensive parts of a radar system. There are two basic types. One is the self-excited oscillator, which converts direct-current power directly into radio frequency energy. The magnetron is a typical example. The other radiation device employs a stable low-power oscillator followed by one or more amplifiers. Typically, the final amplifier is a high-power klystron. The oscillator–amplifier chain is inherently more stable than the self-excited oscillator and thus is more dependable for Doppler radars, in which the amount of frequency change is important.

Use of the high-power klystron

Today klystrons produce powers in the megawatt (10^6 watts) range; many recently developed tubes have relegated the magnetron to a less important role. Even though the klystron amplifier is not as efficient as the magnetron and is relatively larger than most microwave tubes, its stability makes it a preferred source for moving-target-indicator and other Doppler radars.

The travelling-wave tube is a microwave amplifier with an extremely wide bandwidth. Bandwidths of an octave or more (frequency ratio of two to one) are achievable in low-power, travelling-wave tubes, and bandwidths equal to 20 percent of the operating frequency have been obtained with high-power tubes for radar applications. A wide bandwidth is desirable to enable the operator to shift frequency over a large band, to avoid jamming.

Like the klystron, the travelling-wave tube has an electron gun at one end and a collector at the other. An external magnet along the outside of the tube keeps the electron beam from spreading. A radio-frequency signal is fed into the tube near the electron gun and is removed near the collector end. A structure built into the tube slows down this radio-frequency signal so that its velocity is approximately the same as that of the electrons. The electrons give up some of their energy to the signal, greatly amplifying it. The structure for slowing down the wave is usually a long helical coil.

Despite the demands for bigger tubes and more power, there is a growing need for compact, low-power radars for both civilian and military applications. **A** miniature continuous-wave Doppler radar using integrated circuitry is shown in Figure 5. This is a complete transmitter, receiver, and duplexer in a package smaller than a man's hand. With the addition of a small battery, an antenna, and a display, it is a complete radar systcrn. The transmitter produces 50 milliwatts (0.050 watt) of power at X-band (10,000 megahertz).

This type of low-power radar is aimed at the growing civilian market. Since it can determine the velocity of a moving object, it can be used as an automatic collision-avoidance system in an automobile. It can also be used as an intrusion alarm, a traffic monitor, and in other situations in which detection of motion is needed.

Receivers. Two different types of receivers are used in radar systems—the superheterodyne and the video receiver. More complicated than the video receiver, the superheterodyne has far greater sensitivity (see RADIO). In radars for applications in which ranges are short and echoes are strong—such as traffic-monitoring radars and intrusion detectors—a video receiver is usually sufficiently sensitive and is chosen because of its simplicity. For most radar applications, however, the superheterodyne is preferred.

Electrons in motion generate electric currents that have the appearance of signals. In any practical receiver, the constant motion of electrons in tubes, crystals, resistors, and other components produces a measurable voltage at the output. These unwanted "signals," random in frequency and amplitude, are called noise in radio receivers. The main source of noise is the motion of electrons in conductors and resistors due to heat. It is called thermal noise.

Effects of noise

Noise is the limiting factor in a receiver. Without it, any incoming signal, no matter how weak, could be detected. In a practical receiver, however, noise is always generated at the input of the first stage, and any incoming signal must be strong enough to override it.

The sensitivity of a receiver can be expressed in terms of the weakest signal that can be detected. Since this would depend to some extent on the operator, it would not be a reliable measure of the receiver's capability. A more consistent measure is a value of signal related to the noise level at the input of the receiver. The standard measure of sensitivity is when the signal level just equals the noise level.

The noise in a receiver fluctuates continuously, and some of the noise peaks exceed the signal levels of target echoes. These peaks can be mistaken for signals or can mask signals when they occur at the same time. If the receiver is turned off part of the time, some of the noise peaks will be missed; the statistical probability of a noise peak being mistaken for a signal will be reduced. The use of so-called range gates reduces noise peaks in this way. A range gate is simply a switch that permits the receiver to operate only when targets at a desired range are sought. For example, if targets are to be located between 20 and 30 miles (32 and 48 kilometres) from the observing station, an echo from the nearest will arrive at the receiver about 240 microseconds after a pulse is transmitted and an echo from the farthest about 360 microseconds after the transmission (assuming about 12 microseconds per mile). Thus, the range gate might be set to turn the receiver on about 220 microseconds after transmission of each pulse and shut it off about 160 microseconds later. This would reduce the number of noise peaks appearing as signals and in addition would eliminate echoes from unwanted targets outside the desired range.

When two targets are in the same direction but at different distances from the radar, both echoes will occur at one position of the antenna, but the echoes will arrive at different times. If the second echo arrives before the echo pulse from the first is ended, however, it may be hidden by the first pulse. If, for example, two targets are in the same direction but about 500 feet apart, the echo from the second would begin about one microsecond after the echo from the first. If the pulse width of the radar is two microseconds, the first echo will only be half done when the second begins, and the two echoes would not be separable. Range resolution depends on the pulse width and could be improved if the pulse could be compressed on reception. Various techniques have been developed for accomplishing this and thus improving range resolution.

Duplexers

A duplexer is a device that permits use of the same antenna for both receiving and transmitting. It is indicated as a switch in Figure 1, and in most high-power pulsed radars the duplexer *is* a switch, connecting the antenna to the transmitter during transmission and to the receiver when the transmitter is off.

Antennas. A radar antenna is a coupling device between free space and the radar set. During transmission, energy from the transmitter is coupled to the antenna and caused to radiate. On reception, the antenna intercepts signals and couples them to the receiver. If a duplexer is used, the antenna is switched from one function to the other. Alternatively, the receiver and transmitter may have separate antennas that are permanently connected.

The main purpose of the antenna is to shape the transmitted beam so that the radiated energy is aimed in the desired direction in space. In general, the larger the aperture (opening that permits radiation) of the antenna (in terms of wavelengths), the narrower will be the beam. A narrow beam indicates that the energy is concentrated in one direction, which means the antenna has a relatively high gain in that direction. Antenna gain is the electrical output per unit of input, or the electrical efficiency of the antenna. Antennas are reciprocal, exhibiting the same gain and beam widths for reception as for transmission.

When an antenna is used for reception, the amount of power it intercepts is proportional to its area. Since not all parts of the antenna are coupled uniformly to the transmission line, however, the amount of power reaching the receiver seems to come from a somewhat smaller antenna. This "reduced" size is called the effective area of the antenna. The gain of the antenna is proportional to the effective area.

One form of antenna is a horn, formed by flaring out the walls of a wave guide to make a large aperture, which is in effect a large wave guide. It directs the radar beam in much the same way as a megaphone directs a voice.

It is possible to have fan-shaped antenna beams, wide in one direction and narrow in the other. This is accomplished by having an aperture that is wide in one dimension (to produce the narrow beam in that direction) and narrow in the other. It may be a specially shaped horn or a segment of a parabola.

Parabolic dish-shaped antennas are often used as reflectors in microwave systems; they are capable of focussing energy in one direction because of two special geometric properties. First, all rays from a fixed point, called the focal point, to the parabola are reflected as parallel rays. Second, in any plane perpendicular to the axis of the parabola, the reflected rays are all in phase (in step). When installed, the parabola may have holes cut in it or may be made of wire mesh instead of a continuous metal sheet, to reduce weight and decrease the effect of wind blowing on the dish. These openings in the surface have negligible effect as long as they are small compared to a wavelength.

A simple pencil-shaped radar beam cannot determine target position accurately, since, when a target is first detected, it may be at the top of the beam or off to one side. Even if the beam is swept through the target, the top of the beam may be too broad to fix the position accurately enough for gunlaying or mapping. Additional information is needed to find the target's exact position and, if the target moves, to follow it with the beam.

Conical scanning and sequential lobing

One method of supplying this information is called conical scanning. The beam is made to rotate spirally about an axis, so that a target in the "dead-ahead" position would be illuminated by slightly less power than the top of the beam. If the target is slightly off the axis, it will receive more power in one position of the beam as the beam rotates. In fact, the echo will be amplitude modulated (the height of the wave will be changed) at the conical-scanning rate (the rate of rotation). In operation, when a target is detected the antenna is moved so that the modulation is decreased, and when the modulation reaches zero the target lies on the axis of rotation.

Sequential lobing is another method of determining position accurately. Instead of rotating a beam, two or more fixed beams are transmitted sequentially. These beams occupy positions that would occur at equal intervals in a conical-scanning antenna and thus supply the same sort of modulation information.

The word scanning is used in two different senses in radar applications. After a target is acquired, the radar scans it to follow it as it moves. In this sense scanning refers to the comparison of target returns from two or more beam positions to determine the direction accurately. Conical scanning is an example. Scanning also refers to searching for targets. The radar beam is made to sweep over a volume that might contain targets of interest. This is usually done in a prescribed pattern.

In helical scan, the antenna beam rotates through 360° in azimuth (the arc of the horizon) while it is slowly raised in elevation. In spiral scan, the beam rotates in an ever-widening spiral. Helical scanning covers a hemisphere, while spiral scanning is limited to a conical volume. These are illustrated in Figure 6. Rectangular shapes can be covered by moving the antenna beam back and forth horizontally, raising it slightly at the end of each sweep.

APPLICATIONS

Search and tracking. Radar either searches for targets or follows them. A radar that seeks a target is called a search or acquisition radar. During search, the operator may or may not know that a target exists in the covered space. Thus, a weather radar on an airplane searches for storms, which may or may not be in the plane's path. On the other hand, a radar may be used to check a satellite following a known orbit.

A radar that follows a moving target is called a tracking radar. To do this, the radar must sense the direction of motion and must move to keep the transmitted beam always pointed at the target. A scanning radar is sometimes used to sample the position of one or more targets as the beam sweeps through them. Such a radar is called track-while-scan radar.

Tracking implies following the target in azimuth and elevation. This is called tracking in angle. If the tracker also supplies continuous information about range or Doppler shift, it is said to track in range or in Doppler as well as in angle.

If a search radar employed a narrow beam to search a

Fan-shaped and pencil beams

large volume of space, it would take too long to scan the space systematically. For this reason, a search radar frequently uses two fan-shaped beams—one horizontal and one vertical. The horizontal beam moves up and down to determine the elevation of a target, while the vertical beam moves horizontally to determine the azimuth. The search radar can acquire many targets at different ranges simultaneously. For small volumes of space, the search radar can use a pencil beam. Then when a target is acquired, the same radar can be used for tracking.

A tracking radar uses a pencil beam that is pointed at the known position of a target. If the target moves off the centre of the beam, an error signal is produced that indicates the direction of motion and operates a mechanism to move the tracker back on target.

Altimeter. A radar altimeter is a simple form of search radar with the earth as a target. The radar produces a continuous-wave signal that is frequency-modulated. This is directed toward the earth, and the echo is detected in the receiver and compared in frequency with the signal being transmitted at the time of reception. Since the rate of change of frequency (that is, the frequency-modulation rate) is known, the difference in frequency indicates the elapsed time and hence the distance to the earth. The radar altimeter needs less than one watt output and a small antenna because the earth is a large target.

Doppler navigator. A Doppler navigator is a simple continuous-wave Doppler system used to measure a plane's ground speed. The radar carried on the plane has an antenna that directs a beam forward and down at a 45° angle to the direction of flight. In this case the earth is also the target. The true velocity can be determined from the relative radial motion.

Gunlaying. The error signal produced by a tracking radar can be used to point a gun at a target as well as to keep the radar beam pointing in the right direction. The radar then controls the direction of firing and is called fire-control radar. The gun is said to be slaved to the radar. During World War II, anti-aircraft guns were slaved to tracking radar to point in the same direction as the antenna beam. With the faster planes in use today, however, it is necessary to have the guns point ahead of the beam. During the time the shells would reach the plane's altitude, the plane would have moved too far ahead to be hit. In a modern fire-control radar, information from the tracker on range, angle, and rate of change of angle are fed to a computer, which then combines this with the velocity of the shells to calculate an intercept point. The guns are slaved to the computer.

Early warning. This is a long-range search radar that looks for enemy action at a distance in order to provide warning in time for effective counteraction. Typically, an early-warning radar may be used to detect an intercontinental ballistic missile at a distance greater than 2,000 miles. These radars are characterized by very high power, large antennas, and frequencies in the uhf or vhf regions where atmospheric attenuation is low.

Search radars can also be used to keep track of friendly planes in both military and civilian applications. An air-traffic-control radar at an airport monitors movements of planes arriving and departing in order to prevent collisions. Targets are usually displayed on a plan position indicator. When a plane is acquired, the radar operates as a track-while-scan radar for that plane while searching for others.

In a large airport, radars also monitor the movements of ground traffic. These radars must have a very narrow beam width in order to get the required resolution in azimuth and short pulses to separate objects close together on the ground. Plan position indicator displays are used with these radars. Similar radars are used at ports to monitor movement of ships.

Mapping. Radars for mapping transmit very short pulses in order to get sufficient range resolution. Ordinarily, distances to the area illuminated are comparatively short so that high repetition rates can be used without fear of ambiguity.

A weather-avoidance radar is used in a plane to detect storms so that the plane can avoid them. The frequency is chosen so that raindrops in the storm will reflect as much energy as possible without too much atmospheric attenuation of the signal.

Beacons. A beacon is not really a radar, in that it furnishes no information as to range. Beacons, however, are used in conjunction with radars and are usually described as a type of radar. A beacon transmits a signal only when it receives a specific coded signal from a radar. The radar in effect interrogates and the beacon responds. Beacons were originally designed for identification, friend or foe, radars but have many other applications. Weather satellites carry beacons. As these satellites revolve about the earth, they gather information about weather conditions around the world. When a satellite is overhead, its beacon is interrogated and responds with the data it has accumulated. Beacons may also be used in satellites to simplify tracking.

Each time a satellite is successfully launched by any country, it is usually announced publicly. Nevertheless, for political reasons it is necessary to have a capability to detect every satellite in space. The existence of this capability may be the reason why nations normally announce their launchings. Satellite detection in the U.S. requires a network of radars forming a radar fence, so that a satellite must pass through a radar beam to pass over any part of the country.

FUTURE DEVELOPMENTS

Missiles. In the future, if an enemy intercontinental ballistic missile lifts off its launch pad, it will be detected by a long-range early-warning radar; and data on the missile's flight will be fed to a computer, which will calculate the trajectory and estimated time of arrival and then control the firing of an antimissile missile, while the ballistic missile is still 3,000 miles (4,800 kilometres) away. Speeding toward the intercontinental ballistic missile, the antimissile missile will carry an atomic warhead to destroy the ballistic missile out of range of its target.

Each missile will carry its own radar and computer. As the antimissile missile approaches, it will be detected and tracked by the radar on the ballistic missile, which will change course to avoid its pursuer and, after the latter passes, continue toward its target. The radar aboard the antimissile missile will detect the evasive action, however, and the antimissile missile's computer will direct it to follow.

As the antimissile missile approaches, the Doppler shift will indicate the closing speed, and if it does not intercept its target but passes close to it, the Doppler will rapidly drop to zero at the closest point and will then reverse. The computer in the antimissile missile will fire the atomic warhead when the Doppler changes to zero—that is, at the closest point to the ballistic missile.

Computers. Computers play an increasing role in radar technology, eliminating human decision-making in many applications, and the outcome of future wars may depend on the sophistication of the computers that are connected to the radars.

Computers will not only use the information supplied by the radar but will also operate the radar or repair it in case of fault. The computer will check the operation of the radar continuously, and in case of fault or degradation, the cause will be located and a new part substituted automatically.

Radars today can provide accurate information about the direction, range, and velocity of a target. To some extent they can provide approximate indications of size and shape. It is probable that future radar systems will operate at higher frequencies, probably approaching optical frequencies. Improved resolution is possible at these higher frequencies.

Components. Although development of higher power sources continues, it is probable that greater improvement in radar performance will be achieved by advances in receiving techniques. Here again the computer will play a large role—storing information, separating signals from noise, and in general increasing the sensitivity of the receiver.

It is probable that newer tubes will replace the magnetron and klystron. New forms of amplifiers show promise of supplying stable high-power signals in less space than the klystron. For low-power radars, solid-state sources and circuits will eliminate all tubes.

Radar was developed in wartime as a military tool. Civilian applications may, however, come to predominate. Radar has been used for accurate mapping, intrusion detection, weather avoidance, and a number of other nonmilitary applications. Radars can be used to land planes during zero visibility. There are many applications of radar for automobiles under development. A typical collision-avoidance system uses a radar in the front of an automobile to measure the distance to the vehicle ahead and the closing speed. If the rear vehicle is overtaking the forward one too rapidly, a computer circuit connected to the radar takes over to slow the rear vehicle, either by braking or by reducing the flow of gasoline to the motor.

Radiation, Biological Effects of

All life is constantly being bombarded with various kinds of radiation—visible light, infrared, ultraviolet, radio waves, X-rays (from cosmic and terrestrial sources), and particulate cosmic rays—all of which are manifestations of energy transfer from one place to another. In a wide sense, any consequence of the transfer of radiation energy to a living organism is a biological effect of radiation. This definition includes both the normal effects on many life processes (*e.g.*, photosynthesis in plants and vision in animals) and the abnormal or injurious effects resulting from the exposure of life to unusual types of radiation or to increased amounts of the radiations commonly encountered in nature. This article, devoted chiefly to the discussion of the deleterious effects of radiation, is divided into the following sections:

I. Definitions and concepts
  Types and measurement of radiation
    Electromagnetic waves
    Particulate or corpuscular radiations
    Measurement of radiation
  Mode of action
    Mechanisms of energy transfer
    Ionization and penetrating power
    Mechanisms of biological action
II. General biological effects
  Genetic effects
    Gene mutations
    Chromosome mutations
  Bodily (somatic) effects
    Long-term effects
    Short-term effects
III. Radiation and human health
  Man's radiation burden
    Natural sources
    Artificial sources
  Injury from ionizing radiations
    Historical background
    Radiation effects on cells
    Radiation effects on tissues and organ systems
    Acute lethal effects
    Prenatal exposure and exposure of children to radiation
    Protection against external radiation
    Long-term effects, somatic and genetic
    Radioisotopes and fallout
  Accumulation of isotopes in critical organs
    Radiation and cancer
    Chromosome aberrations and radiation
  Effects of Hertzian waves, infrared rays
    Hertzian waves
    Infrared rays
  Effects of visible and ultraviolet light
    Intrinsic action
    Photodynamic action
    Effects on development and biological rhythms
    Effects on the eyes
  Effects of lasers

I. Definitions and concepts

For a better understanding of the later sections of this article, a review of the two main types of radiation—electromagnetic waves and moving atomic particles—and of their measurement, sources, and mechanisms is in order.

TYPES AND MEASUREMENT OF RADIATION

Electromagnetic waves. Energy can be transferred through matter or through space by means of oscillatory variations in electric and magnetic fields originating at various sources. Electromagnetic-wave radiation is classified into several types, depending on frequency and wavelength. The various types (in order of decreasing wavelength and increasing frequency) and their sources are summarized in Table 1.

Table **1: Electromagnetic Waves**

wave type	sources
Hertzian (radio waves and microwaves)	radio transmitters
Infrared	hot bodies
Visible	hot bodies; excited molecules
Ultraviolet	hot bodies; excited gases
X-rays and gamma rays*	atoms struck by high-energy particles; radioactive materials; cosmic sources

*Similar to X-rays but emitted from the nuclei of some radioactive atoms.

Particulate or corpuscular radiations. Simply speaking, an atom consists of a nucleus, composed chiefly of neutrons and protons, surrounded by a cloud of electrons; in addition, there are other special particles. When separated, either by natural radioactive disintegration or by artificial means—as in a cyclotron, for example—these particles, charged or uncharged, are capable of transferring their energy, wholly or in part, to any substance through which they pass. Streams of such particles constitute particulate radiations. The more important types of particles, the magnitudes and signs of their charges (relative to that of an electron, defined as the unit negative charge), their masses (relative to the mass of a hydrogen nucleus, defined as the unit mass), and their main sources are summarized in Table 2. The rate of transfer of energy by a particulate radiation depends on the mass of the particle, its velocity, and, if charged, the magnitude of its charge.

Measurement of radiation. Radiation is detected and measured by various methods that rely on the property of the radiation to cause ionization in gases or emission

Radiation detection

Table 2: Particulate Radiations

particle type	charge	mass	sources
Elecron* and positron	−1	1/1,843	accelerating machines, radioactive materials
Proton†	1	1	accelerating machines and cosmic rays
Alpha (a) particle‡	2	4	radioactive materials and cosmic rays
Neutron	0	1	nuclear reactors, accelerating machines, and cosmic rays
Heavy nuclei	§	§	

*Electrons emitted by radioactive nuclei are called beta (β) particles. †Protons are the nuclei of hydrogen atoms. ‡Alpha particles are the nuclei of helium atoms. §Various.

of light from sensitive materials or blackening of a photographic emulsion. Instruments used are the ionization chamber, Geiger counter, and scintillation counter.

Roentgen unit. The original biological unit of X- (or gamma-) ray exposure, the roentgen unit (R), is defined as that quantity of radiation that produces a given number of charged ions in a given quantity of air under standard conditions.

Rad. A more general and more accurately defined measure of local exposure to all types of radiation is the rad, the radiation dose absorbed in tissue itself. It is equal to 100 ergs per gram.

Rem. The same dose in rads from different radiations may produce different degrees of biological effect. The dose in Rem (roentgen equivalent man) is the product of the dose in rads and a factor called the quality factor, which depends on the relative biological effectiveness (RBE) of the radiation used. The Rem is taken to be that dose from any radiation that produces biological effects in man equivalent to one rad of X-rays.

For more technical definitions, see **RADIOLOGY**; see also **RADIOACTIVITY**.

MODE OF ACTION

Mechanisms of energy transfer. There are several mechanisms by which energy is transferred from radiations to biological materials. Wave radiations yield up their energy through scattering and quantum absorption. The energy of infrared and visible radiation is absorbed mainly by whole molecules and atoms. The energy of ultraviolet radiation is absorbed partly by the planetary electrons of atoms; an electron jumps to a higher energy orbit, thereby bringing the atom into a state of excitation, in which it is chemically reactive. The energy of X-rays is also absorbed mainly by the planetary electrons of atoms, but the amount absorbed is usually great enough to produce ionization—*i.e.*, to induce an electron (or electrons) to escape altogether from the atom, thereby ionizing the atom; an ionized atom is highly reactive, even more so than one in a state of excitation.

Particulate radiations yield up their energy through collision with the planetary electrons or atomic nuclei of the material through which they pass. Charged particles usually react with the planetary electrons and therefore leave the atom in an excited or, more commonly, ionized state. Neutrons, being uncharged, are able to pass through the orbits of the planetary electrons and collide with the nucleus of an atom. The nucleus may then recoil, or it may capture the neutron. In biological material, neutrons yield up most of their energy through collision with hydrogen nuclei, which recoil as hydrogen ions (*i.e.*, protons). The neutron is eventually captured by some nucleus, usually followed by the ejection of one or more charged particles, often accompanied by gamma rays.

High-energy radiation

Ionization and penetrating power. Although all higher energy radiations (*i.e.*, X-rays and particulate radiations) produce ionization in biological material, the spatial distribution of the ionization depends on the type and penetrating Power of the radiation, the nature of the material irradiated, and the spatial distribution of the radiation source or sources. High-energy X-rays produce ionization that is rather sparsely but uniformly distributed along the track of the radiation; alpha particles and heavy ions cause intense ionization along their tracks; in between these come neutrons, protons, and beta particles. In general, the lower the speed of a particle, the denser the ionization along its track, so that all particles tend to be more densely ionizing toward the ends of their tracks. High-energy X-rays penetrate deeply (X-rays commonly used in medicine are less penetrating), but most beta particles penetrate only a few millimetres in biological tissues and alpha particles only a small fraction of a millimetre. Animal tissues, such as bone and teeth, that contain elements of fairly high atomic weight, such as calcium, absorb much more energy from a given radiation than do soft tissues, which are composed mainly of elements of low atomic weight. Ultraviolet radiation is of very low penetrating power.

Mechanisms of biological action. The biological effects of the higher-energy electromagnetic radiations and of all the particulate radiations are mediated through the ionization (and, to a lesser extent, the excitation) that they produce in biological tissue. Thus, all ionizing radiations have broadly similar biological effects; such differences as are found are the result of differences in the spatial distribution of the ionization. An explanation of its mode of action must be sought at the cellular level; effects on the whole organism are likely to be secondary. Two main types of intracellular action have been distinguished; first, direct action through ionization of biological structures along the ionized track; and, second, indirect action through the formation of reactive chemical fragments (free radicals) that diffuse away from the ionized track and undergo further reaction elsewhere.

Types of intra-cellular action

Direct action. Direct biological actions were studied in great detail in the period between **1927** and 1947. **A** detailed quantitative theory was elaborated, the target theory, or *Treffertheorie*, whereby a tissue undergoing irradiation was likened to a field traversed by the fire of a machine gun. It was supposed that, to produce a given effect, there must be one or more hits by an ionized track on a sensitive target, so that the probability of obtaining the effect was dependent on the probability of obtaining the requisite number of hits on the appropriate target. This theory was very successful in giving a quantitative treatment of many of the biological effects of radiations, particularly in the field of genetics.

Indirect action. In the field of radiation chemistry, where free radicals produced by radiation play a vital role as intermediates in chemical reactions, the target theory had little application, and, from about **1940,** the interest of radiation biologists tended to shift toward the indirect actions of radiations. This shift was given impetus by the discovery in **1947** that the induction of chromosome breakage, which had until then been viewed as a target-theory effect *par* excellence, was enhanced if the tension of oxygen was increased in the material irradiated. Similar effects are known in radiation chemistry, in which oxygenated solutions can lead to more extensive radiation damage to solute molecules than do oxygen-free solutions. Highly active molecular particles called free radicals are known to be mainly responsible for the changes produced in these cases. Substances were then sought that have a high reactivity toward free radicals in order to reduce the biological effects of radiation exposure. Two such protective substances are cysteamine and cysteine. Unfortunately, these compounds can themselves cause adverse biological effects.

II. General biological effects

The biological effects of radiations may conveniently be subdivided into somatic effects—short-term somatic effects (*i.e.*, short-term effects on the body of the individual) and long-term somatic effects—and genetic effects. Historically, they were discovered in that order. But, as the genetic effects are nearest to the cellular level and the short-term somatic effects farthest from it, it is more convenient to consider them in the reverse order.

GENETIC EFFECTS

The genetic effects of radiations arise through damage to those intracellular bodies in the germ cells that are the

Effects on sex cells

material basis of heredity (*q.v.*). These are the chromosomes, with their constituent genes (see GENE). Genetic effects therefore occur only if the radiation reaches the germ cells. Thus, in those plants and animals (man is one) in which the germ cells are fairly well covered by tissue, radiations of low penetrating power, such as ultraviolet light and alpha and beta particles, cannot produce genetic changes; however, radiations of high penetrating power, such as X-rays and gamma radiation, can induce genetic effects.

Radiation-induced genetic effects on animals and plants are probably not qualitatively different, if consideration is given to the physiological variations between these two kinds of life. Mutations induced by irradiation of seeds are of interest to plant breeders because of the possibility of producing new varieties. Differences have been found in the mutagenic effect of radiations on plants, which appear to depend upon the density of ionization produced. Fast neutrons and heavy particles were found to be up to 100 times more mutagenic than X-rays. Radioactive elements taken up by plants can also be strongly mutagenic. In choosing a suitable dose for the production of mutations, a compromise has to be reached between the mutagenic and damaging effect of the radiation on the plants. As the number of mutations increases, so also does the extent of damage to the plant. A critical dose is defined as that allowing 40 percent survival. In the irradiation of dry seeds by X-rays, doses of 10,000 to 20,000 roentgens are usually given. Mutants can be produced by radiation that affects such properties as early ripening, resistance to disease, and the like, and economically important varieties of various species have been produced.

In plants and animals, genetic changes of two sorts are induced, namely, gene mutations and chromosome mutations. They differ in important respects and will be considered separately.

Gene mutations. Radiation-induced gene mutations are all of the same types that occur spontaneously in nature. Most gene mutations, whether spontaneous or radiation-induced, are harmful. They reduce the fitness of the organism, in the sense that an individual carrying a mutated gene is usually less capable of surviving and leaving descendants than is an individual carrying the gene in its unmutated form. Favourable mutations produced by radiation and other mutagenic agents are believed to be responsible for continued evolution.

Although the mutations induced by radiations are all of types that occur spontaneously, the relative frequencies with which any two particular genes mutate under irradiation may not be the same as the frequencies with which they mutate spontaneously; however, if whole classes of genes are considered, the mutational idiosyncrasies of particular genes are lost, and the overall picture shows that exposure to radiation causes a proportionate increase in the mutation frequency of all classes of genes.

Increase of mutational frequency

Experiments with animals and plants have established that mutations imply alterations in the molecular structure of genes. The yield of mutation is usually proportional to the amount of energy absorbed in the germ cells; *i.e.*, to the radiation dose. This linear dependence of mutation on dose, which is to be expected on target-theory consideration if gene mutation is the result of a single hit by an ionized track, has been demonstrated experimentally for doses down to a few rads. It would be difficult to obtain experimental verification at doses much lower than this. The implication is that there is no threshold dose for the induction of gene mutation; *i.e.*, any dose, no matter how small, will induce some mutation.

Radiation intensity was originally thought to have no importance, the total amount of mutation induced being dependent only on the total accumulated dose. In 1958 it was shown, however, that this does not hold true for mutation induced in immature germ cells (spermatogonia and oocytes) of the mouse, the amount of mutation induced by a dose accumulated at a rate of about one roentgen per day being only about a third of that induced by the same dose accumulated at about 100 roentgens per minute. If this is true of mammalian spermatogonia and oocytes generally, it holds important implications for man, whose germ cells are present mainly in the form of spermatogonia in the male and oocytes in the female.

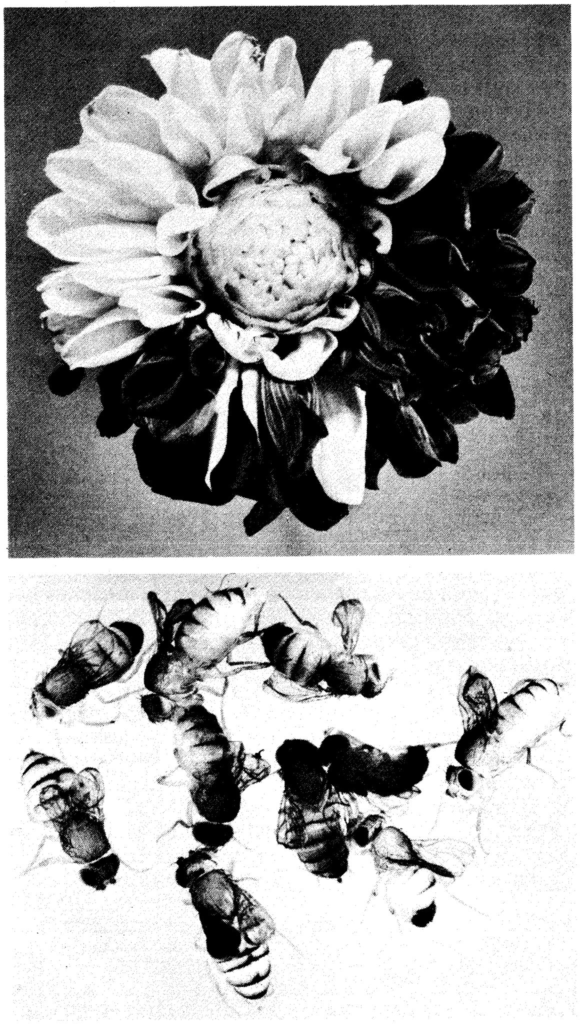
The amount of mutation induced by radiation is usually expressed in terms of the mutation-ratedoubling dose, which is the dose that induces as much mutation as already occurs spontaneously in each generation. This is merely a mathematically convenient way of relating the amount of induced mutation to that arising spontaneously; there is no special biological significance in a mutation rate twice the spontaneous rate. The more sensitive the genes to radiation, the lower the doubling dose. Doubling doses for high-intensity exposure of several different organisms have been found experimentally to lie between about 30 and 150 roentgens; for seven specific genes in spermatogonia of the mouse, the doubling dose is about 30 roentgens for high-intensity exposure and about 100 roentgens for low-intensity exposure. Very little is known about the doubling dose for human genes; most geneticists assume that it is about the same as the doubling dose for the mouse. Studies of the children of survivors of the atomic-bomb explosions at Hiroshima and Nagasaki have not so far yielded radiation-induced mutations in humans (see below).

The linear law

The existence of a linear law relating induced gene mutation to radiation dose holds an important implication for populations: it implies that very small doses of radiation given to very large numbers of individuals may introduce into the population as many mutant genes as would be introduced through large doses to small numbers of individuals. Furthermore, it is necessary to take into consideration the probability that an exposed individual will contribute to the next generation at some time after exposure. It follows that exposure of individuals below reproductive age (including unborn fetuses) is genetically of the greatest importance, and exposure of those above reproductive age is of no importance.

The effect on a population of a rise in its mutation rate depends on the role played by mutation in determining the characteristics of the population. Deleterious genes enter the population through mutation, but, because they reduce the fitness of their carriers, they tend to die out; thus a genetic equilibrium is set up at a point where the flow of deleterious genes into the population through mutation is counterbalanced by the loss through reduction in fitness. At equilibrium a constant fraction of the population rate would increase the gene-handicapped fraction proportionately. The full increase, however, would not be manifest immediately; this would occur only when genetic equilibrium had again been established, which would probably require several generations.

Chromosome mutations. Ionizing radiations not only cause genes to mutate but also may break the chromosomes in which the genes are carried. Chromosome breaks often heal spontaneously, in which case no damage becomes apparent. If a break fails to heal, a germ cell may be formed that lacks an essential part of the gene complement. This is called deletion. Such a germ cell may be capable of taking part in the fertilization process, but the ensuing zygote is usually incapable of full development and dies in an embryonic state. When two chromosomes in the same nucleus are broken, it sometimes happens that the broken ends join together, but in such a way that the order of the genes in the chromosomes is changed; for example, part of chromosome *A* may join onto part of chromosome *B* and vice versa in a process termed translocation. A germ cell carrying such a chromosome structural change may be capable of giving rise to a zygote that may develop into an adult individual, but the germ cells produced by the latter include many that lack the normal chromosome complement and so give rise to zygotes that are incapable of full development. An individual of this sort is called semisterile, and the number of his descendants is correspondingly lower than normal. Chromosome structural changes, therefore, usually die out of a population; for this reason they are of little importance in human populations. In some species, however, there are mechanisms that reduce the loss of fertility usually associated with chromosomal changes, and in them such changes may be present in the majority of



The mutational effects of radiation.

individuals. They include the evening primrose (*Oenothera)* and some species of the fruit fly (Drosophila). As would be expected from target-theory considerations, the induction of two-break chromosome changes is not dependent on radiation dose in a simple linear fashion. High doses and doses given at high intensities induce proportionately more changes of this sort.

BODILY (SOMATIC) EFFECTS

Somatic effects due to radiation include all the injuries, long-term and short-term, to al! the cells of the body of an organism—plant or animal.

Cell and tissue damage

Long-term effects. Long-term somatic effects include damage to cells that are continually proliferating, so that the injury is passed on to succeeding cell generations. Such cells are found in embryonic tissues and in those tissues of the adult in which cell division normally continues throughout life; in vertebrates these include the blood-forming tissues, the basal layer of the skin, the intestinal mucosa, and, in the male, the germ cells. Furthermore, the radiation may affect the rate of cell division: the cells may be killed or otherwise rendered incapable of further division; division may be slowed down; or, conversely, tissues in which cell division normally ceases in the adult may escape their normal biological control and cell division may continue. Mosaic sectors have been observed in many organisms exposed to radiations during embryonic development. They include humans who have been exposed during diagnostic examination of the mother; in some fetuses, there was a brown sector in the otherwise blue iris of an eye; in others, there was a black patch in an otherwise blond head of hair. Unilateral and nonheritable expression of a congenital defect of a type that is normally bilateral and heritable is also believed to arise sometimes through somatic mutation. Sometimes the mutant region includes some of the germ cells, and the genetically mutant nature of the mosaicism can be confirmed by a breeding test.

Effects on embryonic tissues

Slowing down or suppression of cell division, including radiation-induced cell death, may have important end results where embryonic tissues are exposed. This is because the rate of cell division is not uniform throughout an embryo; at any one stage of development, the cells in some parts will be dividing rapidly, while, in other parts, there will be relatively little cell division. Exposure to radiation will affect the rapidly dividing tissues more strongly than the others, with the result that the pattern of development will be distorted, and the individual, when adult, will have djsproportionate parts. This phenomenon, which is well-known in experimental plants and animals, is also known in man.

Radiation exposure of the blood-forming tissues leads to a reduction of cell division and therefore to a reduction in the blood-cell count, which may, if sufficiently great, amount to clinically recognizable anemia (for this reason regular blood-celi counts used to be carried out on all radiation workers). Radiation exposure of the germinal tissues likewise leads to **a** reduction of cell division, which may be sufficient, if the dose is large enough, to induce sterility; a dose of 200 roentgens to the gonads of the human male induces temporary sterility, lasting a few months; a gonad dose of about 500 roentgens to either sex induces permanent sterility. Opacity of the lens of the eye, which may develop into a full cataract, has been observed following exposure to ionizing radiation, especially neutrons.

Shortening of the life-span

A further long-term effect of radiation exposure is a general shortening of the life-span, not associated with death attributable to any specific cause. It is a phenomenon well established in laboratory animals, but evidence about its extent in humans is conflicting; the mechanism, whether through gene mutation in somatic cells, a reduction of cell division, or some other cause, has not been established.

Loss of biological control over cell division (*i.e.*, the induction of cancer in animals and distortion of parts in plants) is one of the more serious long-term somatic effects of excessive radiation exposure. It may occur in any tissue. Cancer of the skin was the first long-term effect to be observed; it may result from exposure to ultraviolet as well as to ionizing radiation.

The nature of the dependence of the long-term effects of radiation on radiation dose, type, and intensity is not yet established with certainty. Many authorities assume that the relationship is of a nonthreshold type, meaning that any additional exposure increases the probability of long-term effects occurring. It is a characteristic of the induction of cancer that there may be a long period of time between the causal exposure and the appearance of the effect: for some skin cancers in man, induction periods of 40 years have been recorded.

Short-term effects. A sufficiently large dose of radiation will kill any organism, but the dose required varies greatly from species to species; mammals are killed by less than 1,000 roentgens, but fruit flies may survive 100,000 roentgens, and many bacteria and viruses may survive even higher doses.

This lethal action of radiation can be used as an alternative to heat treatment for sterilizing materials such as surgical sutures. Its application in the sterilization of foodstuffs requires high doses and is a subject for research.

III. Radiation and human health

MAN'S RADIATION BURDEN

Natural sources. Throughout the ages man has been exposed to what is called natural background radiation. This includes radiation from cosmic as well as terrestrial sources. It has probably played the major role in the evolution of life.

Cosmic rays

Cosmic rays (*q.v.*) rain down incessantly on the Earth's atmosphere. The primary particles, protons, helium ions, heavier nuclei, and some electrons interact with atoms of the air and cause secondary radiations—chiefly electrons, gamma rays, and mesons (a class of atomic particles)—by the time they reach the Earth. There is considerable variation in the intensity of cosmic radiation, both geographically and temporally, since sunspots and solar flares influence the primary intensity. For about every 5,000 feet of altitude, the intensity approximately doubles (see Table *3)*. One of the hazards of space travel is a belt of "trapped" radiation that surrounds the Earth at a height of several thousand miles (see VAN ALLEN RADIATION BELTS).

Table 3: Cosmic-Radiation Exposure

location	mean dose in rads* per year
Sea level, temperate zone	0.020–0.040
5,000 ft	0.040–0.060
10,000 ft	0.080–0.120
40,000 ft	2.8
30–600 km	7–15
Interplanetary space	13–25
Van Allen radiation belt (protons)	<1,500
Single solar flare (protons and helium)	<1,000

*Rad is the unit of radiation dose; it corresponds to 100 ergs energy transferred to one gram tissue.

Variations of cosmic-ray dose have occurred during the geological history of the earth by the reversals of the geomagnetic field, which acts as a protective shield at present. Appearance of a supernova near the solar system could cause a sudden rise in cosmic-ray intensity several hundredfold.

Natural radioisotopes

Man also receives external and internal radiation from natural radioisotopes, particularly radium and its daughters, members of the thorium series, potassium-40, carbon-14, and hydrogen-3 (tritium). The last two are produced by cosmic rays, whereas the former are mainly the result of decay of radioisotopes believed to have been present when the Earth was formed. The greater part of external radiation comes from the radioactivity of minerals, whereas radioactive contamination of drinking water and food plays an integral part internally. Drinking waters vary by a factor of 10,000 in their radioactivity content. Among the foods, radium content of nuts and cereals is higher than of milk or meat. Internal doses in normal persons from natural radioactivity are listed in Table 4.

Table 4: Internal Dose Due to Natural Radioactivity

isotope	radioactivity (in curies*)	radiation	dose in rads (per year)	critical organ
Carbon-14	9×10^{-8} per g	beta rays	0.0016	gonads
Potassium-40	10.4×10^{-8} per g	beta rays	0.0165	gonads
Potassium-40	1.15×10^{-8} per g	gamma rays	0.0023	gonads
Radium and daughters	1×10^{-10} in body	alpha, beta, gamma rays	0.0380	bones

*Curie is the unit of radioactivity; one curie corresponds to 37,000,000,000 disintegrations per second.

There are certain localities with relatively high background due to the presence of radioactive minerals near the soil surface. Such areas occur in Brazil, Sweden, and France. The Kerala province of India is rich in monazite sands, with considerable natural radioactivity. External doses due to natural radioactivity from sources such as these are shown in Table 5.

Table 5: External Dose Due to Natural Radioactivity

source	dose in rads per year
Ordinary regions	0.025–0.160
Active regions	
Granite in France	0.180–0.350
Houses in Sweden (alum shale)	0.158–0.220
Monazite alluvial deposits in Brazil	mean0.500;max 1.0
Monazite sands, Kerala, India	0.37–2.8

Man-made radioactivity

Artificial sources. Since the discovery of radioactivity, man has substantially added to his natural-radiation load. Medical X-rays and radioisotopes often are necessary for the diagnosis or treatment of disease. In some countries almost the entire population is exposed to periodic diagnostic X-rays and a significant fraction to therapeutic doses. Therapeutic doses vary widely, depending on, among other things, the disease being treated. Routine diagnostic doses, though they may vary somewhat depending on the apparatus and the operator, usually fall within certain limits (see Table 6).

Table 6: Typical Doses Received in Routine X-Ray Diagnosis

examination	dose per exposure
X-ray photograph	
Chest X-ray	0.04–1 rad
Gastronomical X-ray	1 rad
Extremities	0.25–1 rad
Fluoroscopy	10–20 rads per minute
X-ray movie	25 rads per examination

High-voltage power supplies for radar or television, X-ray machines in shoe stores, dental X-rays, luminous-dial watches, phonograph static eliminators, and television sets give significant doses of radiation, sometimes more than-is warranted. The yearly dose from diagnostic X-rays has become comparable to the dose received from cosmic rays. The United States leads in annual per capita dose as a result of diagnostic procedures, followed by Japan and the United Kingdom. Efforts are being made to reduce diagnostic exposures by design of more efficient X-ray equipment.

Further contributions of man that have become of concern are fallout resulting from nuclear-weapons testing (Table 7) and radioactivity produced in reactors.

Table 7: Worldwide Dose Commitment from Nuclear Tests Prior to 1970*

source	isotope	half-life	dose to bone surfaces (mrad)
External radiation	short-lived (*e.g.*, iodine-131)	8 days	36
	longer-lived (cesium-137)	30 years	36
Internal radiation	strontium-89 and -90	50 days	131
	cesium-137	28 years	21
	carbon-14t	5,730 years	16
Total			240

*North Temperate zones; doses calculated for bone surface.
†Calculated to year 2000 only.

Most of the radioactivity produced in power reactors is safely contained. **A** small percentage escapes as stack gas or liquid effluent and eventually may contaminate the atmosphere and water supplies. Similar problems exist in nuclear-fuel-reprocessing plants. Planned peaceful uses of atomic explosions in digging harbours or in mining minerals far underground would also produce radioisotopes. While atomic plants promise to be abundant and clean sources of energy, they may eventually contribute considerably to worldwide radiation background (Table 8).

The use of coal instead of atomic energy in future power plants will not solve the problem of radioactive contamination since many sources of coal contain natural radioactivity (*e.g.*, radium), which appears in stack gases, in addition to chemical pollutants.

Portable atomic batteries contain large amounts of dangerous radioisotopes (*e.g.*, polonium or plutonium), safely sealed. Atomic-power rockets will be available soon for interplanetary travel. These will produce some radioactive contamination (*e.g.*, hydrogen-3) in interplanetary space.

It appears from the tables that, if the current trends are maintained, by the end of the 20th century the entire human population may be exposed to twice the radiation level from natural sources. It is important to study and

Table 8: Estimate of Long-Lived Radioactive Gases Released in Air and Water by Power Reactors and Fuel-Reprocessing Plants, Global Scale*

type	1970	1980	2000
Curies, released per year krypton-85 equivalent†	17,000,000	200,000,000	1,900,000,000
Curies, released per year hydrogen-3'	340,000	4,000,000	37,000,000
Curies, hydrogen-3 ‡ accumulated in air and water	1,000,000	62,000,000	590,000,000
Curies, hydrogen-3 in air due to cosmic rays	40,000,000–80,000,000	40,000,000–80,000,000	
Curies, krypton-85 accumulated in air	50,000,000	3,000,000,000	25,000,000,000

*Courtesy of Thomas Pigford, University of California, Berkeley. †In units of krypton-85 equivalent, maximum permissible concentration 0.0003 microcurie per litre air. ‡Maximum permissible concentration 3 microcuries per litre air. Amounts shown are much smaller than the permissible concentration if one assumes uniform distribution in atmosphere. Care must be taken that local concentrations should not exceed allowable limits.

understand the possible consequences of these changes in radiation level. It is interesting to note that fusion processes, if they can be shown to be practical for power sources, will produce considerably less radioactivity than fission reactors at a similar power level.

INJURY FROM IONIZING RADIATIONS

Although all forms of radiation, if intense enough, may produce some adverse effects on man, the "hard," or penetrating, ionizing rays, including X-rays and moving atomic particles, present the greatest hazard. Paradoxically, these same ionizing rays, when judiciously used in medicine, constitute a formidable weapon against cancer and an invaluable aid in diagnosis (see RADIOLOGY).

Maximum permissible exposure limits

The concept of maximum permissible exposure to radiation is a much-debated point, subject to change as more information accumulates. Although the body may not be noticeably affected, genetic damage may occur and pass unnoticed for several generations, as was mentioned earlier. Maximum permissible exposures are proposed for persons who, by the nature of their work, are exposed to amounts of radiation beyond that to which the general population is exposed. (Recommendations vary somewhat in different countries; those given in Table 9 are for the U.S.)

Table 9: Maximum Permissible Exposures to Ionizing Radiation for Professional Radiation Workers

organ exposed	exposure in Rem*
Whole body	3 Rem in 13 weeks
Professional emergency dose (once in life)	25 Rem
Accumulated dose under 18 years	no professional exposure permitted
Accumulated dose over 18 years	average of 5 Rem per year, less than 15 Rern in any single year
Skin	8–10 Rem in 13 weeks or 30 Rem per year
Gonads	5 Rem per year
Bone	10 Rem in 13 weeks or 30 Rem per year

*One Rern denotes the dose of radiation of various kinds that cause effects equivalent to one rad of X-rays.

The limiting factor for persons in the general population is based on the genetic hazard. The greater worldwide concern for these heritable, nonthreshold types of radiation damage is expressed in the recommendation of the International Commission on Radiological Protection: for individuals not engaged in radiation–work, the exposure to ionizing radiation should not exceed five Rern in a lifetime, in addition to natural background radiation and to the lowest practical dosages from medical exposure. The permissible exposure levels are being constantly reviewed and adjusted as new evidence becomes available on biological effects.

Rontgec's discovery of X-rays

Historical background. In December 1895 the German physicist Wilhelm Conrad Rontgen demonstrated the first X-ray pictures, among them that of the left hand of Mrs. Rontgen. Within a few weeks the news of the discovery spread throughout the world, and the penetrating properties of the rays were soon exploited for medical diagnosis without immediate realization of possible deleterious effects. The first reports of X-ray injury to various human tissues and to vision came in 1896. In that same year Elihu Thomson, the physicist, deliberately exposed one of his fingers to X-rays and provided accurate scientific observations on the development of roentgen-ray burns.

Also in 1896, Thomas Alva Edison discovered fluoroscopy; he was engaged in developing a fluorescent roentgen-ray lamp when he noticed that his assistant, Clarence Dally, was so "poisonously affected" by the new rays that his hair fell out and his scalp became inflamed and ulcerated. By 1904 Dally developed severe ulcers on both hands and arms; these lesions, which soon afterward became cancerous, caused his early death. During the next few decades, many investigators and medical doctors developed radiation burns and cancer, and more than 100 persons died, presumably as a result of their exposure to X-rays. These sad early experiences eventually led to an awareness of radiation hazards for professional workers and stimulated development of a new branch of science —radiobiology.

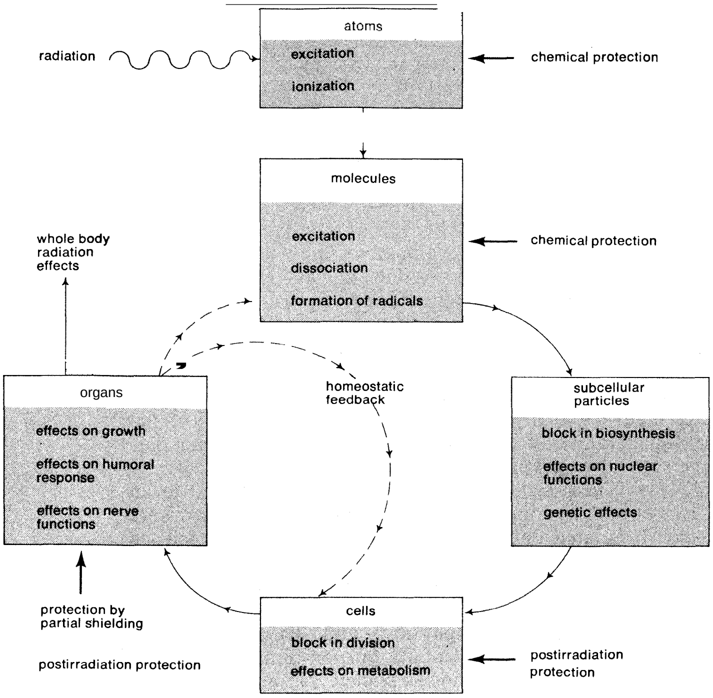
Radiations from radioactive materials were not immediately recognized as being related to X-rays. In 1906 A.-H. Becquerel, the French physicist and discoverer of radioactivity (1896), accidentally burned himself by carrying radioactive material in his pocket. Noting that, Pierre Curie, the codiscoverer of radium, deliberately produced a similar burn on himself. A few months later it was found that radium could be useful in medicine; this discovery led to the founding of the Radium Hospital in Paris in 1906. It was also soon recognized that radium could be very toxic. Beginning about 1925, a number of women in the paint industry, who were exposed to luminescent paint containing radium, became ill with anemia and lesions of the jawbones and mouth; some of these persons later developed bone cancer. The same symptoms appeared in some patients who had received radium internally to relieve arthritis and other diseases. In the 1930s attention was called to these radium hazards, and the practices were stopped.

Accelerator generation of radiation

In 1933 Ernest Lawrence and his collaborators completed the first full-scale cyclotron at the University of California at Berkeley. This machine was a copious source of the neutron rays that had at that time just been discovered by Sir James Chadwick in England. This time, however, human guinea pigs were spared. Ernest, his brother John, and Paul Aebersold exposed rats to the beam of the cyclotron; they found that fast-neutron radiation was about two and a half times more effective in killing power than were X-rays. These facts indicated the need for protection for investigators engaged in research with the cyclotron; thus, a form of shielding was devised for the machine. When the first atomic reactor, built in Chicago, proved Enrico Fermi's principle of self-sustaining fission chain reactions (1942), considerable knowledge of the biological effects of neutrons was already available. Atomic reactors are now rapidly becoming a prime source of power for the world.

Modern accelerators produce a wealth of different types of radiations, including leptons (electrons, positrons, muons, and neutrinos) and hadrons. There are more than 100 known baryons and about 60 known mesons, each with different interaction properties. In addition, since the advent of spaceflight, the effects of certain space radiations on man became of interest. Protons in the Van Allen radiation belts and protons and heavier ions in solar flares and near the top of the atmosphere are of particular importance. As a result, health physics (including radiation shielding and health protection) has become an elaborate discipline.

Radiation effects on cells. To understand radiation effects, it is necessary to study the cellular and subcellular events that succeed a radiation insult and that give rise to gross effects. The work done in this area has already contributed a great deal to the understanding of normal and diseased states. How radiation may inflict biological damage is shown in the accompanying diagram.



General scheme of events *in* radiation action.
Radiation acts on atoms, which in turn cause modification in molecules, cells, and organs as shown. The existence of homeostatic regulation in human body causes highly complex "feedback" interactions. Levels at which various protective agents act are also shown.

Determination of cellular radio-sensitivity

The radiosensitivity of individual human cells in laboratory cultures was first measured in the 1950s on the progeny of human cervical cancer cells (of the strain named HeLa) kept alive in tissue culture. An amazing aspect of radiation effects is that the actual energy needed for producing changes or mutations in genes is exceedingly small—often 1,000 times smaller than chemical or heat energy needed to produce similar changes. HeLa and other available human cells are so sensitive to radiation that half of them are killed by doses of 80 to 300 Rem. The killing effect manifests itself primarily when the cells attempt to divide but cannot do so since their chromosomes are broken and abnormally jointed as a result of radiation. Neuroblasts (nerve-cell progenitors) and cells of the intestinal epithelium, or mucous membrane, and of blood-forming organs exhibit the greatest sensitivity. Rapidly proliferating tissues of the reproductive system are particularly sensitive to radiation. It was demonstrated that spermatozoa in the mouse can be killed by a few roentgens. Given time, however, reproductive organs recover fully from sublethal doses of radiation. Most resistant are adult nerve cells, which owe their resistance to the fact that they do not normally divide; specialized nerve endings and synapses (*e.g.*, in the retina), however, may exhibit great radiosensitivity. At sublethal doses, human cells exhibit delay of cell division following radiation, perhaps as a consequence of a block in the synthesis of new genetic material (deoxyribonucleic acid, or DNA), while the synthesis of proteins goes on. Such cells frequently turn into "giants," having several hundred times normal volume. Late effects—*e.g.*, the initiation of cancerous growth—may have their origin in sublethally injured cells and are in part due to genetic and chromosomal alterations.

Cellular-radiation effects are the complex result of breakage and rejoining of chromosomes and of direct genetic damage of a more subtle nature. The synthesis of new DNA is also usually markedly affected. Effects on membranes and other cell constituents appear to be of secondary importance. In bacterial viruses it is known that radiation can cause breakage in both strands of the DNA molecule, with lethal effect. Many single-strand breaks also occur, but most of these are reparable by enzymes in the cell. Chromosome breakage may be followed by normal or abnormal rejoining of the broken ends. There are mechanisms available in mammalian cells that can repair sublethal injury. Thus, the final effect is dose-rate dependent and is less at low dose rates.

Radiation effects on tissues and organ systems. Since tissues are composed of cells, tissue effects reflect the lethal and sublethal changes in the cells. These initiate a complex defense pattern: cells injured by radiation may release toxic substances; *e.g.*, proteolytic enzymes and nucleases that are able to inflict further injury. The injury is often followed by a regeneration accomplished by increased rate of cell division: the sick cells are often dissolved and removed, and, if recovery is not complete, scar tissue may form.

Inhibition of the proliferation of epithelial tissues with cellular breakdown and increased permeability leads to invasion by pathogens, inflammation, ulceration, loss of fluids, nausea, and diarrhea.

Inhibition of blood formation leads, in the course of days or weeks, to leukopenia (reduction of the number of white cells), which lessens defense against infection; anemia (reduction in the number of red cells), which results in defective oxygen transport; lassitude; anoxia (reduction of oxygen in tissue); bleeding, due to a failure of blood clotting and of platelet synthesis; and some loss of immunity. None of these effects is as yet completely understood by medical science.

Varied effects of radiation

It is known that, because of varied cellular effects of radiation, the function of individual organs can become imbalanced. Since the body has widespread humoral and neuronal interconnections, irradiation of a single organ can modify the functions of the rest of the body. For example, radiation of the spleen and liver causes retardation of nucleic-acid synthesis elsewhere in the body. Another example of this effect is given by irradiation studies on the pituitary of animals and humans. Pituitary irradiation can arrest the growth of a young animal and can affect its sexual development and metabolism. In humans irradiation of the pituitary can arrest proliferation of certain hormone-dependent cancer cells, thereby causing regression of this type of cancer wherever it may be located in the body.

Radiation effects due to whole-body radiation can be lessened by the shielding of particular parts of the body. Shielding of part of the blood-forming system of mice, (*e.g.*, the spleen), increases the radiation tolerance by a factor close to 2. Shielding of other parts of the body also protects, but to a lesser extent. Least protection is afforded by head shielding.

Some investigators claim a chronic deterioration of the central nervous system from moderate dose levels (although others have shown in experiments with monkeys that radiation doses up to lethal levels do not impair learning ability).

Generally speaking, man does not sense a moderate radiation field, though very low doses of radiation, less than one rad, can produce phosphene, a light sensation on the dark-adapted retina. Astronauts on the first spaceship that landed on the moon (Apollo 11, July 20, 1969) observed irregular light flashes and streaks during their flight. These events are probably the result of single heavy cosmic ray particles striking the retina. In some food-preference tests, rats, when given a choice, will avoid radiation fields of even a few roentgens. Three roentgens, probably acting on the olfactory system, are sufficient to arouse a slumbering rat, and a few roentgens can accelerate seizures in mice genetically susceptible to them.

In man and other mammals, the retina and smooth muscle respond to intense pulses of radiation; the cornea and peripheral nerves require much higher dose rates to respond.

Acute lethal effects. Prior to August 6, 1945, there was no known case of widespread loss of human life due to penetrating radiation. On that day the first atomic bomb used in warfare was exploded over Hiroshima causing the death of about 75,000 persons, many of whom died of the effects of radiation. In persons exposed to very large doses of radiation, painful, ugly, and repulsive symptoms occur prior to a delayed death.

During the years since World War II, man has learned to make atomic weapons of more than a thousandfold the power of the Hiroshima bomb, and arsenals of hundreds of such bombs are available in various countries. A study by the United Nations has shown that, if atomic war were to be unleashed in full fury, the effects of the blast, heat, radiation, and fission-product isotopes could kill millions of persons and drastically alter plant and animal populations. This might mean the end of civilization as it is known.

Fatal levels of radiation

In the radiation syndrome leading to death, the greater the dose given, the sooner and more profound the radiation effects. Following a single dose of 400–800 Rem to the whole body, survival is improbable. Very high doses, 5,000 Rem or more, cause immediate and discernible effects on the central nervous system. States of intermittent stupor and incoherence vary with hyperexcitability resembling epileptic seizures. Death is certain within several days This syndrome has been very carefully studied in animals; a human case has been described.

When the dose is between 600 and 1,000 Kem, the earliest symptoms are loss of appetite, nausea, and vomiting, followed by prostration. watery and bloody diarrhea, abhorrence of food, and fever. The blood-forming tissues are profoundly affected, and, in 15 to 30 days, the white-blood-cell count may decrease from about 8,000 to as low as 200 per cubic millimetie. The body loses its defenses against microbial infection, and inflammation of mucous membranes and of intestinal lining may occur. As a result of the reduction in blood platelets, the blood loses its ability to clot, and spontaneous internal or external bleeding may result. Return of the early symptoms, often accompanied by delirium or coma, presages death. Theie can be great individual variation in the symptoms. At lower doses they may be delayed for a few days. Complete loss of hair within ten days has been taken as an indication of the lethal severity of the exposure.

In the dose range 150 to 600 Rem, survival is possible (though in the upper range improbable), and the symptoms appear as above, but in milder form and generally following some delay. Nausea, vomiting, and malaise may begin on the first day, then disappear, and a latent period of relative well-being follow. Anemia and leukopenia set in gradually. After three weeks, internal hemorrhages may occur in almost any part of the body, but particularly in mucous membranes. Susceptibility to infection remains a very great hazard, and some loss of hair occurs. Weight loss, lassitude, emaciation, and fever may last for many weeks before either recovery or death occurs.

Moderate radiation doses

Moderate doses of radiation can interfere seriously with the immunity mechanism. In animals this manifests itself in enhanced sensitivity to bacterial toxins, greatly decreased fixation of antigens, and reduced efficiency of formation of antibodies. Furthermore, antibiotics, unfortunately, appear to have limited effectiveness in combatting postirradiation infections. In the 1960s, plastic isolators became available that allow antiseptic isolation of a person from his environment and thus may protect him from infection from external sources during the period critical for his recovery.

Man is generally able to survive a single dose of less than 150 Rem. The symptoms are similar to those alieady described, but milder and delayed. In doses under 100 Rem, the discernible radiation effects may be so slight that the exposed person is able to continue his normal occupation, though there is measurable depression of his bone marrow, and some persons suffer subjective discomfort from doses as low as 30 Rem. Sublethal doses may have chronic effects many years later.

Prenatal exposure and exposure of children to radiation. During embryonic and fetal development, the human organism is extraordinarily sensitive to changes in the environment that may affect the offspring in spite of the protective mediation of the mother's body. Exposure of the mother to significant doses of radiation may result in chronically expressed injury to her offspring.

Most of the information on the effects of radiation during pregnancy is based on studies with animals. Increased sensitivity is apparent in the period following fertilization. Radiation effects strongly depend on the stage of development of embryo and fetus at the time of exposure. For example, congenital malformations are caused in rats and mice when exposure occurs during periods of initial formation of the organs. Exposure of the rat embryo to 200 rads during early embryonic life is more likely to kill the embryo than to cause congenital malformations, whereas irradiation in late pregnancy is more likely to produce functional abnormalities in the offspring than lethal effects or malformations.

Radiation-caused defects

A wide variety of radiation-induced malformations have been observed in small rodents. Many of these are malformations of the nervous system and include microcephaly (reduced size of brain), exencephaly (part of the brain outside the skull), hydrocephaly (enlargement of the head due to excessive fluid), and anophthalmia (failure of the eyes to develop). Such effects follow doses of 100–200 rads at the appropriate time period. At a dose of 25 rads, only eye anomalies are seen; 20–50 rads in late pregnancy cause disorganization in the microscopic structure of rat brain; ten rads cause some retardation and alteration in the rate of development of the cortex. Functional abnormalities seen in animals after prenatal radiation include abnormal reflexes, restlessness and hyperactivity, impaired learning ability, and susceptibility to externally induced seizures. The malformations induced by radiation are similar to those that can be caused by specific virus infection and certain types of neurotropic drugs, pesticides, and. mutagens.

In human populations, 1 to 2 percent are born with malfunctions of the nervous system. Several studies have established that children born to mothers who received radiation to the pelvic region during pregnancy have much higher incidence of anomalies, particularly of the microcephalic type. A study was conducted among several hundred pregnant women who survived the Hiroshima or Nagasaki atomic explosions. Their children were medically observed for more than 20 years. At the higher dose levels, many of these children developed smaller than normal head size, and among these there was a significant increase in the incidence of mental retardation (10 percent at 100-rad dose). The greatest sensitivity to such effects occurs between the second and sixth months of pregnancy. There is also an increased risk of leukemia and of malignancies for children whose mothers were exposed to radiation during pregnancy. This risk is greater when radiation exposure is prolonged over several weeks: for single doses, the risk of mental retardation is greater.

Radiation exposure of children during the first few years of life causes somewhat similar effects as irradiation of the fetus during late pregnancy. The major source of information is from studies of cases treated for tumours and conditions of the scalp. Therapeutic doses can lead to the induction of tumours, particularly those of the thyroid and of the nervous system, to leukemia, and to retarded mental development. Mongolism (Down's syndrome), a severe form of mental retardation, is associated with a known chromosome abnormality. It probably can be caused by radiation, viruses, and chemical agents.

It is clear from the above that the exposure of pregnant mothers to excess radiation entails risks for their offspring. It is prudent to avoid extensive X-ray diagnosis or therapy unless the mother's health warrants it. At the same time radiation should not be construed as a major current cause of developmental abnormalities or of mental retardation. The latter condition is clearly related to other causes: malnutrition of the mother and the newborn (often related to poverty) and genetic factors are responsible for the great majority of cases.

Protection against external radiation. Great efforts have been made by scientists of many countries to find agents that will increase radioresistance of the body.

Oxygen deprivation and radiation effects

Findings in 1933 that living systems deprived of oxygen are more radioresistant and, in 1942, that newborn rats kept in carbon dioxide atmospheres were twice as resistant as their litter mates kept in air went largely unnoticed until 1950. In that year it was demonstrated that large doses of the amino acid cysteine given prior to irradiation provided substantial protection against radiation effect. Following this discovery, many substances were found with some protective action (Table 10). Although the matter is still under debate, it appears that many of these substances act by producing anoxia or by competing for oxygen with normal cell constituents and radiation-produced radicals. Since anoxia is in itself a highly hazardous physiological state and all protective compounds tried thus far are toxic, it cannot be said that protection of humans by these drugs prior to radiation exposure is a practical matter.

Table 10: Some Chemical Protectors Effective in Mice or Rats

class	specific chemical	effective dose (in milligrams per kilogram of tissue)
Sulfur compounds	glutathione	1,000
	cysteine	1,000
	cysteamine	150
	AET*	350
Hormones	estradiolbenzoate	12
	ACTH	25 for 7 days
Enzyme inhibitors	sodium cyanide	5
	carbon monoxide	by inhalation
	mercaptoethylamine (MEA)	235
	para-aminopropiophenone (PAPP)	30
Metabolites	formic acid	90
Vasoconstrictors	serotonin	50
Nervous system drugs	amphetamine	1
	chlorpromazine	20

*Aminoethylisothiuronium bromide hydrobromide.

Beginning in 1961, some diurnal changes in the radiosensitivity of rodents were reported—an indication that the complex humoral factors responsible for daily rhythms also alter the response of tissues to radiation. On the other hand, a few classes of substances are known that render animals more sensitive to acute radiation effects. Several compounds sensitize mice or rats to radiation. Perhaps the most interesting of these is the hormone thyroxine, a normal secretion of the body. A large class of sensitizers at the cellular level include nucleic-acid analogues (*e.g.*, 5-fluoro-uracil).

It may appear from the foregoing that acute radiation syndrome in mammals is the result of complex interaction from many affected organ systems. Nevertheless, it was shown in the early 1960s that there is some genetic control of radiosensitivity, since susceptible and resistant mouse strains were developed. Inability of recovery of the hemopoietic (blood-forming) system appears to be linked with high radiation sensitivity.

The contribution of germ-free studies

Beginning with the 1950s, the Lobund laboratories of Notre Dame University, which pioneered in the study of germ-free animals, have shown that germ-free mice that spend their entire lives in a sterile environment exhibit greater resistance to radiation than do animals in a normal environment, no doubt due in part to elimination of the hazards of infection.

For many years it was held that cure of radiation disease was hopeless since events were thought to be irreversible once a person had received a lethal dose. It was historically important, therefore, when it was demonstrated in mice that ground substance of embryo, spleen, or bone marrow administered following irradiation allowed the animals to survive what would otherwise be a lethal dose of X-rays. It is hoped that detailed study of this will lead to understanding of various physiological processes.

It has been shown that most of the effect of transfused bone marrow depends on the provision of intact, living cells, which then migrate to the marrow of the irradiated host and proliferate there, repopulating the host's marrow with cells characteristic of the donor. Bone-marrow transfusion between animals of different strains is successful in these cases because the irradiated animal loses its ability to develop antibodies against the injected "foreign" tissue. If the injected bone marrow proliferates rapidly enough, it may save the host from acute lethal effects of radiation.

Mammals that carry successful grafts of bone marrow become chimeras; *i.e.*, organisms producing cells of more than one genotype. Several months later, the transplanted tissue may develop a disease sometimes called wasting disease (or homologous disease). This is an immune reaction between the proliferating donor cells and the irradiated host and is often rapidly fatal.

If bone marrow could be taken with ease (as blood is taken) from normal human volunteers and then cultured and preserved under refrigeration and injected only into immunologically compatible individuals, it might prove to be a powerful therapeutic agent against radiation disease. Transfusion of fresh, normal human bone marrow has already demonstrated some worth in alleviating radiation effects. In 1958 an unfortunate accident occurred at a nuclear reactor in Yugoslavia in which five persons were exposed to near-lethal doses of mixed neutron and gamma radiation. They were flown to Paris, where four of them received human bone-marrow transfusions. As judged by their recovery, several of these men were considerably benefitted. In time it will be feasible to culture cells in the laboratory for transplanting into a victim of radiation sickness. Cultured cells are not yet suitable for the therapy of radiation disease by transfusion.

Organ and tissue transplantation

Bone-marrow transfusion, as well as transplantation of other organs, may be of importance in future control of various seemingly incurable conditions; *e.g.*, leukemia and some types of anemia. The clue to successful bone-marrow transplantation is the complete understanding of the genetic and biochemical aspects of immunological compatibility. Only when this knowledge is attained will transplantation of bone marrow (and also of essential organs such as heart, pancreas, or kidney) become established as a safe and feasible medical practice.

Long-term effects, somatic and genetic. Much of man's radiation exposure is at very low levels. There are some components of natural and man-made radiation (see below) to which persons may be exposed continuously or intermittently through most of their lives. Usually the effects of such low-level radiations are so minute that often even the most refined methods fail to demonstrate immediate functional effects or late deleterious effects that can be unequivocally assigned as the effects of radiation on the individual. Instead, long-term effects must be studied on a statistical basis in a population of individuals, and they are usually described as altered statistical risks for the populations. These risks are: lower average life expectancy, reduction in fertility, acceleration of the rate of mutations, and increase in the occurrence of chronic diseases such as cancer or cataracts. While these effects may be brought about by radiation, they are also affected by a host of environmental and hereditary factors.

Significant doses of radiation delivered daily (*e.g.*, 0.5 rad per day or more) cause rats and mice to become physiologically older than their actual age would indicate, with subsequent shortening of life-span. Some experiments with mice, however, showed a life-span lengthening for 0.1 rad daily dose. It is exceedingly difficult to make valid deductions from animal data to human beings. Data for radiologists, whose radiation exposure is assumed to be greater than that of other segments of the population, provide some information on radiation effects in man. A study of British radiologists showed that their mortality generally was lower than that of other doctors, whereas the mortality of American radiologists was found higher than that of their colleagues in ophthalmology and otolaryngology. A sample of nearly 100,000 survivors of Hiroshima and Nagasaki yielded the anomalous result that groups exposed to doses between 11 and 120 rads actually had a lower death rate in the ensuing 15 years than those receiving a lesser dose. Results such as these point to the fact that there are great variations in life-span due to many factors. Despite conflicting data, for the sake of health-protection estimates, the life-shortening effect of one rad on man may be assumed to lie between two and 15 days.

There are several concepts of the nature of radiation-induced aging. One theory maintains that all disease ex-

Radiation-induced aging

periences from early childhood, as well as toxic factors in the environment, act together to determine the physiological age of an individual. According to this model, the fallout-radiation hazard currently is much less of an aging factor than cigarette smoking, lack of exercise, obesity, or childhood diseases. Another concept, one more specific to radiation injury, states: the aging effect produced by radiation is due to the number of irreversible chromosome aberrations produced in the somatic (tissue) cells of mammals. Many of the chromosome aberrations can be demonstrated in blood cells or in liver cells several months following exposure to radiation, and chromosome aberrations have generally been associated with impaired cellular function. Neither of these theories has thus far been able to account fully for the modifying effects of the hormonal system.

Radiation effects on fertility

A dose of a few hundred Rem is believed unlikely to impair the fertility of normally fertile women, and it is believed that up to 15 Rem yearly will not impair the fertility of normally fertile men. The doses that cause genetic effects to the population are delivered in the years prior to conception of children. Although there are many genetic data for mice, it is difficult to arrive at reliable genetic estimates for man, since genetic effects occur at the chromosome as well as the gene level. H.J. Muller, the discoverer of mutation induction by radiation, suggested that recessive lethal mutations constitute the greatest genetic hazard; they can penetrate the population in the course of many successive generations and exert their toll, mainly when they appear in individuals born to parents who both carry the recessive lethal gene. Furthermore, certain chromosome mutations (*e.g.*, when chromosomes are present in abnormal numbers) also represent important genetic risks. In any case, it appears that lethal mutations exert their greatest effect in the first generation born subsequent to radiation exposure but that in subsequent generations more lethals will appear due to the same recessive genes. In a population of 1,000,000 persons who have been exposed to an average dose of one Rem, about 2,000 fatalities will be observed in the course of ten successive generations. This is, however, less than 0.1 percent of the fatalities that will occur in the same population in the same time due to the normally present "genetic load of lethal genes in the population. The normal lethal genetic load will approximately double when a population is exposed to a dose of 60 Rem. Such estimates usually are made by assuming that all radiation doses are strictly additive and that the effect is proportional to the total dose. Evidence has been mounting, however, that genetic radiation damage is almost completely repaired in the female reproductive system at low dose rates of X- or gamma rays. The effect on the male reproductive system may be less than previously assumed, due to the fact that normal sperm has better viability and motility than sperm carrying radiation-induced damage. Genetic effects from neutrons have been reported to repair less than effects from gamma rays; neutrons also are responsible for many more chromosome aberrations.

"Good" and "bad" mutations

It is generally believed that most of the radiation-induced mutations are "bad" in the sense that they are lethal or usually impair some property. It is also known, however, that a fraction of induced mutations are "good" and that mutations are essential to maintain a steady rate of evolutionary change. Evolutionary changes occur at random and tend to better adapt the species to its environment. Some data on populations of fruit flies indicate that radiation can be useful in accelerating the rate of evolution when the population faces an environmental crisis.

Radioisotopes and fallout. Radioactive isotopes usually emit electrons or positrons, alpha particles or gamma rays, or even characteristic X-rays. The exposure may be external, in which case penetration is an important factor. Alpha particles do not penetrate deeply enough in the skin to cause damage. Beta particles or X-rays over 30 kilovolts can be hazardous to the skin, causing redness, loss of hair, or ulceration. Large doses may cause skin cancer.

Isotopes can also enter the body by ingestion, inhalation, or injection. Their radiation effects then depend on their internal distribution, duration of retention in the body, energies, and rate of radioactive decay (half-life or half-value period). The problem is enormously complicated since isotopes have different and sometimes elaborate distribution patterns.

ACCUMULATION OF ISOTOPES IN CRITICAL ORGANS

The term critical organ has been assigned to that part of the body that is most vulnerable to a given isotope. The critical organ for plutonium, radium, strontium, and many other fission products is bone and the adjacent bone marrow. For soluble fission products (and also some forms of uranium), which will distribute in the entire body, the critical organs are the gonads, or sometimes the kidneys. For iodine the critical organ is the thyroid gland. Insoluble airborne radioactive dust often deposits in the alveoli of lungs, while colloidal particles of very small size can reach the bone marrow, liver, or spleen. Table 11 is an abbreviated list of the maximum permissible concentrations (U.S. recommendations) for man of some radioisotopes. (Maximum permissible concentration is the greatest amount of a radioisotope that can be accumulated in the body without producing noticeable damaging effects; compare with maximum permissible dose, which is applicable to radiation received from external sources.)

Table 11: Maximum Permissible Concentration (MPC) of Some Radioisotopes

isotope	chemical form	critical organ	microcuries in body
Tritium (hydrogen-3)	water		2,000
Carbon-14	carbon dioxide		400
Strontium-90*	water soluble salt		40
		bone	4
Iodine-131	water soluble salt		50
		thyroid	0.7
Cesium-137	water soluble salt		30
Radon-2221	gas		
Radium-226‡	water soluble salt		0.2
		bone	0.1
Uranium	water soluble salt		0.2
		kidney	0.005
Plutonium-239	water soluble salt		0.4
		bone	0.04

*MPC in drinking water: 0.001 microcurie per litre. †MPC in air: 0.00001 microcurie per litre. ‡MPC in drinking water: 0.0001 microcurie per litre.

Since isotopes continuously deliver radiations to the surrounding tissue, one must distinguish between the effect of protracted continuous exposure and simple acute or periodically repeated exposures. For beta and gamma radiations and X-radiation, utilizing split-dose delivery, it has been found that up to about 60 percent of an acute radiation effect "disappears" within several hours; the body, therefore, is able to tolerate a greater total dose when the dose is protracted or when part of it is given at later times. For neutron and alpha radiation the recovery is less. (Neutrons are generally more effective agents of mutation than are X-rays: for acute effects, by a factor of 1 to 8; for long-term effects of chronic radiation, by a factor up to 35.) Studies of such repair processes are complicated by age effects of persons exposed.

Fallout is the deposition of airborne radioactive contamination on earth. Radioisotopes may be produced naturally in the air by cosmic radiation or may enter the air from stack gases of atomic reactors following industrial accidents or from bombs or bomb tests. After 1954 bomb tests carried out by several nations produced fallout measurable on the surface of the entire world, arousing great attention and controversy with respect to its health and genetic effects. It is within the realm of practical feasibility to cover a significant portion of the Earth's surface with fallout in time of war. While much of the bomb hazard is due to blast waves and heat, the radiation dose from fission products could be so intense that only persons remaining in underground shelters for some weeks could hope to survive such an attack. Usually the most prominent isotopes in fallout are fission products; however, all materials exposed to nuclear blasts may become radioactive. A list of exposures to fallout isotopes is given in Table 7.

The hazard of long-lived isotopes

Several of the radioisotopes contained in fallout are especially hazardous because they remain radioactive for relatively long periods (have long half-lives). Cesium-137, strontium-90, and plutonium may be the most important of these. On the ground, fallout material can cover external surfaces and foliage and later be washed into the soil, where plants incorporate strontium-90, along with the chemically similar calcium, and cesium-137 with potassium. Humans obtain these radioactive materials mostly from drinking water and from plant and animal foods, including milk. In the sea much of these materials can eventually lodge in the bodies or skeletons of fishes and in plants near the coast.

Strontium-90 becomes concentrated in bone and remains there in steadily decreasing amounts for almost 30 years, producing local irradiation. Its actual concentration within the body is difficult to measure because of the softness of its rays. There is generally lower concentration of strontium-90 in man than in other animals or in plants or soil. Newborn babies, who have actively growing bones, retain relatively greater amounts of strontium-90 than do older persons.

The most easily detectable fallout product in animals and in man is iodine-131; this isotope emits beta and gamma rays and is enriched about 100 times in the thyroid gland through selective accumulation. Because of its relatively short half-life (eight days), iodine-131 is probably not the most hazardous fallout isotope. If a large population, however, is affected by excessive amounts, radiations from this isotope could lead to metabolic disturbances and increased thyroid-cancer incidence, especially in children.

Discharges of atomic-power plants

Atomic-power reactors discharge a mixture of radioactive gases into the atmosphere. Reactors are placed at sites where the atmospheric mixing and transport are such that the short-lived gases decay and are diluted before they can be inhaled in appreciable amounts by the population. The long-lived gaseous products are usually quoted in units of krypton-equivalent. When inhaled, krypton-85, a radioisotope of ten years half-life (half the radioactivity will disappear in ten years), is preferentially deposited in body fat. Projected krypton-equivalent concentrations from power reactors for the end of this century appear high, suggesting the need for better containment of the gaseous products of reactors in the future (Table 8).

Many fallout isotopes that reach the sea and inland waterways eventually end up in concentrated form in the bodies of waterborne animals and plants and become a source for concern when they are part of the food chain for man. Radioactive iodine, for example, has shown up in many fish and shellfish.

Methods that have been developed for biological protection from fallout extend from efforts for keeping isotopes out of the body to biochemical means for rapid elimination of isotopes from tissues. At times of atomic emergencies, airborne radioactive particles may be kept from the lungs by masks having suitable filters. Ingested isotopes may be prevented from being absorbed in the intestinal tract by certain mucoprotein substances that show great surface affinity for adsorption of strontium and other substances. In 1964 Canadian investigators demonstrated that sodium alginate prepared from the brown seaweed kelp is particularly useful in this regard. It is possible to remove virtually all radioactive strontium from cow's milk without affecting the essential nutritive components. Certain chelates—for example, EDTA (ethylenediaminetetraacetic acid)—will react with strontium and "cover" this atom. As a result, when EDTA is present in the blood, deposition of strontium in bones is reduced (elimination of already deposited isotopes also is somewhat accelerated). Most chelating agents are not specific for strontium; unfortunately, they also chelate the closely related and important element calcium.

Radiation and cancer. The role of large doses of radiation in increasing the incidence of cancer and leukemia cannot be questioned—it has been demonstrated in all animal species tested thus far. Studies of animal populations have indicated that the onset of cancer can be delayed by many years following radiation exposure and that protracted radiation exposure is more carcinogenetic than single exposures. Initially, radiation may produce precancerous lesions in the cells of the body, but it may take some additional factors to turn those lesions into malignant tumours.

It is interesting to note that radiation-induced leukemia in certain strains of mice can later be propagated to other members of the mouse population by a virus factor. It appears that the role of radiation in this instance might be to activate a leukemia virus already present in mice.

Radiation as one of many factors in cancer induction

Generally speaking, the increased cancer incidence in irradiated populations parallels radiation-induced aging and may be a manifestation of the older physiological age of the irradiated individuals. Studies of the origin of cancer point to a number of factors, including genetic, hormonal, and injurious factors (chemical, radiation, or virus), that usually act together to produce cancer. The great majority of cancer and leukemia cases in the Earth's population is probably not caused by radiation but by other agents. Nevertheless, the following generalizations are true in most instances:

1. There is often a long delay between radiation exposure and the appearance of tumours (in human beings the delay may be many years).
2. Higher radiation doses usually lead to more tumours, and sooner, than do lower doses.
3. Tumours often arise from precancerous groups of cells, not necessarily from a single cell.
4. Densely ionizing radiation (*e.g.*, neutrons, alpha particles) are more effective in inducing cancer than lightly ionizing X- or gamma rays.

The relationship of radiation to human cancer has been studied almost exclusively in persons who, by their occupations, are exposed to high radiation doses. Cancer induction from radiation below the permissible exposure levels has not been identified. It is the task of health-protection experts and special government agencies (*e.g.*, the U.S. Federal Radiation Council) to set the permissible radiation levels so that the risk for cancer induction is either negligible compared to other risks or at least tolerable in view of the beneficial effects of radiation to humanity.

Radiation induction of leukemia

The role of induction of leukemia in man at doses higher than 50 rads appears proportional to dose. Only acute leukemia and chronic myeloid leukemia seem to be induced. A number of such leukemias appeared among the survivors of Hiroshima and Nagasaki and in a special group of British patients who received large doses of radiation for the rheumatic condition of ankylosing spondylitis. From these data it appears that one rad induces 1.5 cases of leukemia per 1,000,000 individuals per year, or a total of 20 cases per rad per 1,000,000. The incidence in children, exposed under ten years of age, is about twice as high; the induction of acute lymphatic leukemia is particularly age dependent.

In addition to leukemia, other malignancies also are induced. After large doses of radiation, the number of all induced cases combined appears to be about twice the number of leukemias. There are many questions to be settled in connection with these figures; among these are the problem of accumulation of low daily doses and whether or not cancers that have a high spontaneous incidence are also more prone to be induced by radiation.

Incidence of bone and lung tumours

The human population carries a body burden of about 0.0001 microcurie of radium and has a natural incidence of four to seven bone sarcomas per 1,000,000 individuals per year. Radium, an alpha-particle emitter, has somewhat similar chemical properties as calcium, and it remains deposited in bone for many years. Some hundreds of individuals exist who have several microcuries in their bodies; these were radium-dial painters or individuals who may have received radioactivity as a therapeutic measure (in the 1930s) for arthritis and other conditions.

The incidence of bone tumours in this population appears to be higher when the body burden is more than 0.5 microcurie.

It has been known for some time that radium and uranium miners have a high incidence of lung tumours. Radioactivity can find its way to the lungs by inhalation of gas (radon) or of radioactive-dust particles that may become lodged in the lungs. Since a single dust particle can give off significant local radiation, the radioactive-dust content of the mines must be kept at a safe level. In the initiation of lung tumours, several factors interact; nonradioactive dust can cause silicosis and, perhaps, some cancer. Smoking and radioactive-mine exposure caused more lung cancer than either of these factors singly.

Chromosome aberrations and radiation. It has long been known that a major expression of radiation effect occurs in the form of chromosome aberrations. These have been studied in human-cell cultures, prepared from a variety of organs, and in leucocytes, or white blood cells. Chromosome aberrations, at the rate of a few cases per 1,000 cells, can be found in human blood from very low doses of radiation of only a few rads, and some of these aberrations persist in the body for several years. With the establishment of accurate dose-effect relationships, the frequency of certain types of aberrations can give information on the degree of radiation exposure of individuals.

In addition to causing chromosome breaks and rejoinings, radiation can also produce aneuploidy (abnormal number of chromosomes in cells) and polyploidy (multiple chromosome numbers).

Tumour cells in many forms of cancer also carry chromosome aberrations, and, in advanced forms of cancer, there is often extensive fragmentation and regrouping of chromosomes. Whether radiation-induced chromosome breaks cause cancer or are a consequence of cancer is not known with certainty.

There is only one type of human neoplasm, chronic granulocytic leukemia, where a specific chromosome abnormality is seen in over half of the cases. Chromosome 21, the "Philadelphia" chromosome, named after the city where it was discovered, lacks about one-half of its longer arm. Other conditions where specific chromosome abnormalities are seen include Down's syndrome (see above), Waldenstrom's macroglobulinemia, Burkitt's lymphoma, and multiple myeloma. The study of chromosome aberrations in human cells and tissues is extremely tedious because of the smallness of chromosomes and the need to carefully observe several thousand in each individual case. The use of computers may help to differentiate normal from abnormal patterns.

EFFECTS OF HERTZIAN WAVES, INFRARED RAYS

Effect of long radio waves

Hertzian waves. The effects of Hertzian waves (electromagnetic waves, radio waves, and microwaves or radar waves) and of infrared rays usually are regarded as equivalent to the effect produced by heating. The longer radio waves induce chiefly thermal agitation of molecules and excitation of molecular rotations, while infrared rays excite vibrational modes of large molecules and release fluorescent emission as well as heat. Both types of radiation are preferentially absorbed by fats containing unsaturated carbon chains.

The fact that heat production resulted from bombardment of tissue with high-frequency alternating current (wavelengths somewhat longer than the longest radio waves) was discovered in 1891, and the possibility of its utilization for medical purposes was realized in 1909, under the term diathermy. This method of internal heating is beneficial for relieving muscle soreness and sprain. Diathermy can be harmful, however, if so much internal heat is given that the normal cells of the body suffer irreversible damage. Since man has heat receptors primarily in his skin, he cannot be forewarned by pain when he gets a deep burn from diathermy. Sensitive regions easily damaged by diathermy are those having reduced blood circulation; *e.g.,* bone or the lens of the eye. Cataracts of the eye lens have been produced in animals by microwave radiation applied in sufficient intensity to cause thermal denaturation of the lensprotein.

Microwaves and their application

Recently, microwave ovens have found widespread use in commercial kitchens and some homes. These can heat and cook very rapidly and, if used properly, constitute no hazard to operators. In the radio–television industry and in the radar division of the military, persons are sometimes exposed to high densities of microwave radiation. The hazard is particularly pronounced with exposure to masers, capable of generating very high intensities of microwaves (*e.g.,* carbon dioxide masers). The biological effects depend on the absorbency of tissues. At frequencies higher than 150 megahertz, significant absorption takes place. The lens of the human eye is most susceptible to frequencies around 3,000 megahertz, which can produce cataracts. At still higher frequencies, microwaves interact with superficial tissues and skin, in much the same manner as infrared rays.

Acute effects of microwaves become significant if a considerable temperature rise occurs. Cells and tissues eventually die at temperatures of about 43° C (109" F). Microwave heating is minimized if the heat that results from energy absorption is dissipated by radiation, evaporation, and heat conduction. Normally one-hundredth of a watt (ten milliwatts) can be so dissipated, and this power limit generally has been set as the permissible dose. Studies with animals have indicated that, below the permissible levels, there are negligible effects to various organ systems. Microwaves or heat applied to testes decrease the viability of sperm. This effect, however, is not significant at the "safe" levels.

Some investigators in the Soviet Union have documented a variety of nonthermal effects of microwaves and recommend about 1,000 times lower safe occupational dose levels than are in force in the United States. Most prominent among the nonthermal effects appear to be those on the nervous system. These have resulted in untimely tiring, excitability, and insomnia registered by persons handling high-frequency radio equipment. Nonthermal effects have been observed on the electroencephalogram of rabbits. These may be due to changes in the properties of neural membranes or to denaturation of macromolecules.

The heating effect of high-frequency waves and currents has had some use in surgery. The first surgical use of shortwaves (eight megacycles) was made in destroying a patient's tonsils without the necessity of giving an anesthetic. This procedure produces cutting by heat coagulation of tissue without producing bleeding. It has been used to cut certain structures (*e.g.,* the dura membranes) in brain surgery and in minor skin operations. Higher frequency electromagnetic waves (about ten megahertz) are also used in brain surgery for producing "heat lesions" in the treatment of Parkinson's disease and cerebral palsy. Such heat lesions produced in certain parts of the brain may temporarily relieve the tremors accompanying these diseases. (For laser therapy, see below Effects of lasers.)

Hazards of infrared radiation

Infrared rays. An important part of solar energy reaches the earth in the form of infrared rays. Absorption and emission by the human body of these rays plays an important part in temperature exchange and regulation of the human body. Principles of infrared emission and absorption must be considered in the design of air conditioning and of clothing.

Overdosage of infrared radiation, usually resulting from direct exposure to a hot object (including heating lamps) or flame, can cause severe burns (flame burns). While infrared exposure is a hazard near any fire, it is particularly dangerous in the course of atomic chain reactions. In the course of an atomic detonation, a brief but very intense emission of infrared occurs, together with visible and ultraviolet light emitted from the fireball (flash bums). Of the total energy of nuclear explosion, as much as one-third may be in the form of thermal radiation, moving with the velocity of light (186,000 miles per second). The rays will arrive almost instantaneously at regions removed from the source by only a few miles. Smoke or fog can effectively scatter or absorb the infrared components, and even thin clothing can greatly reduce the severity of bum effects. See also BURNS.

EFFECTS OF VISIBLE AND ULTRAVIOLET LIGHT

Life could not exist on Earth without light from the sun. Plants utilize the energy of the sun's rays in the process of photosynthesis to produce carbohydrates and proteins, which serve as basic organic sources of food and energy for animals. Light is a powerful regulating influence on many biological systems. Most of the strong ultraviolet rays of the sun, which are hazardous, are effectively absorbed by the upper atmosphere. At high altitudes and near the Equator, the ultraviolet intensity is greater than at sea level or at northern latitudes.

Very shortwave ultraviolet light, below 2200 angstroms (A), is highly toxic for cells; in the intermediate range, the greatest killing effectiveness on cells is at about 2600 angstroms (one angstrom equals $\frac{1}{10,000,000}$ millimetre). The nucleic acids of the cell, of which the genetic material is composed, strongly absorb rays in this region. This wavelength, easily available in mercury vapour, xenon, or hydrogen arc lamps, has great effectiveness for germicidal purification of the air.

Since penetration of visible and ultraviolet light in body tissues is small, only the effects of light on skin and on the visual apparatus are of consequence. When incident light exerts its action on the skin without additional external predisposing factors, scientists speak of intrinsic action. In contrast, a number of chemical or biological agents may condition the skin for action of light; these latter phenomena are grouped under photodynamic action. Visible light, when administered following lethal doses of ultraviolet, is capable of causing recovery of the cells exposed. This phenomenon, termed photorecovery, has led to the discovery of enzyme systems capable of restoring damaged nucleic acids in genes to their normal form. It is probable that photorecovery mechanisms are continually operative in some plants exposed to direct action of sunlight.

The surface of the Earth is protected from the lethal ultraviolet rays of the sun by the top layers of the atmosphere, which absorb far ultraviolet, and by ozone molecules at the stratosphere, which absorb most of the near ultraviolet. Even so, it is believed that an enzymatic mechanism operating in the skin cells of individuals continually repairs the damage caused by ultraviolet to the nucleic acids of the genes. Some scientists believe that exhaust gases from supersonic planes flying above the stratosphere could diminish the thickness of the ozone layer, thus exposing persons to more intense ultraviolet radiation at ground level. Others fear that pollution produced at ground level may increase the ozone layer and eventually diminish the overall intensity of light radiation.

Quality of light and its effects

There is some evidence to indicate that not only overall light intensity but also special compositions have differential effects on organisms. For example, in pumpkins, red light favours the production of pistillate flowers, and blue light leads to development of staminate flowers. The ratio of females to males in guppies is increased by red light. Red light also appears to accelerate the rate of proliferation of some tumours in special strains of mice. The intensity of incident light has an influence on the development of light-sensing organs; the eyes of primates reared in complete darkness are much retarded in development.

Intrinsic action. Light is essential to man because of its biosynthetic action. Ultraviolet light induces the conversion of ergosterol and other vitamin precursors present in normal skin to vitamin D, an essential factor for normal calcium deposition in growing bones. While some ultraviolet light appears desirable for formation of vitamin D, an excess amount is deleterious. Man has a delicate adaptive mechanism that regulates light exposure of the more sensitive deeper layers of his skin. The transmission of light depends on the thickness of the upper layers of the skin and on the degree of skin pigmentation. All persons except albinos are born with varying amounts of melanin pigment in their skins. Exposure to light further enhances the pigmentation already present and can induce production of new pigment granules. The therapeutic possibilities of sunlight and ultraviolet light became apparent around 1900, with popularization of the idea that exposure of the whole body to sunlight promotes health.

By that time, it was already known that large doses of ultraviolet radiation caused sunburn, the wavelength of about 2800 angstroms being most effective. It induces reddening and swelling of the skin (due to dilation of the blood vessels), usually accompanied by pain. In the course of recovery, epidermal cells are proliferated, melanin is secreted, and the outer corneal layer of dead cells is thickened. In 1928 it was first shown clearly that prolonged or repeated exposure to ultraviolet light leads to the delayed development of skin cancer. The fact that ultraviolet light, like X-radiation, is mutagenic (induces mutations) may explain its ability to cause skin cancer, but the detailed mechanism of cancer induction is not yet completely understood. There seems very little doubt, however, that skin cancer in man is in some cases correlated with prolonged exposure to large doses of sunlight. Among Negroes who are protected by rich melanin formation and thickened corneal structure of the skin, incidence of cancer of the skin is several times less frequent than it is among white people living at the same latitude.

Light sensitization

Photodynamic action. There are a number of diseases in man and animals in which light sensitivity is involved; for example, hydroa, which manifests itself in blisters on parts of the body exposed to sunlight. It has been suggested that this disease is due to a light-sensitive porphyrin compound found in the blood.

Actually there are many organic substances and various materials of biological origin that make cells sensitive to light. When eosin is added to a suspension of human red blood corpuscles exposed to light, the red corpuscles will break up in a process named hemolysis. Other typical photodynamic substances are rose bengal, hematoporphyrin, and phylloerythrin—all are dyes capable of fluorescence. Their toxicity manifests itself only in the presence of light and oxygen.

Some diseases in domestic animals result from ingestion of plants having photodynamic pigments. For example, St. Johnswort's disease is caused by the plant *Hypericum.* Fagopyrism results from eating buckwheat. In geeldikopp ("yellow thick head"), the photodynamic agent is produced in the animal's own intestinal tract from chlorophyll derived from plants. In humans the heritable condition of porphyria frequently is associated with light sensitivity, as are a number of somewhat ill-defined dermatological conditions that result from exposure to sunlight. The recessively inherited rare disease xeroderma pigmentosum also is associated with light exposure; it usually results in death at an early age from tumours of the skin that develop on exposed areas. The cells of such individuals possess a serious genetic defect: they lack the ability to repair nucleic-acid lesions caused by ultraviolet light.

Certain drugs (*e.g.*, sulfanilamide) sensitize some persons to sunlight. Many cases are known in which ingestion of or skin contact with a photodynamic substance was followed by increased light sensitivity.

Effects on development and biological rhythms. In addition to its photosynthetic effect, light exerts an influence on growth and spatial orientation of plants. This phototropism is associated with yellow pigments and is particularly marked in blue light. The presence of illumination is a profound modifier of the cellular activities in plants as well. For example, while some species of blue-green algae carry out photosynthesis in the presence of light, they do not undergo cell division.

Diffuse sensitivity to light exists also in several phyla of animals. Many protozoans react to light. Chameleons, frogs, and octopuses change colour under the influence of light. Such changes are ascribed to special organs known as chromatophores, which are under the influence of the nervous system or endocrine system. The breeding habits and migration of some birds are set in motion by small consecutive changes in the daily cycle of light.

Light is an important controlling agent of recurrent daily physiological alterations (circadian rhythms) in many animals and probably in humans (see PERIODICITY, BIOLOGICAL). Lighting cycles have been shown to be important in regulating several types of endocrine function: the daily variation in light intensity keeps the secretion of adrenal steroids in synchrony; the annual breeding cycles of many mammals and birds appear to be regulated by light. Ambient light somehow influences the secretions of a tiny gland, the pineal body, located near the cerebellum. The pineal body, under the action of enzymes, produces melanotonin, which in higher concentrations slows down the estrous cycle; low levels of melanotonin, caused by exposure of animals to light, accelerates estrus. It is believed that light stimulates the retina, and information is then transmitted by sympathetic nerves to the pineal body.

Effects of light on biological rhythms

Effects on the *eyes*. The wavelength of light that produces sunburn can also cause inflammation of the cornea of the eye. This is what occurs in snow blindness or after exposure to strong ultraviolet-light sources. Unusual sensitivities have been reported. Ultraviolet light, like infrared or penetrating radiations, can also cause cataract of the eye lens, a condition that is characterized by denatured protein in the fibrous cells forming the lens. The retina usually is not reached by ultraviolet light, but large doses of visible and infrared light can irreversibly bleach the visual pigments, as in sun blindness. Numerous pathological conditions of the eye are accompanied by abnormal light sensitivity and pain, a condition that is known as photophobia. The pain appears to be associated with reflex movements of the iris and reflex dilation of the blood vessels of the conjunctiva. Workers in situations where they can expect to be exposed to ultraviolet-light sources or to atomic flashes should wear protective glasses.

EFFECTS OF LASERS

Masers and lasers are devices capable of generating exceedingly intense microwave and light beams, respectively, that travel in narrow beams. Laser beams can carry radio broadcasts and have made possible refined studies of the surface of the Moon. They also have potentially useful applications in biology and medicine.

The destructive action of lasers

The highly intense laser beam can instantly vaporize the surface of a target. This has led to its application in research as well as in surgery. The laser microprobe is used for microanalysis of surface composition. Laser beams have been found to have a selective effect on cellular components, or organelles: those components that absorb light of the wavelength of the beam are destroyed, whereas transparent parts of the cells remain unaffected. Organelles such as mitochondria, which are responsible for cell respiration, or chloroplasts, which are involved in plant-cell photosynthesis, can be separately studied in this manner.

The use of special dyes can alter laser action. The availability of high-pulse-intensity laser beams is also revolutionizing medical photography and microscopy. It is becoming possible to photograph microaction in a very small fraction of a second and to use the relatively new technique of holography for image synthesis.

It was found that, at the appropriate intensity, initial local thermal effects of a laser beam are followed by formation of scar tissue. This property is used in microsurgery of the eye, particularly for treating retinal detachment. Since light can be focussed to a small spot on the retina, damage to lens and cornea can often be avoided; vascular tumours and retinoblastomas also have been treated. In performing such procedures, care must be taken to avoid hemorrhage; the nature and extent of scars and the hazard of developing cataract must be also considered.

Lasers have been used in investigative therapy for a number of conditions of the skin, including hemangiomas and various types of skin cancer. The cells of malignant melanoma tumours carry a dark pigment, which, it is believed, might selectively absorb laser wavelength and thereby destroy the cell. Nerve cells are more sensitive to laser beams than are a variety of the supporting cells, suggesting neurosurgical applications. Laser treatment of the surface of teeth may have an eventual role in the control of tooth decay.

BIBLIOGRAPHY. General information is given in C.W. SHILLING (ed.), ***Atomic Energy Encyclopedia in the Life Sciences*** (1964); and, on the effects of atomic weapons, by S. GLASSTONE and P.J. DOLAN (eds.), ***The Effectsof Nuclear Weapons,*** 3rd ed. (1977). The national and international nuclear science field is monitored by the INTERNATIONAL ATOMIC ENERGY AGENCY (IAEA), ***INIS Atomindex*** (semimonthly), which includes abstracts and indexes of U.S. government reports and other documentation. Early history of the development of the field is found in O. GLASSER, ***Wilhelm Conrad Röntgen and the Early History of the Roentgen Rays*** (1933); and P. BROWN, ***American Martyrs to Science Through the Roentgen Rays*** (1936). Historically important technical books on radiobiology are D.E. LEA, ***Actions of Radiations on Living Cells*** (1946); and A. HOLLAENDER (ed.), ***Radiation Biology,*** 3 vol. (1954–56). Radiological units and measurements are discussed in R.E. LAPP and H.L. ANDREW$ ***Nuclear Radiation Physics,*** 4th ed. (1972), and in publications of the International Commission on Radiation Units and Measurements (ICRU). Introductory information on radiation biology is given in J.E. COGGLE, ***Biological Effectsof Radiation*** (1971); and E.J. HALL, ***Radiarion and Life*** (1976). More advanced texts include: M. ERRERA and A.G. FORSSBERG (eds.), ***Mechanisms in Radiobiology,*** 2 vol. (1960–61); INTERNATIONAL ATOMIC ENERGY AGENCY, ***Biological and Environmental Effects of Low-Level Radiation,*** 2 vol. (1976); J.M. YUHAS, R.W. TENNANT and J.D. REGAN (eds.), ***Biology of Radiation Carcinogenesis*** (1976); W.H. BLAHD (ed.), ***Nuclear Medicine,*** 2nd ed. (1971); L.G. TALIAFERRO and B.N. JAROSLOW, ***Radiation and Immune Mechanisms*** (1964); D.S. GROSCH, ***Biological Effects of Radiations,*** 2nd ed. (1979); D.J. KIMELDORF and E.L. HUNT, ***Ionizing Radiation: Neural Function and Behavior*** (1965); A.C. UPTON, ***Radiation Injury*** (1969); and M.M. ELKIND and G.F. WHITMORE, ***The Radiobiology of Cultured Mammalian Cells*** (1967). Radiation genetics is discussed in C. STERN, ***Principles of Human Genetics,*** 3rd ed. (1973); B. WALLACE and T.G. DOBZHANSKY, ***Radiation, Genes, and Man*** (1959), as well as in WORLD HEALTH ORGANIZATION, ***Effect of Radiation on Human Heredity*** (1957).

Radiation effects on human beings are discussed in J.W. GOFMAN, ***Radiation and Human Health*** (1981); H. BLATZ, ***Introduction to Radiological Health*** (1964); and E.P. CRONKITE and V.P. BOND, ***Radiation Injury in Man*** (1960). Examples of works calling attention to the hazards of radiation include the following: A.R. TAMPLIN and J.W. GOFMAN, ***Population Control Through Nuclear Pollution*** (1970); R. CURTIS and E. HOGAN, ***Perils of the Peaceful Atom: The Myth of Safe Nuclear Power Plants*** (1969). The problems of atomic power for society are discussed in HARRY FOREMAN (ed.), ***Nuclear Power and the Public*** (1970); and in G.T. SEABORG and W.R. CORLISS, ***Man and Atom; Building a New World Through Nuclear Technology*** (1971).

Radiation accidents are discussed in L.H. LANZL, J.H. PINGEL, and R.H. RUST (eds.), ***Radiation Accidents and Emergencies in Medicine, Research, and Industry*** (1965); and in U.S. HOUSE OF REPRESENTATIVE$ COMMITTEE ON SCIENCE AND TECHNOLOGY, ***Three Mile Island Nuclear Plant Accident*** (1979). Fallout and its biological consequences are covered by F.C. MCLEAN and A.M. BUDY in ***Radiarion. Isotopes, and Bone*** (1964); E.B. FOWLER (ed.), ***Radioactive Fallout, Soils, Plants, Foods, Man*** (1965); and INTERNATIONAL ATOMIC ENERGY AGENCY, ***Transuranium Nuclides in the Environment*** (1976). The effects of the Hiroshima and Nagasaki explosions on humans are discussed in a series of reports of the Atomic Bomb Casualty Commission. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) issues occasional reports on the biological effects of radiation and on fallout. The Office of Radiation Programs, a branch of the U.S. Environmental Protection Agency (EPA), issues studies of the effects of radiation on the environment. Standards and permissible levels of radiation exposure are available through reports of the National Council on Radiation Protection and Measurements (NCRP), and the International Commission on Radiological Protection (ICRP). The U.S. Nuclear Regulatory Commission issues many technical reports and educational materials, including films. IAEA also has a series of publications. Radiation problems in space flight are discussed in NATIONAL RESEARCH COUNCIL, SPACE RADIATION STUDY PANEL, ***Radiobiological Factors in Manned Space Flight*** (1967).

Ultraviolet and associated radiations are covered in A. HOLLAENDER (ed.), ***Radiation Biology,*** vol. 2, ***Ultraviolet and Related Radiations,*** vol. 3, ***Visible and Near-Visible Light*** (1956); and W. HARM, ***Biological Effects of Ultraviolet Radiation*** (1980). An international journal, ***Photochemistry and Photobiology*** (monthly), is devoted to this field.

Laser research is discussed in the following publications: S. FINE and E. KLEIN, "Biological Effects of Laser Radiations,"

Advances Biol. Med. Phys., 10:149–226 (1965); and S.J. WYARD (ed.), ***Solid State Biophysics: Applications of Electron Spin Resonance, Dielectric Measurements, the Mössbauer Effect, and Lasers to Biology and Medicine*** (1969).

There are additional specialized journals available in the field, including ***Radiation Research*** (monthly); ***International Journal of Radiation Biology*** (monthly); ***Radiobiologiya*** (bimonthly); ***Journal of Nuclear Medicine*** (monthly); ***Environmental and Experimental Botany*** (quarterly); and ***Nuclear News*** (monthly).

(C.A.T.)

Radiation Detection and Characterization

Radiation detection is concerned with a great variety of atomic and subatomic particles moving at different speeds and with electromagnetic waves of different wavelengths moving always at the speed of light. Both waves and particles are constantly present on Earth and in space. They emanate from the Sun, other stars, naturally occurring radioactive elements, synthetically produced radioactive isotopes, nuclear reactors, nuclear fission, and in general from interactions between colliding particles, between waves and particles, and between bulk matter and particles or waves.

The particles considered in this context are long-lived electrons, protons, alpha particles (*i.e.*, helium nuclei), neutrons, several hundred short-lived subatomic particles, and all antiparticles. The whole spectrum of electromagnetic waves is also considered in this context, from long radio waves through light waves and X-rays, to the shortest of gamma rays.

For details of the phenomena treated here in general terms relevant to radiation detection, see RADIOACTIVITY; X-RAYS; METALS, THEORY OF; SEMICONDUCTORS AND INSULATORS, THEORY OF; SOLID STATE OF MATTER; RADIATION EFFECTS ON MATTER.

The fundamental mechanism underlying the operation of all radiation detectors is the dissipation of energy by a charged particle in a suitable medium and the distribution of this energy among atoms and molecules of the detecting material. Radiations such as electromagnetic waves and neutral particles that react only weakly with the electronic structure of many detection media must first interact with some suitable material in a way that will produce a charged particle, which can then dissipate its energy in the detection media. The essential concept of detection lies in the fact that energy is provided by the radiation, and in this article it is therefore appropriate first of all to consider general aspects of matter and energy in relation to the charged particles that have already been mentioned and to electromagnetic waves and neutrons; following this, the characteristics of the various types of radiation are described and, finally, the detectors themselves are briefly reviewed.

THE STRUCTURE OF MATTER AND INTERACTIONS WITH RADIATION

A normal atom consists of a central nucleus, composed of electrically neutral neutrons and positively charged protons, around which orbit several negatively charged electrons. The number of electrons equals the number of protons in the nucleus, the negative charge on each electron just balancing the positive charge on each proton, so that the atom is electrically neutral; this number is called the atomic number of the atom, Z, and determines its chemical identity. Electrons around the nucleus exist in stable groups of orbits, the innermost, called the K shell, containing two electrons, the next, the L shell, containing eight electrons when it is complete, and each larger shell, M, N, O, P, etc., being complete with larger numbers of electrons. Each orbit corresponds to a definite state of energy, and movement of an electron from one orbit to another can take place only by the emission or absorption of a fixed amount of energy, an amount that depends on the initial and final orbits. It takes energy to move an electron away from the nucleus. When an electron is removed entirely from the atom, excess energy can be absorbed by it in such a way that this excess is manifested as kinetic energy (motion) of the free electron. A convenient unit of energy for describing atomic phenomena is the electron volt (eV), which is equal to 1.6×10^{-12} erg. The minimum energy that is needed to remove an outer electron from its orbit is called the ionization potential (E_i) and is about 15 electron volts for atoms in the gaseous state. To eject one of the innermost electrons from the innermost or K shell, a minimum energy, E_K, of much greater value is needed, and E_K is approximately equal to 10 times the square of the quantity, atomic number minus one ($E_K = 10\,[Z - 1]^2$eV). An atom from which an electron has been removed is left with a positive charge and is called a positive ion.

Energy of ionization

The energy required to ionize an atom can be provided either by collision with a charged particle, such as an electron or a proton, or by absorption of electromagnetic radiation in the form of light, X-rays, or gamma rays. In the latter type of interaction, electromagnetic energy behaves as though it existed in packets, or quanta, of energy proportional to the frequency of the radiation. Such quanta are called photons. Blue light, for instance, has a quantum energy of about three electron volts, whereas photons of deep-red light of twice the wavelength and half the frequency interact as quanta of 1.5 electron volts. An X-ray photon capable of providing just enough energy to remove one of the K electrons from an atom of argon, ($Z = 18$), has an energy of 3,000 electron volts. A photon of higher energy than E_K removes one of the K electrons and provides an excess kinetic energy to the electron, but it is rather less likely to cause ionization by photoelectric absorption than radiation having a quantum energy just equalling E_K; the probability of interaction by this process decreases as the photon energy increases. Usually, radiations of the highest frequencies and photon energies are the gamma (γ) rays. The probability of photoionization as a function of photon energy is expressed as the effective cross-section area presented to the radiation by each atom. The unit of cross section is the barn, equal to 10^{-24} square centimetre.

When a photon of high energy strikes an atom, it can remove an electron by a scattering process called Compton scattering, the energy of the primary photon being shared between the released electron and a scattered photon. The cross section for Compton scattering is proportional to the number of electrons in the atom and inversely proportional to the square root of the photon energy.

A fundamental mode of interaction for high-energy photons is by pair production, in which a photon of energy slightly greater than 1,000,000 electron volts (MeV) materializes into an electron and its antiparticle, a positive electron, or positron, in the proximity of an atomic nucleus. This interaction is possible because of the equivalence of matter and energy first enunciated by Albert Einstein in his theory of relativity (*i.e.*, energy equals mass times speed of light squared: $E = mc^2$). An electron (or a positron) of mass m_0 has a self-energy m_0c^2 equal to just over 500,000 electron volts (in fact, 0.51 MeV), and a photon of energy 1.02 MeV can thus provide the energy for two electron masses, one negative and one positive, because the net charge must remain zero. The cross section—*i.e.*, the probability—for pair production increases as the square of the atomic number of the target atom and roughly as the square of the excess energy (photon energy less 1.02 MeV).

Ionization caused by a charged particle colliding with an atom is a much less well-defined process than those described above, and electrons may be ejected with a range of energies depending on the mass and energy of the incident-charged particle. The average energy abstracted from the particle is about twice the ionization potential of the atom ionized, and the symbol w is used for this parameter (a constant that is characteristic for different conditions); w, the average energy per ionizing event, depends to a slight extent on the mass and energy of the incident particle. The probability of ionization at collision is much larger for slow-moving particles; therefore, as an energetic charged particle traverses a given thickness of material, it is slowed down more and more rapidly as energy is dissipated in the ionizing process, until all the energy is lost and the particle is absorbed. Massive particles, such as protons, which have a mass about 1,800 times that of an electron, are not greatly deflected by the electron structure of the atoms through which they pass and a fairly definite range for them can be assigned, depending on their initial energy. Electrons, on the other hand, are easily deflected; a beam of electrons initially having the same energy (*i.e.*, being monoenergetic) undergoes exponential absorption as it passes through matter, owing to electrons being scattered out of the beam. A maximum range, however, can still be measured.

Neutron reactions

Neutrons, having no electric charge, cannot interact with the electron structure of atoms but can penetrate the nucleus and cause a reaction. In some cases, the disturbed nucleus splits apart, as in the case of the uranium isotope of mass 235 (^{235}U), which breaks up into two fission fragments carrying kinetic energy of 150 MeV. In other cases, a charged particle, either a proton or an alpha particle (a; a helium nucleus) is ejected; for example, a boron-10 (^{10}B) nucleus ejects an alpha particle, and a lithium-7 nucleus is left, after reaction with a neutron. The reaction is written: $^{10}\text{B} + n \rightarrow \text{Li} + \text{a}$ (2.5 MeV); or $^{10}\text{B}(n, \text{a}) + {}^{7}\text{Li}$. Sometimes a neutron is absorbed by a nucleus. When a stable nucleus is formed by absorption of a neutron, the excess energy is released as a gamma ray. Some nuclei that result, however, are unstable and decay by what is called radioactive emission of electrons (usually referred to as beta [β] particles) and gamma rays. The radiation resulting from such neutron capture and reaction appears many seconds, days, or years later. In the other examples mentioned, the radiation is prompt; *i.e.*, it is emitted in a time less than a nanosecond (10^{-9} second) after the reaction.

In one class of interaction, an elastic collision takes place, and the energy of the neutron is shared between a scattered neutron and a projected nucleus. Scattering of fast neutrons on hydrogen nuclei gives rise to protons.

DETECTION PROCESSES AND DETECTION MEDIUMS

The distribution of energy among the atoms and molecules of a suitable detection medium is the fundamental process in a radiation detector.

A charged particle (electron, proton, alpha particle, or fission fragment) of energy E that dissipates all its energy in a gas, by knocking electrons out of atoms, leaves a column of positive ions and free electrons along its track. The number of such electron–ion pairs produced is equal to the energy E, divided by the value of w, the energy per ion pair appropriate to the gas and the particle. If electrodes are set up on either side of the track, to produce an electric field, free electrons are attracted to the positive electrode, or anode, and positive ions are attracted to the negative electrode, or cathode. If all of the separated ions and electrons are collected, the electric charge available for measurement is equal to E/w multiplied by e, the electron charge, of value 1.6 X 10^{-19} coulomb (unit of charge). For an energy of 1,000,000 electron volts and energy per ion pair of 30 electron volts, the charge collected would be 5×10^{-15} coulomb. Because the minimum value of a pulse of electric charge that can be measured by available electronic apparatus is about 1,000 electron charges (1.6×10^{-16} coulomb), an ionization chamber can be used for detecting the passage of a charged particle that dissipates a minimum energy of about 30,000 electron volts in the detection medium; *i.e.*, the gas in the chamber.

One source of charged particles

The charged particle providing energy to ionize the gas may be produced by decay of a radioactive material emitting an alpha or beta particle; and the radioactive source may be placed outside the detector, so that the radiation must pass through a suitably thin portion of the chamber wall (a window) to reach the gas. If the absorption of particle energy in a window would be inconveniently large, the source is mounted inside the detector, directly in contact with the gaseous detection medium. In some circumstances, the radioactive material is available in the form of a gas—*e.g.*, carbon dioxide with carbon-14 (^{14}CO$_2$)—which can be mixed with the ionization-chamber gas or can itself be used as the detection medium.

When the charged particles are produced as a result of gamma ray or neutron interactions, similar considerations apply; the interacting material may be in the form of a radiator outside the detector, inside the detector but separate from the detection medium, or distributed throughout the detection medium. For example, a neutron detector might consist of an ionization chamber containing a layer of boron-10, or it might be made by filling an ion chamber with boron trifluoride containing boron-10 (^{10}BF$_3$), a gas at room temperature. In either case, neutron interactions would be detected by ionization produced in the gas by the $^{10}\text{B}(n, \text{a})$ reaction.

Ionization detection. A detection system meant to produce electrical signals when a particular type of radiation is present thus consists of a source of radiation, an interacting medium (for neutrons and gamma rays), and a detecting medium together with some means of converting the energy dissipated in this material into the required signal. Such an active detector may make use of ionization and charge collection in the detection process; the ionization medium may be a gas or may be a suitable semiconducting solid. The class of detectors comprises ionization chambers and conduction counters.

Geiger-Muller counter tubes. In some gas-filled devices, a sufficiently high electric field is applied to cause the free electrons produced by the primary particle to move sufficiently fast to ionize more atoms, thereby increasing the original charge by the process of gas multiplication. Proportional counters use this process to give internal amplification factors of up to 1,000,000 times while still giving an output proportional to the initial signal. At higher values of gas multiplication, complex processes come into play that give a large output signal from the smallest levels of initial ionization, and the output is then independent of the primary signal. Such tubes are called Geiger-Miiller counter tubes.

Spark chamber. A gas detector using high values of gas multiplication is the spark counter, in which a spark jumps between two electrodes along the track of an ionizing particle. Because the spark indicates the position of the particle, assemblies of spark counters are arranged inside spark chambers to indicate the paths of penetrating particles by observation of the sparks produced.

Cloud *and* bubble chambers. Rather less active track delineating devices depending directly on the production of ions along the path of the particle are cloud chambers and bubble chambers. In the former, vapour from a supersaturated atmosphere of water or alcohol condenses on ions to form visible droplets, which can be photographed. In the bubble chamber, a superheated liquid is used, and ions form nuclei for local boiling, again giving a visible track.

The detailed physics of the various types of ionization detector summarized above depends to a large degree on the behaviour of electrons and ions under the applied electric field.

Fluorescent detectors. A second main class of radiation detectors depends on the conversion of the distributed energy of the primary ionizing particle into light, which is then used to generate photoelectrons (electrons emitted from a surface as a result of light falling on that surface) from the cathode of a photomultiplier tube. The photoelectron current is multiplied in the tube to give an adequately large output signal. Detection mediums that convert the energy of moving electrons into light are known as phosphors. The light of a television picture tube is produced by the impact of energetic electrons on a phosphor deposited on the inner surface of the faceplate of the picture tube. The process of light production is known as fluorescence. Early examples of its use in radiation detection, albeit with visual rather than instrumental observation of the light, are the detection of X-rays by the German physicist Wilhelm Conrad Rontgen in 1895 using barium-platinocyanide, and the detection of alpha particles by observation of the scintillations produced in zinc sulfide by the British physicist Ernest Rutherford during the early 1900s.

Fluorescence

As well as the rather transient effects so far considered, the passage of an ionizing particle through certain types of material can give rise to more or less permanent changes along the track. A familiar example is the photographic film. Perhaps less well known is the blackening of glass under intense irradiation from beta particles or gamma rays. The degree of darkening either of film or glass can be used to determine the total exposure of the sample to radiation, and badges containing sensitive substances are sometimes worn to indicate the amount of invisible radiation to which their wearers are exposed.

The properties of ionization **mediums.** Gases. Once a gas has been ionized. the free electrons must be separated from the positive ions by an electric field if a useful charge signal is to be produced. In the absence of a field, the attraction between positive and negative charges, combined with the random motion of the gas molecules, causes the oppositely charged particles to recombine. At room temperature, molecules of a gas are in constant random motion with an average kinetic energy of 0.04 electron volt. This energy is proportional to the absolute temperature (°K) of the gas, which is equal to the temperature in °C plus 273. For a given mass of gas in a fixed volume (*i.e.*, a given gas density), the pressure exerted by the gas on the walls of the vessel is proportional to the absolute temperature and to the density. The average distance travelled by a gas molecule before it collides with another molecule is called the mean free path and is inversely proportional to the number of molecules per unit volume.

In a gas at the standard temperature of 0° *C* and the standard pressure of one atmosphere, one cubic centimetre contains 2.7×10^{19} molecules, and the mean free path (symbolized by the Greek letter lambda, A) is about 2×10^{-5} centimetre.

Drift velocity

Between collisions with gas molecules, a positive ion obtains energy from an electric field produced between electrodes in an ion chamber and thus is accelerated toward the negative electrode, or cathode. This energy is small compared with the average kinetic energy that the ion possesses in common with the surrounding gas molecules, and because the ion and the molecules are similar in mass, velocity (the downfield velocity component) is lost at each collision. The positive ion thus drifts toward the cathode in a series of steps that have an average value proportional to the field strength multiplied by the square of the free time between collisions. The drift velocity is proportional to this average step distance divided by the free time. Since the free time is inversely proportional to the mean free path, the drift velocity, $W+$,is proportional to field strength, E, multiplied by the mean free path, λ. At a constant temperature, mean free path is inversely proportional to the gas pressure, *p,* and the ion drift velocity can be written $W^+ = \mu E/p$, in which the constant symbolized by the Greek letter mu, μ, is called the mobility of the ion for the particular gas. With the electric field, E, expressed in volts per centimetre and the velocity, $W+$, in centimetres per second, the mobility, μ, is given in cm/sec per V/cm, otherwise written as centimetres squared per volt-second.

The electric field between plane parallel electrodes is equal to their potential difference (P.D.) divided by their spacing. With a spacing of x cm and a P.D. of v volt, E $= v/x$ volts per centimetre, and for a gas pressure of p atmospheres, the ion drift velocity (see above) is $W^+ = \mu(E/p)$, which, substituting for E, gives $W^+ = \mu v/px$ centimetres per second; the time *t* for the ion to travel a distance *s* centimetres is t $= s/W^+ = spx/\mu v$ second (*i.e.*, the distance multiplied by spacing and pressure, divided by field, multiplied by mobility). For an ion formed close to the anode, so that $s = x$, the transit time is proportional to the square of the electrode spacing. With argon at one atmosphere, an applied voltage of 500 volts and a spacing of five centimetres, E is 100 V/cm; W^+, for the argon ion Ar_2^+, is 190 cm/sec; and the transit time is 26 milliseconds. With a gas filling pressure of one-tenth atmosphere, the velocity would be 10 times higher and the transit time 10 times smaller.

A free electron, having a mass only 1/70,000 of that of an argon molecule, cannot transfer much kinetic energy to a gas molecule in an elastic collision, being somewhat analogous to a table-tennis ball bouncing off a cannon ball. The energy acquired by the electron from the electric field thus accumulates, and the agitation energy becomes much larger than that of the thermal energy (heat) of the gas. The electron changes direction at each collision with a molecule, so that the motion remains random; with a superimposed drift velocity, as with the ion, and, by a similar argument, the drift velocity, W–, is found to be proportional to field multiplied by mean free path. The mean free path of an electron in a gas, λ, is affected by the value of E, because this determines the agitation energy, and a simple value of mobility is not applicable. In fact, it can be shown that the drift velocity is proportional to the field E multiplied by electron mean free path λ divided by the square root of the parameter symbolized by the Greet letter eta, η, which is the ratio of average agitation energy of electron and gas molecule: $E\lambda/\eta^{1/2}$. A free electron thus has an agitation energy of 0.04η electron volt in a gas at room temperature, and, under sufficiently high values of electric field, this energy can increase to a value at which inelastic collisions with molecules occur, when the electron transfers energy to the structure of the molecule. In a monatomic gas such as argon, the lowest level at which energy can be transferred from an electron is 11.57 electron volts, so η can rise to about 300. In a more complex gas, such as carbon dioxide, energy can be exchanged at low values with the vibrational and rotational energy systems of the polyatomic molecule, keeping the electron agitation energy down to a low value for fields below 2,000 volts per centimetre.

Mean free path in argon

The mean free path of free electrons in argon decreases markedly as the agitation energy increases. As a result, the drift velocity of electrons in pure argon at a pressure of one atmosphere does not exceed 10^6 centimetres per second. The admixture of a small proportion of a complex gas to argon reduces the agitation energy of electrons, however, and allows much higher values of drift velocity to be obtained. In an ion chamber containing argon plus 1 percent nitrogen, at one atmosphere, an electron has a drift velocity of 0.5×10^6 centimetres per second in a field of 100 volts per second and crosses a distance of five centimetres in 10 microseconds (10^{-5} second). A knowledge of the value of drift velocity and the way it depends on electric field strength is necessary to understand the mechanism of ionization detectors.

The effectof small admixtures of other gases to a noble gas such as argon has been described in relation to electron drift velocity. A similar profound effect is produced on the ionizing efficiency of fast charged particles.

The value of w, the energy per ion pair abstracted from, say, an alpha particle in pure neon, is 36.3 electron volts. (The ionization potential of neon is 21.5 electron volts.) If, however, about 0.1 percent of argon is added to the neon, w is reduced to 26.3 electron volts, which is the energy per ion pair for pure argon. The improvement in energy transfer is caused by the fact that much of the energy abstracted from the primary particle in pure neon is used in exciting a level in the neon electron system that requires 16.6 electron volts but that does not result in ejection of an electron. This excited state in neon lasts for a long time (on the time scale of atomic phenomena) and has an average lifetime of about a millisecond, after which it decays by emission of an ultraviolet quantum. Such long-lived excited conditions are called metastable states. The mean free time between collisions is about 10^{-7} second, so that a neon atom excited into its metastable state will undergo many collisions in its life, and in the gas mixture containing argon it will certainly collide with an argon atom, having an ionization potential of 15.7 electron volts. Because the excitation energy, E_r, of the neon atom is 16.6 electron volts, there is a high probability that the energy can be transferred to the argon atom, causing ionization. Such collisions of the second kind, as this type of energy transfer is called, greatly increase the efficiency of production of ionization in a mixture of a noble gas with another gas having an ionization potential less than E, the energy of excitation of the metastable state of the noble gas.

The same principle that allows energy transfer from a metastable state of one molecule to ionize a second molecule allows a charge transfer from a positive ion to a molecule of lower ionization potential. Thus, in an argon–alcohol mixture, collision between an argon ion and a molecule of ethyl alcohol results in neutralization of the argon ion by extraction of an electron from the alcohol molecule. This process is of particular importance in understanding the operation of a Geiger counter tube.

At high values of electric field, electrons obtain high average energy, the instantaneous value being distributed statistically about the average. Occasionally an electron attains an energy larger than the ionization potential of the gas molecule with which it collides, and ionization occurs. The actual number of ions produced by an electron in moving one centimetre through a gas under the influence of a field E (in units of volts per centimetre per atmosphere [V/cm/atm] is given by a coefficient, called the first Townsend coefficient and symbolized by the Greek letter alpha, ***a.*** Values are given in the Table, as is the effect of adding argon to neon.

Townsend Coefficient for Various Gases

E	*a,* ion pairs per centimetre			
(V/cm/atm)	argon	neon	neon + 0.1% argon	air
3,800	0.2	6	120	—
7,600	3.8	38	230	—
19,000	40	200	380	—
38,000	530	530	830	38

Electron avalanche

In such high electric fields, electrons produced by an ionizing collision are themselves accelerated and cause further ionization, and the tertiary electrons thus produced go on to produce further ionizing collisions, an electron avalanche rapidly building up. The process can be visualized by considering two parallel electrodes in a chamber filled with argon at a pressure of one atmosphere and supporting a voltage difference of just over 10,000 volts. At this field, the first Townsend coefficient in argon produces about 10 electron–ion pairs per centimetre. An electron produced at the cathode—for instance, by an incident ultraviolet photon—is accelerated toward the anode; after passing through one millimetre of gas, it is probable that one ionizing collision has occurred, and so there are now two electrons; after two millimetres each electron has ionized again, and there are four electrons. This process continues, and, at the nth millimetre, there are 2^n electrons; when the avalanche reaches the anode it contains 2^{10} electrons ($2^{10} =$ 1,024). This analysis is only illustrative. An accurate analysis shows that an electron formed at the cathode under the given conditions produces 150 times more ion pairs on its way to the anode than does an electron formed halfway between the plates. Some possible arrangements, therefore, are not all suitable for use in a gas multiplication detector, because the amount of multiplication varies markedly with the position of the initial ionization in the chamber. A cylindrical geometry. consisting of an anode wire stretched along the axis of a cylindrical cathode, provides an electric field that has a high value close to the anode surface and falls away rapidly as distance from the anode increases; this arrangement allows of controllable gas multiplication in the proportional counter.

At higher values of electric field than the 10,000 volts per centimetre per atmosphere applied across a parallel plate system in an argon filled chamber that gives a coefficient α equal to 10, the initial part of the electron avalanche is so intense that ultraviolet photons of high enough energy to ionize the gas are produced, generating electrons at a little distance from the primary region. A second bead of intense ionization is produced, generating photons in its turn, and the discharge is propagated across the gap between the electrodes to form a spark, in a time of about 10^{-8} second, short compared with the transit time of an electron, which is about one microsecond (10^{-6} second). Providing the high voltage supply to the electrodes is capable of supplying the required current without reduction in voltage, the spark becomes a sustained discharge, fed by electrons generated from the cathode by photoemission (from the ultraviolet photons produced in the spark) and by electrons produced at the cathode by the arrival of positive ions. An ion of argon having a potential energy of 15.7 electron volts, extracts an electron from the metal of the cathode against the surface force (symbolized by the Greek letter phi, ϕ) of phi electron volts and becomes a neutral atom with an excitation energy of (15.7 $-$ ϕ) electron volts. All this happens at a distance of about 5 $\times$ 10^{-8} centimetre from the surface, and in a time of 10^{-12} second the excited atom strikes the metal. If the excitation energy is greater than the surface force, ϕ, which is called the work function, then there is some probability that a further electron will be extracted and move into the discharge. Typical values of the work function lie around four electron volts, and, because $\frac{1}{2}E_i$ (E_i is the ionization potential) for many gases is greater than five electron volts, this process is quite effective in generating electrons.

Certain complex gas molecules, such as ethyl alcohol, dissipate the excitation energy left after neutralization among the vibrational states; in this case, no electron is extracted.

If the high voltage supply to the electrodes is not capable of supplying a continuous current to the discharge, the spark persists until the charge drawn from the capacitance here, the capacitance is formed by the electrodes and the connections to the system) causes the field to drop below the level at which ionization by collision can occur: the spark is then extinguished.

The processes described above are of importance in Geiger counters and spark chambers.

Solids. In an ionization chamber using gas as the detection medium, no current passes between the electrodes in the absence of ionization in the gas; the neutral gas is an insulator. It is equally difficult, however, to make a gas detector with adequate stopping power to absorb the energy from a penetrating particle, such as a high-energy electron, or with a high enough atomic number and atomic density to provide a high detection efficiency for gamma rays, and it would be desirable to use a solid detection medium. In such solid material, atoms are relatively immobile, and their electronic structures interact with each other to such an extent that it is not possible to assign specific outer orbital electrons to a particular atom. The concept of ionization is thus not as clear-cut as it is with a gas, in which the atoms or molecules are essentially independent; furthermore, in metals and semiconductors at room temperature, some electrons are always free to move under the influence of an electric field, and so these materials show electrical conductivity. An insulating solid has the outer electrons sufficiently firmly bound to the array of atoms so that they are not free to move. Absorption of energy from a photon or a charged particle may break the bonds holding an electron in place, and it is then free to move in a field. The vacancy thus created in the electron structure of the atomic array leaves a net positive charge in the locality, which charge is referred to as a positive hole. The imbalance in forces produced by an electric field causes a neighbouring valence electron to move toward the anode, filling up the original vacancy; the hole has now migrated one step toward the cathode. Conduction in an insulator can thus take place by migration of holes and electrons. In some materials, however, the holes have low or zero mobility.

Ionization process in solids

The minimum energy needed to free an electron from the valence band of energy to the conduction band of energy, so that it can move in an electric field, is called the band gap, which is about five electron volts in diamond and in silver chloride. In semiconductors, the band gap is lower; in silicon, it is 1.1 electron volts, and in germanium it is 0.72 electron volt. In these materials, which are used for making transistors, the conductivity is lower as the material is purer (pure silicon has a resistivity in excess of 100 megohms at room temperature, between

The band gap

opposite faces of a cube with sides of one centimetre). This conductivity results from the presence of electrons raised into the conduction band by the statistical fluctuation of thermal energy and corresponds to an electron density of 10^{10} per cubic centimetre and a lifetime of 100 microseconds before the electron is trapped. Each electron produced under these circumstances generates a hole, so that the hole density in silicon of a high purity is also 10^{10} per cubic centimetre at room temperature. High-purity material in which all charge carriers (both electrons and holes) are thermally generated is said to have intrinsic conductivity. The rate of generation is 10^{14} per second per cubic centimetre at room temperature.

The movement of a free electron in a solid under the influence of an electric field is similar to the description given for the movement of an ion in a gas; energy is obtained from the field and is lost when the electron is scattered by the pattern of forces formed by the interlocking electron bonds that hold the solid together. The drift velocity thus turns out to be proportional to the product of field and mean free path, as in the case of the gas ion, and a mobility, μ, can be assigned. For silicon at room temperature μ_- is 1,350 centimetre squared per volt-second, whereas μ_+, hole mobility, is 500 centimetres squared per volt-second.

The range of an electron of initial energy of two million electron volts in solid silicon is 0.5 centimetre, compared with 500 centimetres in argon gas at atmospheric pressure, and the energy per electron-hole pair, w, is 3.5 electron volts. A conduction counter made from a one-centimetre cube of intrinsic conductivity silicon could thus be used to absorb the energy from high-energy particles. An energy of 250,000 electron volts absorbed generates about 75,000 electron-hole pairs, giving a collected charge of 1.2×10^{-14} coulomb, which is well above the limit of detection set by amplifier noise. With a potential difference of 100 volts between opposite faces of the cube, this charge is collected in a time of about 10 microseconds.

During this time, however, 10^9 charge carriers generated by thermal energy have been collected, and this number is not constant for each 10-microsecond period but is subject to statistical variation about this average value. For 5 percent of the time the value will deviate from the mean by more than twice the square root of the average number; in this case by more than 6 × 104. If the conduction detector is imagined as a device sampling the charge collected in successive periods of time, each of which is equal to the time taken for charge carriers to cross the block from anode to cathode (10 microseconds in the example considered), then the statistical fluctuation described would make it difficult to identify with any certainty the extra signal caused by the absorption of 0.25 million electron volts from a charged particle in the sensitive volume of the silicon block. In order to reduce this conductivity noise, it is necessary to cool the material because the density of thermally generated carriers is proportional to the thermal agitation energy of the electron in the solid. At the temperature of liquid nitrogen, the density of free carriers is reduced from 10^{10} per cubic centimetre of silicon to effectively zero, and the cooled silicon should then be suitable for detecting electrons.

Need for cooling a medium

Unfortunately, it is difficult to make silicon of intrinsic purity, and the impurities that are commonly present decrease the resistivity. Silicon is tetravalent, which means that the outer shell of the atom contains four electrons. In the lattice of the crystalline form in which silicon is normally prepared, each atom shares its valence electrons with four neighbouring atoms, so that each electron pairs with an electron from the adjacent atom. An atom of phosphorus is pentavalent (*i.e.*, has five outer shell electrons); when it is incorporated in the silicon lattice as an impurity, it forms electron pair (or covalent) bonds with the four adjacent silicon atoms. This bonding leaves a spare electron that has a binding energy of only 0.054 electron volt and so is readily freed from its parent atom by thermal energy at room temperature and is free to take part in conduction. Trivalent impurities, such as boron, bind three adjacent atoms with covalent bonds, leaving a positive hole that can drift away under thermal excitation and having an effective binding energy of 0.08 electron volt.

Silicon of the highest purity contains about 10^{13} atoms per cubic centimetre of excess impurity of either type, giving rise to resistivity of about 10^4 ohms per centimetre cube at room temperature, which increases to about 10^6 ohms per centimetre cube if the temperature is lowered to 77° K. Material with excess of pentavalent (donor) impurity conducts by electrons and is called an n-type semiconductor. With trivalent (acceptor) impurity and conduction by hole migration, the material is called a p-type semiconductor.

Various methods have been developed to manufacture materials with low electronic conductivity, with p- and n-type layers, and with p–n junctions. Although silicon and germanium are by far the most commonly used materials for solid-state ion chambers, the classical work in this area was carried out on single crystals of silver chloride cooled to 77° K.

Scintillation counter. The distributed energy of a charged particle may be used to cause the emission of light from a suitable medium; the absorption of this light by a cathode, called a photocathode, produces electrons (photoelectrons) that escape from the surface of the cathode into the evacuated interior of an electron tube called a photomultiplier. The photoelectrons are accelerated by an electric field and strike an electrode coated with secondary emitting material. Each electron striking this surface with an energy of 1–500 electron volts knocks out secondary electrons that can be accelerated in turn onto a second electrode, or dynode, as the coated electrodes are called, and so on through a series of dynodes that are at successively more positive potential.

Photo-multiplier

With a secondary emission coefficient of four electrons per primary electron of energy 100 electron volts, a 10-dynode multiplier gives a gain of four raised to the 10th power, (4^{10}), which is slightly more than 1,000,000. Each primary photoelectron produced by the absorption of a light photon then produces at the anode of the tube a pulse of charge containing 1,000,000 electrons and of magnitude 1.6×10^{-13} coulomb. Two primary electrons striking the first dynode simultaneously produce a pulse of 2,000,000 electron charges at the output, and so on. The photomultiplier is a linear amplifier—*i.e.*, giving an output proportional to the primary photoelectron signal. A light-emitting detection medium (a phosphor), coupled to the photocathode of a photomultiplier operated to give a suitable value of gain, forms a scintillation counter; and in this type of detector the useful primary signal, comparable to the electrons and ions formed along the track of a particle in a gas, is the emission of photoelectrons. A high yield of photoelectrons for a given energy dissipated in the phosphor requires a photocathode of high quantum efficiency (efficiency measured by photoelectrons per incident photon), coupled with minimum light loss to a transparent phosphor that converts ion excitation energy into photons, with high efficiency. The wavelength of the fluorescent light must match the photocathode efficiency curve. In practice it is found that the most useful photocathodes give high quantum efficiency in the blue region of the spectrum and that the most useful phosphors emit blue fluorescence.

Photocathodes. Cathodes useful for scintillation counters are formed by semiconducting compounds of antimony and the alkali metals cesium, sodium, and potassium. Most commonly used are cesium–antimony (Cs_3Sb) and cesium–potassium antimony (K_2CsSb).

Secondury *emitters.* The two cathodes described above are good secondary emitters and are conveniently formed in photomultiplier tubes by reacting the alkali metals (cesium and potassium) with antimony-coated dynodes at the same time as the cathode is formed. Another useful material is beryllium oxide.

In a photomultiplier tube, dynodes are arranged so that an electric field accelerates secondary electrons from the surface and directs them to the next dynode in line. One method of doing this is to make a dynode in the form of parallel inclined slats with the upper plane covered by a

Types of dynodes

fine, transparent mesh. Electrons pass through the mesh of the first dynode to strike the inclined slats. The field from the mesh of the second dynode, spaced two millimetres below, extracts the secondaries from the space between the slats of the dynode of origin and accelerates them through the mesh to strike the second dynode slats, and so on. The efficiency of extraction of secondary electrons in this "venetian-blind" geometry lies between 90 and 95 percent.

Other types of dynode in common use are the box-and-grid and the linear-focussed structure. The latter consists of carefully shaped electrodes arranged in facing but offset pairs and designed to direct the secondaries from their point of origin to the next dynode without producing low-field regions, which are inherent in the venetian-blind and box-and-grid systems.

Photonzultiplier tubes. The great majority of scintillation counters use end-window photomultiplier tubes having semitransparent photocathodes of diameter ranging from two to 30 centimetres. All of these employ a dynode system fitting into a neck of five centimetres diameter, the cathode being spaced away from the first dynode by a distance of about half the end-window diameter. An electron optical system provides shaped electric fields to direct photoelectrons into the first dynode, and larger tubes in general require higher voltages between cathode and first dynode. With the gain of an individual dynode varying as the seven-tenths power of the inter-dynode voltage, a 10-dynode tube has a gain varying as the seventh power of the overall tube voltage, so that it is necessary to provide stable high voltage supplies to operate photomultiplier tubes at constant gain.

The secondary emission coefficient of dynode surfaces is slightly dependent on temperature, and most photomultiplier tubes decrease in gain by about 0.5 percent as the temperature (around 20° C, or 68° F) increases by one degree Celsius (1.8 degrees Fahrenheit). For accurate measurement, it is therefore necessary to hold the system at constant temperature or to provide a circuit that makes slight adjustments to the tube operating voltage to keep the gain constant. The transit time of an electron from the cathode to its arrival at the anode as a pulse of charge depends on the tube design and the operating voltage.

Because scintillation counters are often used to measure the strength of small sources of radioactive isotopes, it is necessary to construct the photomultiplier tube with the minimum amount of radioactive contamination. In practice this condition requires the use of glass containing the minimum amount of potassium-40, which is a beta- and gamma-emitting isotope, and sometimes calls for the tube envelope to be made, as far as possible, of fused silica.

Phosphors. In a scintillation counter, a large, transparent block of phosphor is coupled to the end window of a photomultiplier tube and surrounded by an efficient diffuser to ensure efficient transfer to the photocathode of the fluorescent light provided by particle excitation. With such an arrangement the energy, absorbed from a charged particle that results in the emission of a single photoelectron from the cathode of 24 percent quantum efficiency for three-electron–volts photons, can be measured. This figure is analogous to ***w***, the energy per ion pair, for a conduction medium, and the most efficient phosphors in use require about 200 electron volts to give a single photoelectron.

One useful class of phosphors is provided by fluorescent organic materials derived from benzene, typified by anthracene and naphthalene, that can be made as transparent crystals of useful size. As molecules excited by absorption of energy from a primary particle return to their ground state, light is emitted, and the decay time of this fluorescence is a few nanoseconds (10-9 second). If a small amount of anthracene is dissolved in naphthalene, however, the composite crystal emits light characteristic of anthracene fluorescence—but with the longer decay time of naphthalene. It appears that energy is transferred from molecule to molecule without radiation until radiation occurs, and this will take place from molecules having the highest emission probability.

This effect is exploited in liquid and plastic phosphors, which consist of efficient organic fluors, such as p-terphenyl dissolved in toluene or in polymerized polyvinyl–toluene.

Quenching

All of these materials show a marked loss of efficiency as the rate of energy loss from the primary particle increases, a loss that has been explained in terms of nonradiative dissipation of energy by damaged molecules. The reduction of fluorescent efficiency by competing routes for energy dissipation is called quenching; oxygen dissolved in the solvent of a liquid phosphor must be carefully removed to prevent quenching.

Inorganic phosphors are transparent insulating crystals containing a small proportion of a suitable impurity. Production of an electron-hole pair by an energetic ionizing particle occurs as described above. The hole is neutralized by extracting an electron from a nearby impurity centre, and this ionized centre in turn attracts the free electron from the conduction band to form a neutralized but excited impurity centre. The excess energy is emitted as a photon of energy which is less than the band-gap of the crystal and dependent on the properties of the impurity.

The phosphor in greatest use in scintillation counters is thallium activated sodium iodide; this can be grown into single crystals up to 75 centimetres in diameter and 25 centimetres thick. The material is extremely hygroscopic (moisture absorbing) and must be protected from the water vapour in the atmosphere by mounting it in a hermetically sealed can, with a window for coupling to a photomultiplier tube. In order to maximize the collection of fluorescent light, all the surface of the crystal except that facing the window is covered with a tightly packed thin layer of white diffusing titanium dioxide. This method of mounting is applied to many types of phosphor, whether hygroscopic or not.

Non-scintillating phosphors. Some phosphors are used for radiation detection because of their ability to store up energy in the crystal lattice over a period of exposure to nuclear radiation. Such materials are inefficient scintillators because the metastable state of the excited impurity centre is long-lived at room temperature and requires thermal excitation to temperatures perhaps 200"—300" *C* above room temperature to cause de-excitation. Calcium fluoride activated with manganese is one such phosphor. Energy stored in the lattice is estimated at some later time by rapidly heating the material, which starts to emit light at a temperature of about 200° *C* (392" F). The light rapidly rises in intensity to a peak at about 260" (500" F), then falls off as the temperature rises further and all the excited states are returned to ground level. The light output from the thermoluminescent phosphor is observed by a photomultiplier tube and plotted against the temperature of the sample. The total amount of light emitted is proportional to the energy absorbed.

The energy dissipated in a solid can be stored, after a fashion, by disrupting the bonds holding atoms to their neighbours, thus changing their potential energy. A special glass made from equal proportions of aluminum and lithium phosphate incorporating a few percent silver phosphate is nonfluorescent under ultraviolet light. Exposure to ionizing radiation breaks the silver atom bonds and produces silver impurity centres that turn the glass into a phosphor that fluoresces under ultraviolet light with an intensity depending on the energy dose absorbed. The weak fluorescence is orange in colour, and the intensity is measured in a photoelectric instrument.

Photographic emulsion

A mechanism similar to the above operates in photographic emulsion, in which the bonds of silver atoms to bromine atoms are disrupted by energy absorption. In this material, however, the evaluation technique involves development of the emulsion that causes each grain or small crystal of silver bromine (AgBr) to contain two or three free silver atoms reduced to atomic silver, thus becoming visible. Photographic films are widely used for measuring exposure to radiation, as are thermoluminescent and radiation-activated phosphors.

Ionization counters. The basic detection process, the collection of separated charge carriers produced by energy from a fast ionizing particle, and the properties of conduction mediums, have been described. In the case of a gas, it has been shown that the value of w, the energy per ion pair, is about 30 electron volts but depends on the gas and is modified by small admixtures of other gases. The movement of electrons in the collecting field also depends on the gas composition and pressure.

Detectors using variations of the same principles are pulse ion chambers, silicon and germanium detectors, Geiger counters, spark chambers, and cloud chambers.

Spark chambers, cloud chambers, and bubble chambers. The production of a spark, initiated by the presence of one or more primary electrons, has been described. In a spark chamber, an assembly of accurately parallel plates spaced perhaps one centimetre apart has plates 1, 3, 5, etc. connected together and to electrical ground. Plates 2, 4, 6, etc. are connected via a resistor to a relatively low voltage supply of 100 volts or so and also to a pulsed high-voltage unit, which applies a field of about 20,000 volts per centimetre across the plates in the opposite sense to the low-voltage field when triggered from a coincidence detector. Such chambers are made with dimensions up to three metres on a side and contain up to 80 plates. They are mounted between the poles of large magnets to measure particle momentum by forcing a particle to move in a circular path the radius of which depends on the magnetic field and the particle's mass, velocity, and charge. The gas used in a spark chamber is commonly air.

Spark location is usually obtained by photographing the chamber, but electronic methods of locating the spark within the chamber have also been developed.

The Wilson cloud chamber

A venerable precursor to the spark chamber for track delineation was the cloud chamber, developed by the Scottish physicist C.T.R. Wilson between 1896 and 1912. A chamber with a glass window opposite a movable floor is filled with a gas saturated with ethyl alcohol vapour. Expansion of the chamber volume by rapidly lowering the floor of the chamber, thus increasing its volume and thereby reducing the pressure suddenly, causes supersaturation of the alcohol vapour, which then condenses as droplets on any ions (or dust particles) present. With a dust-free filling and a clearing field between electrodes in the chamber. which is switched off when an observation is to be made; droplet-delineated particle tracks show up clearly against the black floor of the chamber and can be photographed. The reset time after expansion is five to 10 seconds, a time that compares unfavourably with the few milliseconds of the spark chamber.

The bubble chamber, developed by a U.S. nuclear physicist, Donald A. Glaser, in 1952, uses a superheated liquid in place of a vapour to obtain better stopping power in the track medium. Diethyl ether, compressed to a pressure of several atmospheres and heated well above the boiling point, remains superheated when the pressure is released, long enough for tiny bubbles to form around the ions in a particle track. Liquid hydrogen is used in neutron detection chambers. Being built up to two metres in diameter, bubble chambers, with their large magnet systems, are impressive engineering achievements. Their recycle time is about one second.

APPLICATIONS IN SCIENCE, INDUSTRY, AND TECHNOLOGY

Dosage measurement

The dissipation of energy by ionizing radiation in matter causes damage, either temporary, as in the ionization of a gas, or more permanent, as when chemical bonds are broken or atoms are displaced from their position in the lattice structure (see RADIATION EFFECTS ON MATTER). The unit used for the measurement of radiation dosage is called the rad. This unit corresponds to the dissipation of an energy of 100 ergs per gram of material at the point of interest. Devices for measuring dosage are ion chamber dosimeters; photographic dosimeters; thermoluminescent phosphor dosimeters; and radio-photoluminescent glass dosimeters. The use of a Geiger counter for uranium prospecting is part of general public knowledge. It is one example of an instrument used to detect gamma rays emitted by a radioactive material; it gives an electrical pulse each time a gamma ray interacts in the sensitive volume of the counter tube. Radioactive elements may also emit beta particles, which are high-velocity electrons, and alpha particles, which are positively charged nuclei of helium atoms, and specialized detectors are necessary for these radiations. The distinction between alpha and beta particles, which are components of ordinary matter, and gamma rays is that the latter consist of electromagnetic waves, essentially similar to X-rays and light waves but extending to higher energies and shorter wavelengths.

In nuclear reactors, uranium undergoes fission when bombarded with neutrons, and the two (or sometimes three) fragments of the uranium nucleus fly apart with great velocity, generating heat as they lose energy to the surrounding material. Neutrons are uncharged particles, about 1,840 times more massive than electrons, and are produced in fission and in a number of nuclear reactions. Detectors are needed for the detection and measurement of neutrons and sometimes for fission reactions.

Extraterrestrial radiation

The surface of the Earth is bombarded day and night with cosmic rays, possessing extremely high energy, even after passing through the full depth of the atmosphere. Outside this protective mantle there is a continuous bombardment of ultraviolet rays and X-rays, protons from the Sun, and, passing through space and through the Earth as though it were transparent, a cosmic flux of neutrinos, which are almost indetectable uncharged particles produced during radioactive decay.

Scientists seek to detect these different radiations, to measure their energies and to determine the instant at which they interact with instruments, and to measure the total amount of particles or radiation that has passed through a particular position over a period of time. The absorption of radiation may also be used to provide information on the thickness of the absorbing material.

The widespread use of X-rays and radioisotopes in medicine and industry, the lethal concentrations of radioactive material in nuclear reactors, the possibilities of widespread contamination following nuclear warfare, all combine to generate a need for detectors and instruments that measure the degree of hazard existing in any given environment—the so-called health-physics instruments. The possibility of tagging individual molecules with radioactive atoms, and so extending the sensitivity of analytical methods, has produced a huge demand for detectors used in analytical instruments that find application in medicine, biology, and chemical analysis. Improvements in spectrographic techniques both on the surface of the Earth and in satellite environments give rise to a need for detectors of hard (high-energy) ultraviolet radiation, which merges into the soft (low-energy) X-ray region; these in general have to be specially developed for the experiments in hand.

Nuclear physics experiments demand increasingly complex arrays of detectors that are connected together in elaborate computer-controlled systems and that may involve the precise measurement of position of interaction of a particle of known energy and its time of interaction to an accuracy of a fraction of a nanosecond. In the industrial field, the control of nuclear reactors demands the use of specialized detectors, and the application of radioisotopes (radioactive atoms) in thickness gauges and in analytical instruments generates a need for a wide range of equipment. In the search for raw materials for nuclear power, a range of portable instruments involving rugged detectors has become necessary, and, of course, similar instruments merge into the health-physics aspects of civil-defense instrumentation. More complex instruments and detectors are used in geological evaluation of rock strata for the petroleum industry and in the search for other raw materials.

BIBLIOGRAPHY. JACK SHARPE, *Nuclear Radiation Detectors*, 2nd ed. rev. (1964), is a compact survey of the basic physics of detectors; W.H. TAIT, *Radiation Detection* (1980), is an introductory text; GLENN F. KNOLL, *Radiation Detection and Measurement* (1979), is more extensive, covering techniques. Specific detectors are dealt with in the following: GEOFFREY DEARNALEY and D.C. NORTHROP, *Semiconductor Counters for Nuclear Radiations*, 2nd ed. rev. (1966); C.H. WANG, DAVID L. WILLIS, and WALTER D. LOVELAND, *Radiotracer Methodology in the Biological, Environmental and Physical Sciences* (1975),

which includes a detailed explanation of liquid scintillation counting; D.H. WILKINSON, ***Ionization Chambers and Counters*** (1950, reissued 1970); BRUNO B. ROSSI and HANS H. STAUB, ***Ionization Chambers and Counters*** (1949, reprinted 1977). Of the last two books, Wilkinson's is predominantly theoretical in nature, whereas Rossi and Staub's deals with experimental techniques developed in the Manhattan Project. The International Atomic Energy Agency (IAEA), Vienna, publishes a number of books and reports that are readily available. In the field of health physics, reports no. 109 and 120 in the IAEA "Technical Reports Series" deal with personnel dosimetry systems and the monitoring of radioactive contamination on surfaces, respectively, whereas ***Nuclear Accident Dosimetry Systems*** is one of the IAEA "Proceedings Series" (all 1970). Papers on detectors are regularly published in many journals, including the ***Review of Scientific Instruments*** (monthly), of which the May 1961 issue was devoted entirely to spark chambers; ***Nuclear Instruments and Methods*** (bimonthly); and ***IEEE Transactions: Nuclear Science*** (bimonthly), which include the proceedings of the Scintillation and Semiconductor Counter Symposium held every other year since 1948.

Radiation Effects on Matter

The term radiation implies a flow or streaming of atomic and subatomic particles and of waves, such as those that characterize heat rays, light rays, and X-rays. A simple way of classifying radiation is by the speed of particles or waves in *vacuo:* all waves travel with the speed of light, whereas particulate matter moves with somewhat slower speeds. A comprehensive study of radiation includes the emission, propagation, and absorption of the particles or waves. This article is concerned only with the absorption of radiation as it encounters matter; that is, the behaviour of the radiation and the matter with which it interacts, and how energy is transferred from the radiation to its surroundings.

I. General background

RADIATION PHYSICS

Types of radiation. The first type of radiation to be considered consists of waves and is called electromagnetic radiation, because the concept of wave motion is an outgrowth of the theory of electromagnetic fields. Electromagnetic radiation travels with the velocity of light, approximately 3 × 10^{10} centimetres (186,000 miles) per second in free space. The second general type, particulate radiation, includes all radiations travelling at less than the speed of light in free space.

Electromagnetic radiation. According to the theory of relativity (*q.v.*), the velocity of light is a fixed quantity independent of the velocity of the emitter, the absorber, or a presumably independent observer, all three of which do affect the velocities of other kinds of waves, such as sound. In an extended definition, the term light embraces all waves that have the velocity of visible light, whether they be longer or shorter. It includes the following: the long electromagnetic waves predicted by the British physicist James Clerk Maxwell in 1864 and discovered by the German physicist Heinrich Hertz in 1887 (now called radio waves); infrared and ultraviolet light waves; the X-rays discovered in 1895 by Wilhelm Rontgen, a German physicist; the gamma rays that accompany many radioactive-decay processes; and some even more energetic (with higher energy) X-rays and gamma rays produced as the normal accompaniment of the operations of ultrahigh-energy machines (*i.e.*, particle accelerators, once erroneously called atom smashers, such as the Van de Graaff generator, the cyclotron and its variants, and the linear accelerator).

X-rays and gamma rays

Particulate radiation. Unlike X-rays and gamma rays, some high-energy radiations travel at less than the speed of light. Some of these were identified initially by their particulate nature and only later shown to travel with wavelike character. One example of this class is the electron, first established as a negatively charged particle in 1897 by the English physicist Joseph John Thomson and later as the component of beta rays emitted by radioactive elements. The electron was shown by the U.S. physicist Robert Millikan in 1910 to have a fixed charge and by George Paget Thornson, an English physicist, and the U.S. physicists Clinton Joseph Davisson and Lester Halbert Germer (1927) to have wavelike as well as particulate character. Electrons classified as radiation have velocities that range from as low as 10^8 centimetres per second to almost the speed of light. The negative electron, still commonly called an electron, is identified more precisely as a negatron. In 1932 the U.S. physicist Carl Anderson demonstrated the existence of a positive electron, generally called a positron and identified as one of the antiparticles of matter (every subatomic particle has an antiparticle, and a collision between them annihilates both, ultimately producing energy). The collision of a positron and an electron results in the intermediate production of a short-lived atom-like system called positronium, which decays in about 10^{-7} second into two gamma rays. Other particles commonly classified as radiation when travelling with high velocity include the positively charged nucleus of the hydrogen atom, or proton; the nucleus of deuterium (*i.e.*, heavy hydrogen, the nucleus of which has double the mass of normal hydrogen's nucleus), or deuteron, also positively charged; and the nucleus of the helium atom, or alpha particle, which has a double positive charge. The more massive positive nuclei of other atoms show similar wavelike properties when sufficiently accelerated in an electric field. All charged-particle radiations have a charge exactly equal to that of the negative or positive electron or to some integral multiple of that charge.

Annihilation radiation

The neutron is also a radiation; it is a particle emitted in certain radioactive-decay processes and in fission, the process in which a nucleus splits into two smaller nuclei; it decays in free space with a 12- to 13-minute half-life; *i.e.*, one-half of any given number of neutrons decay within 12–13 minutes, each into a proton and a negatron plus an antineutrino. The antineutrino is an uncharged particle that has zero mass when at rest and a velocity equal to that of light. The mass of the neutron approximates that of the hydrogen atom, about 1,850 times the mass of the electron.

Another class of elementary particles, called mesons, includes both positively charged particles and negatively charged particles (*i.e.*, with the same charge as that of an electron), as well as uncharged particles. The masses of mesons are always greater than those of electrons, and most have a mass less than that of the proton; a few have slightly greater mass. Although all these particles are classified as radiations, they are so few that their chemical effects are not presently studied. Because they are part of the constant bombardment from free space to which all matter is constantly exposed, however, they may have considerable effects, such as contributing to the processes of aging and evolution.

Radiation effects of mesons

The structure and properties of matter. Matter in bulk is composed of particles that, compared to radiation, may be said to be at rest, but the motion of the molecules that compose matter, which is attributable to its temperature, is equivalent to travel at the rate of hundreds of metres per second. Although matter is commonly considered to exist in three forms, solid, liquid, and gas, a review of the effects of radiation on matter must also include mention of the interactions of radiation with glasses, attenuated (low-pressure) gases, plasmas, and matter in states of extraordinarily high density. A glass appears to be solid but is actually a liquid of extraordinarily high viscosity, or a mixture of such a liquid and embedded microcrystalline material, which unlike a true solid remains essentially disorganized at temperatures much below its normal freezing point. Low-pressure gases are represented by the situation that exists in free space, in which nearest neighbour molecules, atoms, or ions may be literally centimetres apart. Plasmas, by contrast, are regions of high density and temperature in which all atoms are dissociated into their positive nuclei and electrons.

The capability of analyzing and understanding matter depends upon the details that can be observed and to an important extent upon the instruments that are used. Bulk, or macroscopic, matter is detectable directly by the senses supplemented by the more common scientific instruments, such as microscopes, telescopes, and balances.

It can be characterized by measurement of its mass and, more commonly, its weight, by magnetic effects, and by a variety of more sophisticated techniques, but most commonly by optical phenomena—by the visible or invisible light (*i.e.*, photons) that it absorbs, reflects, or emits or by which its observable character is modified (cf. PHOTOCHEMICAL REACTIONS). Energy absorption, which always involves some kind of excitation, and the opposed process of energy emission depend on the existence of ground-state and higher energy levels of molecules and atoms. A simplified system of energy states, or levels, is shown schematically in Figure 1. Such a system is exactly fixed for each atomic and molecular system by the laws of quantum mechanics; the "allowed," or "permitted," transitions between levels, which may involve energy gain or loss, are also established by those same laws of nature. Excitation to energy levels above those of the energetically stable molecules or atoms may result in dissociation or ionization: molecules can dissociate into product molecules and free radicals, and, if the energy absorption is great enough, atoms as well as molecules can yield ions and electrons (*i.e.*, ionization occurs). Atomic nuclei themselves may exist in various states in which they absorb and emit gamma rays under certain conditions, and, if the nuclei are raised to, or by some process left in, energy states that are sufficiently high, they may themselves emit positrons, negatrons, alpha particles, or neutrons (and neutrinos), or dissociate into the nuclei of two or more lighter atoms. The resulting atoms may be similarly short-lived and unstable or they may be extremely long-lived and quite stable.

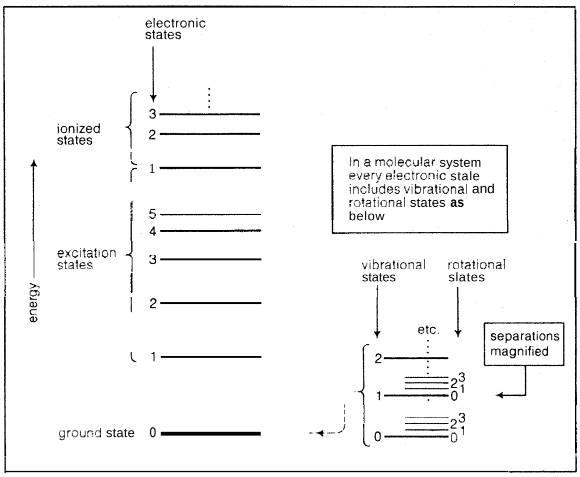


Figure 1: Energy states in molecular systems (see text).

Absorption and quantum laws

CHEMICAL AND BIOLOGICAL EFFECTS OF RADIATION

All matter is subject to the effects of radiation. Effects of radiation on chemical structure and physical properties of matter are, respectively, the concerns of radiation chemistry and of radiation physics. The two subjects are not sharply delineated, however, and, apart from such phenomena as induced radioactivity, are included in the general province of the radiation chemist. Photochemistry is the study of the chemical effects of light. Although radiation chemistry can be considered to include photochemistry, the latter has sufficient history and scientific content to be studied and reported separately. Common photochemical changes are exhibited in the photographic processes: photosynthesis of sugars, amino acids, and related compounds in living plants; and the tanning of living (light-coloured) skin exposed to the sun's rays. In certain cases the excited states that result from light absorption lose their energy in luminescence (the spontaneous emission of light, as in the processes called fluorescence and phosphorescence). Many of the photochemical changes induced by visible and ultraviolet light can also be produced to some degree by higher energy radiations. The rays and fast charged particles of high-energy radiation can be more penetrating than light. They may fog apparently unexposed photographic plates (Becquerel discovered radioactivity in this way); they may cause cancers in inadequately protected flesh or, on the other hand, be used to cure cancers under controlled conditions; and they can cause both destructive and (very infrequently) viable mutations in living organisms at all stages of complexity, from single cells to fruit flies, plants, and highly developed mammals.

Radiation sickness

Radiation sickness is a disagreeable and potentially dangerous consequence of exposure to large doses of high-energy radiation. The more obvious form of such sickness is accompanied by indigestion and nausea of varying intensity, lasting from hours to a month or more. General overexposure (as in accidents) also results in more subtle damage to the bone marrow, which in extreme cases can require total replacement to effect a cure—if a cure is possible at all.

Evolution of life forms. From the human point of view, the interaction of radiation with matter can be considered the most important process in the universe. When the universe began to cool down, at an early stage in its evolution, stars, such as the Sun, and planets appeared, and elements such as hydrogen (H), oxygen (0), nitrogen (N), and carbon (*C*) combined into simple molecules such as water (H_2O), ammonia (NH,), and methane (CH,). As a result of the action of far-ultraviolet light (wavelength less than 185 nanometres) before oxygen appeared in the atmosphere, and of penetrating alpha, beta, and gamma radiations, as well as of electric discharges from lightning storms when the temperature dropped and water began to condense, compounds such as the larger hydrocarbons, alcohols, aldehydes, acids, and amino acids were ultimately built. These simple compounds interacted and eventually developed into living matter. To what degree—if at all—the radiations from radioactive decay contributed to the synthesis of living matter is not known, but the existence of high-energy-irradiation effects on matter at very early times in the history of this world is recorded in certain micas as microscopic, concentric rings, called pleochroic haloes, produced as the result of the decay of tiny specks of radioactive material that emitted penetrating products, such as alpha particles. At the termini of their paths, such particles produced chemical changes, which can be seen microscopically as dark rings. From the diameters of the rings and the known penetrating powers of alpha particles from various radioactive elements, the nature of the specks of radioactive matter can be established. In some cases, alpha particles could not have been responsible for the effects observed; in other cases, the elementary specks that occupied the centres of the haloes were not those of any presently known elements.

It can be readily surmised that some of the elements that participated in the evolution of the world were not originally present but were produced as the result of external high-energy bombardment; that some disappeared as the result of such processes; and that many compounds required for the living processes of organisms evolved as a consequence of the high-energy irradiation to which all matter is subjected.

Role of radiation in life systems. Most of the effects of radiation on living matter are destructive. Mutations produced by radiation are rarely viable and persistent, but those that are can be useful, as in the production of new strains of seeds in botany and agriculture. X-rays, gamma rays, and beta and alpha particles are used in cancer treatment because the mutants produced by their action on a cancer may be nonviable; *i.e.*, the cancer can be stimulated to its self-destruction. On the other hand, healthy tissue may be so affected by penetrating radiation that a viable cancer, ultimately destructive to the host, is produced. This last effect is the danger against which those who work with radioactive materials or penetrating radiation must protect themselves.

Necessity of radiation to life

Radiation effects are essential to the existence of life on Earth. Radiation in its various forms is ultimately responsible not only for the existence of life but for the variety of its forms. Light from the Sun, through photosynthesis, is the primary source of foodstuffs and of the fossil fuel deposits represented in coal, petroleum, and natural gas. Higher energy radiations, both from the Sun and from outer space, affect weather and radio communications and, supplemented by natural and artificially produced radioactivity, are sources of both adventitious and deliberately induced mutations. The probability of ultimately lethal effects has stimulated such work as research on tsetse flies and malarial mosquitoes, in which it has been found an effective control procedure to expose males to gamma radiation and thus to make them sterile. Released into a general population of females that mate but once, the irradiated males mate frequently and thus reduce the number of offspring.

Radiation in photographic process. The effect of radiation on silver halides is the basis of the photographic process. It was originally confined to recording merely what can be seen with the eye, but the same process was also soon found to report effects produced by the more energetic (and invisible) ultraviolet light. Improvements involving the use of photosensitizers made it possible to take photographs in the dark with infrared light and with suitable filters to photograph the limited areas of a scene that reflect infrared to some special degree. From the military point of view, infrared photographic surveillance greatly diminishes the effectiveness of protective camouflage. Weather satellites are another example of an effective use of infrared surveillance.

The discovery of X-rays in 1895 was soon followed by employment of X-ray photography in medicine, and later by the use of both X-rays and gamma rays in routine examination of metallurgical products for voids and defects.

STUDIES OF RADIATION CHARACTERISTICS

The behaviour of light seems to have interested ancient philosophers but without stimulating them to experiment, though all of them were impressed by vision. The Greek philosopher Aristotle considered vision to involve a light source, the passage of a beam from the eye of the observer to the thing observed, and passage of a beam from the thing observed to the eye of the observer. The first meaningful optical experiments on light were performed by the English mathematician Isaac Newton (beginning in 1666), who showed (1) that white light diffracted by a prism into its various colours can be reconstituted into white light by a prism oppositely arranged and (2) that light of a particular colour selected from the diffracted spectrum of a prism cannot be further diffracted into beams of other colour by an additional prism. Newton hypothesized that light is corpuscular in its nature, each colour represented by a different particle speed, an erroneous assumption. Furthermore, in order to account for the refraction of light, the corpuscular theory required, contrary to the wave theory of the Dutch scientist Christiaan Huygens (developed at about the same time), that light corpuscles travel with greater velocity in the denser medium. Support for the wave theory came in the electromagnetic theory of Maxwell (1864) and the subsequent discoveries of H.R. Hertz and of Rontgen of both the very long and the very short waves Maxwell had included in his theory. Max Planck, a German physicist, proposed a quantum theory of radiation to counter some of the difficulties associated with the wave theory of light, and in 1905 Einstein proposed that light is composed of quanta (later called photons). Thus, experiment and theory had led around from particles (of Newton) that behave like waves (Huygens) to waves (Maxwell) that behave like particles (Einstein), the apparent velocity of which is unaffected by the velocity of the source or the velocity of the receiver. Furthermore it was found, in 1922, that the shorter wavelength electromagnetic radiations, such as X-rays, have momentum such as may be expected of particles, part of which can be transferred to electrons with which they collide (*i.e.*, the Compton effect).

Quantum theory of light

Electrons themselves had already been shown to be particles of fixed charge. In 1927 experiments were reported that demonstrated the wave nature of the electron: diffracted from crystals, electrons behave like waves of measurable wavelength; in passage through thin metallic foils, electrons are scatteied like waves also of measurable wavelength. As mentioned earlier, the wavelike character of all fast particles has been established.

II. Fundamental processes involved in radiation interaction with matter

THE PASSAGE OF ELECTROMAGNETIC WAVES

The field concept. A discussion of this subject requires preliminary definition of a few of the more common terms. Around every particle, whether it be at rest or in motion, whether it be charged or uncharged, there are potential fields of various kinds. As one example, a gravitational field exists around the Earth and indeed around every particle of mass that moves with it. At every point in space, the field has direction in respect to the particle. The strength of the gravitational field around a specific particle of mass, m, at any distance, r, is given by the product of g, the universal gravitational constant, and m divided by the square of r, or gm/r^2. The field extends indefinitely in space, moves with the particle when it moves, and is propagated to any observer with the velocity of light. Newton showed that the mass of a homogeneous spherical object can be assumed to be concentrated at its centre and that all distances can be measured from it. Similarly, electric fields exist around electric charges and move with them. Magnetic fields exist around electric charges in motion and change in intensity with all changes in the accompanying electric field, with the magnetic field at any point being perpendicular to the electric field in free space. Any regular oscillation is time-dependent, as is any change in field strength with time.

Time-dependent electric and magnetic fields occur jointly; together they propagate as what are called electromagnetic waves. In an assumed ideal free space (without intrusion from other fields or forces of any kind, devoid of matter, and, thus, in effect without any intrusions, demarcations, or boundaries), such waves propagate with the speed of light in the so-called transverse electromagnetic mode; *i.e.*, the directions of the electric field, the magnetic field, and the propagation of the wave are mutually perpendicular. They constitute a right-handed coordinate system; *i.e.*, with the thumb and first two fingers of the right hand perpendicular to each other, the thumb points in the direction of the electric field, the forefinger in that of the magnetic field, and the middle finger in that of propagation. A boundary may be put on the space by appropriate physical means (bound space), or the medium may be something other than a vacuum (material medium). In either case, other forces and other fields come into the picture, and propagation of the wave is no longer exclusively in the transverse electromagnetic mode. Either the electric field or the magnetic field (a matter of arbitrary choice) may be considered to have a component parallel to the direction of propagation itself. It is this parallel component that is responsible for attenuation of energy of the waves as they propagate.

Light: transverse electromagnetic waves

Frequency range. Electromagnetic waves span an enormous range of frequencies (*i.e.*, number of oscillations per second), only a small part of which fall in the visible region. Indeed, it is doubtful that lower or upper limits of frequency exist, except in regard to the applicability of present-day instrumentation. Figure 2 indicates the usual terminology employed for electromagnetic waves of different frequency or wavelength. Customarily, scientists designate electromagnetic waves by fields, waves, and particles in increasing order of the frequency ranges to which they belong. Traditional demarcations into fields, waves, and particles (*e.g.*, gamma-ray photons) are shown in the figure. The distinctions are largely of classical (*i.e.*, nonquantum) origin; in quantum theory there is no need for such distinctions. They are preserved, however, for common usage. The term "field" is used in a situation in which the wavelength of the electromagnetic waves is larger than the physical size of the experimental setup. For wave designation, the wavelength is comparable to or smaller than the physical extent of the setup, and at the same time the energy of the photon is low. The particle description is useful when wavelength is small and photon energy is high.

Classification of electromagnetic regions

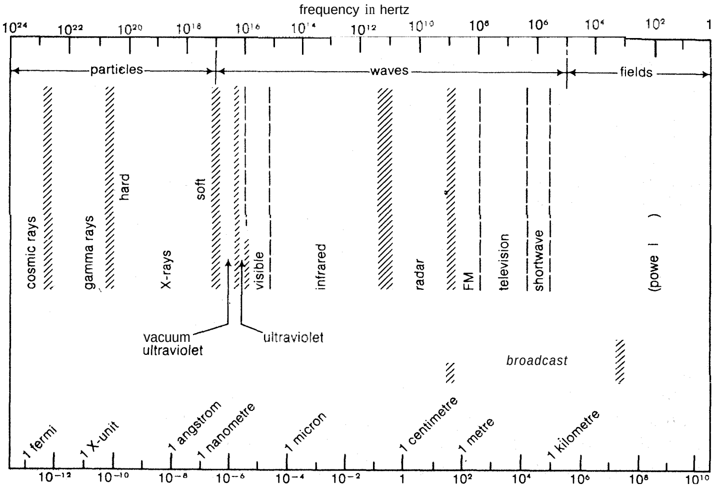

Figure 2: Electromagnetic spectrum.
Two scales are shown: the frequency scale, expressed in hertz (Hz), or cycles per second, and the wavelength scale, expressed in centimetres. Other units of wavelength customarily used to define certain regions of the spectrum are also given; *e.g.,* the nanometre (nm, 1/1,000,000,000 metre) the unit useful in the visible region, with an approximate range from 760 nm (red) to 380 nm (violet). Demarcations between the various classifications of radiations (*e.g.,* gamma rays and X-rays) are not sharp.

Properties of **light.** The ordinary properties of light, such as straight-line propagation, reflection and refraction (bending) at a boundary or interface between two mediums, and image formation by mirrors or lenses, can be understood by simply knowing how light propagates, without inquiring into its nature. This area of study, essentially, is geometrical optics. On the other hand, the extraordinary properties of light do require answers to questions regarding its nature (physical optics). Thus, interference, diffraction, and polarization relate to the wave aspect, while photoelectric effect relates to the particle aspect of light. Apparently light has dual character. It is the duality in the nature of light, as well as that of matter, that led to quantum theory.

In general, radiation interacts with matter; it does not simply act on nor is it merely acted upon. Understanding of what radiation does to matter requires also an appreciation of what matter does to radiation.

When a ray of light is incident upon (falls on) a plane surface separating two mediums (for example, air and glass) it is partly reflected (*i.e.*, thrown back into the original medium) and partly refracted (*i.e.*, transmitted into the other medium). Laws of reflection and refraction state that all the rays (incident, reflected, and refracted) and the normal (a perpendicular line) to the surface lie in the same plane, called the plane of incidence. Angles of incidence and reflection are equal; for any two mediums the sines of the angles of incidence and refraction have a constant ratio, called the mutual refractive index. All these relations can be derived from the electromagnetic theory of Maxwell, which constitutes the most important wave theory of light; but electromagnetic theory is not necessary to demonstrate these laws.

Maxwell's theory of radiation

Double refraction. In double refraction, light enters a crystal the optical properties of which differ along two or more of the crystal axes. What is observed depends on the angle of the beam with respect to the entrant face. Double refraction was first observed in 1669 by Erasmus Bartholin in experiments with Iceland spar crystal and elucidated in 1690 by Huygens.

If a beam of light is made to enter an Iceland spar crystal at right angles to a face, it persists in the crystal as a single beam perpendicular to the face and emerges as a single beam through an opposite parallel face. If the exit face is at an angle not perpendicular to the beam, however, the emergent beam is split into two beams at different angles, called the ordinary and extraordinary rays, and they are usually of different intensities. Clearly, any beam that enters an Iceland spar crystal perpendicular to its face and emerges perpendicular to another face is of changed character—although superficially it may not appear to be changed. Dependent on the relative intensities and the phase relationship of its electric components (*i.e.*, their phase shift), the beam is described as either elliptically or circularly polarized. There are other ways of producing partially polarized, plane-polarized, and elliptically (as well as circularly) polarized light; but these examples illustrate the phenomena adequately.

Polarization of an electromagnetic wave can be shown mathematically (see ELECTROMAGNETIC RADIATION) to relate to the space–time relationship of the electromagnetic-field vector (conventionally taken as the electric vector, a quantity representing the magnitude and direction of the electric field) as the wave travels. If the field vector maintains a fixed direction, the wave is said to be plane-polarized, the plane of polarization being the one that contains the propagation direction and the electric vector. In the case of elliptic polarization the field vector generates an ellipse in a plane perpendicular to the propagation direction as the wave proceeds. Circular polarization is a special case of elliptic polarization in which the so-described ellipse degenerates into a circle.

Kinds of polarization

An easy way to produce circularly polarized light is by passage of the light perpendicularly through a thin crystal (*e.g.*, mica). The mica sample is so selected that the path difference for the ordinary and the extraordinary rays is one-quarter the wavelength of the single-wavelength, or monochromatic, light used. Such a crystal is called a quarter-wave plate, and the reality of the circular polarization is shown by the fact that, when the quarter-wave plate is suitably suspended and irradiated, a small torque —that is, twisting force--can be shown to be exerted on it. Thus, the action of the crystal on the light wave is to polarize it; the related action of the light on the crystal is to produce a torque about its axis.

The ratio of the intensity of the reflected light to that of the incident light is called the reflection coefficient. This quantitative measure of reflection depends on the angles of incidence and refraction. or the refractive index, and also on the nature of polarization.

It can be shown that the reflection coefficient at any angle of incidence is greater for polarization perpendicular to the plane of incidence than for polarization in the plane of incidence. As a result, if unpolarized light is incident at a plane surface separating two media, reflected light will be partially polarized perpendicular to the plane of incidence, and refracted light will be partially polarized in the plane of incidence. An exceptional case is the Brewster angle, which is such that the sum of the angles of incidence and refraction is 90". When that happens, the reflection coefficient for polarization in the plane of incidence equals zero. Thus, at the Brewster angle, the reflected light is wholly polarized perpendicular to the plane of incidence. At an air–glass interface, Brewster's angle is approximately 56°, for which the reflection coefficient for perpendicular polarization is 14 percent. Another important angle for refraction is the critical angle of incidence when light passes from a denser to a rarer medium. It is that angle for which the angle of refraction is 90° (in this case the angle of refraction is greater than the angle of incidence). For angles of incidence greater than the critical angle there is no refracted ray; the light is totally reflected internally. For a glass-to-air interface the critical angle has a value 41"48'.

Brewster's angle

Dispersion. The variation of the refractive index with frequency is called dispersion; it is this property of a prism that effects the colour separation, or dispersion, of white light. An equation that connects the refractive index with frequency is called a dispersion relation. **A** simple classical dispersion relation can be obtained by consideration of the joint effect of (1) the oscillation of the electrons bound to the atoms in the absence of an external field and (2) the frequency of the external electromagnetic field imposed on the system, with appropriate consideration (3) of the effect of the number of electrons per cubic centimetre of the material and (4) of the charge and mass of the electron. For visible light the index of refraction increases slightly with frequency, a

Propagation velocity of electromagnetic energy

phenomenon called normal dispersion. The degree of refraction depends on the refractive index. The increased bending of violet light over red by a glass prism is, therefore, the result of normal dispersion. If experiments are done, however, with light having a frequency close to the natural electron frequency, some strange effects appear. When the radiation frequency is slightly greater, for example, the index of refraction becomes less than unity (<1) and decreases with increasing frequency; the latter phenomenon is called anomalous dispersion. A refractive index less than unity refers correctly to the fact that the speed of light in the medium at that frequency is greater than the speed of light in vacuum. The velocity referred to, however, is the phase velocity or the velocity with which the sine-wave peaks are propagated. The propagation velocity of an actual signal or the group velocity is always less than the speed of light in vacuum. Therefore, relativity theory is not violated. An example is shown in Figure 3. in which a light source is initially pointed in the direction *A*. The source rotates in such a way that the velocity of the light image moves from D to E with a velocity v approximating c. Thus, the phase velocity with which the image moves from *A* to B is greater than c, but the relativity principle is not violated because the velocity of transmission of matter or energy does not exceed the velocity of light.

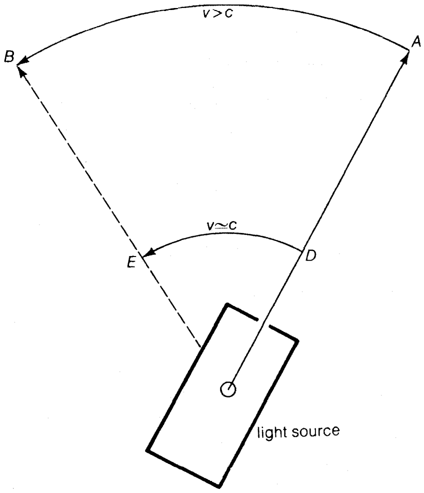

Figure 3: Contrast of phase velocity, v, and wave velocity, *c*. As the light source turns counterclockwise on its axis, the velocity with which the signal moves (*e.g.*, from *A* to *B*) can exceed the velocity of light without violation of the relativity principle (see text).

The quantum-mechanical form of the dispersion relation is similar to the form of that relation in classical theory but is different in concept and details.

Electromagnetic waves and atomic structure. Quantum concepts. Quantum mechanics includes such concepts as "allowed states"; *i.e.*, stationary states of energy content exactly stipulated by its laws. The energy states shown in Figure 1 are of that kind. A transition between such states depends not only on the availability (*e.g.*, as radiation) of the precise amount of energy required but also on the quantum-mechanical probability of such a transition. That probability, the oscillator strength, involves so-called selection rules that, in general terms, state the degree to which a transition between two states (which are described in quantum-mechanical terms) is allowed. As an illustration of allowed transition in Figure 1, the only electronic transitions permitted are those in which the change in vibrational quantum number accompanying a change in electronic excitation is plus or minus one or zero,-except that a 0 ↔ 0 (zero to zero) change is not permitted. All electronic states include vibrational and rotational levels, so that the probability of a specific electronic transition includes the probabilities of transition between all the vibrational and rotational states that can conceivably be involved. Figure 1 is, of course, a simplified picture of a compendium of energy states available to a molecule (polyatomic structure)—and the selection rules are accordingly more involved in such a case. The selection rules are worked out by scientists in a process of discovery; the attempt is to state them systematically so that the applicable rules in an experimentally unstudied case may be stated on the basis of general principle.

Oscillator strengths

Resonance. Calculations based on quantum-mechanical principles yield resonance frequencies or oscillator strengths between two states that, as an example, describe dispersion.

It is notable that the refractive index in the classical and quantum-mechanical relations is complex; that is, it includes a factor of the square root of minus one, which is imaginary. Its imaginary part is associated with the damping factor symbolized by the Greek letter gamma, Γ, a measure of the rate at which the intensity of radiation diminishes along its path. The real and imaginary parts of the refractive index can be separated into a general form so that the index of refraction (n) for a given frequency symbolized by the Greek letter omega, ω, expressed as $n(\omega)$, is equal to the difference between a real index $n_1(\omega)$ and an imaginary index, written as $in_2(\omega)$, in which i is the imaginary $\sqrt{-1}$; *i.e.*, as $n(\omega) = n_1(\omega) - in_2(\omega)$. The real part of the refractive index, $n_1(\omega)$, represents no attenuation but only a time delay; the imaginary part, $n_2(\omega)$, represents a true attenuation. The intensity of light decreases exponentially with distance; that is, it decreases in the same ratio of final to initial intensity in travel through the same distance. The energy loss from the light wave appears as energy added to the medium, or what is known as absorption. The coefficient of absorption, *a*, is equal to the reciprocal of the distance over which the light intensity is reduced by a factor of *e* (the logarithmic base e $=$ 2.718). The index of absorption is simply the imaginary index n_2. They are both dependent on frequency and are related so that the coefficient of absorption is equal to the frequency times the index of absorption divided by the velocity of light (c), or a $= \omega n_2/c$.

Reflection and transmission coefficients

Reflection and transmission coefficients (ratio of intensity of the reflected and transmitted beams to the incident) at a boundary of an absorbing medium are valid as long as the refractive index is considered to be complex. In addition to attenuation it implies a phase shift between the two polarization components, parallel and perpendicular to the plane of incidence, for both the reflected and the transmitted light. Thus, even if the incident light is unpolarized, both the reflected and the transmitted light are elliptically polarized. Another effect of absorption on reflection is that, at Brewster's angle (at which the sum of the angles of incidence and refraction is 90°), the reflection coefficient for the parallel polarization component is not zero but finite.

Absoiption *and* emission. Absorbing mediums are classified as weskly or strongly absorbing depending upon whether the real index is much greater or much less than (symbolized $<<$) the imaginary index ($n_2 << n_1$ or $n_1 << n_2$). The intermediate situation is characterized by the two indices being approximately (symbolized $\simeq$) the same ($n_1 \simeq n_2$). A medium can, of course, be weakly absorbing at one region of the electromagnetic spectrum and strongly absorbing at another. Most substances that are transparent in the visible range also absorb weakly in the visible range. Frequently, however, they absorb strongly in the ultraviolet at or close to their resonance frequencies. If a medium is weakly absorbing, its dispersion and absorption can be measured directly from the intensity of refracted or transmitted light. If it is strongly absorbing, on the other hand, the light does not survive even a few wavelengths of penetration. The refracted or transmitted light is then so weak that measurements are at best difficult. The absorption and dispersion in such cases, nevertheless, may still be determined by studying the reflected light only. This procedure is possible because the intensity of the reflected light contains the refractive index of which the real and imaginary parts separate neatly into dispersion and absorption, respectively. In the far ultraviolet, it is the only practical means of studying absorption, a study that has revealed valuable information about electronic energy levels and collective energy losses (see below *Molecular* activation) in condensed material.

Laser source of radiation

Experimental studies of the chemical effects of radiation on matter can be greatly forwarded by the use of beams of high intensity and very short duration. Such studies are made possible by employment of the laser, a light source developed by United States physicists A.L. Schawlow and C.H. Townes (1958) from the application of one of the Einstein equations. Einstein suggested (on the basis of a principle of detailed balancing, or microscopic reversibility) that, just as the amount of light absorbed by a molecular system in a light field must depend on the intensity of the light, the amount of light emitted from excited states of the same system must also exhibit such dependency. In this fundamentally important idea of microscopic reversibility can be seen one of the most dramatic illustrations of the physical effects of radiation.

Under any circumstance, the absorption probability in the ground state is given by the number of molecules (or atoms), N_i, in that state multiplied both by the probability, B,$_j$, for transition from state i to state *j* and by the light intensity, $I(\nu)$, at frequency symbolized by the Greek letter nu, ν; *i.e.*, $N_iB_{ij}I(\nu)$. Light emission from an excited state to the ground state depends on the number of molecules (or atoms) in the upper state, N,, multiplied by the probability of spontaneous emission, A_{ji}, to the ground state plus the additional induced emission term, $N_jB_{ji}I(\nu)$, in which B_{ji} is a term that Einstein showed to be equal to B,, and that relates the probability of such induced emission, so that in the general case in any steady-state situation (in which light absorption and emission are occurring at equal rates):

$$N_iB_{ij}I(\nu) = N_j[A_{ji} + B_{ji}I(\nu)].$$

There is a well-developed theoretical relationship (not here presented) of a quantum-mechanical nature between **A,,** and B_{ij}. Ordinarily, the light intensity, $I(\nu)$, is so low that the second term on the right can be neglected. At sufficiently high light intensities, however, that term can become important. In fact, if the light intensity is high, as in a laser, the induced-emission probability can easily exceed that of spontaneous emission.

Spontaneous emission of light is random in direction and phase. Induced emission has the same direction of polarization and propagation as that of the incident light. If by some means a greater population is created in the upper level than in the lower one, then, under the stimulus of an incident light of appropriate frequency, the light intensity actually increases with path length provided that there is enough stimulated emission to compensate for absorption and scattering. Such stimulated emission is the basis of laser light. Practical lasers such as the ruby or the helium–neon lasers work, however, on a three-level principle.

Mechanism of pair production

The Compton effect. The energy required to remove an orbital electron from an atom (or molecule) is called its binding energy in a given state. When light of photon energy greater than the minimum binding energy is incident upon an atom or solid, part or all of its energy may be transformed through the photoelectric effect, the Compton effect, or pair production—in increasing order of importance with increase of photon energy. In the Compton effect, the photon is scattered from an electron, resulting in a longer wavelength, thus imparting the residual energy to the electron. In the other two cases the photon is completely absorbed or destroyed. In the pair-production phenomenon, an electron–positron (positively charged electron) pair is created from the photon as it passes close to an atomic nucleus. **A** minimum energy (1,020,000 electron volts) is required for this process because the energy of the electron–positron pair at rest—the total mass, $2m$, times the velocity of light squared ($2mc^2$)—must be provided. **If** the photon energy (hv) is greater than the rest mass, the difference ($h\nu - 2mc^2$), called the residual energy, is distributed between the kinetic energies of the pair with only a small fraction going to the nuclear recoil.

The photoelectric effect. The photoelectric effect is caused by the absorption of electromagnetic radiation and consists of electron ejection from a solid (or liquid) surface, usually of a metal, though nonmetals have also been studied. In the case of a gas, the term photo-ionization is more common, though there is basically little difference between these processes. Despite experimental difficulties connected with surface-adsorbed gas and energy loss of ejected electrons in penetrating a layer of the solid into vacuum, early experimenters established two important features about the photoelectric effect. These are: (1) although the photoelectric current (*i.e.*, the number of photoelectrons) is proportional to the incident-light intensity, the energy of the individual photoelectrons is independent of light intensity; and (2) the maximum energy of the ejected electron is roughly proportional to the frequency of light. On the basis of these observations, Einstein argued that the light is absorbed in quanta of energy equal to Planck's constant (h) times light frequency, $h\nu$, by electrons, one at a time. **A** minimum energy symbolized by the Greek letter psi, ψ, called the photoelectric work function of the surface, must be supplied before the electron can be ejected. When a quantum of energy is greater than the work function, photoelectric emission is possible with the maximum energy symbolized by the Greek letter epsilon, ε, of the photoelectron (ε_{max}) being stated by Einstein's photoelectric equation as equalling the difference between the photon energy and the work function; *i.e.*,,,& $= h\nu -$ $. Einstein's interpretation gave strong support for the quantum theory of radiation. Early experiments determined Planck's constant, h, independently through the above equation and also established the fact that an immeasurably small time delay is involved between absorption of a quantum of light and the ejection of an electron.

Photoelectric threshold frequency

Accurate and reliable values of the work function and ejection energy are now available for most solids; the chief obstacles to the development of such data were the difficulty of preparation of clean surfaces and the energy loss of electrons in penetration into vacuum. The photoelectric threshold frequency, symbolized by the Greek letter nu with subscript zero, ν_0, is one at which the effect is barely possible; it is given by the ratio of the work function symbolized by the Greek letter psi, ψ, to Planck's constant ($\nu_0 = \psi/h$). The photoelectric yield, defined as the ratio of the number of photoelectrons to that of incident photons, serves as a measure of the efficiency of the process. Photoelectric yield starts from a zero value at threshold, reaches a maximum (about 1/1,000) at about twice the threshold frequency, and falls again when frequency is further increased. Some unusual alloys exhibit yields a hundred times greater than normal (*i.e.*, about 0.1). Normally the yield depends also on polarization and angle of incidence of the radiation. Parallel polarization (polarization in the plane of incidence) gives higher yield than does perpendicular polarization, sometimes by almost ten times.

Light interacts with matter in a variety of ways (*e.g.*, reflection, refraction, interference, scattering); it can induce chemical change in a molecule almost exclusively by absorption only.

Cross section. **A** useful concept in describing the absorption of radiation in matter is called cross section; it is a measure of the probability that photons interact with matter by a particular process. When the energy of each individual photon ($h\nu$) is much smaller than the rest energy of the electron (its mass times the velocity of light squared [mc^2]), the scattering of photons is described by a cross section derived by the English physicist J.J. Thomson. This cross section is called the Thomson cross section, symbolized by the Greek letter sigma with subscript zero, ***a,,*** and is equal to a numerical factor times the square of the term, electric charge squared divided by electron rest energy, or $\sigma_0 = (8\pi/3)(e^2/mc^2)^2$. When the photon energy is equal to or greater than the electron's rest energy of ($h\nu \geq mc^2$), inelastic (*i.e.*, energy loss) scatterings begin to appear. One such is Compton scattering, in which an X-ray or gamma ray (electromagnetic radiation from an atomic nucleus) experiences an increase in wavelength (reduction in energy) after being scattered through an angle. Arthur Holly Compton, a physicist in the United States, correctly interpreted the effect by using laws of classical relativistic mechanics. He showed that the increase in wavelength symbolized by the Greek letters delta and lambda, *Ah,* is independent of the energy of the photon and is given by an expression in which the product of two terms appears. The first is a universal constant symbolized by the Greek letter lambda with subscript zero, λ_0, generally called the Compton wavelength, and itself equal to Planck's constant, *h*, divided by the mass of the electron at rest and the velocity of light; *i.e.*, X, $= h/mc = 2.4 \times 10^{-10}$ centimetre. The second is a term dependent on the angle symbolized by the Greek letter theta, θ, through which the photon is scattered; it is one minus the cosine of that angle, or $1 - \cos \theta$. The increase in wavelength observed at that angle is simply AX = X, $(1 - \cos \theta)$. In discussion of the Compton effect the electron is treated as free—that is, not bound to a nucleus—because, in the study of that effect for most materials of low atomic number, the incident photon has energy much greater than the binding energy. For bound electrons, the corrections to the Compton relation are small but complicated. When photons are scattered, the concept of differential cross sections may be used; differential cross section is a measure of the probability that a photon will be scattered within a given small angle.

Compton wavelength

The differential cross section for the Compton process was derived by the Swedish physicist Oskar Klein and the Japanese physicist Yoshio Nishina. The Klein–Nishina formula shows almost symmetrical scattering for low-energy photons about 90° to the beam directions. As the photon energy increases, the scattering becomes predominantly peaked in the forward direction, and, for photons with energies that are greater than five times the rest energy of the electron, almost the entire scattering is confined within an angle of 30". When averaged over the angle, the Klein–Nishina cross section shows variation with the incident photon energy. At low energy this cross section increases uniformly and approaches the classical Thomson value as energy is decreased; at high energy the cross section is inversely proportional to the energy. The energy distribution of Compton electrons (recoil or scattered electrons) and outgoing photons may also be derived from the Klein–Nishina theory. The result shows a wide distribution; for atoms of low atomic number and incident photon energies in the region of importance (*i.e.*, 1,000,000 to 100,000,000 electron volts), the probability of scattering per unit energy interval is fairly constant—except that, for the case of nearly total conversion of the photon energy into electron kinetic energy, a plot of energy versus angle shows a sharp, narrow peak. Thus, as a crude approximation, the average energy of a Compton electron is about half the incident photon energy.

Compton scattering plays a key role in the interaction of matter with intermediate-energy gamma rays and high-energy X-rays. For these radiations, it is almost the exclusive mechanism by which energy is transferred from the radiation and added to the matter. An example may be cited of the penetration of gamma rays from the radioactive substance cobalt-60 into a sample of water or aqueous solution. The electron density is approximately 3×10^{23} per millilitre. Taking the Compton cross section as approximately 3×10^{-25} square centimetre per electron, calculation yields a mean free path for Compton scattering of about ten centimetres (*i.e.*, a photon will move about ten centimetres between successive encounters with electrons). The dominant radiation effect produced by a gamma ray, therefore, is attributable to the recoil electron and the vast number of progeny (such as secondary and tertiary electrons) that are produced. These higher generation electrons are produced through electron-impact ionization (*i.e.*, an electron is removed from an atom by the collision of another electron), a process that continues until barred either by energetic limitation or by low cross section. For cobalt-60 gamma rays the average Compton energy in a material of low atomic number, such as water, is approximately 600,000 electron volts. The study of chemical transformation resultant from interaction of radiation with matter is called radiation chemistry. Normally the incident radiation is an X-ray or a gamma ray or a charged particle. There are areas of overlap between photochemistry and radiation chemistry, particularly in the range of wavelengths from about 150 to about 85 nanometres.

Energy transfer from gamma rays

Puir production. Pair production is a process in which a gamma ray of sufficient energy is converted into an electron and a positron. A fundamental law of mechanics, given by Newton, is that in any process total linear (as well as angular) momentum remains unchanged. In the pair-production process a third body is required for momentum conservation. When that body is a heavy nucleus, it takes very little recoil energy, and therefore the threshold is just twice the rest energy of the electron; *i.e.*, twice its mass, m, times the square of the velocity of light, c^2, or $2mc^2$. Pair production can also occur in the field of an atomic electron, to which considerable recoil energy is thereby imparted. The threshold for such a process is four times the rest energy of an electron, or $4mc^2$. The total pair-production cross section is the sum of the two components, nuclear and electronic. These cross sections depend on the energy of the gamma ray and are usually calculated in an electron theory proposed by British physicist P.A.M. Dirac through a method of approximation that is a simplification of a method (a "first approximation") given by the German physicist Max Born (*i.e.*, a "first Born approximation"). The process is envisaged by Dirac as the transition of an electron from a negative to a positive energy state. Corrections are required for these cross sections at high energy, at high atomic number, and for atomic screening (*i.e.*, the intrusion of the field of the electrons in an atom); these are normally made via numerical procedures. The fraction of residual energy, symbolized by the Greek letter alpha, unexpended in conversion of energy to mass, that appears in any one particle (*e.g.*, the electron) is thus given by the kinetic energy of that electron E_e minus its rest energy mc^2 divided by the energy of the gamma ray hv (*i.e.*, the product of Planck's constant and the frequency of the gamma ray) minus twice the rest energy of the electron $2mc^2$, or $\alpha =$ (E, $- mc^2)/(h\nu - 2mc^2)$. Because the same equation applies to each of the two electrons that are formed, it must be symmetric about the condition that each of the particles has half the residual energy, symbolized by the Greek letter alpha, α (in excess of that conveyed to the "third body"); *i.e.*, that $\alpha = 0.5$. Below an energy of about 10,000,000 electron volts for the gamma ray, the probability for pair production (*i.e.*, the pair-production cross section) is almost independent of the atomic number of the material, and, up to about 100,000,000 electron volts of energy, it is also almost independent of the quantity α. Even at extremely high energies the probability that a certain fraction of the total available energy will appear in one particle is almost independent of the fraction as long as energy is comparably distributed between the two particles (*i.e.*, excepting in cases in which almost all energy is dumped into one particle alone). Typical pair-production cross sections at 100 MeV (million electron volts) are approximately 10^{-24} to 10^{-22} square centimetre, increasing with atomic number. At high energies, approximately equal to or greater than 100 MeV, pair production is the dominant mechanism of radiation interaction with matter.

Born's "first approximation"

Clearly, as the photon energy increases, the dominant interaction mechanism shifts from photoelectric effect to Compton scattering to pair production. Rarely do photoelectric effect and pair production compete at a given energy. Compton scattering, however, at relatively low energy competes with the photoelectric effect and at high energy competes with pair production. Thus, in lead, interaction below 0.1 MeV is almost exclusively photoelectric; between 0.1 MeV and 2.5 MeV both photoelectric and Compton processes occur; between 2.5 MeV and 100 MeV Compton scattering and pair production share the interaction. In the pair process the photon is annihilated, and an electron-positron pair is created. On the other hand, an electron or positron with energy approximately

Brems-strahlung production

equal to or greater than 100 MeV loses its energy almost exclusively by production of high-energy bremsstrahlung (X-rays produced by decelerating electric charges) as the result of interaction with the field of a nucleus. The cross section for bremsstrahlung production is nearly independent of energy at high energies, whereas at low energies the dominant energy-loss mechanism is by the creation of ionizations and excitations. A succession of bremsstrahlung and pair-production processes generates a cascade or shower in the absorber substance. This phenomenon can be triggered by either an electron, a positron, or a photon, the triggering mechanism being unimportant as long as the starting energy is high. A photon generates a pair through pair production, and the charged particles generate photons through bremsstrahlung, and so on repeatedly so long as the energy is kept sufficiently high. With penetration into the substance, the shower increases in size at first, reaches a maximum, and then gradually reduces. Loss of particles by degradation to lower energies (in which the yield of bremsstrahlung is low), ionization loss, and production and absorption of low-energy photons eventually reduce the size of the cascade. The mathematical theory of cascades has been developed in great detail.

X-rays and gamma rays. When light of sufficiently high frequency (or energy equal to $h\nu$), independent of its source, is absorbed in a molecular system, the excited molecular state so produced, or some excited state resultant from it, may either interact with other molecules or decompose to produce intermediate or ultimate products; *i.e.*, chemical reactions ensue. Study of such processes is encompassed in the subject of photochemistry (see also below Molecular activation).

Electromagnetic waves of energy greater than those usually described as ultraviolet light (see Figure 2) are included in the classes of X-rays or gamma rays. X-ray and gamma-ray photons may be distinguished by definition on the basis of source. They are indistinguishable on the basis of effects when their energy is absorbed in matter.

The total effect of X-ray or gamma-ray irradiation of matter, in the almost immediate time interval, is the production of high-energy electrons of energy related to that of the incident ray. Such electrons behave like beta rays (electrons emitted from atomic nuclei) or electrons from a machine source of the same energy. They lose energy by excitation and ionization of atoms and molecules of the systems they traverse. The amount of energy such an electron gives to an atom or molecule tends to exceed that deposited in photochemical processes, and the variety of initial physical (and consequent chemical) effects is more numerous and diverse. The situation is further complicated by the fact that the secondary electrons produced in ionization processes in which the input of energy is high may themselves initiate other ionization and excitation processes that can yield further chemistry, the totality of which is embraced in the title of radiation chemistry (see below Molecular activation and Ionization and chemical change).

THE PASSAGE OF NUCLEAR PARTICLES AND RADIATION

Ionization tracks

Heavy charged particles. Charged particles, such as atomic or molecular ions or molecular fragments, that travel in a material medium deposit energy along their paths, or tracks. If the medium is sufficiently thick, the velocity of the charged particle is reduced to near zero so that its energy is practically totally absorbed and is totally utilized in producing physical, chemical, and, in viable (living) matter, biological changes. If the sample is sufficiently thin, the particle may ultimately emerge, but with reduced energy.

Linear energy transfer.. The stopping power of a medium toward a charged particle refers to the energy loss of the particle per unit path length in the medium. It is specified by the differential $—dE/dx$, in which $—dE$ represents the energy loss and dx represents the increment of path length. For extremely high-speed particles (velocities 99 percent the speed of light or greater), a part of the deposited energy is carried away from the vicinity of the track in the time scale for electronic transition (about 10^{-15} second) in the form of energetic secondary electrons (delta rays) and radiation (bremsstrahlung). The radiation chemist is interested in the distance in the track in which a specific amount of energy is deposited. In approximate terms, it is customary to refer to the LET (or linear energy transfer), the energy actually deposited per unit distance along the track (*i.e.*, $—dE/dx$). For not-so-fast particles, stopping power and LET are numerically equal; this situation covers all heavy particles studied so far in chemistry and biology, but not electrons. In a refined study and redefinition of linear energy transfer or restricted linear collision stopping power, a quantity symbolized by the letter L with subscript Greek letter delta, L_Δ, is defined as equal to the fractional energy lost ($—dE$) per unit distance traversed along the track (dl), or $L_\Delta = -(dE/dl)_\Delta$, in which the subscript delta (A) indicates that only collisions with energy transfer less than an amount Δ are included (the quantity L_Δ is expressed in any convenient units of energy per unit length). The symbol L_{100} would indicate—as nearly as theory is useful or helpful—that only the energy actually deposited in the track (*e.g.*, in the spurs or regions of high ionic and excitation density) is of interest. Energy deposited in "blobs" or "short tracks," to the side of the main track, as described in the Mozumder–Magee theory of track effects (after A. Mozumder, an Indian physicist, and J.L. Magee, a United States chemist), is purposefully not included in the definition of L,,,,.

Stopping *power*. By use of classical mechanics, Bohr developed an equation of stopping power, $—dE/dx$, given as the product of a kinematic factor and a stopping number.

The kinematic factor includes such terms as the electronic charge and mass, the number of atoms per cubic centimetre of the medium, and the velocity of the incident charged particle. The stopping number includes the atomic number and the natural logarithm of a term that includes the velocity of the incident particle as well as its charge, a typical transition energy in the system (cf. Figure 1; a crude estimate is adequate because the quantity appears within the logarithm), and Planck's constant, h. Bohr's stopping-power formula does not require knowledge of the details of atomic binding.

Bethe's stopping number

For a heavy incident charged particle in the nonrelativistic range (*e.g.*, an alpha particle, a helium nucleus with two positive charges), the stopping number B, according to Hans Bethe, a physicist in the United States, is given by quantum mechanics as equal to the atomic number (Z) of the absorbing medium times the natural logarithm (ln) of two times the electronic mass times the velocity squared of the particle, divided by a mean excitation potential (I) of the atom; *i.e.*, $B = Z \ln (2mv^2/I)$.

Bethe's stopping number for a heavy particle may be modified by including corrections for particle speed in the relativistic range ($\beta^2 + \ln [1-\beta^2]$), in which the Greek letter beta, β, represents the velocity of the particle divided by the velocity of light, and polarization screening (*i.e.*, reduction of interaction force by intervening charges, represented by the symbol $\delta/2$), as well as an atomic-shell correction (represented by the ratio of a constant C to the atomic number of the medium); that is, $B = Z (\text{In } 2mv^2/I - \beta^2 - \ln [1 - \beta^2] - C/Z - \delta/2)$.

The most important nontrivial quantity in the equation for stopping number is the mean excitation potential, I. Experimental values of this parameter, or quantity, are known for most atoms, but no single theory gives it over the whole range of atomic numbers because the calculation would require knowledge of the ground states and all excited 'states. Statistical models of the atom, however, come close to providing a theory. Calculations by the United States physicist Felix Bloch in **1933** showed that the mean excitation potential in electron volts is about 14 times the atomic number of the element through which the charged particle is passing ($I = 14Z$). A later calculation gives the ratio of the potential to atomic number as equal to a constant (a) plus another constant (b) times the atomic number raised to the $-\frac{2}{3}$ power in which a = 9.2 and b = 4.5; *i.e.*, $I/Z = a + bZ^{-2/3}$. This formula is widely applicable. Other exact quantum-mechanical calculations for hydrogen give its mean excitation potential as equal to 15 electron volts.

Bragg's rule

Even though the basic stopping-power theory has been developed for atoms, it is readily applied to molecules by virtue of Bragg's rule (after a British physicist, W.H. Bragg), which states that the stopping number of a molecule is the sum of the stopping numbers of all the atoms composing the molecule. For most molecules Rragg's rule applies impressively within a few percent, though hydrogen (H_2) and nitrous oxide (NO) are notable exceptions. The rule implies: (1) similarity of atomic binding in different molecules having one common atom or more and (2) that the vacuum ultraviolet transitions, in which most electronic transitions are concentrated under such irradiation, involve energy losses much higher than the strengths of most chemical bonds.

The charge on a heavy positive ion fluctuates during penetration of a medium. In the beginning, it captures an electron, which it quickly loses. As it slows down, however, the cross section of electron loss decreases relative to that for capture. Basically, the impinging ion undergoes charge-exchange cycles involving a single capture followed by a single loss. Ultimately, an electron is permanently bound when it becomes energetically impossible for the ion to lose it. A second charge-exchange cycle then occurs. This phenomenon continues repeatedly until the velocity of the heavy ion approximates the orbital velocity of the electron in Bohr's theory of the atom, when the ion spends part of its time as singly charged and another part as a neutral atom. On further slowing down, the electronic-energy-loss mechanism becomes ineffective, and energy loss by nuclear collision dominates.

Range. The total path length traversed by a charged particle before it is stopped is called its range. Range is considered to be taken as the sum of the distance traversed over the crooked path (track), whereas the net projection measured along the initial direction of motion is known as the penetration. The difference between range and penetration distances results from scattering encountered by the particle along its path.

Computation of particle ranges

Particle ranges may be obtained by (numerical) integration of a suitable stopping-power formula. Experimentally, range is more easily measured than is stopping power. For heavy particles a critical incident energy in low-atomic-number mediums is 1,000,000 electron volts divided by the mass of the particle in atomic mass units (numerically the same as its atomic weight). For incident energies higher than this critical value, range is usually well-known, and computation agrees with experiment within about 5 percent. In the case of aluminum, which is the best studied material, the accuracy is within about 0.5 percent. For incident energies less than the critical value, however, range calculations are usually uncertain, and agreement with experiment is poor. The range–energy relation is often given adequately as a power law, that range (R) is proportional to energy *(E)* raised to some power (n); that is, $R \propto E^n$. Protons in the energy interval of a few hundred MeV conform to this kind of relation quite well with the exponent *n* equal to 1.75. Similar situations exist for other heavy particles. Measurements of range and stopping power are of great importance in particle identification and measurement of their energies. Many experimental data and computations are available for ranges of heavy particles as well as of electrons. The theory by which Bethe derived a stopping number is generally accepted as providing the framework for understanding the variation of range with energy, though in practice the mean excitation potential, I, must be obtained in many cases by experimental curve fitting.

Both stopping power and range should be understood as mean (or average) values over an ensemble of atoms or molecules, because energy loss is a statistical phenomenon. Fluctuations are to be expected. In general, these fluctuations are called straggling, and there are several kinds. Most important among them is the range straggling, which suggests that, for statistical reasons, particles in the same medium have varying path lengths between the same initial and final energies. Bohr showed that for long path lengths the range distribution is approximately Gaussian (a type of relationship between number of occurrences and some other variable). For short path lengths, such as those encountered in penetration of thin films, the emergent particles show a kind of energy straggling called Landau type (after Lev Landau, a Soviet physicist). This energy straggling means that the distribution of energy losses is asymmetric when a plot is drawn, with a long tail on the high-energy-loss side. The intermediate case is given by a distribution according to Sergey Ivanovich Vavilov, a physicist in the Soviet Union, that must be evaluated numerically. There are evidences in support of all three distributions in their respective regions of validity.

Braggpeak

The ionization density (number of ions per unit of path length) produced by a fast charged particle along its track increases as the particle slows down. It eventually reaches a maximum called the Bragg peak close to the end of its trajectory. After that, the ionization density dwindles quickly to insignificance. In fact, the ionization density follows closely the linear energy transfer (LET). With slowing, the LET at first continues to increase because of the strong velocity denominator in the kinematic factor of the stopping-power formula. At low speeds, however, LET goes through a maximum because of: (1) progressive lowering of charge by electron capture and (2) the effect of the logarithmic term in the stopping-power formula. In general, the maximum occurs at a few times the Bohr orbital velocity. A curve of ionization density (also called specific ionization or number of ion pairs—negative electron and associated positive ion—formed per unit path length) versus distance in a given medium is called a Bragg curve. The Bragg curve includes straggling within a beam of particles; thus, it differs somewhat from the specific ionization curve for an individual particle in that it has a long tail of low ionization density beyond the mean range. The mean range of radium-C′ alpha particles in air at NTP (normal temperature and pressure), for example, is 7.1 centimetres; the Bragg peak occurs at about **6.3** centimetres from the source with a specific ionization of about 60,000 ion pairs per centimetre.

Electron stopping number

Electrons. In the first Born approximation, inelastic cross section depends only on velocity and the magnitude of the charge on the incident particle. Hence, an electron and a positron at the same velocity should have identical stopping powers, which should be the same as that of a proton (a nuclear particle having about 1,850 times the mass of a positron, but the same charge) at that velocity. In practice there is some difference in the case of an electron because of the indistinguishability of the incident and atomic electrons. In describing an ionization caused by an incident electron, the more energetic of the two emergent electrons is called, by convention, the primary. Thus, maximum energy loss (ignoring atomic binding) is half the incident energy. Incorporating this effect, the stopping number of an electron is given by a complicated expression that involves a different arrangement of the parameters found in the stopping number of heavy charged particles; *i.e.*,

$$B_e = \frac{Z}{2}\Big[\ln mc^2\beta^2E/2I^2(1-\beta^2) - (2\sqrt{1-\beta^2} - 1 + \beta^2)$$
$$\ln 2 + (1-\beta^2) + \frac{1}{8}(1-\sqrt{1-\beta^2}) - 2\frac{C}{Z} - \delta\Big].$$

This stopping-power formula has a wide range of validity, from approximately a few hundred electron volts to a few million electron volts in materials of low atomic number. For low velocities, the Born approximation gradually breaks down, and highly excited states begin to be inaccessible to transitions by virtue of small maximum energy transfer. Yet, with some corrections the electron-stopping-power formula may be extended down to about 50 electron volts. Below that value any stopping-power formula is of doubtful validity, even though it is certain that most of the energy is still being lost to electronic states down to a few electron volts of energy.

On the high-velocity side, relativistic effects increase electron-stopping power from about 1,000,000 electron volts upward. Except for the term δ (Greek letter delta), attributable to polarization screening, the relativistic stopping power tends to infinity as the electron velocity approaches the speed of light $(v/c = \beta \rightarrow 1)$. One-half of the stopping power, called the restricted stopping power, is numerically equal to the linear energy transfer and changes smoothly to a constant value, called the Fermi plateau, as the ratio β approaches unity. The other half, called the unrestricted stopping power, increases without limit, but its effect at extreme relativistic velocities becomes small compared with energy loss by nuclear encounters.

At extremely high velocities an electron loses a substantial part of its energy by radiative nuclear encounter. Lost energy is carried by energetic X-rays (*i.e.*, bremsstrahlung). The ratio of energy loss by nuclear radiative encounter to collisional energy loss (excitation and ionization) is given approximately by the incident electron energy (E) in units of *1,000,000* electron volts times atomic number (Z) divided by *800; i.e.*, $EZ/800$. For a large class of mediums (atomic number equal to or greater than 8; *i.e.*, that for oxygen) the electron stopping is dominated by bremsstrahlung radiation for energies greater than *100* MeV.

Cherenkov radiation

Cherenkov radiation. When the speed of a charged particle in a transparent medium (air, water, plastics) is so high that it is actually greater than the group velocity of light in that medium, then a part of the energy is emitted as Cherenkov (Cerenkov) radiation, first observed in 1934 by Pavel Alekseyevich Cherenkov, a physicist in the Soviet Union. Such radiation rarely accounts for more than a few percent of the total energy loss. Even so, it is invaluable for purposes of monitoring and spectroscopy. Cherenkov radiation is spread over the entire visible region and into the near ultraviolet and the near infrared. The direction of its propagation is confined within a cone, the axis of which is the direction of electron motion.

Energy-transfer mechanism. At the low-velocity end of its path, an electron continues to excite electronic levels of atoms or molecules until its kinetic energy falls below the lowest (electronically) excited state (see Figure 1). After that it loses energy mainly by exciting vibrations in a molecule. Such a mechanism proceeds through the intermediary of temporary negative ion states, for direct momentum-transfer collisions are very inefficient. In a condensed medium (liquid, solid, or glass) very low-energy (less than one electron volt) electrons continue to lose energy by a process called phonon emission and by interaction with other low-frequency intermolecular motions of the medium.

An electron and a singly charged heavy particle with the same velocity have about equal stopping powers. Because of the smali mass of the electron, however, the relative retardation (*i.e.*, decrease in velocity per unit path length) is much more for it. This larger retardation for an electron means that, if an electron and a heavy particle start with the same velocity, the electron will have a much smaller range. Electron tracks show much more straggling and scattering compared with that of a heavy particle. The first effect results from the fact that the electron can lose a large fraction of its energy in a single encounter; the second is the result of small mass. A power law may be used to connect range and energy of electrons in a given medium—*i.e.*, the range is proportional to energy raised to a power n; as in the case of a heavy particle, the index n is slightly less than two at high energies. At low energies the relationship is such that the exponent is one or less. Many formulas and tables are available for stopping powers and for ranges of electrons as well as of heavy particles over a wide range of energies.

Electron and heavy-particle straggling

Neutrons. A neutron is an uncharged particle with the same spin as an electron and with mass slightly greater than a proton mass. In free space it decays into a proton, an electron, and an antineutrino (a fundamental particle of radioactivity), and has a half-life (the time required for half of a large number of neutrons to decay) of about *12–13* minutes, which is so large compared with lifetimes of interactions with nuclei that the particle disappears predominantly by such interactions.

Neutron beams may be produced in a variety of ways. A modern method is to extract a high-intensity beam from a nuclear reactor. A simpler, but expensive, device is one that employs a mixture of radium and beryllium. The reaction of the alpha (a) particles emitted by the radium with beryllium nuclei produces a copious output of neutrons. The neutron is a major nuclear constituent and is responsible for nuclear binding. A free neutron interacts with nuclei in every conceivable way, more or less depending on its velocity and the nature of the target. Ordinary interactions include scattering (elastic and inelastic), absorption, and capture by nuclei to produce new elements. Pure absorption does not result in a new element, even though it is sometimes accompanied by emission of gamma rays. In certain cases of capture, radioactivity follows, often with production of beta (β) particles. In another class of interaction, a heavy charged particle is ejected (such as an α-particle or proton); the resultant nucleus is often but not always radioactive. As an example, the reaction of neutrons on boron to produce alpha particles provides the basis for alpha-particle welding. The principle of such welding, invented by the Soviet chemist V.I. Goldansky, is to deposit a thin layer of a boron (or lithium) compound in the interface between diverse materials, which is thereafter irradiated with neutrons. The high-energy a-particles produced from the nuclear reaction weld the materials together.

Neutron diffraction

Extraordinary interactions of the neutron are represented by diffraction, nuclear fission, and nuclear fusion. Diffraction, exhibited by low-energy neutrons (approximately equal to or less than *0.05* electron volt), demonstrates their wave nature and is consistent with de Broglie's hypothesis. Neutron diffraction complements X-ray technique in locating the positions of atoms in molecules and crystals, especially atoms of low atomic number, such as hydrogen. Fission is the breakup of a heavy nucleus (either spontaneously or under the impact, for example, of a neutron) into two smaller ones with liberation of energy and neutrons. Spontaneous-fission rates and cross sections of fission induced by agencies other than the neutron are so small that in most applications only neutron-induced fission is important. Also, the neutron-induced-fission cross section depends on the particular isotope (species of an element with the same atomic number and similar chemical behaviour but different atomic mass) involved and the neutron energy. The fission process itself generates fast neutrons, which, when suitably slowed down in a process called moderation, are again ready to induce more fission. The ratio of neutrons produced to neutrons absorbed is called the reproduction factor. When that factor exceeds unity, a chain reaction may be started, which is the basis of nuclear-power reactors and other fission devices. The chain is terminated by a combination of adventitious absorption, leakage, and other reactions that do not regenerate a neutron. At the power level at which a reactor operates, the loss rate always balances the generation rate through fission.

Unlike the electron, a neutron loses energy significantly through elastic collisions, because its mass is comparable to.masses of atoms of low atomic number. (According to the laws of mechanics, in elastic collision, on the average, an object loses half its energy to another object of equal mass.)

The average fraction of energy transferred from a neutron per collision, symbolized by $(\Delta E/E)_{av}$, is twice the atomic mass number (A) of the struck atom divided by the square of the mass number plus one; *i.e.*,

$$(-\Delta E/E)_{av} = 2A/(A + 1)^2.$$

Thus, only 18, *25, 42, 90,* and *114* collisions are required to thermalize (reduce the energy of motion to that of the surrounding atoms) a fast neutron in hydrogen, deuterium, helium, beryllium, and carbon, respectively. The effectiveness of a moderator is not determined by moderation considerations alone; the other factor is absorption.

A United States physicist, Eugene Wigner, in the course of consideration of the possible effects of fast neutrons, suggested in 1942 that the process of energy transfer by collision from neutron to atom might result in important

The "knock on" process

physical and chemical changes. The phenomenon, known as the Wigner effect and sometimes as a "knock on" process, was actually discovered in 1943 by Milton Burton and T.J. Neubert, United States chemists, and found to have profound influences on graphite and other materials.

III. Secondary effects of radiation

PURELY PHYSICAL EFFECTS

With respect to radiation effects the terms primary and secondary are used in a relative sense; the usage depends on the situation under study. Thus, ionization and excitation may be considered as primary with respect to some physical and chemical effects. For other chemical effects, production of free radicals (molecular fragments) may be considered as primary even though that process requires a much longer time for its accomplishment. Still longer times are involved in biological processes, in which the end product of an earlier chemical reaction may be considered as primary.

Generally, an atomic solid exhibits little or no permanent chemical change upon irradiation. Important among the atomic solids are such materials as metals and graphite. Production of molecular carbon (C_2) or bigger clusters upon irradiation of carbon and graphite may, in a certain marginal sense, be considered a chemical change. Ionization of a condensed atomic medium followed by recombination regenerates the same atom, but its locale may be affected. For a molecular medium the situation is quite different. Excited electronic states are often dissociative for a molecule and yield chemically reactive radicals. Positive ions, similarly produced, can experience a variety of reactions even before neutralization occurs. Such an ion may fragment all by itself, or it may react with a neutral molecule in what is called an ion–molecule reaction. In either case new chemical species are created. These transformed ions and radicals, as well as the electrons, parent ions, and excited states, are capable of reacting with themselves and with molecules of the medium, as well as with a solute (a dissolved substance) that may be present in homogeneous distribution. The end products of the reactions can be, on the one hand, new stable compounds or, on the other, regenerated molecules of the original species, as in the case of water irradiation.

Physical changes caused by irradiation

A variety of purely physical effects have been observed in different substances under irradiation. They may be broadly classified as: (1) structural change in the crystal, sometimes accompanied by change in the structural dimensions; (2) change in static mechanical properties, such as elasticity and hardness; (3) change in dynamic mechanical properties, such as internal friction and strain; and (4) changes in transport properties, such as heat conductivity and electrical resistivity. Such changes are considered in the section below on Tertiary effectsof radiation.

MOLECULAR ACTIVATION

A molecule is considered activated when it absorbs energy by interaction with radiation. In this energy-rich state it may undergo a variety of unusual chemical reactions that are normally not available to it in thermal equilibrium. Of especial importance is electronic activation; *i.e.*, production of an electronically excited state of the molecule (see Figure 1). This state can be reached (1) by direct excitation by photon absorption; (2) by impact of charged particles, either directly or indirectly through charge neutralization, or by excitation transfer from excited positive ions; and (3) by charge transfer in collision with (relatively) slow incident positive ions. Among the variety of ensuing processes is light emission, or luminescence.

Luminescence. The language of luminescence is clouded by history. Originally, fast luminescence was called fluorescence and slow (*i.e.*, delayed or protracted) luminescence was called phosphorescence. Present scientific practice is to define the terms on the basis of so-called quantum-mechanical selection rules: fluorescence is an allowed transition (*e.g.*, singlet–singlet) and occurs in a typical time of about 10^{-9} second; phosphorescence is a forbidden transition (*e.g.*, triplet–singlet) and may require 10^{-6} second or longer.

In the gas phase (gaseous state), an excited molecule either luminesces, undergoes a process called internal conversion, or undergoes dissociation. Luminescence is the rule for anthracene, whereas for water it is dissociation into hydrogen (H) and hydroxide (OH). As a rule, luminescence processes occur by default—*i.e.*, only if dissociation is energetically impossible or involves a complicated energy-transfer process or if internal conversion to a nonluminescing state is inefficient.

Fluorescence

Fluorescence usually takes place from the lowest electronically excited state (see Figure 1); if higher states are excited they either dissociate or energetically cascade to the lowest excited state by one of several possible internal transition mechanisms before emission occurs. (A notable exception to this rule is afforded by azulene.)

A similar situation exists for triplet excited molecules. The rate of emission, however, is even slower, for in this case it is forbidden by selection rules. If the triplet excitation energy is insufficient for molecular-bond breakage (dissociation), the molecule may remain in a metastable state (*i.e.*, a state of apparent, not real, stability) for a long time until it either phosphoresces, undergoes internal conversion, or combines with other triplets. Such a combination produces a highly excited state, which has enough energy for dissociation. Some of the latter excited states are formed as singlets capable of light emission. This discussion relates to the more common, general features. There are also special cases, not discussed, that do not follow the general pattern.

Ionization phenomena. Ionization (see Figure 1) is that extreme form of excitation in which an electron is ejected leaving behind a positive molecular ion. The minimum energy required for this process is called the ionization potential (IP). The actual energetics are described by the Franck–Condon principle, which simply recognizes that, during the extremely short time of an electronic transition, the nuclear configuration of a molecule experiences no significant change. As a consequence of this principle, in an optical process the ion is almost invariably formed in some kind of excited state by input of energy greater than the IP. Also, because of Franck–Condon restrictions, excitation of an inner electron may result in initial production of nonionized, superexcited molecules (suggested by R.L. Platzman, a United States physicist) with energy exceeding the ionization potential. A superexcited molecule is short-lived and usually converts rapidly (in a time as short as 10^{-14} second) either to neutral products or to an ion plus a free electron with marked excess energy. The ion itself may fragment to give other species with excess kinetic or internal vibrational and rotational energy.

Excitation states. All the various kinds of excitation that occur in the gas phase may occur also in the condensed states of matter (liquid, glass, or solid), but their relative contributions may be affected. In addition, special activated states are produced for which there is no analogue in the gaseous state. They owe their existence to the collective behaviour of atoms and molecules in close proximity. The more important of them are the exciton state, the polaron state, the charge-transfer, or charge-separated, state, and the plasmon state.

Exciton and polaron states

The exciton state is a cooperative state of molecules in which the excitation energy belongs simultaneously to all.

In a polaron state, an electron belongs to the association of molecules, but its motion is relatively slow so that it carries with it its own polarization field, which is described as "a cloud of virtual phonons." A solvated electron (*i.e.*, an electron associated with a particular molecule or group of molecules) is an example of this.

The charge-transfer, or charge-separated, state is an excited state. In a certain sense, electronic excitation involves motion of an electron from a lower orbit to a higher one. Quantum mechanics notes that the electron does not revolve around an atomic nucleus in a precise classical orbit but rather that it occupies an orbital in which it is to be found with maximum probability in the location of the classical orbit. When a molecule in a condensed system is excited, the resulting electronic orbital may overlay one or more adjacent molecules, and, in that sense, the electron belongs to the group because its excitation level does not correspond to the electronic properties of a single, isolated molecule.

The plasmon state is a highly delocalized state formed collectively through coulombic (electrostatic) interaction of weakly bound electrons. Energy losses, approximating 10–20 electron volts in most materials, resulting from formation of plasmon states are seen in the impact of electrons of a few tens of kilovolts' energy on thin films. Both metals and nonmetals, including plastics, show plasma energy losses. The lost energy may reappear in the form of ultraviolet or visible radiation (Ferrell radiation, 1960); no chemical effect is known to have occurred from such losses.

Energy transfer. In general, a small, simple molecule luminesces in the ultraviolet, and a more complex one emits near the blue-violet end of the visible spectrum. Dye molecules, on the other hand, may emit throughout the visible region, including the red end. The ground electronic state of most molecules is a singlet state. Usually, therefore, the optically allowed (*i.e.*, permitted) emission, or fluorescence, is from the lowest excited singlet state to the ground state. The lowest triplet state of the molecule lies somewhat below the excited singlet. Light emission from this triplet state is forbidden by the quantum-mechanical selection rules, but it does occur by default when other processes are even less probable. Such emission is called phosphorescence. It is relatively weak, slow, and shifted toward longer wavelength. Triplet states may be produced from higher singlets by processes called internal conversion and intersystem crossing. The states may also be produced in excitation from the ground state by impact of relatively slow charged particles, such as electrons.

Much of the effect of optical radiation in a condensed system is not on the molecule in which the energy is initially absorbed but on a more remote molecule to which the energy is transferred in a variety of possible processes. They include excitation transfer either directly between adjacent molecules, by a direct quantum-mechanical interaction of an excited molecule with a remote one at a distance of 40 angstroms (*i.e.*, 4×10^{-7} centimetre) or less, or by the so-called trivial process of fluorescence emission from one molecule and reabsorption by one at any distance. These processes are studied mostly in regard to fluorescence and phosphorescence phenomena.

Production and reactions of ions in solution

With high-energy radiation (such as that of electrons, X-rays, and gamma rays), an additional mechanism involving ions is also available. In the case of a solute M in a solvent S, for example, a simplified description of some possible effects of radiation is represented by the following expressions, in which the symbol $+$ is read, "—is acted upon by high-energy radiation, to give—" and *e* represents an ejected electron:

$$S \rightsquigarrow S^{+} + e \qquad \text{(ionization of solvent)}$$

$$e + M \longrightarrow M^{-} \qquad \text{(electron attachment to solute)}$$

$$M^{-} + S^{+} \longrightarrow \begin{cases} M^{*} + S \\ M + S^{*} \end{cases} \qquad \text{(neutralization)}$$

$$M^{*} \longrightarrow M + h\nu \qquad \text{(light emission)}$$

or

$$M \longrightarrow \mathrm{A} + B \qquad \text{(product formation)}$$

Any actual process is considerably more complicated and involves a larger number of species.

Photographic process. One of the most important effects of radiation on matter is seen in photographic action. Apart from its various uses in art, commerce, and industry, photography is an invaluable scientific tool. It is used extensively in spectroscopy, in photometry, and in X-ray examinations. Also, photographic emulsion techniques have been widely used in the detection and characterization of high-energy charged particles. It is important to note that all speculation regarding the primary phenomena involves the notion that, in an energy absorption process, either direct or sensitized, a chloride (or other halide) ion in a silver halide lattice loses an electron. That electron is thereafter captured by a silver ion located at such a point in the lattice that under suitable conditions of exposure and development a silver grain grows to a size representative of the duration and intensity of the light exposure.

IONIZATION AND CHEMICAL CHANGE

Earlier in this section, the ionization phenomenon was briefly discussed as a special case of molecular activation. The ionization process, however, does have certain characteristic features. Most notably, the probabilities (or cross sections) for ionization by light (*i.e.*, photo-ionization) and for ionization by charged-particle impact are different in magnitude and in lowest energy of occurrence (*i.e.*, threshold behaviour) for the same atom or molecule. The photo-ionization cross section shows abrupt onset (*i.e.*, a step behaviour) to a high value at threshold, falling thereafter only gradually with increase of photon energy. Electron-impact ionization in simple atoms (such as hydrogen and helium) begins at the ionization potential, increases in direct proportion to the energy near the threshold, and shows a peak at about 100–200 electron volts' incident energy. With molecules the behaviour is similar except that the peak is broad and much less pronounced. When the incident energy is high and the ejected electron has kinetic energy (energy of motion) largely in excess of its binding energy, the cross section for the process approaches a limit called the classical Rutherford value, after the British physicist Ernest Rutherford.

Electron-impact ionization

In general, the initial processes resulting from the action of high-energy radiation on matter involve the intermediate production and participation of positive ions (both stable and unstable), electrons, negative ions, excited species, and free radicals and atoms, which in turn may enter into the processes of classical reaction kinetics.

Ordinary low-energy (or optical) processes usually involve only excited species and free radicals and atoms.

The important feature that characterizes the chemistry both of optical processes (photochemistry) and of high-energy radiation (radiation chemistry) is that they are conveniently employed and their kinetics studied at room temperature and lower.

Grotthus–Draper and Stark–Einstein laws

Photochemistry. There are two "laws" of photochemistry. The first, the Grotthus–Draper law (for the German chemist C.J.D.T. von Grotthus and the United States chemist J.W. Draper), is simply: for light to produce an effect upon matter it must be absorbed. The second, or Stark–Einstein law (for the German physicist J. Stark and Albert Einstein), in its most modern form is: one resultant primary physical or chemical act occurs per photon (*i.e.*, quantum of light) absorbed. The quantum yield of a particular species of product is the number of moles of that product divided by the number of einsteins of light (*i.e.*, units of 6.02×10^{23} photons)---or the number of molecules of product per photon—absorbed. In the ideal case the quantum yield, frequently denoted by the Greek letters gamma, y, or phi, Φ, is unity. In real cases, Φ may approach zero on the one hand—particularly if a back reaction is involved---or it may be of the order of 1,000,000, in which case the primary product may start a chain reaction, as in a clean, dry mixture of hydrogen (H) and chlorine (Cl). In the following chemical equations each symbol for an element stands for one atom, and the number of atoms bonded into a molecule is given as subscripts following the symbol, while the number of molecules precedes the formula; the arrow indicates the course of the reaction:

$$\mathrm{Cl_2} \xrightarrow{h\nu} \mathrm{2Cl} \qquad (1)$$

$$\mathrm{Cl} + \mathrm{H_2} \longrightarrow \mathrm{HCl} + \mathrm{H} \qquad (2)$$

$$\mathrm{H} + \mathrm{Cl_2} \longrightarrow \mathrm{HCl} + \mathrm{Cl} \qquad (3)$$

etc.,

in which reactions 2 and 3 reoccur repeatedly in a chain reaction. The symbol $h\nu$ may be read "when a photon of light frequency, symbolized by the Greek letter nu, ν (which is always stipulated), is absorbed, gives." Because h is Planck's constant of action (approximately 6.6 × 10 ^{27} erg second) and ν is expressed in reciprocal seconds (*i.e.*, second^{-1}), the product $h\nu$ indicates the energy absorbed per photon. Some reactions may give two primary products; *e.g.*,

$$CH_3CHO \xrightarrow{h\nu} CH_3 + HCO \text{ or } CH_4 + CO.$$

In that case there are different quantum yields for each of the primary reactions, and the ratio of those yields varies with the frequency, ν (or the wavelength, A, or the wave number, $\bar{\nu}$), of the light absorbed.

Radiation chemistry. Although radiation chemistry embraces the effects of the whole range of ionizing particles and radiations, they really cannot be considered as a simple unit.

Nature of positive-ion tracks

When the initial bombardment is by a positive ion such as the hydrogen ion H^+ or the deuterium ion D^+ from a cyclotron, or the alpha particle $^4He^{2+}$ from nuclear decay, or indeed any high-energy heavy positive ion, the initial effects differ significantly from those of a high-energy electron. This situation results from the fact that, for the same kinetic energy, $\frac{1}{2}mv^2$, a particle of greater mass, m, travels with smaller velocity, v. The smaller the velocity of a particle of a particular charge, the greater is its probability of interaction with the medium traversed; *i.e.*, the greater is the linear energy transfer. Thus, positive ions produce their initial effects close together in the ionization track in a condensed medium such as water (perhaps one or two angstroms, 1 or 2 × 10^{-8} centimetre, apart), whereas equally energetic electrons travelling through the same medium deposit energy in small collections called spurs, which may be 1,000 angstroms (10-5 centimetre) or so apart. The appearance of the excitation and ionization track has been likened to a rope (in the case of positive-ion bombardment), on the one hand, as compared with isolated beads on a string (in tbe case of electron bombardment), on the other. The dense track, as well as the isolated spurs, contains ions, excited molecules, and electrons; but the distributions in the two essentially different types of tracks are so different that the ensuing chemical reactions (*i.e.*, the track effects) may be quite dissimilar. As an example, alpha-particle irradiation of pure water produces substantial yields of hydrogen and hydrogen peroxide (H_2O_2), whereas irradiation with beta particles, X-rays, or gammas is essentially without effect. One of the reaction sequences suggested in overall considerations of the radiation chemistry of water is

$$H_2O \rightsquigarrow H + OH \qquad (1)$$

$$2H \longrightarrow H_2 \qquad (2)$$

$$2OH \longrightarrow H_2O_2;\ \textit{i.e.}.\ HOOH, \qquad (3)$$

in which reaction (1) summarizes the early chemical consequences both of ionization and of excitation. It has been suggested that reactions (2) and (3) occur with high probability in dense tracks (*e.g.*, of alpha particles), but that, in isolated spurs (as in fast-particle tracks), such reactions may occur only with low probability. In such a case, the hydrogen atoms and OH radicals enter with somewhat greater probability into back-reaction chains with any $H_2 + H_2O_2$ already produced and existent in the body of the liquid:

$$H + HOOH \longrightarrow H_2O + OH \qquad (4)$$

$$OH + H_2 \longrightarrow H_2O + H \qquad (5)$$

The H atom produced in reaction (5) thereupon enters into reaction (4), so that whatever small amounts of H_2 and H_2O_2 are actually produced in reactions (2) and (3) are consumed in reactions (5) and (4), respectively, and remain essentially undetectable no matter how long the reaction is run.

Mechanism of radiation chemical reactions

Radiation chemical reactions. In more detailed discussions of the mechanism of radiation chemical reactions, the roles of both excitation and ionization are considered. Information regarding the former is available from the extensive data of photochemistry; frequently, the initial excitation process leads to no significant chemical effect. By contrast, ionization may result in a large variety of chemical changes involving tbe positive ion, the outgoing electron, and the excited states resultant from charge neutralization, as well as (parent) positive-ion fragmentation and ion-molecule reactions. Some such consequences are summarized for a few cases.

Different channels of fragmentation from the same parent ion (*e.g.*, the propane ion $C_3H_8^+$), such as

$$C_3H_8^+ \longrightarrow C_3H_7^+ + H \qquad \text{atom elimination}$$

$$\left.\begin{array}{l} C_3H_8^+ \longrightarrow C_2H_5^+ + CH_3 \\ C_3H_8^+ \longrightarrow C_2H_5 + CH_3^+ \end{array}\right\} \text{radical elimination}$$

$$C_3H_8^+ \longrightarrow C_3H_6^+ + H_2 \qquad \text{molecule elimination}$$

compete unless barred by energetic considerations. Because ionization potentials of various possible fragments may differ greatly, charge localization may occur on only one of them. On the other hand. because the initial ionization rarely leads to the ground state of the positive ion, the energy is usually adequate for bond breakage.

Ion–molecule reactions such as that between a water ion and a molecule,

$$H_2O^+ + H_2O \longrightarrow H_3O^+ + OH$$

are more important in the condensed phase, and fragmentation is more important in the gas phase. The parent ion in liquid water almost invariably undergoes ion–molecule reaction as indicated above. Many ion–molecule reactions have high cross sections. The same ion may undergo fragmentation or ion–molecule reaction, depending on circumstances. Thus, methane (CH_4), acted upon by high-energy gamma radiation, producing an electron, symbolized by

$$CH, \rightsquigarrow CH_4^+ + e^-,$$

may be followed by fragmentation

$$CH_4^+ \longrightarrow CH_3^+ + H \text{ or } CH_2^+ + H_2,$$

as well as an ion–molecule reaction

CH_4^+ t CH, [redacted] $CH_5^+ + CH_3$

Electrons in chemical transformations

The electron ejected in an initial ionization process may further ionize and excite other molecules in its path, thus causing other chemical transformations. Additionally, it may produce chemical changes of its own by dissociative attachment as in carbon tetrachloride (CCl_4) and nitrous oxide (N_2O)

e- + CCl_4 [redacted] $CCl_3 + Cl^-$

$$e^- + N_2O \longrightarrow N_2 + O$$

and by formation of negative ions of either permanent or virtual (*i.e.*, very short-lived) nature. Many of the negative ions produced in a dissociation process are chemically reactive (H-, O-, etc.) as well. Virtual negative ions are almost invariably in a high vibrational state; *i.e.*, they are vibrationally hot.

The important point to note from this limited discussion of primary physical effects and their consequences in radiation chemistry is that, in general, each such effect is the progenitor of many ionizations and excitations, the distribution of which in space depends on the energy of the particle involved as well as on the system traversed. There is no single resultant primary process corresponding to the result of absorption of a single optical photon and thus no analogue to the concept of quantum yield in photochemistry.

In radiation chemistry, yields are conventionally reported on the purely empirical basis of the number of molecules of a particular kind produced (or destroyed) per 100 electron volts' input of a particular type of radiation. In the radiolysis (radiation-induced decomposition) of cyclohexane, for example, by cobalt-60 gamma radiation or by electrons of about 2,000,000 electron volts' energy, the overall yield of hydrogen per 100 electron volts' input is frequently given as approximately 5.6 or G $(H_2) \simeq 5.6$, in which the symbol G is read as "the 100-electron-volt yield of." Sometimes, a small *g* is used to denote the 100 electron-volt yield of a postulated intermediate, not directly determinable by measurement. Table I summarizes some typical G values.

Table 1: Examples of Yield Studies at Room Temperature

state	system	radiation	yields
Gas	hydrogen and chlorine	alpha (radium)	$G(HCl) \sim 10^6$
	perfluoroethane	gamma (cobalt-60)	$G(CF_4) = 1.6$ $G(c\text{-}C_3F_6) = 0.30$ $G(C_3F_8) = 0.21$ $G(C_4F_{10}) = 0.14$
Liquid	ferrous sulfate and sulfuric acid in aerated water (Fricke solution)	gamma (cobalt-60)	$G(Fe^{3+}) = 15.6$
		alpha (from neutron irradiation of boron)	$G(Fe^{3+}) = 4.2$
		alpha (from neutron irradiation of lithium)	$G(Fe^{3+}) = 5.7$
	cyclohexaue	1.8 MeV electrons	$G(H_2) = 5.6$ $G(C_6H_{10}) = 2.86$ $G[(C_6H_{11})_2] = 1.55$ $G(C_6H_{11} . C_6H_9?) \sim 0.068$
		1.8 MeV or gamma (cobalt-60)	$G(C_6H_{10})/G[(C_6H_{11})_2] = 1.85$
		alpha (polonium-210)	$G(C_6H_{10})/G[(C_6H_{11})_2] = 3.0$
	benzene	1.5 MeV electrons	$G(H_2) = 0.022$ $G(C_2H_2) = 0.017$ $G(C_6H_6 \rightarrow \text{"polymer"}) \sim 0.8$
Solid	ferrocene	1 MeV electrons	$G(H_2) = 0.0101$ $G(C_5 \text{ products}) = 0.0036$ $G(\text{inorganic Fe}) = 0.042$

Symbolism of *radiation chemistry.* The symbolism of radiation chemistry differs from that of photochemistry; the chemistry is somewhat more complicated, and the establishment of the variety of initial chemical processes is somewhat more of a chore. For the action of high-energy radiation on water, the variety of early products is typically indicated by the relation

$$H_2O \rightsquigarrow H, OH, H_2, H_2O_2, e^-_{aq}, \text{etc.},$$

in which $\rightsquigarrow$ is read "acted upon by high-energy radiation, gives" and e_{aq}^- is the symbol for the hydrated electron. Particular note is addressed to the species e_{aq}^- (*i.e.*, an electron solvated by water) indicated in the same reaction. For many years there was an awareness in the radiation chemistry of water of the anomalous behaviour of the hydrogen atom, H, as compared with the same atom produced in established chemical processes. The anomaly was resolved on the one hand by J.W. Boag, a British biophysicist, and E.J. Hart, a U.S. chemist, who spectroscopically observed the species e_{aq}^- in the spectral region predicted by R.L. Platzman, and on the other hand by H.A. Schwarz, a U.S. chemist, and Gideon Czapski, an Israeli chemist, who showed the existence of the ionic reducing species with charge of minus unity.

Time scales in radiation chemistry. The time scale characteristic of radiation chemistry ranges from the extraordinarily short time (about 10^{-18} second) required for a fast electron to traverse a molecule to the time (about three hours) required for essential completion of some neutralization processes in very viscous media. In between, there can be a variety of reactions involving intermediate formation and disappearance of the collections of the various species already discussed. The time-scale spread is so great that a pt scale (in which pt is defined as minus the logarithm, to the base 10, of the time t [*i.e.*, $-\log_{10}t$], and t is the time in seconds) is conveniently employed. Actual observances in the long-time-scale region follow fairly well-established chemical practice. The short-time region, on the other hand, presents interesting challenges. The Van de Graaff generator and the linear accelerator both made possible irradiations by electrons and X-rays in the microsecond (10^{-6} second) region, and spectroscopic devices were quickly devised to make observations in that region. Improvements in irradiation technique (with X-rays by Herbert Dreeskamp, a German physicist, and Milton Burton, a U.S. chemist, and with ultraviolet by P.K. Ludwig, a German chemist, and Juan d'Alessio, an Argentine physicist) and in observation techniques in study of luminescence extended precision of observation to 5×10^{-10} second in the work of W.P. Helman, a U.S. chemist. J.K. Thomas, a British chemist, combined use of a fast linac (linear accelerator) with Cherenkov radiation as a marker to extend chemical studies into the same region. Use of the same radiation as light source for spectroscopic observation of the chemistry produced by a travelling electron front (from a linac) enabled J.W. Hunt, a Canadian chemist, to make actual observations in the time range of (2 to 4) $\times 10^{-11}$ second. Table II summarizes an approximate time scale of events.

Chemical studies with linac

Table 2: Approximate Time Scale of Events in a Condensed System

-log *t* (seconds) $\equiv pt$	events	Stage		
18	fast electron traverses molecule	↑ p ys cal		
17	1-MeV proton traverses molecule; time for energy loss to fast secondary electrons			
16	time for energy loss to electronic states (Franck–Condon process)			
14	fast ion–molecule reactions involving hydrogen-atom transfer; molecular vibration; fast dissociation		↑ physicochemical	
12	electron thermalizes; self-diffusion time scales for liquids of low molecular weight			
II	dielectric relaxes in water; neutralization time for polar media	↓		
10 9 8 7 6	spur* formed spur* reactions intratrack reactions completed neutralization times in media of low viscosity and low dielectric constant		↓	↑ chemical
4 3 0 −2 −4	escape time for electrons in media of low viscosity and low dielectric constant radiative lifetime of triplet excited states neutralization times for media of high viscosity and low dielectric constant			↓

*A spur is a region about 2×10^{-7} centimetre in diameter in a liquid and of high ionic and excitation density.

IV. Tertiary effects of radiation

The electrons liberated by high-energy irradiation that have sufficient energy cause further ionizations in which additional electrons are produced. Some of such second-generation electrons also cause additional ionizations, and this process continues until their remaining energy becomes inadequate. Even though this process goes through several generations of events, it actually takes little time, and therefore it appears as an impact phenomenon as far as radiation-induced chemical changes are concerned. For this purpose, then, they may be considered as primary. Fast chemical changes induced by radiation may take time of the order of nanoseconds (a nanosecond is 10^{-9} second) or less to complete; slower reactions involving (relatively) less reactive scavengers (reagents that eliminate residues) in dilute concentrations may need time of about a microsecond ($\frac{1}{1,000,000}$ second).

This section is concerned with radiation effects on much longer time scales, arbitrarily greater than about one minute. Attention is here addressed to physical changes in the solid state, of which there is a wealth of experimental information. It should again be emphasized that little chemical change is expected in an atomic medium in which the absorption of ionizing radiation also results ultimately in structural changes and induced imperfections. With neutron irradiation, except for specific nuclear interactions, one gets "knocked off" atoms or ions (note the discussion of Wigner effect in *Neutrons* above). These ions quickly capture electrons and then travel as neutral atoms. Even though a small effect occurring in ionization and electronic excitation attributable to knocked off ions cannot be denied, it is believed that this effect is small compared with that brought about by the neutral knock offs in the form of structural changes.

HEATING EFFECTS

The simplest ultimate effect of absorption of radiation is heating. It can be argued that, for low-linear-energy-transfer (LET) ionizing radiation, the heating effect is negligible. A spur created by a low-LET radiation is a small spherical region in which the energy deposit is localized in isolation. The temperature rise, AT, of the spur above the surrounding temperature has a space–time dependence that, by hypothesis, has a statistical distribution, called Gaussian, because of random superposition of events leading to the heating process. The temperature rise at a point located a distance r away from the spur centre at time t is given by the equation

Temperature rise in spur

$$\Delta T(r,\ t)=\Delta T_{max}(1+\frac{4\gamma t}{a^2})^{-3/2}\exp\ (-\frac{r^2}{a^2+4\gamma t}),$$

in which a is the initial spur-size parameter, the Greek letter gamma, y, is the thermal diffusivity of the medium (equal to heat conductivity divided by the product of density and specific heat at constant volume). and ΔT_{max} is the initial maximum temperature rise at the centre of the spur. Taking reasonable values for energy deposition (30 electron volts) and spur size a (20 angstroms, or 2 × 10^{-7} centimetre) and using (for water) density equal to one gram per cubic centimetre and specific heat 4 × 10^7 ergs per gram-degree, AT,,,, may be estimated to be 30" ***C*** (54" F). The time required for the central temperature to drop to half its initial value (*i.e.*, $t_{1/2}$) is given by $(1 + 4\gamma t_{1/2}/a^2)^{3/2} = 2$. With the thermal diffusivity, symbolized by the Greek letter gamma, y, equal to 10^{-3} centimetre squared per second for water, $t_{1/2} = 6 \times 10^{-12}$ second. The conclusion is that for low-LETradiation the local temperature rise is too small and drops too fast to have any appreciable chemical (or physical) effect. It is particularly notable that the actual temperature rise is smaller than that estimated here because part of the deposited energy is invariably utilized in ionization, dissociation, and similar processes. This part of the energy resides in the potential form and is not completely available for heating. With high-LETionizing radiations (such as fission fragments, stripped nuclei, α-particles) the situation is somewhat different. In such a case, a large amount of energy is deposited per unit path length, resulting in cylindrical tracks (rather than spherical spurs). The equation for temperature rise in this case is written in a form much like the equation for spur geometry; that is,

$$\Delta T(r,\ t)=\Delta T_{max}(1+\frac{\gamma t}{a^2})^{-1}\ \exp\ (\frac{-r^2}{a^2+4\gamma t}),$$

except that, in this case, a is the initial size parameter for the track cylinder and AT,,, is the maximum initial temperature rise on its axis. For fission fragments with LET of 500 electron volts per angstrom (*i.e.*, 10^{-8} centimetre) and a equal to 20 angstroms, AT,,, for water is 1.6 × 10^{4}° K. Admittedly, this figure is an overestimate for reasons similar to those that apply for low-LETradiations, but it is believed that the temperature rise is high and may approach 10^4° K. The time for this temperature to drop to half the initial value is given by $t_{1/2} = a^2/4\gamma$, which in this case is estimated to be about 10^{-11} second. This time is not much larger than the corresponding time for survival of an isolated spur. Because of the high local temperature, however, the reaction time of the radiation-produced intermediates is also very small. In an intermediate ·+ substrate (*i.e.*, solvent) reaction, for example, with an activation energy of approximately eight kilocalories per mole, the rate constant, k, for such a typical pseudo-first-order reaction may be written. according to the simple usage of chemical kinetics, in the form

$$k \simeq 10^{-11} \exp(-8{,}000/RT)\ \text{cubic centimetre per molecule per second,}$$

in which R is the gas constant in units of two calories per degree and T is the absolute temperature. For a substrate concentration of 10^{22} molecules per cubic centimetre and a temperature of 10^4° K, $-d(\ln \nu)/dt = 6.6 \times 10^{10}$ reciprocal seconds, in which the Greek letter nu, ν, here denotes the concentration of intermediates still existent at time t. Therefore, the time required for the intermediate concentration to drop to an "e-folding" value (*i.e.*, to fraction $1/e$) is approximately 1.5×10^{-11} second, a time that compares favourably with the duration of the temperature pulse. The conclusion is that for very high LET radiation there is indeed a high degree of local heating, and, even though the heat pulse survives only a short time, that time is enough for acceleration of substrate reactions.

Temperature rise to 10,000° K

CRYSTAL-LATTICE EFFECTS

In neutron irradiation of a solid, atoms are dislodged from normal lattice positions and set in motion (the Wigner effect). The fractional amount of energy transfer depends, as in any elastic collision, on the mass ratio of the neutron to that of the recoil atom. Thus, in graphite a carbon atom, on first collision with a 1,000,000-electron-volt neutron (produced, say, in a fission process), receives a kinetic energy of approximately 10^5 electron volts, which is large compared with its binding energy in the lattice (about 10 electron volts). It is estimated that the 1,000,000-electron-volt neutron strikes about 60 carbon atoms before it is thermalized or its speed is so much reduced that it cannot knock off other carbon atoms. Much of the structural damage caused by radiation is attributable to these (relatively heavy) carbon atoms rather than to the original neutron. In this sense radiation damage by fast neutrons may be viewed as an indirect action. Slowing of the fast carbon (or other dislodged) atoms is basically governed by interaction time. This fact means that the stopping is light in the beginning of the journey of a dislodged atom and results only in occasional displacement of atoms. Toward the end of its career **a** large number of atoms are displaced in quick succession along a row, and finally a large amount of residual energy is dumped locally into a relatively small group of atoms. This process generates the displacement (or thermal) spike; the local temperature rise is estimated to be about 10^3°. Even though the temperature rise lasts only about 10^{-11} second before the track is cooled down, this duration is enough for permanent structural damage. **At** least a part of the swelling of graphite under reactor-neutron irradiation is the result of this local heating; another part originates in change in lattice dimension under irradiation.

Cause of structural damage

The high temperature rise in a thermal spike probably results in local melting of the solid. Evidence in that direction has been obtained from the study of copper–zinc alloy under neutron bombardment at low temperature. Before irradiation the structure is ordered; each copper atom lies next to zinc atoms only as nearest neighbours and vice versa. After irradiation, a general random rearrangement of atoms is seen, presumably the result of melting and refreezing.

Long-term effects of radiation on crystals are numerous, and the magnitudes of these effects depend on the crystal structure and previous history. Only some general features of these effects are recounted here.

Long-term effects. 1. Radiation damage may be considered as attributable to the production of Frenkel defects, the result of ejection of a struck atom into an interstitial position with the associated generation of **a** vacancy.

2. In a certain sense radiation-induced damage to the crystal structure is qualitatively similar to that produced

by cold-working (for example, by hammering). Neutron irradiation of pure copper, which is naturally soft at room temperature, makes it so hard that it can be made to sing like a tuning fork.

Neutron effect on pure copper

3. A solid has a tendency to recover spontaneously from radiation damage. If it were not for this property it would indeed be extremely difficult to operate nuclear reactors (which are permitted to heat up periodically to remove the effect in the graphite core). The healing (or so-called annealing) is presumably attributable to the recombination of interstitial atoms and vacancies, thereby removing Frenkel defects. It is not necessary that an interstitial atom always recombine with its corresponding vacancy. Often it may recombine with a vacancy that resembles the one that it left; the result is approximate restoration of the original properties of the crystal. Such annealing is facilitated by the increased mobility of the vacancies and interstitials at higher temperature. At a particular temperature called the annealing temperature, the healing becomes fast and essentially complete. The same substance may have somewhat different annealing temperatures depending on the particular property under study. Many experiments on radiation damage must be done at low temperatures to freeze in the defects produced.

4. So far as radiation sensitivity is concerned, pure metals are the most resistant and the most easily annealed. Annealing temperatures in such cases are relatively low. Thus, the annealing temperature for the increase of electrical resistance in pure copper is only around 40° K. On the other hand, changes in elastic modulus and hardness, such as are required to produce tuning-fork characteristics, persist up to room temperature; *i.e.*, 293" K (20" C or 68° F). Quick annealing in pure metals is directly attributable to the high mobility of atoms in perfectly ordered structures. At the other extreme are organic solids, particularly polymers, composed of large molecules. Here the damage originates in breaking of bonds that usually do not rejoin in the original manner but instead produce chemically different material. Inorganic materials are between metals and organics in their radiation sensitivity. Semiconductors such as silicon and germanium and crystals such as diamond resemble metals in this behaviour.

5. In simple metals irradiation decreases conductivity for both heat and electricity. Conduction of both in metallic crystals is attributable to their ordered structure. The more perfect the structure, the better is the conduction. Frenkel defects, generated by irradiation, therefore, decrease both conductivities. In extreme cases conductivity decrease of orders of magnitude has been observed. With moderate irradiation, however, both thermal and electrical conductivities decrease usually by about half.

Change in conductivities

6. Hardness and ductility depend on perfection of the crystal structure. It is therefore found, as is to be expected, that irradiation results in loss of ductility and increase in hardness. Such effects are attributed to glide-plane obstruction in the crystal. Most structured materials become harder, less ductile, and sometimes more brittle as the result of neutron irradiation. Similarly, most polymers (substances composed of giant molecules) also lose ductility on irradiation.

Properties of irradiated crystals. A few of the properties of irradiated crystals are the following.

1. Expansion. Expansion and lattice distortion produced by neutron irradiation are generally more pronounced than those produced by gamma irradiation. Other general features are: (a) the more disordered the starting crystal, the less is the expansion and the more is the tendency for volume contraction; (b) the expansion is not linear with dose—with continued exposure, a material expands much less for the same dose when it is administered later in its history; and (c) the expansion is anisotropic (*i.e.*, not the same in all directions)—the irradiated material looks more isotropic than the unirradiated control. A perfect crystal of graphite consists of planes of carbon atoms, layer upon layer. Upon neutron irradiation, graphite expands perpendicular to the base plane and contracts slightly parallel to the base plane. After moderate exposure in a nuclear reactor, the expansion is about **1** percent for a flux of 10^{20} neutrons per square centimetre. The actual amount of expansion, of course, depends on the fabrication history and operating temperature of the graphite. Beryllium oxide expands about **1** percent over the first day of usage in a nuclear reactor; the subsequent expansion is much less. Fast-neutron irradiation of natural zircon crystal gives a density loss of about 1 percent per total flux of 10^{20} neutrons per square centimetre. In barium titanate the unirradiated tetragonal crystal has lattice separations that are different in two directions. Upon fast-neutron irradiation, both lattice separations increase, but in differing degrees. Eventually, at about 10^{20} neutrons per square centimetre total flux, the lattice separations become almost equal. Expansion of moderator materials such as graphite is of great importance in the design of nuclear reactors. Even a small percentage change in dimension can result in large total change in the reactor structure; if this change is not allowed for in the engineering design of the reactor, it may create strained operating conditions eventually leading to failure.

Influence on nuclear-reactor design

2. Mechanical properties. Graphite experiences increase in strength and hardness upon irradiation. Annealing is faster at elevated temperatures; also, damage is less when the irradiation is at a higher temperature. A similar effect is seen for the compressive stress–strain curve. Studies of dynamic properties in ceramics indicate a saturation effect at large doses.

3. Conductivity. Thermal conductivity of graphite falls to about half the unirradiated value with an exposure of **3** $\times$ 10^{20} neutrons per square centimetre at room temperature. Like other property changes, this effect can also be annealed at elevated temperatures with concomitant release of stored energy. Energy storage in graphite amounts to about 200 calories per gram per 10^{20} neutrons per square centimetre total flux. Interstitial carbon atoms produced in the irradiation scatter electrons and thus decrease electrical conductivity. The pattern of conductivity decrease and increase depends on the nature of the graphite and the duration of exposure in a reactor. With ceramic materials, loss of thermal conductivity by a factor of about **3** to 5 may be observed under conditions in which the decrease is about one-half in graphite. In mica, on the other hand, the change is somewhat less than in graphite.

BIOLOGICAL EFFECTS

The discussion here is of a cursory nature. For details, the reader is referred to the articles PHOTOSYNTHESIS; RADIATION, BIOLOGICAL EFFECTS OF. Effects of radiation on biological systems are usually investigated from two extremes, viz., with whole-animal experiments and with experiments on individual cells or unicellular organisms, such as bacteria. Closely associated with these investigations are experiments on biological material such as enzymes, amino acids, and DNA (deoxyribonucleic acid).

Action of light on living organisms is a subject that has been studied in the past in great detail. The study still continues because of its obvious importance to photosynthesis and vision. Indeed, it is through photosynthesis that oxygen is replenished in the atmosphere and carbon dioxide is fixed in plants for support of animal life. It has been estimated that the entire oxygen supply of the atmosphere is replenished by plants in a cycle of **2,000** years. The similar cycle time for carbon dioxide fixation is **200** years. Some general biological implications of the effects of light follow.

Oxygen and carbon dioxide replenishment cycles

Effects of light. 1. It has been known over a long period of time that bacteria such as Escherichia coli and Staphylococcus *aureus* absorb light in the near-ultraviolet; *i.e.*, approximately in the region **300–240** nanometres. This absorption results directly in bactericidal action.

2. Ultraviolet also does damage to DNA and interferes with the replication process. Indeed, uninterrupted replication of nucleic acids and proteins would not have been possible on the Earth's surface were it not for the protection afforded by the absorption of ultraviolet by the ozone in the upper atmosphere.

The role of chlorophyll

3. The absorption spectrum of chlorophyll, the chemical substance responsible for the initiation of the photosynthetic process, matches the broad peak of solar radiation observed on Earth in the visible range at 680 nanometres corrected for absorption by ozone and water vapour in the atmosphere. Thus, photosynthesis makes good use of the sunlight available on the surface of the Earth. In this process six water molecules combine with six carbon dioxide molecules utilizing 29 electron volts of energy from the sunlight to produce one molecule of carbohydrate and six molecules of oxygen. This "balance sheet" refers to a series of complex chemical reactions, not all of which are completely understood; many of them, however, are known in detail at present. Chlorophyll-a, present uniformly in all green plants, is the prime material for photosynthesis. Other chlorophyll molecules, such as b, *c*, and *d*, which may be present in algae and also in land plants, absorb energy and transfer to chlorophyll-a before photosynthesis occurs. Similar mechanisms, but utilizing sunlight in a different spectral region, presumably are responsible for photosynthesis in red and blue-green algae.

4. It is apparent that there are many metabolic, behavioral, and physiological processes in plants and animals that are controlled periodically by sunlight. This photoperiodic phenomenon is believed to be regulated by various internal (biological) clocks, which are in turn (probably) governed by one master clock. Examples are well-known in sleep, body temperature, and pathological and physiological functions. Indeed, flowering in seasonal plants is connected with photoperiodicity (flowering of poinsettia at the Christmas season is a good example). Detailed experimentation has shown that it is the night duration rather than the day duration that controls flowering.

Biological effects of ionizing radiations are classified as acute or chronic depending on whether the effect is observable immediately or after a delay. Chronic effects include inherited abnormality and malignancy; in these effects, damage of DNA is probably involved. DNA in the cell is not easily replaced or repaired. Any radiation-induced change in DNA that results in faulty duplication is a potential source of danger of cellular malfunction or of abnormal inheritance or both.

Other radiation effects. Most radiation biological damage results from ionization, though excitation effects can also be significant. Repair of radiation biological damage at an early stage results from the return of a small fragment to a complex molecule, from which it was torn away as a result of the effect of ionizing radiation. Often, that fragment is a hydrogen atom. A relatively heavy fragment recombines more easily. Sometimes it is seen that complete recovery follows acute radiation damage in whole-animal irradiation. It is not that damage has not occurred but simply that the damage has been quickly repaired. Thus, in many cases, there is an apparent threshold dose below which the animal recovers completely. Above the threshold, the recovery is partial or may not occur at all.

A radiation biological effect is primarily cellular in origin. Extracellular material is not immune to radiation; the cellular material is just more sensitive, and its changes have profound influence on the gross biological behaviour of the living organism.

Radiation sensitivity of cells

Radiation sensitivity of a cell depends on a variety of factors, including the conditions of its environment. Cells of higher organisms are generally more radiation sensitive than cells of lower organisms. Thus, such unicellular organisms as bacteria are most resistant to irradiation; it should be realized, however, that bacteria differ greatly among themselves in respect to radiation sensitivity. For the same organism, usually but not always, radiation sensitivity increases with the linear energy transfer of radiation; sometimes a saturation effect may be seen, or, on the other hand, a falloff of radiation sensitivity occurs, at very high LET. If damage requires multiple ionizing events in order to occur (such as a chromosome injury), it is easy to understand why high-LET radiation is more effective in production of damage. If only one ionization is sufficient to bring about damage (as in bacteriophage, a body-waste virus), however, multiple ionization is relatively inefficient; it merely overkills. Radiation sensitivity of a cell depends also on the presence or absence of other molecules, particularly oxygen. Most cells are two or three times as sensitive in the presence of oxygen as in its absence. The cause of the oxygen effect is probably the intermediate production of the free perhydroxyl radical HO_2. Malignant tissues are usually in an anoxic state (*i.e.*, in an oxygen-free environment). To be rendered ineffective they therefore need a greater radiation dose than does similar healthy tissue.

Two kinds of survival curves

Quantitative radiation sensitivity of a cell (mammalian, bacteria, bacteriophage) is expressed by a survival curve in which the surviving fraction is plotted as a function of radiation dose. There are basically two types of survival curves. The first type shows exponential survival; *i.e.*, the type of survival that results if a single hit (by radiation) in a cell is sufficient to produce the biological damage. The second type represents sigmoidal survival; *i.e.*, the survival curve shows a threshold, or a substantial dose is required for perceptible radiation damage. Theoretically, such survival results if multiple hits are required in a cell for its deactivation.

V. Significance *of* radiation-induced changes

BIOLOGICAL PROCESSES

Protophotosynthesis and *photosynthesis.* The most important chemical process to life is botanical photosynthesis; *i.e.*, the process of production of amino acids, carbohydrates, and their derivatives in living plants as the consequence of the absorption of light. In the history of the world, however, there was a time when no living thing existed. Indeed, there was a period in which high temperature itself precluded formation or survival of any of the complicated organic compounds necessary for life. At that time, the atmosphere of the Earth consisted of water (H_2O), ammonia (NH_3), and methane (CH,). It was only as the planet continued to cool that water could condense. Meanwhile, as a result of the absorption of far-ultraviolet light (see Figure 1) and of the action of X-rays and gamma rays and of corpuscular radiations, chemical reactions began to occur in the atmosphere. These processes, when the atmosphere was still quite hot, resulted principally in molecular decomposition and the loss of some (low-molecular-weight) hydrogen from the gravitational field of the Earth. Later, in the cooling process, liquid water began to form, and the rains that thereupon periodically occurred were accompanied by electrical discharges (lightning) and electron bombardment of the components of the atmosphere. The result—as the cooling process continued—was protophotosynthesis of the first compounds (fatty acids, aldehydes, ketones, amino acids, ring compounds, heterocyclics) essential for the existence of even the most primitive forms of life.

Consequences of accidental absorption

Photochemistry and radiation chemistry have contributed in most essential ways to both the very existence and the perpetuation of life processes. By comparison with such immensely important processes, the man-determined applications of photochemistry (such as photography in all its complicated variations, improvements, and subtleties) and of radiation chemistry are trivial indeed. The accidental consequences of the absorption of radiation (in the sense that man has little control over them) still remain the most important of the processes that affect all living creatures, including man.

Both electromagnetic (as represented particularly by ultraviolet light) and corpuscular radiations can cause chemical reactions and mutations in living matter. In the smaller living units, the effects can be either immediately lethal or terminative for production of progeny. In the larger biological units, there can be immediate destruction of some of their component parts or production of mutations, most of which are regressive and ultimately lethal. Only a small fraction of the mutations so produced are viable and persistent in modified progeny and only a minor few of the progeny are improvements on the original organism. Such occasional improvements, in the sense of their increased ability to survive and to interact favourably with their environment, may be an important contribution to the evolutionary process. In contrast, the destructive effects of the absorption of radiation can be important indeed; one suggestion is that they are important contributors to the aging process. The reason for such speculation is simple enough but some definitions are first required.

The rern unit. The rem is a quantity of biologically effective radiation that was originally written as an abbreviation for "roentgen equivalent man"; actually it is the dose in rads multiplied by a term called RBE, or "relative biological effectiveness." The rad is a unit of exposure to high-energy radiation. One rad is the energy deposited by radiation in units of 100 ergs per gram. (One erg equals 2.389×10^{-8} calorie.) RBE is itself a characteristic of the type of radiation employed and is typically about 0.7 for high-energy gamma rays.

Natural background radiation

According to U.S. federal radiation standards, 500 millirem (*i.e.*, one-half rem) of high-energy irradiation per year is set as the threshold of danger for human beings. The natural background dose from cosmic rays, radioactivity in concrete, radioactive contaminants in the smoke of burning fossil fuel, and even radiation from the soil and equally "safe" sources, however, is estimated to average 90 to 200 millirem per year. Permitted contributions from known sources are considerably smaller. Human tissue is regularly insulted (injured), in spite of any precautions, by radiation-induced, physically undetectable chemical changes.

Mutations. The most immediately apparent and dramatic evidences of the effects of high-energy radiation in humans were in the accidental causing of cancers (among many of the scientists who worked with radium in the early days after its discovery) and are in the deliberate destruction of cancers (as in the radioactive iodine treatment of thyroid cancers). Careful regulation of the many sources of radiation has reduced accidental exposure to a minimum. Nevertheless, experimentation continues to present hazards. Particularly notable is an incident that occurred at the Boris Kidrić "zero power" nuclear reactor at Vinča, Yugoslavia, on October 15, 1958. On that occasion, a girl at the control desk, who was using the quiet hours for study, accidentally permitted the reactor to run above zero power for a protracted period. She died 32 days later, and six other people at the reactor suffered near-fatal injury. No even mildly similar incident, however, has ever occurred at a power reactor; operations of nuclear-power plants are rigorously regulated and highly automated.

TECHNOLOGICAL FIELDS

The principal applications of photochemistry (including photography) are in the initiation of reactions by light that can pass through glass or quartz windows. Such light has a wavelength not less than about 185 nanometres. Light of shorter wavelength is also effective, but the windows required (sapphire, lithium fluoride, or extraordinarily thin aluminum) and the associated mechanical difficulties seriously limit application of photochemical methods in the range from 185 nanometres down to a conceivable lower limit of about 85 nanometres. Photochemical techniques are particularly applicable when a specific initial process (*e.g.*, the breakage of a particular bond in a molecule of a particular substance) is required. For such purposes, high-intensity ultraviolet lamps are usually employed, the window is glass or quartz, and the initiation reaction is limited to the relatively thin layers in which the light is absorbed. The processes include photochlorination of aromatic compounds (such as benzene, toluene, and xylene), sulfhydration of olefins, production of cyclohexanone oxime, photopolymerization (principally in surface-curing processes), sulfoxidation, and vitamin D synthesis.

High-energy electrons in industrial applications

High-energy radiation has a much greater range of potential applicability. Electrons penetrate about half a centimetre per 1,000,000 electron volts in a medium of unit density (*e.g.*, water), proportionally less in mediums of higher density, and proportionally more in mediums of lower density (*e.g.*, hydrocarbons). Low-energy electrons (including low-energy beta rays) have proved effective in the rapid curing of paints. Electrons produced (by Van de Graaff generators, as an example) at energies up to 3,000,000 electron volts have been used advantageously in many industrial processes. Gamma rays from radioactive decay have the advantage of deep penetration through the walls of pressure vessels and through the irradiated media.

An advantage of using high-energy radiation as a reaction initiator is the fact that it may be employed to start and control the rates of reactions that must be maintained, for example, at very low temperature. In the case of high-energy radiation like X-rays or gamma rays a window is not required for the admittance of the rays. Consequently, such radiation can be conveniently employed for initiation of high-pressure reactions. Principal industrial applications of high-energy radiation have been in the synthesis of ethyl bromide, synthesis of graft copolymers, curing of specialized surface coatings and paints, synthesis of ion-exchange membranes, preparation of polyethylene oxide (of carefully regulated molecular weight) for textile finishing, and preparation of polymer-impregnated woods and concrete–polymer composites. Such impregnated woods include water-resistant structural materials, parquet flooring, knife handles, and a variety of other products in which impact strength and resistance to cracking are required. Polymer-impregnated concrete is potentially important in both building and road construction. Use of high-energy radiation in the textile field has been promoted principally in Japan, but there are numerous other places throughout the world where techniques of (high-energy) radiation chemistry are promoted vigorously and employed effectively on a regular large-scale industrial basis. These include sterilization of surgical materials, sterilization of rabbit hair (principally in Australia), prevention of germination of potatoes, and production of thermoshrinkable, cross-linked polymer. The last (in diameter ranging from a fraction of an inch to a few feet) may be used, on the one hand, as insulating tubing (insulating spaghetti) for electrical wiring and, on the other, as a protective coating tubing for joints on long-distance oil and gas pipelines. Radiation treatment of foodstuffs for improved storage is actively investigated and promoted.

In the United States, use of high-energy radiation for any purpose, including manufacturing, is strictly regulated both by the federal government and by a variety of state agencies.

Radiation Injury

The severity of radiation damage to living tissue depends upon the type of radiation, the size of the exposure, and the rate at which it is experienced. The two main categories of radiations are non-ionizing and ionizing; the latter category comprises those radiations of sufficient energy to cause electrons to be added to, or removed from. atoms or molecules previously electrically neutral (an electron is an elementary particle with a negative electrical charge and an extremely small mass). Non-ionizing radiations include visible and ultraviolet light, radio wave, and microwaves. Of these, ultraviolet radiations are a common source of injury.

ULTRAVIOLET RADIATION

Types of ultraviolet rays

Sources and terminology. Ultraviolet radiation comes from the sun and from many man-made devices such as arc welding equipment and ultraviolet lamps. This form of electromagnetic radiation is called ultraviolet because it is slightly more energetic than violet light. Three groups of wavelengths are commonly described: the "far" ultraviolet region, with wavelengths of 160 to 280 millimicrons; the "middle," from 280 to 320 millimicrons; and the "near"—closest to visible light—of 320 to 400 millimicrons. Wavelengths even shorter than 160 millimicrons can be produced under special conditions. Another way of expressing wavelength is in terms of the Angstrom (symbol Å), which is equal to 0.1 millimicron or $^1/_{100,000,000}$ centimetre. (There are 2.54 centimetres in an inch.) The longer the wavelength the more penetrating the radiation; those in the near region go through significant thicknesses of glass, water, and tissue; those in the middle region are almost completely absorbed by window glass; and those in the far region are poorly transmitted even through air. Most of the radiations reaching man from the sun have wavelengths in the middle and near classes; the earth's atmosphere shields out those of less than 295 millimicrons quite effectively.

Depending on the source of the ultraviolet radiations and the amount of shielding interposed, a particular distribution of wavelengths, or spectrum, may be encountered. Certain wavelengths are believed to be especially effective in producing specific biological effects; thus both the spectrum and the total amount of energy deposited are important in determining the result.

Even the longer ultraviolet wavelengths do not penetrate very far in tissues, and therefore the effects ordinarily seen are limited to the skin and eyes. Under laboratory conditions it is possible to study the changes produced in other types of living cell systems; important alterations, qualitatively different from those produced by ionizing radiations, are seen.

Sunburn and tanning

Injuries produced. ***Skin.*** Sunburn and tanning, well-known effects of ultravioiet radiations from the sun, are produced by mechanisms not entirely understood. The redness, swelling, and pain of sunburn are associated with denaturation—a change in the molecular structure with consequent change in characteristics—and coagulation of some of the substance of the epidermal cells, and enlargement of the small vessels beneath the outer layer (epidermis) of the skin. In severe cases, blisters and even ulcers may form, and the victim may experience a serious generalized illness with fever. Unfortunately, there is a latent period of several hours between exposure and the onset of symptoms, so that a person may receive serious injury without knowing it. Sun bathers often fail to realize that the hazard is not limited to perfectly clear days but can occur in the presence of a hazy atmosphere.

Tanning, a later manifestation, or the result of repeated exposures, is due to the darkening of existing melanin granules in the epidermis and the stimulated production of new granules of the pigment. With prolonged exposure to ultraviolet radiation, as experienced by farmers, sailors, and other outdoor workers, a definite set of chronic changes are seen in the skin. The epidermis becomes irregularly pigmented, wrinkled, and somewhat thin, and loses much of its elasticity. The connective tissues beneath the epidermis undergo undesirable changes, including alterations in the intercellular substance and damage to small blood vessels. In the general population chronic ultraviolet exposure contributes greatly to the skin changes ordinarily attributed to aging.

It is unfortunate that sunburn is often considered a trivial and healthful ailment and that deep tanning is looked upon as a manifestation of health and beauty, when, in fact, excessive exposure to ultraviolet radiation is distinctly harmful. In addition to hastening the aging process, sunlight contributes to the development of keratoses—elevated, scaling, pigmented areas—and to the development of cancer of the skin. Evidence for the role of sunlight in skin cancer is that this disease most commonly develops on exposed rather than clothed areas of the body, that it is more prevalent in people living near the Equator, and that it is more frequent in outdoor workers.

It is well known that persons with pale skin and blonde or red hair are more susceptible to most of the undesirable effects of ultraviolet light than are people with dark skin and hair; they have less melanin to protect the deeper tissues. Certain disease states specifically predispose to sensitivity to light, and some reactions to drugs are associated with severe skin manifestations at the sites reached by ultraviolet radiation. Sunlight does, however, play a part in the synthesis of vitamin D in the skin, a function useful to those with inadequate dietary intake.

Flash burn and snow blindness

Eye. Ultraviolet light can produce keratitis—an injury to the cornea of the eye with an associated inflammatory response. When produced by arc welding this may be known as a flash burn; a similar injury, known as snow blindness, may be caused by long exposure to sunlight reflected by snow, especially at high altitudes (where there is less atmosphere to absorb the radiation). After either type of injury there is usually a latent period of several hours before the onset of symptoms, which consist of intense pain and visual impairment. Some of the injured cells of the cornea may swell and die while others proliferate. The small blood vessels become swollen with blood, and there is leakage of serum and white blood cells at the site of injury. Usually the damage is repaired spontaneously within several days, leaving no significant residual abnormality, but abnormal sensitivity to light may persist for some time. These types of injury can be prevented by suitable protective lenses.

IONIZING RADIATION

Sources and terminology. The term ionizing is applied to all forms of radiation that directly or indirectly ionize the atoms with which they interact. X-rays and gamma rays are forms of electromagnetic radiation, much more energetic than ultraviolet, with wavelengths of less than ten millimicrons. Gamma and X-ray differ in the way they are produced but have identical effects on tissues. Particulate radiations, also considered as ionizing, include beta particles, which usually penetrate tissues a few millimetres or less, and alpha particles, which, in general, have even less penetrating power. Neutrons are particles without electrical charge; they may travel for some distance in tissue and have special biological effects.

The amount of ionization produced can be measured and the result used to describe the amount of energy transferred and thus to express the dose. The roentgen (R) is a unit of exposure stated in terms of an effect in air. The rad is the unit of absorbed dose in tissue; one rad is equivalent to the absorption of 100 ergs of energy per gram of absorbing material. (The rad is a small unit; when one pound receives one rad the energy deposited is equivalent to about $^1/_{300}$ of that required to lift the pound one foot.)

Injuries produced. The types of injury that ionizing radiation can cause have been extensively studied in experimental animals and in human beings who have been accidentally exposed. The damage produced depends on the type of radiation, its penetrating ability, the portion of the body exposed, the duration of exposure, and the total dose. In describing the effects it is convenient to compare a single large absorbed dose received all at once and an identical total dose that is administered in small increments over a long period. It is also convenient to discuss separately the observed results from an exposure caused by an external source of radiation, such as an X-ray machine, and one caused by radioactive material located within the body.

Acute total body irradiation. If the whole body is exposed to penetrating ionizing radiation, a rather characteristic pattern of injury occurs. Figure 1 shows, within the limits of information now available for man, what the results would be if a large number of normal persons were exposed to a single short burst of radiation and absorbed doses from a few rads up to several thousand rads. Each fine horizontal line symbolizes a dose group, and the termination of that line in the heavy black line represents the average time of death.

When therapy may be successful

In the known examples of human exposure, many more people have received relatively low doses, from which recovery is possible, than have received the higher, inevitably fatal doses. Thus the outlook for successful therapy of acute radiation injury may be good—a fact often not recognized. The change in the survival curve that can be achieved by therapy is shown in Figure 1 as a broken line.

From G.A. Andrews and R.J. Cloutier, Archives of Environmental Health, vol. 10 (March 1965); © 1965 American Medical Association

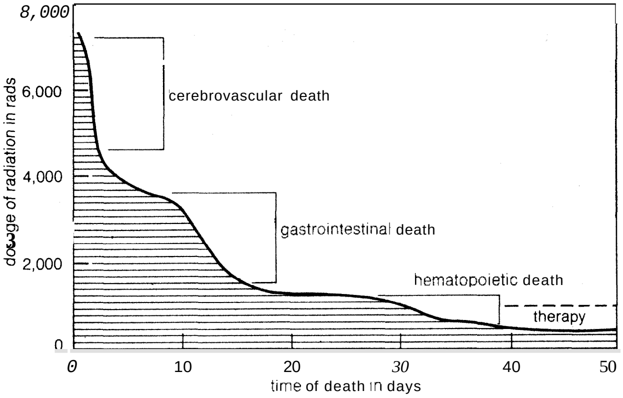

Figure 1: Expected period of survival after the entire body has been exposed to ionizing radiation (see text).

It can be seen that the survival for those receiving more than about 4,000 rads is two or three days or less and that they die with manifestations related chiefly to the nervous system and to the heart and blood vessels. Within less than an hour of exposure they experience vomiting and diarrhea. Mental changes and a fall in blood pressure soon occur, and death is preceded by convulsions and a period of unconsciousness.

The gastrointestinal syndrome claims those who receive a somewhat lower dose; the commonest time of death for persons receiving this dose is about ten days after exposure. Nausea, vomiting, and diarrhea develop a little less promptly than in persons who receive higher doses. The symptoms are very persistent, and a progressively more severe illness develops; this is believed due mainly to death of cells lining the intestinal tract. Fever, loss of fluid and of soluble salts from the blood, early damage to the bone marrow, and infection toward the close of the illness are also features of the clinical picture.

In the fraction of the population that absorbs below about 1,000 rads (but over 150) the syndrome involving the hematopoietic (blood-forming) system ensues; it is the syndrome of greatest importance because it is the one most commonly seen and the only one for which effective treatment is available. For example, a man receives an average absorbed dose of 300 rads in a radiation accident. Figure 2 shows the effects of this dose. It might correspond to an air exposure of 450 roentgens or so and is in a range that might prove lethal for some persons. The alterations produced in the numbers of circulating blood cells are caused mainly by irradiation damage to precursor cells (stem cells) in bone marrow and lymphatic tissues. Nausea and vomiting, early effects that last a day or two (and are not to be confused with the gastrointestinal symptoms produced at much higher doses), are followed by a virtually symptom-free latent interval, a hazardous period of marrow depression, and a recovery phase. The dangerous marrow depression phase is characterized by bleeding, due mainly to a lack of platelets, and by susceptibility to infection, due mainly to a lack of certain white cells (neutrophils) in the blood. Death, if it occurs, is most likely to come approximately 30 days after exposure. Effective treatment is directed toward keeping the affected person alive for about five weeks, until natural recovery processes have time to come into play. Specific measures include protection from outside infection, use of antibiotics and other antimicrobial drugs, and administration of donor platelets. Other, less established forms of treatment may be tried when recovery is doubtful with standard treatment.

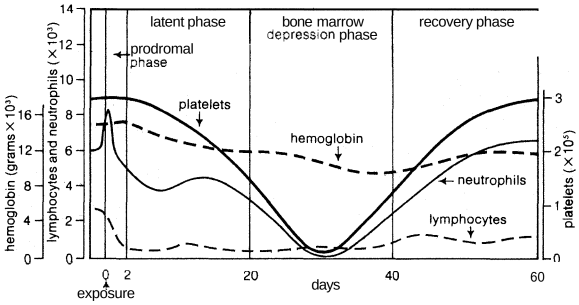

Figure 2: Changes in blood composition during successive stages of radiation illness caused by a dose of 300 rads.

From G.A. Andrews and R.J. Cloutier, Archives of Environmental Health, vol. 10, p. 501 (March 1965); © 1965 American Medical Association

In considering the three characteristic sets of effects (syndromes) caused by total body irradiation, one should not make the assumption that high doses affect only the cerebrovascular tissues, lower ones only the gastrointestinal tract, and still lower ones the hematopoietic system. Of these systems the hematopoietic is most sensitive, the gastrointestinal next, and the cerebrovascular system least. The order of promptness of manifestation is just the opposite, however. Thus it follows that a person who receives 500 rads will not show the cerebrovascular syndrome because he has not received a dose high enough to cause it. On the other hand, a person who receives 5,000 rads dies before he can show the full picture of the gastrointestinal and hematopoietic syndromes, but he would show them in severe form if somehow he could be kept alive long enough to do so. It is striking that, while the injury may all be incurred instantaneously, the manifestations of acute damage, especially the hematopoietic syndrome, develop inexorably over a period of days or weeks, in a time pattern that is rather rigidly maintained for a given species.

A person who has been irradiated by an external source usually has not been made radioactive and therefore cannot expose anyone else. In special circumstances, such as neutron irradiation, atoms naturally present in the body can be made radioactive by an external beam, but usually when this happens the amount of radioactivity produced is too small to be hazardous to other people. The only way that a person can become dangerously radioactive is by taking in a large amount of radioactive material or by having it spilled upon him.

Acute local radiation. When small parts of the body are exposed to ionizing radiation, the total dose tolerated is usually much higher than for total body exposure. Since partial body irradiation almost always leaves some of the most sensitive organ, the bone marrow, unexposed, the protected portion can save the injured person from the effects of complete marrow depletion. After local irradiation the effects are often limited to the part of the body exposed; but irradiation to the abdominal area can cause nausea and vomiting.

Irradiation for cancer

When local radiation therapy is given for cancer, the treatments are usually extended over a period of weeks, but the effects produced are more those of acute than of chronic exposure. At the doses commonly used, some degree of reddening of the skin may occur, sometimes followed by darkening of the colour of the skin. In the deeper tissues early inflammatory changes are followed by some scarring. The cancer tissues, which in cases favourable for radiation therapy have greater sensitivity to radiation than the surrounding tissues, and on which the radiation is concentrated, may undergo partial or total cell death, with prevention or curtailment of future growth.

When acute partial body exposure is received in a radiation accident, the dose may be enormously high, with the death of much tissue. Damage to blood vessels is of great significance in these cases. The blood vessels, like the bone marrow, fail to manifest the full degree of their injury at the outset; unlike the marrow, they do not have a great capacity for recovery but show progressively greater degrees of impairment. Initial swelling of the cells lining the vessels may be followed by the death of many of them, with subsequent thickening of vessel walls and eventual blocking of the vessel channels, leading to the death of the tissues that they normally supply. Early evaluation of damage in accidents involving partial body radiation often underestimates the extent of the injury. After the exposure has occurred there is no known treatment that will interrupt the progression of the manifestations of injury. The lesions need protection from infection, and treatment is required for infections that do occur. Surgical removal of dead tissue may be useful, and for some parts of the body repair by plastic surgery may be pcssible; this often tends to be limited by the fact that surrounding tissues may also have received enough radiation injury to make such repair especially difficult.

There may be acute exposures to total body irradiation combined with much higher doses to local areas of the body. In these cases, if the total body injury is not severe enough to be fatal, the affected person will be recovering from the systemic total body effects by two months after exposure but may still face many months of progression of the local injury, often without a satisfactory final healing.

Prolonged exposure. When irradiation is experienced continuously or intermittently over a period of weeks, months, or years, as might happen in an uncontrolled occupational exposure, the effects are quite different from those caused by a single acute exposure. In general the protraction allows a much larger total dose to be tolerated, because biological reparative processes tend to heal part of the damage while the exposure is still going on. Once a dose is reached that is high enough to produce clinical effects, however, the outlook for recovery is not nearly as good as it is for the single, acute exposure. If recovery does occur it is slow. The degree and types of injury are less predictable than those from an acute exposure and may include profound damage to the bone marrow as well as the manifestations discussed below in the section on delayed effects.

Isotopes and their half-lives

Internal radioisotopes. Radioisotopes are varieties of atoms that spontaneously emit radiation because of transformation of their nuclei; this process is also called decay. Each particular isotope has a half-life, which is the time required for its disintegration rate to fall by one-half; with succeeding half-lives, there is left %, %, %, 1/16, 1/32, and so on, of the original activity. For different isotopes, half-lives may vary from tiny fractions of a second to billions of years. The unit of measurement is the curie, which is the amount of a radioisotope that at the time of reference is undergoing 3.7×10^{10} (37,000,000,000) disintegrations per second. It follows that over an extended period a curie of an isotope of long half-life will have many more disintegrations than a curie of one of short half-life. Disintegration produces radiations (alpha and beta particles, gamma rays) of various energies, with a specific pattern for each radioisotope. Depending upon the type and energy of these radiations and the nature of the matter that they encounter, they may interact with the tissues close to their site of origin or at a great distance from it. Because many factors are involved, there is no simple overall relationship between the curie (the unit of measurement for radiation at its origin) and the rad (the unit of measurement for the energy deposited at the site of interaction of radiation with tissue).

Some radioisotopes when absorbed internally spread diffusely throughout the body (*e.g.*, radioactive sodium) and give what amounts to total body irradiation. Others, because of their biochemical properties, concentrate in certain types of tissue and irradiate mainly the areas where they are deposited (*e.g.*, radioactive iodine). Still others are not absorbed, being insoluble, but can become lodged internally; for example, certain inhaled particles, tend to stay in the lung, and inert radioactive substances may be deposited in penetrating wounds.

Radiations of short range, particularly alpha particles, can be especially dangerous internally, even though they are not able to travel as far as a thickness of skin. When alpha emitters are lodged internally they often cannot be detected by means of external radiation measurements.

Delayed radiation effects

It is rare for a person to take in enough radioactive material to have nausea and vomiting or other signs of acute radiation sickness. There is much more likelihood of chronic or delayed radiation effects; these occur particularly as a result of radioisotopes of long half-life that are not excreted promptly. For each radioactive material the effects produced depend upon the sites in which it localizes, its half-life, the nature of its radiations, and other factors. General types of response include degeneration of the irradiated tissue and the induction of cancer. These responses may not become manifest for many years, but once they appear there is little chance of the spontaneous improvement seen after acute radiation injury.

Characteristics of Four Radioisotopes and Their Internal Effects

radioisotope and half-life	radiations	characteristics
Radium-226 1,620 years	alpha and gamma	a naturally occurring radioactive element, discovered by Pierre and Marie Curie in 1898; when injected internally it seeks bone and is a potent cause of cancer; for modern medical use it is kept encapsulated and used as a source of gamma radiation
Iodine-131 8.1 days	beta and gamma	a product of nuclear fission and artificially produced in other ways; when absorbed internally most of it concentrates in the thyroid gland (or in certain kinds of thyroid cancer); when taken in accidentally it can damage the thyroid and may produce tumours in it; very useful medically for diagnosis and treatment of thyroid disorders
Plutonium-239 24,000 years	alpha, small amount of weak gamma	artificially produced, usually by bombarding uranium in a reactor; used, because it undergoes fission, for nuclear power and weapons; hazardous when inhaled as particles, or accidentally deposited in wounds; it is difficult to detect from outside the body
Strontium-90 28 years	strong beta	a product of nuclear fission and an important component of fallout; main source of intake is with the diet; in the body it behaves like calcium, depositing in bone, where, if present in large enough amounts, it may produce cancer

The table summarizes information on four radioisotopes that have important effects when deposited in the internal organs.

Effects on specific tissues. Immediate effects. The hematopoietic tissues of the bone marrow, which is made up of cells that undergo division frequently, constitute the most radiosensitive of all vital systems; this has been discussed in the section on acute total body irradiation.

Male and female reproductive organs are especially sensitive to ionizing radiation. Doses of several hundred rads can produce sterility that lasts several months. With uniform total body irradiation a nonlethal dose usually will not produce permanent sterility. Doses not high enough to kill the germ cells can cause damage to their chromosomes and thus lead to genetic defects.

The lining cells of the gastrointestinal tract are highly radiosensitive; they have a rapid rate of cell replacement by division, a feature generally associated with high radiosensitivity. Through death of these cells radiation thus causes denudation of the surface of the tract.

Blood vessels are easily damaged by irradiation, and damage to local tissues seen after irradiation is often a result of blood-supply impairment arising from injury to the blood vessels.

Effects of radiation on a developing embryo, which is highly radiosensitive, are dependent upon the embryo's exact stage of development at the time the radiation is received. Here again, sensitivity is associated with cell division. When a particular organ system is in its most active stage of development it is most sensitive, and radiation sustained at that time will produce abnormalities at birth that are easily identified as having occurred during the period of growth of the organ system. Many of the critical stages in human embryologic development occur very early, even before the mother is aware of her own pregnancy.

Delayed effects. The delayed effects of ionizing radiation are much less predictable and less clearly related to dose than are the acute ones. Degenerative changes can be produced in many organs, leading to impaired function; probably damage to blood vessels is an important factor in many of these changes. Organs typically damaged include the bone marrow, the bones, the kidneys, and the lungs. The lenses of the eyes may become opaque months or even years after the eyes have been irradiated. It is believed that a total dose of at least 200 rads of gamma radiation is required, and many persons tolerate more than this without any injury to the lenses (*i.e.*, getting cataracts). Neutron irradiation is especially dangerous in this respect.

Cancer. Perhaps the most severe latent effect of radiation is the predisposition to cancer in some exposed persons. The causes of most naturally occurring cancers are not known, but it is clear that the incidence of at least some types can be increased by radiation, and that the increase in the cancer rate can be significant if the doses of radiation are high. The interval between exposure and onset of the cancer is usually several years. In the early days of diagnostic radiology physicians were not as careful as they are today, and they exposed their hands while X-raying their patients. Many suffered radiation injury to their hands that later developed into skin cancer. Another type of cancer, developing in bone or in tissues adjacent to bone, is seen in persons irradiated there by radium that has been taken into the body, as occurred in workers who painted radium watch dials. Still another example is the increased incidence in cancer of the lung that occurs among uranium miners, whose respiratory systems are exposed to radiation from radon. In those miners who are cigarette smokers, the smoking appears to combine with the occupational exposure to accentuate the hazard greatly.

Cancer of the skin, bone, and lung

Leukemia, a malignant disease involving the blood-forming tissues, is clearly influenced by radiation. In the atomic bomb casualties of Japan a distinct increase in this disease began a few years after the exposure and continued for many years. Confirmatory evidence is seen in certain other groups. It is estimated that one or two added cases of leukemia per year will occur if one rad is received by each person in a population of 1,000,000. Leukemia is a rare disease, and, even when its incidence is increased in a population exposed to radiation, it occurs in a very small percent of the people. Other blood disorders, such as those characterized by bone marrow failure, fibrosis (formulation of scar tissue) of the bone marrow, or other abnormalities of blood cell formation, may sometimes result from irradiation.

In experimental animals it has been shown that radiation exposure can hasten aging processes and thus can shorten life. No such effect has been clearly shown in humans.

Genetic effects. The genetic effects of radiation are a potentially serious problem in a society that is using an increasing amount of radiation for diagnostic medical purposes and that is expanding its use of industrial processes involving radiation. To determine the hazard there has been a great deal of intense, well-supported effort by highly qualified scientists, but the problem is inherently very difficult to answer. The genetic effects of large doses of radiation in small animals are clear enough; the difficulty is in determining the genetic effects of exceedingly small doses given over a long time period to a human population. Experiments involving hundreds of thousands of animals over periods of many years are necessary to obtain statistically valid information for answering these questions. Even when answers are obtained for one species, such as the mouse, and for one set of circumstances, it is not certain that the results that have been obtained apply to humans.

Gene mutations

Two major types of effects can be produced: true gene mutations and chromosome breakage; the latter involves a number of genes. The true gene mutations might be produced by a "single hit" of a charged particle. Their probability has been stated to be directly proportional to total radiation dose and was formerly believed independent of the rate at which the radiation dose is delivered. Even though mutations are the basis of evolution, almost all of them are obviously undesirable. Since a single radiation event could cause a mutation, one would not expect a threshold—that is, a radiation dose below which no effect could be produced. Many of the mutations would be recessive and thus would not be apparent until chance pairing with a matching defect. Harmful gene mutations tend eventually to be eliminated from the population at a rate proportional to their harmfulness. It would be possible for undesirable recessive mutations to persist for many generations, however, and for the human gene pool to build up a dangerous level of them—and this has been a clearly expressed apprehension.

The other type of genetic defect—breakage of chromosomes, involving multiple genes—is believed to require more than a "single hit." These defects would increase with the square of the radiation dose, would produce many fetal deaths, but usually would not persist for generations as a hidden hazard in the gene pool of the population.

Extensive studies of the mouse suggest that the inexorable piling up of harmful recessive mutations may not be as great a hazard as has been thought by some. It is now known that when the dose is protracted, rather than given all at once, fewer persistent single-hit mutations are produced; there is apparently a repair process that is effective when the dose is not given all at once. Furthermore, at least for the female germ cell, an elapse of time between the radiation exposure and conception decreases the number of mutations that appear. In addition, the mouse studies show that the incidence of true gene mutations per rad is lower for small radiation doses than for large radiation doses,.

Without any unusual radiation exposure, about 1 percent of newborn human beings show some visible defect in development that might be caused by a mutation. Little is known about the role of existing radiation levels in producing these abnormalities, but there is good reason to believe that a great majority of them are caused by factors not related to radiation.

Some of the most direct information available regarding the genetic effects of radiation on human beings has come from the offspring of the atomic bomb casualties in Japan. It appeared at first that there was an alteration in the sex ratio in births from previously irradiated parents, suggesting selective fetal mortality, but this finding has not been substantiated. The pregnancies from this group, when compared with those of nonirradiated controls, have been reported as failing to show any detectable increase in stillbirths, neonatal deaths, gross malformations, or mortality during childhood.

(G.A.A.)

Radicals, Free

Most molecules contain even numbers of electrons, and the covalent chemical bonds holding the atoms together within a molecule normally consist of pairs of electrons jointly shared by the atoms linked by the bond. Under certain circumstances, however, fragments of such molecules may be formed. Among these are groups of atoms containing single or unpaired electrons. Such fragments may be considered to have arisen by cleavage of normal electron-pair bonds, every cleavage having produced two separate entities, each of which contains a single, unpaired electron from the broken bond (in addition, of course, to all the rest of the normal, paired electrons of the atoms). Molecular fragments with unpaired electrons are called free radicals or often, when the meaning is unambiguous, simple radicals.

Although free radicals contain unpaired electrons, they may be electrically neutral. Charged fragments, such as carbonium ions and carbanions, which also are formed by breaking molecular bonds, on the other hand, need not contain unpaired electrons. Because of their odd electrons, free radicals are usually highly reactive. They combine with one another, or with single atoms that also carry free electrons, to give ordinary molecules, all of whose electrons are paired; or they react with intact molecules, abstracting parts of the molecules to complete their own electron pairs and generating new free radicals in the process. In all these reactions, each simple free radical, because of its single unpaired electron, is able to combine with one other radical or atom containing a single unpaired electron. Under special circumstances diradicals can be formed with unpaired electrons on each of two atoms (giving an overall even number of electrons), and these diradicals have a combining power of two.

Certain free radicals are stabilized by their peculiar structures; they exist for appreciable lengths of time, given the right conditions, and can be studied by relatively straightforward techniques. Most free radicals, however, including such simple ones as the methyl ($\cdot CH_3$) and ethyl ($\cdot C_2H_5$) radicals, are capable of only the most fleeting independent existence, and very special techniques have had to be developed to study them. In spite of the difficulties, research on short-lived free radicals is actively pursued, in part because these substances are known to be active intermediates in many chemical reactions, including industrially important polymerizations. It is also believed that free radicals play a role in vital biological oxidation-reduction processes, such as photosynthesis.

An earlier usage

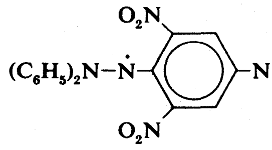
The term radical was first used in 19th-century chemical nomenclature to designate a group of atoms that comprised part of a molecule and that remained together through a number of chemical transformations. One of the first such radicals to be described was the benzoyl radical (C_6H_5CO-). Each radical of this type had an unfulfilled valence—*i.e.*, an atom whose valence number was one less than normal, such as a trivalent carbon or a bivalent nitrogen atom. In combination with another radical, or with a single atom, any of these hypothetical groupings of atoms could, in principle, be converted into a normal molecule. The interactions and transformations of radicals were presumed to make up all observed chemical reactions. When, somewhat later, the first independently existing substances corresponding in structure to one of the theoretical radicals was actually produced in the laboratory, it was designated, naturally enough, a "free" (meaning "uncombined") radical. Since that time the term radical has been used less and less frequently in the original sense; but the odd-electron molecular fragments studied today are still usually referred to as free radicals to avoid confusion with the earlier usage, which remains in the older literature.

Stable radicals. Types. The first relatively stable free radical, triphenylmethyl (structure I), was discovered by Moses Gomberg in 1900. In this compound the central carbon

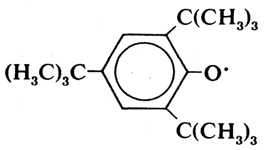
$$\underset{\text{I}}{(C_6H_5)_3C}\ .\ \underset{\text{II}}{(C_6H_5)_3C{-}C(C_6H_5)_3}$$

is trivalent since it is combined with three substituents instead of four, and its unshared electron is represented by a dot. By withdrawing chlorine from chlorotriphenylmethane, $(C_6H_5)_3CCl$, Gomberg expected to obtain hexaphenylethane (structure II) as a result of the combination of two triphenylmethyl radicals. The product obtained (in solution) was, however, a mixture of I and another substance recently shown to be an isomer hexaphenylethane which remains unknown. Actually, in solution, I and this dimer are in rapid equilibrium with each other, the dimer dissociating into two triphenylmethyl radicals, and the radicals continually recombining. Free radicals of the triphenylmethyl type are stable only in certain organic solvents; they are rapidly destroyed by irreversible reactions in the presence of air, water, or strong acids. The degrees of dissociation of such radical dimers vary considerably when the phenyl groups are replaced by other aromatic groups. Thus, when each phenyl, C_6H_5, is replaced by diphenyl, $C_6H_5-C_6H_4$, dissociation into free radicals is practically complete.

In a manner analogous to the above, free radicals are formed to a small extent by the breaking of the nitrogen–nitrogen bond in aromatic hydrazines of the general structure R_2N-NR_2, or to a greater extent, by the breaking of the central nitrogen–nitrogen bond in aromatic tetrazanes, $RN-RN-NR-NR_2$. Thus, the radical 1,1-diphenyl-2-picrylhydrazyl (structure III) exists as a stable violet solid, showing no tendency to dimerize to a tetrazane even in the solid state. Similar examples of free radicals, in which, however, the odd electron is on oxygen, are also known; *e.g.*, the 2,4,6-tri-*tert*-butyl-phenoxy radical (structure IV), a blue substance that is also known in the dimeric form.

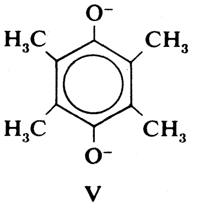


III

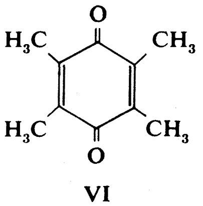


IV

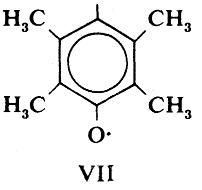
Another variety of free radical with a degree of stability is represented by the class of compounds known as semiquinones. If the dianion of the durohydroquinone (structure V) that exists in alkaline solutions of durohydroquinone is treated with oxidizing agents, it loses two electrons and is converted to duroquinone (structure VI). An intermediate stage of oxidation is possible, however, in which a single electron has been lost to yield the free



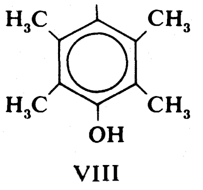
V



VI



VII



VIII

Radical ions

radical smiquinone ion (structure VII). Actually, in partially oxidized systems all three species are in mobile equilibrium, and mixing colourless solutions of V and VI immediately gives rise to detectable quantities of the yellow semiquinone. Semiquinones of a variety of types are known and in some cases may be obtained in pure form in the solid crystalline state. Most semiquinones, however, are usually in rather unfavourable equilibrium with the completely oxidized and reduced forms of the molecule, so that for many years their existence was overlooked.

Still another type of stable radical ion, a metal ketyl, forms when a substance such as benzophenone,

$(C_6H_5)_2C{=}O,$

is treated with metallic sodium to give the coloured substance $(C_6H_5)_2C{-}O^-$. The reaction involved is essentially a reduction, the sodium being oxidized to sodium ion, Na^+. Rather similarly in certain solvents such as tetrahydrofuran, sodium reacts with complex aromatic hydrocarbons such as naphthalene, converting them to the highly coloured radical ions.

A final class of relatively stable organic free radicals are those containing the group > NO. Such a group necessarily contains an odd electron (apparently distributed between the nitrogen and oxygen), and the resulting molecule is thus a free radical. An example is diphenylnitrogen oxide, $(C_6H_5)_2NO$, which is obtained by the oxidation of diphenylhydroxylamine, $(C_6H_5)_2NOH$, and which shows no tendency to dimerize or to disproportionate to products of higher and lower oxidation state. A somewhat similar behaviour of nitrogen is found in nitric oxide, NO, and nitrogen dioxide, NO_2, which are also molecules with odd numbers of electrons.

Structural requirements. Certain structural features appear to be required for the existence of stable free radicals. One condition of particular importance is shown by the semiquinone radical ion VII. As depicted, the upper oxygen atom has a negative charge and the lower one an odd electron. This assignment is arbitrary, however, and the same molecule would be represented if the charge and the odd electron were interchanged. When a situation of this type is encountered, the actual average distribution of electrons within the molecule is presumed not to be that of either of the structures just described but to be intermediate between the two. This circumstance is called delocalization or resonance; according to quantum mechanics, the resonance considerably increases the stability of the substance and, as in this case, the probability of its existence. When the oxidation of duroquinone is conducted in an acid medium, so that the semiquinone anion would be converted to the neutral radical VIII, the opportunity for delocalization disappears, and under such conditions no semiquinone can be detected.

Delocalization

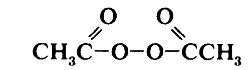
Similar arguments account for the stability of the other free radicals discussed above. In the case of triphenylmethyl I, it is considered that the odd electron is in effect distributed over the three phenyl groups as well as the central carbon atom. In addition, the dissociation of hexaphenylethane may be considerably facilitated by repulsive forces between the three bulky phenyl groups on one carbon atom and those on the other. As a measure of the magnitude of these two phenomena, dissociation of the carbon-carbon bond in the simple molecule ethane, $H_3C{-}CH_3$, requires an energy input seven times that needed to break the comparable bond in the molecule hexaphenylethane.

Unstable radicals. ***Preparation and detection.*** Simple free radicals such as methyl, $\cdot CH_3$, also are capable of existence and play important roles as transient intermediates in many chemical reactions. The existence of the methyl radical was first demonstrated by Friedrich Adolf Paneth and W. Hofeditz in 1929 by the following experiment. The vapours of tetramethyllead, $Pb(CH_3)_4$, mixed with gaseous hydrogen, H_2, were passed through a silica tube at low pressure. When a portion of the tube was heated to about 800" C, the tetramethyllead was decomposed and a mirror of metallic lead deposited on the internal surface of the tube. The gaseous products of the decomposition were found capable of causing the disappearance of a second lead mirror, deposited at a more distant cool point in the tube. Since none of the recognized stable products of the decomposition was able similarly to dissolve a lead mirror, the inference was drawn that methyl radicals formed in the high-temperature decomposition reacted with lead at the cool mirror to regenerate tetramethyllead. Methyl radicals obtained in this way proved to be highly reactive and short-lived. They not only reacted with lead and other metals but disappeared rapidly and spontaneously, largely by dimerization to ethane, $H_3C{-}CH_3$. In hydrogen at a total pressure of two millimetres, for example, the concentration of methyl radicals was estimated to decrease to half its original value in about 0.006 seconds. In subsequent years, techniques for producing reactive free radicals in the gas phase have been greatly extended by Paneth and his coworkers and many other investigator~It has been found that a variety of unstable species, such as ethyl, $(\cdot C_2H_5)$ propyl, $(\cdot C_3H_7)$, and hydroxyl, (OH) can be obtained by several methods including: (1) thermal or photochemical decomposition of a wide variety of organic and inorganic materials, (2) reaction between sodium vapour and an alkyl halide, and (3) discharge of electricity through a gas at low pressure. Atoms that arise from dissociation of a diatomic molecule (such as the chlorine atom, .Cl, from the dissociation of the chlorine molecule Cl_2) can also be obtained and have the properties of short-lived radicals of this type.

Disappearance of metal mirrors

The existence of the various known unstable free radicals, like that of methyl itself, is most commonly demonstrated by the reactions that they undergo. Thus, ethyl radicals, formed from tetraethyllead, $Pb(C_2H_5)_4$, dissolve zinc and antimony mirrors. The resulting ethyl derivatives of zinc and antimony, $Zn(C_2H_5)_2$ and $Sb(C_2H_5)_3$, have been isolated and chemically identified. In a few instances, unstable radicals also have been identified spectroscopically. Here the important technique of flash photolysis, the use of a single, intense flash of light to produce a momentary high concentration of free radicals, is used.

Transient, unstable free radicals also may be produced in solution by several means. A number of molecules, of which organic peroxides are typical, possess such weak chemical bonds that they decompose irreversibly into free radicals on warming in solution. Diacetyl peroxide, for example,



is considered to decompose, at least in large part, into carbon dioxide, CO_2, and methyl radicals. These, in turn, rapidly attack most organic solvents, often by abstracting hydrogen to given methane, CH_4, together with other products. Irradiation of solutions of many organic substances with ultraviolet light leads to the absorption of sufficient energy to disrupt chemical bonds and produce free radicals, and, in fact, most photochemical processes are at present thought to involve free radical (sometimes diradical) intermediates. The chemical changes that occur when solutions (and also gases) are exposed to high-energy radiation (α-β-γ-rays from nuclear reactions, X-rays, electrons beams, etc.) also frequently appear to involve the transient formation of free radicals. Thus, a major consequence of passing high-energy radiation into water, H_2O, is believed to be its dissociation into hydroxyl radicals, $\cdot OH$, and hydrogen atoms, $H\cdot$, together with solvated electrons. Short-lived radicals also are formed in some oxidation-reduction processes. Organic hydroperoxides of the general formula R–OOH react rapidly with ferrous ion, Fe^{2}+, the first step being the formation of ferric ion, Fe^{3}+, hydroxide ion, OH–, and an alkoxy radical, $\cdot RO$.

Radicals from radiation

An interesting method for prolonging the lifetime of highly reactive radicals is to produce them in a glassy or solid medium where they are unable to diffuse together and disappear by dimerization and similar processes. The technique was first developed by Gilbert Newton Lewis, who irradiated various organic molecules, chiefly dyes, in glassy solvents at liquid air temperatures and was able to observe the colours of the resulting unstable radicals, which in some cases could be preserved for days. Similarly, the irradiation of organic plastics (and many other solid organic materials) with high-energy radiation at ordinary temperatures can produce high concentrations of trapped radicals that may be detected and studied via their electron paramagnetic resonance spectra (see below).

Short-lived radicals as intermediates. It is generally considered that free radicals are transient intermediates in many high-temperature reactions (such as combustion and the thermal cracking of hydrocarbons), in many photochemical processes, and in a number of other important reactions in organic chemistry, although the concentrations of the free radical intermediates are in general too low for direct detection. One class of free radical reaction is of particular importance and is illustrated by the following example. Methane, CH_4, reacts with chlorine, Cl_2, by an overall process that gives chloromethane, CH_3Cl, and hydrogen chloride, HCl. The reaction is enormously accelerated by light and apparently involves the following steps:

$$\begin{aligned} Cl_2 &\rightarrow {}_2Cl\cdot \\ Cl\cdot + CH_4 &\rightarrow \cdot CH_3 + HCl \\ \cdot CH_3 + Cl_2 &\rightarrow CH_3Cl + Cl\cdot \\ {}_2Cl\cdot &\rightarrow Clz \end{aligned}$$

Radical chain reaction

Chlorine atoms are produced in (1) and destroyed in (4), while the products that are actually isolated arise from (2) and (3). Since chlorine atoms consumed in (2) are regenerated in (3), a single atom of chlorine can lead to the production of many (actually many thousand) molecules of chloromethane. Such processes, in which an intermediate is continually regenerated, are known as chain reactions, and their study constitutes an important branch of chemical kinetics. Similar chains involving transient free radicals are involved in the halogenation of many other organic molecules, in many of the polymerization reactions employed in the manufacture of plastics and synthetic rubber, and in the reaction of molecular oxygen, O_2, with a great number of organic molecules. In general these chain processes occur with great rapidity—a typical lifetime of a chain may be of the order of a second, during which many thousands of individual steps such as (2) and (3) may occur—although at any one time perhaps only one molecule out of 10^9 in the system exists as a free radical. Since a relatively small number of free radicals can produce significant chemical reaction in this manner, the initiation of typical radical chain processes (such as polymerization of certain unsaturated molecules) provides one of the best demonstrations of the existence of transient free radicals in chemical systems.

While most reactions of molecular oxygen with organic molecules appear to involve free radical intermediates, the situation in other oxidations and reductions depends much upon the particular system involved. Thus, the oxidation of isopropyl alcohol, $(CH_3)_2CHOH$, to acetone, $(CH_3)_2C = O$, by ferrous ion and hydrogen peroxide apparently involves the intermediate radical $(CH_3)_2COH$. On the other hand, there is good evidence that when chromic acid, H_2CrO_4, is the oxidizing agent, the oxidation occurs in one step without the intervention of any intermediate radical. Basically, the presence or absence of intermediate free radicals in oxidations and reductions depends upon whether the reactions involve the transfer of single electrons (which necessarily produces an odd molecule as an intermediate) or involve two-electron transfers (which do not produce odd molecules). In many reactions, including most of the important oxidation-reductions occurring in biochemical systems, which path is followed is not yet known.

Magnetic properties of free radicals. The magnetic properties of free radicals provide a powerful tool for their detection and study. Molecules with even numbers of paired electrons are diamagnetic; *i.e.*, they are slightly repelled by a magnet. Free radicals, however, are paramagnetic (attracted by a magnet) because of the spin of the odd electron, the spins of the remaining paired electrons effectively cancelling each other. The magnetic property of a substance most commonly studied is its magnetic susceptibility, effectively its behaviour in an inhomogeneous magnetic field, and the extent of paramagnetism of the substance is described in terms of its magnetic dipole moment. The magnitude of this dipole moment, which is the same for all free radicals containing single electrons, can be calculated, and the value obtained (1.73 Bohr magnetons) has been confirmed experimentally with free radicals in the solid state or at known concentrations in solution. Magnetic susceptibility measurements may be used to demonstrate the existence of free radicals and to measure the position of equilibrium between radicals and their dimers or disproportionation products. Diradicals, with even numbers of electrons, two of which, however, are not paired, are also paramagnetic, the oxygen molecule, O_2, being probably the simplest example of the kind.

Paramagnetic resonance spectra

The electron paramagnetic resonance spectra of free radicals provide another technique for their detection and study. According to quantum mechanics, the spin of the odd electron of a free radical, when placed in a magnetic field, may have two, and only two, orientations, one with and the other against the field. These two orientations differ slightly in energy by an amount proportional to the strength of the magnetic field, and the majority of the electrons have the orientation of lower energy. If a system containing free radicals is placed in a magnetic field and exposed to electromagnetic radiation (usually in the microwave region of very short radio waves), molecules with the lower energy orientation absorb radiation of a frequency corresponding to an energy just sufficient to flip the odd electron into its higher energy state. This phenomenon gives rise in the simplest case to a paramagnetic resonance absorption spectrum consisting of a single sharp absorption line. The technique is sensitive and will detect extremely small concentrations of free radicals, as little as one part in 10^7 having been reported detected. In many organic free radicals, interaction of the odd electron with the magnetic moments of the nuclei of different atoms in the molecule (most commonly with the nuclei of hydrogen atoms) gives rise to a more complicated system of energy levels and an absorption spectrum consisting of a series of lines. The nature of the spectrum permits the identification of particular free radicals and also gives information about their electronic structure. As an example, the simple semiquinone radical ion, $\cdot OC_6H_4O^-$ (analogous to VII, with the CH_3 groups replaced by hydrogen atoms), exhibits a spectrum of five equally spaced lines, indicating that the odd electron spends part of its time near the hydrogen nuclei. Accordingly, it is not only associated with the two oxygen atoms but is effectively delocalized over the entire molecule. Similarly, the triphenylmethyl radical I shows a complex spectrum, consistent with the idea that its stability arises from the spreading of the odd electron over all three phenyl groups.

BIBLIOGRAPHY. Short accounts of free radicals and their reactions appear in most general texts on organic chemistry. The following specialized works are especially recommended: C. WALLING, *Free Radicals in Solution* (1957), a comprehensive account at the time it was written; W.A. PRYOR, *Free Radicals* (1966), less detailed but covers more recent data; A. FORRESTER, J. HAY, and R. THOMSON, *Organic Chemistry of Stable Free Radicals* (1968), a comprehensive discussion of free radicals sufficiently stable for direct observation; and P.B. AYSCOUGH, *Electron Spin Resonance in Chemistry* (1967), a discussion of the principles and application of electron spin resonance to the study of free radicals.

(C.T.W.)

Radio

The term radio covers the radiation and detection of signals propagated through space as electromagnetic waves to convey information. One of the chief branches of telecommunication, radio embraces wireless telegraphy, telephony, and television. Specialized communications applications include radar and certain navigation aids, and an industrial application is radio-frequency heating.

GENERAL PRINCIPLES

Elecromagnetic radiation (*q.v.*) includes light as well as radio waves, and the two have many properties in common. Both are propagated through space in approximately straight lines at a velocity of about 300,000,000 metres (186,000 miles) per second and have amplitudes that vary cyclically with time; that is, they oscillate from zero amplitude to a maximum and back again. The number of times the cycle is repeated in one second is called the frequency (symbolized as f) in cycles per second, and the time taken to complete one cycle is l/f seconds, sometimes called the period. To commemorate the German pioneer Heinrich Hertz, who carried out some of the early radio experiments, the cycle per second is now called a hertz so that a frequency of one cycle per second is written as one hertz (abbreviated Hz). Higher frequencies are abbreviated as shown in Table 1.

Table 1: Frequency Terms and Their Abbreviations

term	cycles per second	abbreviation	equivalent
1 hertz	1	1 Hz	
1 kilohertz	1,000	1 kHz	1,000 Hz
1 megahertz	1,000,000 (10^6)	1 MHz	1,000 kHz
1 gigahertz	1,000,000,000 (10^9)	1 GHz	1,000 MHz

A radio wave being propagated through space will at any given instant have an amplitude variation along its direction of travel similar to that of its time variation, much like a wave travelling on a body of water. The distance from one wave crest to the next is known as the wavelength.

There is a definite relationship between wavelength and frequency. Dividing the speed of the electromagnetic wave (*c*) by the wavelength (designated by the Greek letter lambda, A) gives the frequency: $f = c/\lambda$. Thus a wavelength of ten metres has a frequency of 300,000,000 divided by ten, or 30,000,000 hertz (30 megahertz). The wavelength of light is much shorter than that of a radio wave. At the centre of the light spectrum the wavelength is about 0.5 micron (0.0000005 metre), or a frequency of 6×10^{14} hertz or 600,000 gigahertz (one gigahertz equals 1,000,000,000 hertz). The maximum frequency in the radio spectrum is usually taken to be about 45 gigahertz, corresponding to a wavelength of about 6.7 millimetres. Radio waves can be generated and used at frequencies lower than ten kilohertz (A = 30,000 metres).

Mechanism of wave propagation. Like all other electromagnetic waves, a radio wave is made up of electric and magnetic fields vibrating mutually at right angles to each other in space. When these two fields are operating synchronously in time, they are said to be in time phase; *i.e.*, both reach their maxima and minima together and both go through zero together. As the distance from the source of energy increases, the area over which the electric and magnetic energy is spread is increased, so that the available energy per unit area is decreased. Radio-signal intensity, like light intensity, decreases as the distance from the source increases.

Function of transmitting antenna

A transmitting antenna is a device that projects as much as possible of the radio-frequency energy generated by a transmitter into space. The antenna can be designed to concentrate the radio energy into a beam like a searchlight and so increase its effectiveness in a given direction (see ANTENNAS AND WAVE GUIDES).

Frequency bands. The radio-frequency spectrum is divided arbitrarily into a number of bands from very low frequencies to superhigh frequencies. The bands are designated in Table 2. Sections of the radio-frequency spectrum have been allocated by international agreement to the various users (see Table 3), such as telegraph, telephonic speech, telemetry, and radio and television broadcasting.

Table 2: Frequency Band Designations

frequency designation	frequency range	wavelength range
Very low frequencies (vlf)	3–30 kilohertz	100,000–10,000 m
Low frequencies (lf)	30–300 kilohertz	10,000–1,000 m
Medium frequencies (mf)	300–3,000 kilohertz	1,000–100 m
High frequencies* (hf)	3–30 megahertz	100-10 m
Very high frequencies (vhf)	30–300 megahertz	10–1 m
Ultrahigh frequencies (uhf)	300–3,000 megahertz	1 m–10 cm
Superhigh frequencies (shf)	3–30 gigahertz	10–1 cm

'Also called shortwaves.

The radio-frequency bandwidth is the range of frequencies covered by the modulated radio-frequency signal. The information carried by the radio-frequency signal has a certain bandwidth associated with it, and the radio-frequency carrier must have a channel width at least as great as the information bandwidth. For regular amplitude-modulated (AM) broadcasting (see below) the radio-frequency bandwidth must be twice the information-frequency bandwidth. When other techniques of modulation are employed, bandwidth may have to be much greater. Teleprinter and telex operation requires only a small bandwidth, on the order of 200 hertz, depending on the maximum speed of the pulses forming the information code. Telephonic speech must have high intelligibility, but naturalness (high fidelity) is not of great importance. Tests have shown that the main components of speech lie between about 300 and 3,500 hertz, and telephonic channels carried by radio are therefore normally confined to a bandwidth of about four kilohertz. The smaller the information bandwidth employed the more speech channels can be carried in a given carrier bandwidth and the more economical the system will be.

Minimum acceptable bandwidths

Young people can hear audio frequencies ranging from about 30 hertz to 18 kilohertz, but as humans grow older, hearing ranges from about 100 hertz to 10 kilohertz. For high-quality (high-fidelity) reproduction of voice or speech (as in radio sound broadcasting), the range should be not less than about 30 hertz (the lowest frequency of a large organ pipe) to 15 kilohertz (piccolo, cymbal, triangle). Acceptable audio quality under certain circumstances may be achieved with a bandwidth as small as five kilohertz, as in AM (amplitude-modulated) radio; a much larger bandwidth is needed for transmitting a moving picture, as in television broadcasting, because it is necessary to convey the overall average light content of a picture as well as the picture detail. The average light content requires frequencies as low as 20 hertz to be transmitted, and picture detail demands frequencies up to five megahertz for a standard television picture.

Radar apparatus is used to determine the distance to an object or to provide a visual image of the position of objects in a given area. For this purpose, very short pulses of radio energy are transmitted to and reflected back by an object. The reflected pulses are in turn picked up by receiving apparatus, and distance is determined by the time delay between outgoing and returning pulses. The pulse must not be distorted upon its return or distance determination will be inaccurate. Thus radar requires a bandwidth on the order of five megahertz, similar to that for television broadcasting.

Modulators and demodulators. A carrier wave is a radio-frequency wave that carries information. The information is attached to the carrier wave by means of a modulation process that involves the variation of one of the carrier-frequency characteristics, such as its amplitude, its frequency, or its duration. (All of these processes are discussed in greater detail in the article TELEPHONE AND TELECOMMUNICATIONS SYSTEMS.)

In amplitude modulation the information signal varies the amplitude of the carrier wave, a process that produces a band of frequencies known as sidebands on each side of the carrier frequency. These sidebands (a pair to each modulation frequency) cover a range of frequencies equal to the sum and difference between the information signal and the carrier frequency.

Frequency modulation involves varying the frequency (the number of times the wave passes through a complete cycle in a given period of time, measured as cycles per second) of the carrier in accordance with the amplitude of the information signal. The amplitude of the carrier wave is unaffected; only its frequency changes. Frequency modulation produces more (often many more) than one pair of side frequencies for each modulation frequency.

The variation of carrier frequency is known as the fre-

Table 3: Utilization of Radio-Frequency Spectrum

very low frequencies (vlf)		timc signals, standard frequencies
	30 kHz	
low frequencies (If)		fixed, maritime mobile, navigational, radio broadcasting
	300 kHz	
medium frequencies (mf)		land, maritime mobile, radio broadcasting
	3 MHz	
high frequencies (hf)		fixed, mobile, maritime and aeronautical mobile, radio broadcasting, amateur
	30 MHz	
very high frequencies (vhf)		fixed, mobile, maritime and aeronautical mobile, amateur, radio and television broadcasting, radio navigation
	30Q MHz	
ultrahigh frequencies (uhf)		fixed, mobile, maritime and aeronautical mobile, amateur, television broadcasting, radio location and navigation, meterological, space communication
	3 GHz	
superhigh frequencies (shf)		fixed, mobile, radio location and navigation, space and satellite communication
	30 GHz	

quency deviation, and for very-high-frequency broadcasting it can reach ± 75 kilohertz. The greater the frequency deviation the greater is the effective modulation. Though theoretically its maximum value need not be limited to 75 kilohertz, any increase beyond this value requires a wider channel, which adds to the cost of reception and reduces the number of transmitters that can be accommodated in the band. The total channel width is approximately twice the sum of the maximum deviation frequency and modulating frequency. If channel width is restricted in either transmitter or receiver circuits, distortion of the information signal occurs.

A radio broadcast normally consists of only one information signal. The listener hears what he would hear at the microphone position if only one of his ears was functioning; *i.e.*, it is a monaural system. In such a system it is not possible to gain any impression of the position of the instrument groupings in an orchestra, nor can lateral movement be indicated, though movement toward or away from the microphone is conveyed by a change in sound volume.

Stereophonic broadcasting requires two microphones, one to collect sounds from the left and one from the right; the two sets of information must be separable in the receiver and be fed to loudspeakers on the left and on the right at the listening position. For high-fidelity reproduction the full audio range up to 15 kilohertz is transmitted; this can only be achieved satisfactorily at very high frequencies with frequency modulation. The broadcast signal is received on monaural receivers by making one set of information the sum of left and right signals (L + R). The other set of information is the difference of left and right (L − R). Summation of the two sets of information at the receiver output recovers the left (L) signal and subtraction recovers the right (R) signal.

Pulse code modulation

Another system of modulation switches the carrier on and off in pulses, the duration or position of the pulse being determined by the information signal. This system of pulse-coded modulation can provide better protection from noise, and a number of separate speech channels can be combined by allocating specified groups of pulses for each information channel and then interleaving these pulses in a process called time division multiplex. A comparatively wide transmission channel is needed, and the carrier must be an ultrahigh or superhigh frequency.

The ionosphere. An English mathematician, Oliver Heaviside, and a U.S. electrical engineer, Arthur Edwin Kennelly, almost simultaneously suggested about 1901 that radio waves, which normally travel in straight lines, are returned to Earth when projected skyward because electrified (ionized) layers of air above the Earth (the ionosphere [*q.v.*]) reflect or refract (bend) them back to Earth, thus extending the range of a transmitter far beyond line of sight. In 1923 the suggestion was proved to be accurate when pulses of radio energy were transmitted vertically upward and returning pulses were received back from the reflecting layer. By measuring the time between the outgoing and returning pulses, it was possible to estimate the height and number of layers. Three layers can normally be distinguished at distances from 50 to about 400 kilometres (30 to 250 miles) above the earth's surface. The layers result from a breakdown of gas atoms into positively charged ions and free electrons caused by energy radiated from the sun. The electrons maintain a separate existence in the lower layers for as long as the Sun's energy is being received, and in the upper layers some can remain free throughout the hours of darkness.

The three layers are designated D, E, and F. The D layer is approximately 80 kilometres (50 miles) high and exists only during daylight hours. Because it absorbs medium frequencies and the lower frequencies of the shortwave bands, it limits the range of such stations during daylight. The E layer, about 110 kilometres (68 miles) high, maintains its reflectivity for four or five hours after the Sun sets and so extends the range of such stations to as much as 1,000 kilometres (620 miles). This layer also serves as a good reflector of shortwaves during the day and into the night, until its reflectivity drops.

Most important of the three layers is the F layer, which has considerable power to reflect the higher frequencies. During the day it often splits into two layers (F_1 and F_2) at about 200 and 400 kilometres (125 and 250 miles), but at night only one layer is generally present at a height of about 300 kilometres (190 miles).

Radio noise, fading, and interference. Any sudden discharge of electrical energy, like that of lightning, produces transient (short-duration) radio-frequency waves, which are picked up by antennas in the same way as normal signals. These packets of radio-frequency energy produce the crackle heard on an amplitude-modulated radio receiver when an electrical storm is nearby and may be classed as natural noise.

Switching of high-voltage power lines can produce similar effects; the lines help to carry the noise-producing signals over long distances. Local switching of lights and electrical machinery can also produce the familiar crackle when the receiver is close to the noise-producing source. These sources are classed as man-made noise.

Generally noise of both types decreases as the frequency is increased. An exception is automobile ignition noise, which produces maximum effect in the very-high-frequency range, causing a sound in nearby loudspeakers every time a spark plug fires. Many countries have legislation requiring the suppression of man-made noise by means of filters that reduce the amount of radio-frequency energy released at the source. Metallic shielding of leads to and from the noise source curtails the radiated interference. It is also possible to install various noise-reducing devices at the input to radio receivers.

Filters in noise production

Noise is also caused by irregularities in the flow of electrons in metals, transistors, and electron tubes. This source of noise ultimately limits the maximum useful signal amplification that can be provided by a receiver. Noise due to the random movement of electrons causes a hiss in the loudspeaker. Radio noise can also be picked up from outer space as a hiss similar to random electron noise.

Fading of a signal, on the other hand, is due to variation in the propagation characteristics of the signal path or paths. This is particularly true when propagation depends on reflection from the ionosphere as it does for shortwaves. Propagation of waves in the very-high-frequency range and above, which penetrate the ionosphere, can be affected by temperature changes in the stratosphere, that part of the atmosphere up to about 15 kilometres (nine miles) from the Earth's surface. The fading effect can be greatly reduced at the receiver loudspeaker by various electronic controls, such as automatic volume control.

The phenomenon of interference occurs when an undesired signal overlaps the channel reserved for the desired signal. By interaction with the desired carrier, the undesired information may cause speech to become unintelligible. Countermeasures include narrowing the desired channel, thus losing some information but preventing overlap, and using a directional antenna to discriminate against the undesired transmission.

EARLY HISTORY

Maxwell's prediction. Early in the 19th century, Michael Faraday, an English physicist, demonstrated that an electric current can produce a local magnetic field and that the energy in this field will return to the circuit when the current is stopped or changed. James Clerk Maxwell, professor of experimental physics at Cambridge, in 1864 proved mathematically that any electrical disturbance could produce an effect at a considerable distance from the point at which it occurred and predicted that electromagnetic energy could travel outward from a source as waves moving at the speed of light.

Hertz: radio-wave experiments. At the time of Maxwell's prediction there were no known means of propagating or detecting the presence of electromagnetic waves in space. It was not until about 1888 that Maxwell's theory was tested by Heinrich Hertz, who demonstrated that Maxwell's predictions were true at least over short distances by installing a spark gap (two conductors separated by a short gap) at the centre of a parabolic metal mirror. A wire ring connected to another spark gap was placed about five feet (1.5 metres) away at the focus of another parabolic collector in line with the first. A spark jumping across the first gap caused a smaller spark to jump across the gap in the ring five feet away. Hertz showed that the waves travelled in straight lines and that they could be reflected by a metal sheet just as light waves are reflected by a mirror.

Maxwell's prediction verified

Marconi's development of wireless telegraphy. The Italian physicist Guglielmo Marconi, whose main genius was in his perseverance and refusal to accept expert opinion, repeated Hertz's experiments and eventually succeeded in getting secondary sparks over a distance of 30 feet (nine metres). In his experiment he attached one side of the primary spark gap to an elevated wire (in effect, an antenna) and the other to Earth, with a similar arrangement for the secondary gap at the receiving point. The distance between transmitter and receiver was gradually increased first to 300 yards (275 metres), then to two miles (three kilometres), then across the English Channel. Finally, in 1901, Marconi bridged the Atlantic when the letter *s* in Morse code travelled from Poldhu, Cornwall, to St. John's, Newfoundland, a distance of nearly 2,000 miles (3,200 kilometres). For this distance, Marconi replaced the secondary-spark detector with a device known as a coherer, which had been invented by a French electrical engineer, Edouard Branly, in 1890. Branly's detector consisted of a tube filled with iron filings that coalesced, or "cohered," when a radio-frequency voltage was applied to the ends of the tube. The cohesion of the iron filings allowed the passage of current from an auxiliary power supply to operate a relay that reproduced the Morse signals. The coherer had to be regularly tapped to separate the filings and prepare them to react to the next radio-frequency signal.

The Fleming diode and De Forest audion. The next major event was the discovery that an electrode operating at a positive voltage inside the evacuated envelope of a heated filament lamp would carry a current. The American inventor Thomas A. Edison had noted that the bulb of such a lamp blackened near the positive electrode, but it was Sir John Ambrose Fleming, professor of electrical engineering at Imperial College, London, who explored the phenomenon and in 1904 discovered the one-directional current effect between a positively biassed electrode, which he called the anode, and the heated filament; the electrons flowed from filament to anode only. Fleming called the device a diode because it contained two electrodes, the anode and the heated filament; he noted that when an alternating current was applied, only the positive halves of the waves were passed—that is, the wave was rectified (changed from alternating to direct current). The diode could also be used to detect radio-frequency signals since it suppressed half the radio-frequency wave and produced a pulsed direct current corresponding to the on and off of the Morse code transmitted signals. Fleming's discovery was the first step to the amplifier tube that in the early part of the 20th century revolutionized radio communication.

Fleming failed to appreciate the possibilities he had opened up and it was the American inventor Lee De Forest who in 1906 conceived the idea of interposing an open-meshed grid between the heated filament and positively biassed anode, or plate, to control the flow of electrons. De Forest called his invention an Audion. With it he could obtain a large voltage change at the plate for a small voltage change on the grid electrode. This was a discovery of major importance because it made it possible to amplify the radio-frequency signal picked up by the antenna before application to the receiver detector; thus, much weaker signals could be utilized than had previously been possible.

Invention of the Audion

Early research by commercial companies. The first commercial company to be incorporated for the manufacture of radio apparatus was the Wireless Telegraph and Signal Company, Ltd. (England) in July 1897 (later changed to Marconi's Wireless Telegraph Company, Ltd.); other countries soon showed an interest in the commercial exploitation of radio.

Among the major developments of the first two decades of the 20th century was De Forest's discovery in 1912 of the oscillating properties of his Audion tube, a discovery that led to the replacement of the spark transmitter by an electronic tube oscillator that could generate much purer radio waves of relatively stable frequency. By 1910, radio messages between land stations and ships had become commonplace, and in that year the first air-to-ground radio contact was established from an aircraft. In 1918 a radiotelegraph message from the Marconi long-wave station at Caemarvon, in Wales, was received in Australia, over a distance of 11,000 miles (17,700 kilometres).

Though early experiments had shown that speech could be transmitted by radio, the first significant demonstration was not made until 1915 when the American Telephone & Telegraph Company successfully transmitted speech signals from west to east across the Atlantic between Arlington, Virginia, and Paris. A year later, a radiotelephone message was conveyed to an aircraft flying near Brooklands (England) airfield. In 1919 a Marconi engineer spoke across the Atlantic in the reverse direction from Ballybunion, Ireland, to the U.S.

From 1920 onward radio made phenomenal progress through research activities in Europe, America, and Asia. The invention of the electron tube and later the transistor (1948) made possible remarkable developments in fields such as control and computing as well as telecommunications.

Sarnoff's proposals

Beginning of broadcast service. In 1916 David Sarnoff, then contracts manager to the American Marconi company, recommended that transmitting stations be built for the purpose of broadcasting speech and music and that "a radio music box" should be manufactured for general sale. Sarnoff wrote,

> a radio music box . . . this device must be arranged to receive on several wavelengths with the throw of a switch or the pressing of a button. The radio music box can be supplied with amplifying tubes and a loudspeaking telephone, all of which can be neatly mounted in a box.

Sarnoff's proposals were not implemented at once, partly because of America's entry into World War I in 1917, but they proved highly practical. Technically, the first entertainment broadcasting was done by the German Army in 1917, but the first regular broadcasting station was KDKA in Pittsburgh, which started operations in November 1920. The service gained instant popularity, and the idea spread at once around the world (see BROADCASTING).

The medium-wave band of frequencies proved inadequate in both Europe and America to provide sufficient broadcast channels. As a result, there was considerable development of the very-high-frequency band after World War II. The greater availability of channel space in the very-high-frequency band allowed the use of frequency-modulation techniques (see below) for broadcasting stereo (two-channel) programs so coded that the one transmission can provide monaural listening from the normal type of frequency-modulated receiver and binaural (stereo) listening from a receiver fitted with a special decoder.

Shortwaves are also used for broadcasting, and the lower frequencies (about four megahertz) are used in the tropics for local broadcasting. These have some advantage over medium waves during the tropical rainy season, when atmospheric noise due to thunderstorms is serious; but the signal must be obtained by almost vertical reflection from the ionosphere, and fading and distortion are generally greater than with medium waves.

Long-distance broadcasting (unless a satellite is employed) is only possible by means of shortwaves, because the shortwaves are reflected back to Earth from the ionosphere. Groups of channels are allocated throughout the shortwave band for the purposes of external broadcasting beyond the national boundaries of the originating authority. The number of channels available is now insufficient for the countries wanting to broadcast, and, in spite of a degree of international control, interference is often a serious problem, particularly on the lower frequency channels at night when more channels are in use because higher frequency channels tend to be unusable due to reduced ionospheric reflection.

Broadcasting from a synchronous satellite (one that maintains a relatively fixed position with respect to Earth) is a possibility, but power-supply and antenna-size limitations on the satellite require the carrier frequency to be in the ultrahigh-frequency range. The distance of the satellite from Earth, about 22,300 miles (36,000 kilometres), results in the signal at the Earth's surface being very weak. A sensitive receiver and directional antenna system is therefore essential. Another disadvantage is that over the area of Earth covered by the radio beam from the satellite antenna, the particular carrier frequency cannot be used by any other transmitters.

RADIO CIRCUITRY

Components. The basic operating principles of the major circuitry and passive components used in radio are described in the article ELECTRONICS. Active devices such as tubes and transistors are treated in the articles ELECTRON TUBE; and SEMICONDUCTOR DEVICES. In this article, only enough description is included to permit the reader to understand the applications to radio circuitry.

Primary function of the electron tube

Active devices: *vacuum* tubes and transistors. An electron tube or transistor, designated an active element, functions basically as an amplifier, and its output is essentially an amplified copy of the original input signal. The simplest amplifying electron tube is the triode, consisting of a cathode coated with material that provides a copious supply of electrons when heated, an open-mesh grid allowing electrons to pass through but controlling their flow, and a plate (anode) to collect the electrons. The plate is maintained at a positive voltage with respect to the cathode in order to attract the electrons; the grid usually has a small negative voltage so that it does not collect electrons but does control their flow to the plate. The output voltage is usually many times greater than the input voltage to the grid. The tube must be pumped to a high degree of vacuum, or the plate current flow is very erratic.

Other electrodes, also in the form of open-mesh grids, may be included in the tube to perform various special functions. An example is the four-electrode tube known as the tetrode, in which an open-mesh grid (screen grid) maintained at a positive voltage is placed between plate and control grid. This reduces the effect of plate voltage on electron flow and increases the amplifying property of the tube. Introduction of a third grid, known as a suppressor grid, produces the pentode (five-electrode tube), which can provide even greater amplification.

The transistor, which has largely replaced the electron tube as the active element in low-voltage electronic circuits, is made from semiconductor materials—that is, substances that are neither good conductors nor good insulators. Two common semiconductor materials are germanium and silicon, to which small amounts of impurities such as indium, gallium, arsenic, or phosphorus are added to impart electrical charges to them. Arsenic and phosphorus, for example, provide extra negative charges, giving n-type (signifying excess negative charges) material; indium or gallium yield a shortage of electrons or an excess of positive charges or holes, giving p-type (signifying excess positive charges) material (see also SEMICONDUCTOR DEVICES).

A transistor is a sandwich of semiconductor materials with the same impurity in the two outer layers and a different impurity in the centre layer providing current carriers of opposite charge to those produced by the outer layers.

If the outer layers are reservoirs of positively charged current carriers (p type) and the centre layer provides an excess of electrons (n type), the transistor is known as a *p–n–p* (positive–negative–positive carriers) type. If the p and *n* layers are reversed, the transistor is an n–p–n type. The two outer layers are termed the emitter and collector, and the centre layer is known as the base.

A transistor is an amplifier of current; the vacuum tube, in contrast, is an amplifier of voltage. The transistor produces a very adequate supply of current carriers (electrons and holes) at room temperature and does not require a heated cathode like the vacuum tube. Thus the power required from the power supply is much reduced, much less heat is produced, and the transistors and their circuitry can be packed into a smaller space. Transistors are also physically much smaller than comparable electron tubes. Thus the transistorized portable radio can fit in a pocket in contrast to the cumbersome tube radio it has replaced.

In its early form the transistor was capable of amplifying only comparatively low frequencies because the exchange of electrons and positive charges across the sandwich was slow. Modem techniques however, have overcome this difficulty so that amplification up to frequencies over 1,000 megahertz is commonplace.

Modulation

Tuned circuits and the superheterodyne principle. For information (voice, music, television) to be transmitted, it must be attached to a radio-frequency carrier wave, which is then transmitted in a given frequency channel. The carrier wave and information can be picked up by a receiver tuned to this channel. The process by which the information is attached to the carrier wave is known as modulation. Modulated carriers are isolated in their separate slots or channels; if transmitters are geographically close to each other, they must not use the same channel or overlap each other's channels. If such overlap occurs, serious interference results—two radio programs may be heard simultaneously or one may form a distorted background to the other.

In most modern radio receivers, reception is based on what is known as the superheterodyne principle. The incoming radio frequency is mixed (heterodyned) with the output of an oscillator the frequency of which is adjusted so that the difference between it and the incoming signal is constant; the result is called the intermediate frequency. Amplification is thereafter carried out at this intermediate frequency. Both preliminary selection of the incoming frequency and adjustment of the local oscillator frequency are accomplished by variable tuned circuits consisting of inductance and capacitance. Tuning may be accomplished by varying the capacitance, which consists of interleaved metal plates separated by air spaces with one set of plates movable. Another method of tuning involves varying the inductance by insertion or withdrawal of an iron dust or ferrite (*q.v.*) core in a cylindrical coil of copper wire. To simplify the tuning procedure, the variable elements of all stages requiring tuning are ganged together and coupled to a tuning knob. The intermediate-frequency amplifier stages always operate at the same frequency and so require tuning only when the receiver is manufactured or serviced. The intermediate frequency is usually around 455 kilohertz for AM receivers, 10.7 megahertz for FM receivers, and 38 megahertz for television receivers. Most of the amplification in a radio receiver is carried out in the intermediate-frequency stages, and most of the selectivity (ability to separate adjacent stations) is obtained in these stages.

Oscillators. A self-oscillating circuit consists of a vacuum tube or transistor, a tuned circuit, and some form of positive feedback (energy fed from the output back to the input in such a way as to increase the input). Since both tubes and transistors can function as amplifiers, they can also function as oscillators. For receiver circuits, adequate oscillator stability can be obtained with conventional tuned circuits, but the transmitter oscillator must be highly stable, and a circuit made up of inductance and capacitance, tuned to the desired frequency, is not sufficiently stable. A piezoelectric crystal oscillator (a device that vibrates or oscillates at a given frequency emitting radio waves when voltage is applied to it) or its equivalent is ordinarily used.

Amplifiers. Amplifiers may be classified in a number of different ways; according to bandwidth (narrow or wide); frequency range (audio, intermediate or radio frequency); or output parameter requirement (voltage or power).

Wide-band radio-frequency amplifiers are not needed for audio signals unless a frequency-modulated system is used. Amplitude-modulated signals for sound broadcasting should have a radio-frequency bandwidth of ±10 kilohertz though on medium waves it is often limited to about ±5 kilohertz (total bandwidth of 10 kilohertz). High-quality frequency-modulated audio needs a bandwidth of about ±100 kilohertz.

Use of negative feedback to minimize distortion

Audio-frequency amplifiers present few design problems, and negative feedback of the output into the input can overcome distortion problems. Radio-frequency amplifiers, which can be tuned, suffer from variation of selectivity (ability to separate adjacent stations) and gain (amplification) over the tuning range. Selectivity tends to broaden and gain to increase as capacitance is decreased, and instability can be troublesome at the highest tuning frequency. Intermediate-frequency amplifiers do not suffer from these defects since the tuning frequency is fixed.

The main problem with radio-frequency amplifiers. in receivers is the possibility of cross modulation—that is, the mixing of two information channels, which can occur if an undesired modulated signal enters the radio-frequency input together with the desired signal.

High-power amplifiers are not required for radio reception but are needed for radio transmission. Semiconductors are not as yet able to fill the high-power role. Vacuum tubes are essential for providing the required kilowatts of radio-frequency power to the antenna.

Antennas. The antenna is an essential part of a radio transmission and reception system (see ANTENNAS AND WAVE GUIDES). Its purpose at the transmitter is to project electromagnetic energy into space and at the receiver to extract energy from the travelling electromagnetic wave produced from the transmitter antenna.

The size of the antenna relative to the wavelength of the electromagnetic radiation is important. The wavelength of medium waves is about 300 metres (1,000 feet), and a vertical transmitting mast or self-supporting tower 150 to 210 metres (490 to 690 feet) high may be used with a high-power transmitter (200 kilowatts or more). An equally tall receiving antenna would be ideal but impractical. A vertical rod or suspended wire about six metres (20 feet) long is a workable solution. If the transmitting antenna is vertical, the receiving antenna must also be vertical; if the former is horizontal the receiving antenna must be horizontal. This rule applies at all radio frequencies except shortwaves because the plane of their electromagnetic field can be twisted in its passage through the ionosphere, and a vertical shortwave antenna may pick up a good signal from a horizontal transmitting antenna. The antenna system becomes progressively smaller as the transmitting frequency is increased, and at ultrahigh frequencies (300 megahertz or more) the individual antenna may be only about 50 centimetres (20 inches) long.

For normal amplitude-modulated broadcasting, the receiver antenna may be composed of a fairly short coil of wire wound on a powdered iron or ferrite core. This type of design permits adequate signal pickup with a very small antenna which may be located in a small space, a necessity for small, battery-operated portable receivers.

Directional characteristics

Antennas may have their directional characteristics modified by employing multiple elements. Thus an antenna may be omnidirectional (transmitting in all directions) horizontally but narrowly beamed vertically, or it may be bidirectional (transmitting in two directions) in a figure eight pattern with two main directions of energy projection at 180". It may be unidirectional, having energy projected to one side, or the energy may be concentrated in a relatively narrow beam both horizontally and vertically.

In point-to-point communication, as from one network centre to another, highly directional antennas are used. Local broadcasting uses an omnidirectional antenna, radiating equally in all directions, except in such special cases as a coastal location or proximity to a neighbouring transmitter.

Broadcasting planned to serve distant areas, employing shortwaves and depending on reflection from the ionosphere, normally uses a relatively narrow beam of energy projected skyward at an angle from 5° to 10° to the horizontal. A reflecting curtain is placed behind the antenna to prevent loss of energy in the reverse direction. The beam is divergent (spreads out) so that after two or three reflections between ionosphere and Earth it covers a relatively large area.

Transmission lines. The lines that carry radio waves from the radio transmitter to the antenna are known as transmission lines; their purpose is to convey radio-frequency energy with minimum heating and radiation loss. Heating losses are reduced by conductors of adequate size. Only the outer layers of the conductor carry radio-frequency current.

Concepts of selectivity and sensitivity. Radio-frequency communication requires the receiver to reject all but the desired signal. Were the number of frequency channels equal to the demand, each channel could be given its correct width in the tuning stages of a receiver. Thus, for audio broadcasting each carrier channel should be 20 kilohertz wide to accommodate both side bands, and each transmission carrier should be 20 kilohertz, separated from those on either side. In much of the world, the medium-wave and shortwave bands are in such demand that transmitters must share the same channel and channels thus must overlap. Though efforts have been made to arrange sharing by geographically separated transmitters, the congestion has forced receiver manufacturers to reduce the receiver bandwidth to about eight kilohertz (±four kilohertz).

Very-high-frequency transmissions can generally be received at full bandwidth because their signals are confined to line of sight and are, in effect, local-station signals to the receiver. Frequency-modulated transmissions must be received on full bandwidth (about 200 kilohertz) if serious distortion is to be avoided on loud programs.

Receiver sensitivity is the ability of a receiver to pick up weak signals. Though a communication receiver should always have a high sensitivity, there is a maximum determined by the noise generated inside the receiver itself. Little value is gained by increasing sensitivity if noise at the receiver output is already considerable and comparable with desired signal output. Normally, radio broadcasting systems operate with the signal voltage at least 10 to 50 times greater than the noise. To take full advantage of high sensitivity, receiving antennas for communications links are usually located in an area where there is little man-made noise. A receiver intended only for local-station reception can have a much lower sensitivity than a shortwave receiver intended for picking up signals from the other side of the world.

Effect of noise on sensitivity

APPLICATIONS

Applications of radiotelephony. The major use of radio is in the communications industry (see also TELEPHONE AND TELECOMMUNICATIONS SYSTEMS). Telephone, telegraph, and television signals are transmitted by microwave-radio (above 1,000 megahertz) systems, either between land-based towers or via satellite, and shortwave radio is used for overseas circuits. Radio broadcasting (AM, FM, TV) is a worldwide industry of tremendous scope, and mobile radiotelephone service to moving vehicles such as automobiles, boats, and aircraft has become a major world industry.

Development of commercial radiotelephone. Until the early 1920s all commercial radiotelephone developments had concentrated on the use of long-wave carriers because these ensured worldwide communication. Medium-wave transmissions were known to have a comparatively short service range during the day, but even at night when their range was greatly increased their signal strength decreased at a much greater rate than that of long-wave carriers. It was consequently assumed that the longer the wavelength the better the propagation. A short wavelength of 120 metres (2.5 megahertz) had been employed for communicating between ships from 1901 to 1909, and it had been noted that reception over distances of 1,000 miles (1,600 kilometres) or more could be obtained, but this was thought to be caused by freak conditions.

Marconi experimented with shortwaves in 1916 because the shorter wavelength permitted directional antennas to be used to concentrate the transmitted energy into a narrow beam. Only the direct wave launched parallel to the Earth was utilized, however.

Radio had already attracted numerous amateur enthusiasts and experimenters, and at the end of World War I they were granted permission to communicate by radio with each other at the upper end of the medium-wave band and in the shortwave band, frequencies then thought to be useless for long-distance links. Nevertheless, amateurs in Britain and the United States hopefully arranged a series of test transmissions on 230 metres (1.3 megahertz) during December 1921, and contact was established on several occasions. Other amateurs maintained contact across the Atlantic during daylight throughout most of February 1925 with the aid of shorter wavelength transmissions in the order of 100 metres.

Tests by amateurs

Meantime Marconi had also been experimenting with shortwaves and had been able to pick up signals from Cornwall, England, at the Caribbean island of St. Vincent, 2,300 miles (3,700 kilometres) away, using a one-kilowatt transmitter of about 100 metres (three megahertz) carrier wavelength. It was found that short wavelengths could be used to provide a satisfactory service at great distances, and daylight contact was maintained on 32 metres (9.8 megahertz) with Australia. On the basis of these tests, the Marconi company constructed links between Britain and Canada, Australia, India, and South Africa.

The Canadian circuit was opened in October 1926; the others followed at regular intervals during 1927. Marconi's faith in the successful commercial operation of the system was more than justified, and radio engineers elsewhere were quick to change from skepticism to enthusiasm. Shortly after the start of the radiotelegraph transmissions, the Marconi company developed a method (called multiplex) of transmitting two telegraph channels and one telephone channel on the same carrier wave, but this was not taken up by the British government, which had decided to preserve a monopoly in telephone communication. Meantime, the Radio Corporation of America, which in September 1924 had tried out a 100-metre service to South America as an auxiliary to long-wave transmission, began to test the efficacy of shortwaves for commercial speech circuits. The U.S. Navy and Bell Telephone Laboratories also began research into shortwave propagation. In Germany the Telefunken Company set up stations early in 1925 to transmit to South America.

Shortwaves are now a well-established means of commercial telephonic communication, and sufficient information has been gained over the years to develop frequency schedules allowing a regular service to be maintained at any time of the day between any two populated points on Earth, except on the comparatively rare occasions of severe ionospheric storms.

Attention was subsequently paid to even shorter wavelengths, and in 1931 Standard Telephones and Cables set up a commercial circuit across the Straits of Dover using an ultrahigh-frequency wavelength of 18 centimetres (1,700 megahertz).

Exploitation of all radio-frequency ranges has steadily continued since the 1930s, and parts of the very-high-, ultrahigh-, and superhigh (microwave)-frequency spectrum are allocated to commercial communication. As a general rule, these frequency ranges can provide a satisfactory service only over a line-of-sight path. There is some bending of the transmitted wave as it travels over the Earth, however, and transmission is sometimes carried to distances beyond the actual optical range. The longer wavelengths of the very-high-frequency range can be used for longer distance communications (up to 300 miles [480 kilometres]) by employing a technique called "tropospheric scatter," in which high-powered radio beams are scattered from the upper layers of the troposphere.

Line-of-sight path

Satellite communication has greatly extended facilities because microwave transmission may be used, and these high frequencies allow a very large number of conversations to be transmitted on a single carrier. Microwave frequencies in the range three to 20 gigahertz suffer little loss of power in penetrating the ionosphere and their very short wavelengths allow the construction of highly directional small-sized antennas, which concentrate the radio energy into a very narrow beam (see also SATELLITE COMMUNICATION).

Long-distance intercontinental radiotelephone service. Until Marconi had proved the worth of the shortwave-beam system, communication engineers had continued to develop radiotelephony on long-wave transmissions, and there were a number of such systems operating between 1920 and 1930. The limited number of channels available in the long-wave band and the large antenna systems and high power output needed from the transmitters made it clear that development could not go far. The discovery of shortwave propagation created new possibilities, and the 1930s saw the rapid growth of a worldwide system of shortwave telephonic communication. In October 1929 the International Telephone and Telegraph Corporation set up a circuit from Madrid to Buenos Aires, and in 1930 further shortwave telephonic circuits were established among London, Sydney, Buenos Aires, and ships at sea and from Buenos Aires to Paris, Berlin, and New York. The years 1932 and 1933 brought the radiotelephone to South Africa and India.

The need for economic operation, conservation of available frequency channels, and better rejection of noise led to the development of single-side-band pilot-carrier systems. The transmission of a carrier as well as side bands simplifies the design of the receiver but represents a considerable expenditure of power at the transmitter. When the transmission is modulated to its maximum extent, for example, the speech content is only one-third of the total power supplied to the antenna. The economics of point-to-point communication justify the installation of a complicated and expensive receiver if the saving on the transmitter is greater than the additional receiver cost; this occurs if the carrier is generated in the receiver itself. The frequency of the generated carrier must be very accurate if distortionless detection is to be achieved; a small degree of carrier signal is transmitted and used to synchronize the receiver-generated carrier frequency. Hence the term pilot carrier.

All the speech-signal information on such a system is present in one of the two side bands; elimination of one side band halves the frequency channel width as well as improving the strength of the signal with respect to noise. It is possible to use the eliminated side-band frequency space for another speech channel so that one transmission carries two different conversations simultaneously. This is an independent-side-band pilot-carrier circuit.

Greatly improved performance as regards signal-to-noise ratio, fading, and distortion on shortwave telephone links resulted from a British Post Office invention called Lincompex, in which speech variations are compressed electronically into a narrow volume range to maintain modulation at a high level; a pilot signal containing information on the degree of compression is also transmitted with the speech. At the receiver an expander, the gain of which is controlled by the pilot signal, restores the original speech volume variations.

Earth satellites

The successful placing of satellites into prescribed orbits around the Earth has made possible the realization of a revolutionary communications system. A satellite placed in an equatorial orbit of the Earth at a height of approximately 22,300 miles (36,000 kilometres) above the Earth's surface maintains a fixed position relative to the Earth. In any other orbit there is relative motion between Earth and satellite, and ground-station antenna systems must keep the satellite in sight and follow its movement by means of a complicated tracking system. Frequencies above those affected by the ionospheric layers (*i.e.*, very high frequencies and above) can be used for satellite communication; superhigh frequencies at about six gigahertz (to the satellite) and four gigahertz (from the satellite) are employed because small, highly directional antennas can be constructed on the satellite at these very short wavelengths (7.5 to 5 centimetres). The satellite must be accurately stabilized to prevent "swinging" of the antenna system since this would lead to appreciable variations of signal strength at satellite and ground station.

Ship-to-shore service. The first recorded radiotelephone contact from ship to shore was made in 1916 by the United States Navy. Tests of long-wave low-power transmissions took place in 1920, and Marconi installed the first commercial equipment in 1922. During the 1920s, progress continued and expanded to include lightships and harbour craft; the British lifeboat service was fitted with radiotelephone apparatus beginning in 1926.

In 1927 a shortwave telephone link on the British liner "Carinthia" established contact with Britain from the Pacific, halfway around the world, and all passenger ships were soon equipped with radio for passenger service. The radiotelephone was adopted by fishing fleets during the 1930s because it had the advantage of not requiring a skilled operator with knowledge of Morse code. After 1934 many small coastal craft were equipped for radio contact with the shore. After World War II radiotelephone systems for ship-to-shore communication multiplied, communication over distances up to about 70 miles (112 kilometres) being provided by very high frequencies and over greater distances by shortwaves.

Passenger ships equipped with radio

Mobile radiotelephone. Communication with moving vehicles is an important application of radiotelephone. Frequency allocations for this use have been made at the top end of the medium-wave band, at a number of points in the shortwave band from two to five and from about 23 to 27 megahertz, and in the very-high-frequency band. The latter band has the advantage that wavelength is small so that antennas need not be large, and the attenuation (loss of power) with increasing distance from the transmitter is very much less than for shortwaves with a given height of antenna from ground, but it is more susceptible to loss of signal due to intervening obstacles and to multiple signals by reflection from tall buildings.

Broad-band microwave radio relay. A large number of speech channels of four kilohertz (the normal channel width for commercial speech) can be impressed on a single radio carrier by proper modulation and multiplexing techniques. These techniques are used in broad-band cable and also microwave transmission systems operating with from 12 to 960 channels; successful transmissions have been carried out with as many as 2,700 channels.

Microwave frequencies from three to 12 gigahertz are employed for line-of-sight transmission; their antennas must be well clear of the ground on towers not less than 150 feet (46 metres) high, and the direct radio path must clear the summit of any intervening hill by at least 50 feet (15 metres). Spacing of the towers depends on intervening terrain but averages around 30 miles (48 kilometres).

Dish antennas, generally parabolic in shape, or horn antennas are used at each end of a link. Amplification may be provided in a so-called head amplifier very close to the centre of the dish, though to reduce maintenance problems at very exposed sites it is customary to provide the amplification at the base of the mast and a connection made to the antenna by cable or wave guide. In some instances a 45° reflector is used at the top of the mast to reflect the energy downward to an antenna dish placed at the foot of the mast.

Emergency radio service. Before radio, ships' distress signals were limited to optical distances. One of the first important applications of radio was for broadcasting the maritime distress signal, the morse coded SOS. For the signal to be effective, all ships' receiving equipment had to be manned continuously 24 hours a day, and in 1927 it was made obligatory for all ships not maintaining a permanent radio watch to carry an automatic alarm receiver tuned to 500 kilohertz, the internationally agreed marine distress frequency.

A similar provision is made for aircraft to call on a distress frequency of 121.5 megahertz, but it is more usual to call "Mayday" (French *m'aidez*, "help me") on the frequency already being used for communication with the airport controllers.

Distress signals

Applications to marine and air communications. ***Early developments in the airline and maritime field.*** Maritime radio communication has now become the main method of shipping control by owners and port authorities, **a** vital disabled-ship warning device, and an aid in dealing with injury or sudden illness. Radio is also used for weather warnings.

The development of passenger air traffic stimulated the need for radio communication between plane and ground station, for landing and takeoff instructions, and for exchanging positional data.

Radio direction finding was the earliest method of using two known sites to determine the position of an unknown transmitter, a principle used by the British during World War I for keeping track of German fleet activities. A ship can determine its position by direction finding when two or more transmissions are available from separated sites; this facility is especially valuable in conditions of poor visibility. In World War II direction-finding equipment was standard in bombing planes.

Frequencies used. Frequencies have been allocated in the various radio transmission bands for marine and air communication as well as navigation. Maritime communication has been given allocations in parts of the long-wave, medium-wave, and shortwave bands as well as in the very-high- and ultrahigh-frequency bands. Aeronautical communication has been allotted a small section at the top end of the long-wave band, is well distributed throughout the shortwave band, and has two allocations in the very-high-frequency band. No allocations are made above 144 megahertz.

Radio navigation is allocated a large number of frequencies in the long-wave band, a very small section of the medium-wave and shortwave bands (at the lower frequency end of each), and some parts of the very-high-, ultrahigh-, and superhigh-frequency bands. Radar functions only in the ultrahigh- and superhigh-frequency bands.

Radio aids to navigation. Radio-navigation systems can operate from a moving vehicle, aircraft, or ship, giving the pilot or captain a sound or visual indication of his position relative to a fixed object; or they may operate from a given site, the information being transmitted to the moving vehicle. Both systems may be necessary for safe navigation.

Navigation aids are classified into those that provide direction but not distance (direction-finding equipment) and those that give continuous readings of position through laying out over the surface of the Earth a radio-frequency grid of identifiable electrical parameters by combination and analysis of signals, generally from three fixed slave stations, all controlled from one master station. The loran (long-range navigation) and Decca systems are examples of this type of navigational aid. Finally there is radar, which can give distance, azimuth, and elevation (see also NAVIGATION; RADAR).

Use of loop antenna

The radio direction finder consists of a highly directional loop antenna, which is either rotatable or has circuits which simulate rotation, together with a sensitive receiver. Transmissions from two geographically separated points and a knowledge of true north are needed in order to fix position. The directional-antenna system is rotated until the transmitted signal is minimum or zero (this is called the null position), and the angle of the antenna relative to true north is noted. The bearing of the transmitting site is on a line at right angles to the null position. Ambiguity results, however, because there are two null positions at 180" to each other. The rotatable antenna has a figure-eight pattern of reception; to determine on which side the transmitter is located, it is necessary to add the signal from an omnidirectional vertical wire antenna. The correct addition of the two produces a cardioid (heart-shaped) pattern with a null pointing to the true transmitter bearing.

Although the line of direction to the transmitting station can be drawn on a map, a bearing on another known transmitting station must be taken as the intersection of the two bearings determines true position.

Direction finding, which dates from 1911, is the simplest method of determining position, and a radio transmitter at a site near a seaport or airport can serve as a beacon line by which to steer. There are two disadvantages: time is needed to obtain position from the bearings, and reflections from terrestrial objects and the ionosphere as well as refraction (bending of radio signals) at the seacoast can cause bearing errors.

The loran system of long-range navigation by radio provides positional information of high accuracy from a measurement of the time difference between two pairs of pulse-modulated signals transmitted on different carrier frequencies from specially selected sites. The carrier frequencies are at the top end of the medium-wave band from approximately 1,700 to 2,000 kilohertz, and coverage is about 700 miles (1,100 kilometres) by day and 1,400 miles (2,300 kilometres) at night.

The so-called Decca system employs a master and three slave stations, all sending continuous waves and placed at the corners of an equilateral triangle of about 200-mile (320-kilometre) sides. The master is located near the centre of the triangle. Only two slaves are used at one time for information on bearing, and Decca charts tell the user which ones to tune to. The slave transmitters receive their basic frequency from the master. The frequency is adjusted so as to have the same time phase at all slave stations. Interaction between frequencies from each pair of slaves produces a relationship dependent on the difference in distance. A special circuit and an instrument called a decometer accurately determine the relationship and register it with the aid of rotating pointers. The reading on the pointers can then be translated to position by consulting the Decca chart. The decometer pointers can be reset if for any reason the apparatus has been switched off or there has been a transmission fault.

The transmissions are in the long-wave band, and satisfactory operation is obtainable to a distance of about 240 miles (380 kilometres) from the master station.

The great advantage radar possesses over direction finding and loran is that it requires no cooperation from shore, other ship, or ground station.

Radar apparatus measures the time elapsing between the sending and reception of a pulse of radio energy reflected from an object. The pulse duration is longer or shorter for longer or shorter ranges, typical values being 0.1 to 0.2 microsecond or millionths of a second, and repetition frequency is in the range of 500 to 4,000 pulses per second, being higher for short ranges. Microwave frequencies are employed so that very narrow beam antennas can be constructed.

Radio altimeter

An aircraft needs to know its height above ground, and this can be obtained from a radio altimeter that measures the time taken for an outgoing radio pulse projected vertically downward to be reflected from the ground back to the plane.

Applications of radiotelegraphy. ***Early commercial history.*** Radiotelegraphic communication represents one of the simplest methods of conveying information because it is an on–off system. When undertaken manually it is much slower than speech, about 20 words per minute being the maximum speed. Faster communication can be obtained by machine operation; a teleprinter can deal with *75* words per minute and a tape puncher with about 400 words per minute. An advantage of automated transmission and reception is that a record of the message is available (see TELEGRAPH).

The first radiotelegram for which payment is recorded was transmitted in June 1898 on the occasion of a visit by Lord Kelvin to Marconi's experimental station at Alum Bay, Isle of Wight (England). Kelvin was so impressed by the transmission that he insisted on paying for the telegrams even though he knew that a financial transaction was illegal by the terms of the British Post Office's monopoly.

By March 1915 there were 706 coast stations and 4,866 ships throughout the world fitted for radiotelegraphy. Radio was soon made compulsory on ships carrying 50 or more passengers, and research followed by new design improved accuracy and speed of telegraphic messages.

Trend of radio transmission since 1900. Early radiotelegraph transmission was by manual operation of a Morse key and by aural and visual monitoring and translation of the message. Though the teleprinter speeded, and automated, the operation, present mechanical limitations prevent speeds beyond about 100 words per minute. Paper tape and magnetic tape allow records to be made of much higher speed signals.

Effect of distortion on speed

Transmission and reception speeds of telegraph signals are limited primarily by distortion occurring over the propagation path and only secondarily by the bandwidth that can be made available. In this respect, microwave transmission is superior to shortwave radio or even cable links since the carrier frequency is very high and a wide bandwidth is still only a small proportion of the carrier frequency. Shortwave radio suffers from selective fading of the signal-frequency components (worse for high-speed operation requiring a greater transmission bandwidth), from comparatively low carrier frequencies, and from an overloaded frequency spectrum due to too many users. Cable transmission over very long distances sets a limit on bandwidth and can distort the shape of the telegraphic signals.

Radio transmission, particularly on shortwaves, tends to be more susceptible to distortion, noise, and interference than land lines, and an important development for ensuring message accuracy was an automatic error-correction system pioneered during World War II.

Spark transmitters were originally employed for telegraph signalling and continued in service long after the electron tube had taken over for speech transmission. Spark signals caused considerable interference outside the channel carrying the telegraph code because of the broad spectrum occupied by their frequency components, and in 1941 their further use was banned by international agreement.

Modern radiotelegraph practice. Modem radiotelegraph practice employs a seven-unit code to transmit telegraph characters by frequency–shift keying (in which the frequency of the carrier is shifted for mark or space transmission) with single-side-band, independent-side-band, or double-side-band transmitters. It is possible to send several separate telegraph signals in the same frequency spectrum as one speech channel. Thus a telegraph signal having 50 intervals per second (one interval equals one on–off period and is known as a baud) requires a bandwidth of 100 hertz; and 24 of these channels can be transmitted in the same bandwidth as a speech channel. If channels at higher speeds must be accommodated, the number of channels must be proportionally reduced.

Amateur and professional radio operation. ***History of amateur radio.*** From its beginnings, radio communication has attracted armies of amateur enthusiasts all over the world. By 1912 these were numerous enough to require control measures to avoid interference with commercial signals. Control was first instituted in 1911; during World War I there was a ban on amateur activity in belligerent countries, and receiving sets were sealed.

After the war, amateur activities in the medium-wave band were permitted only at the top end (above about 1.3 megahertz) but were given complete freedom in the shortwave band. Experimentation by amateurs soon revealed the unexpected favourable propagational qualities of shortwaves. An American amateur, in association with British amateurs in 1921, installed a receiver in Scotland with which transatlantic contact was made on 1.3 megahertz from a one-kilowatt transmitter 3,200 miles (5,100 kilometres) away. Radiotelegraph signals were exchanged over considerable distances using low-powered transmitters operating at 180 metres (1.7 megahertz) and later at 100 metres (3 megahertz). In 1924 shortwave transmissions were sent from England to New Zealand.

Amateurs are allocated frequencies at the extreme high-frequency end of the medium-wave band, five groups of frequencies in the shortwave band, two groups in the very-high-frequency band, three in the ultrahigh-frequency band, and seven in the superhigh-frequency band for telegraphic and telephonic communication using amplitude and frequency modulation. There are restrictions on the power of the transmitters, and certain of the frequencies must be shared with due regard for the needs of other users. Experimental transmissions still being made seem unlikely to yield such spectacular results as those of the 1920s.

Military use of radio. During World War I relatively little use was made of radio except in naval conflict, though some artillery spotting aircraft were fitted with transmitters late in the war. World War II saw a vast expansion of radio communication, with constant contact maintained between forward units, including mobile units such as tanks, and headquarters. All messages likely to be intercepted are normally coded, though in certain combat situations voice messages are sent in clear.

All radio-frequency bands may be brought into service for military purposes. Long-distance communication in World War II depended entirely on shortwaves, but the development of satellites .has made possible, microwave communication with greater reliability and less message error because of the elimination of multipath difficulties.

One of the main problems with military radio communications is the possibility of enemy jamming and interference. Very highly directive antenna systems, the use of meteor trails for reflecting signals, and various detection techniques are helpful in reducing the effects.

Radio also plays an important part in guiding aircraft, in artillery aiming, in remote control of missiles, and in surveillance of enemy activity by radar and by satellite observation.

Military equipment, especially that for combat use, is rugged, simple to operate, and as light in weight as possible. It requires an adequate supply of spare components on hand since proper maintenance can be undertaken only at base workshops.

Government and civil authority radio operation. Radio is an essential instrument of national and, to a lesser extent, local government all over the world. Microwaves play a vital role in national telephone, telegraph, and data links, and shortwaves in communication with embassies abroad; satellite links are becoming more important in this field.

Broadcasting is not only a medium for government announcements but for educational purposes, especially in the underdeveloped countries that are short of qualified teachers. It can be a potent weapon in maintaining or undermining morale and is widely used for propaganda and psychological-warfare purposes. Many countries have resorted to jamming unwelcome foreign broadcasts, even at the cost of obliterating a number of communication channels.

To collect and assess news from all parts of the world, many governments use news-agency-teleprinter-radio services and monitoring posts.

Civil authorities require radio communication for the control of fire, police, ambulance, and traffic services and for dealing with emergencies caused by natural disasters such as floods, hurricanes, and earthquakes. The very-high-frequency band is most useful.

Shortwave listening. Shortwave transmission plays a very important part in external broadcasting beyond the land frontiers of many nations. Developed nations use this method of keeping in touch with their nationals residing abroad as well as for ideological purposes.

The disadvantage of shortwave radio is that the signal is highly variable because of its dependence on reflection from the ionosphere, and it is often distorted. Speech is generally at least intelligible, but music may be distorted out of all aesthetic value. A further disadvantage is that the frequency giving optimum listening conditions varies over the 24 hours, the season of the year, and the sunspot cycle. Experience suggests that listeners commonly prefer to listen to the same frequency, even though the signal is deteriorating, rather than retune to another frequency. This is due partly to natural laziness and partly to the difficulties of tuning and of maintaining correct tuning. The shortwave band itself possesses 1,500 channels 10 kilohertz wide, whereas the medium-wave band has only 100. If both bands are covered by one sweep of the tuning scale, it will clearly be 15 times more difficult to tune a shortwave signal. This problem is reduced by dividing the wave band into three or more sections, or better still by using band spreading, in which a band encompassing about 200 kilohertz is given the full sweep of the tuning scale. Receivers providing this facility are much more expensive.

Band spreading

Special applications of radio. ***Remote-control radio.*** There are many circumstances in which control and monitoring signals cannot be carried by wires; examples are moving objects such as a model boat, an aircraft making a blind landing, or a spacecraft being placed in orbit. Radio control can be used in these circumstances. Coded signals for control are used to modulate a carrier frequency, and the moving object has a receiver permanently tuned to this frequency. The control may be a simple on–off signal operating a relay to switch the motor of a model boat on or off, or it may be a series of coded signals controlling the altitude, azimuth, elevation, and speed of an aircraft making an automatic or a blind landing.

The remote operation of radio apparatus is now well-established practice, and many commercial installations for telephony and telegraphy transmitting and receiving as well as broadcasting transmitters are remotely controlled by signals sent along wires. The operator can select the desired carrier frequency, the telegraph, speech, or music channel, and the antenna and can adjust the tuning of transmitter radio-frequency stages. Receivers can be remotely controlled from a single control desk, which has means for selecting the desired incoming signal and the correct antenna, as well as for tuning the circuits, adjusting output level, and directing output to any required destination.

Broadcasting transmitters may be time-switch operated or switched and monitored from a main station; monitoring may involve checking all program quality conditions and providing warning that these are unsatisfactory or that the transmitter is off. There are also interrogating systems giving the operator information on the situation at specified points in the apparatus. Unattended transmitters generally have their most vulnerable circuits such as the output circuit duplicated so that failure of one leaves the transmission still functioning, though frequently at reduced power.

Radio paging. The efficient employment of many types of personnel besides police is enhanced by an effective means of signalling an emergency or change of plan. A doctor may carry a lightweight portable alarm device operated by induction from wires built into the ceiling or walls of hospital wards. The frequency used may be in the audio or low-radio range and the receiver sharply tuned to accept the selected paging frequency. This system can only be used in confined areas, and coverage of a large area generally requires speech communication using amplitude or frequency modulation of carriers in the very-high- or ultrahigh-frequency bands. If a "return to base" or "call base by the nearest telephone" is all that is needed, a simple alarm can be employed and made selective to any number of individuals.

Citizen's band radio. Citizen's band radio involves the use of radio for business and personal communication or remote-control purposes over 10 to 15 miles (16 to 24 kilometres). Channels are made available for voice communication and remote control, such as opening of garage doors, at frequencies around 27 megahertz and 465 megahertz, and a band centred on 75 megahertz is available for model-aircraft control. There were over 1,000,000 licenses in force in the United States alone in 1967, and the government insisted on stringent conditions to avoid excessive local interference. Maximum transmitter power and antenna height are fixed; personal calls are permissible, for example, from a remote campsite or in case of emergency, only if a satisfactory telephone service is not available, and calls are limited to a maximum of five minutes. Each user is given a call sign that must be announced before a message is sent.

Industrial radio. Radio-frequency energy is of value in a number of industrial heating applications, and radio-frequency electric furnaces, operating at about 10 kilohertz, produce materials of very high purity. Radio-frequency heating (*q.v.*) is employed in removing impurities from the two elements, germanium and silicon, that form the basis of semiconductor technology, as well as from other elements and compounds. The process is known as zone melting (*q.v.*).

Heating of glues bonding nonmetallic surfaces is often best undertaken by placing the material between the plates of a capacitor to which radio-frequency energy is applied. Frequencies at the upper end of the shortwave band are valuable in diathermy—*i.e.,* therapeutic heat treatment of the human body. Recovery from muscular injury is often helped by subjecting the injured limb to diathermy. Microwave energy is now used on a limited scale for cooking; because of the nature of microwaves, such an oven cooks the food from inside to outside.

All radio-frequency heating equipment must be fully shielded to prevent interference with radio communication.

Radio telemetry. Remote reading of instruments taking measurements in conditions dangerous to human life, or in places inaccessible or not easily accessible, can be undertaken over long distances by radio; the technique is known as radio telemetry (see also TELEMETRY). Control of nuclear-power sources and of the manufacture of toxic materials, as well as experiments aimed at exploring conditions in the stratosphere, ionosphere, and outer space may involve radio telemetry. The measurement is converted to a change of an electrical quantity and is transmitted as an information signal superimposed on a radio-frequency carrier, which may be continuous or pulsed. Change of temperature. for example, can change the length of a coil or the spacing of the plates of a capacitor in the tuning circuit of a small transmitter; the transmitter frequency can then be calibrated in terms of temperature. Pressure and humidity changes can be converted in a similar manner; this is the principle of operation of the radiosonde that carries by balloon a small transmitter and instruments for measuring the temperature, pressure, and humidity of the upper atmosphere.

Information about solar radiation, solar wind, magnetic fields, and ionospheric soundings from probes in outer space may have to be stored on magnetic tape for subsequent transmission either on command, or by prearrangement, to the information centre on Earth. Telemetry signals have been received back satisfactorily from space probes at distances greater than 35,000,000 miles (56,000,000 kilometres).

Miscellaneous applications. Radio has found applications in many fields besides communications and has accelerated developments in almost all branches of science; medicine, surgery, astronomy, and mathematics have all benefitted. Diagnosis of disease has been speeded up and made more positive by the adoption of radio methods. The radio-frequency scalpel has proved its worth in delicate brain and eye surgery.

Radio waves from outer space

Radio astronomy, now an important branch of science, was born with the reception (1932) of appreciable 20 megahertz radio emissions from the Milky Way galaxy. In 1942 investigators measured radio emissions from the Sun. Subsequent work has shown that emissions reaching the Earth from outer space cover a range of at least 10 megahertz to 30 gigahertz. Well-defined sources of radiation have been discovered, and some have been associated with visible stars or have led to the discovery of hitherto unknown stars; but many of these quasars, as they are called, emanate from a part of space where no stars have yet been seen. Certain of the radio sources have shown a slow periodic variation in emission, and these have been named pulsars.

Clear resolution of the longer wavelength emission is difficult without very large antenna systems; such systems may be movable or may consist of fixed installations on Earth depending on the Earth's rotation to scan the sky. Such fixed systems are in action in Britain, the United States, The Netherlands, France, Germany, Australia, and the Soviet Union.

RADIO RECEIVER MANUFACTURING

Hand wiring. In the early days of radio and up to the end of World War II, radio receivers consisted of resistors, capacitors, inductors (coils), and electronic tubes joined together by wires with coloured insulation. A colour code, whereby a particular colour was assigned to a particular circuit connection, such as black leads for filaments, green for grid, was adopted throughout the world to facilitate manufacture and the tracing of faults. Later, wires cut to the right length were laced together into a harness to speed assembly. Plugs and sockets were employed for connecting one major part with another. Printed circuit wiring, developed during the 1940s, eliminated much of the hand work and produced important manufacturing economies.

Printed circuits. With printed wiring, the layout of the circuit is planned with component size and position in mind, and connections are made by suitably shaped copper strip or foil bonded to an insulating board or substrate. An extension of this technique was the printed component; resistors, capacitors, and low value inductors became a part of the printing process.

The development of the transistor simplified the exploitation of printed circuitry by eliminating one of the bulkiest components, the vacuum tube. Further development led to the manufacture of the integrated circuit (*q.v.*), which can perform a multiplicity of tasks such as amplification and switching. These circuits are widely used in computers where space is at a premium. Integrated-circuit amplifiers are likely to become more important because of their ability to amplify very high frequencies.

The size of a portable receiver constructed from microminiature circuits is now dictated almost entirely by the loudspeaker and the quality of reproduction required. The smaller the loudspeaker the lower the power it can accept and the less the output of low audio frequencies.

Safety considerations. Voltages involved in a portable radio receiver operated from batteries are so low (less than 20 volts) that it represents no safety hazard, but a receiver that has an alternative power-line connection (that is, it can operate either from batteries or from a wall plug) must be designed with care so that all metal that could come into contact with the user is properly isolated from power-line voltages.

Receivers supplying a large audio output power need adequate ventilation, especially in the neighbourhood of the power transformer and output transistors, because these may be destroyed by overheating. Ventilating openings in the receiver must not be blocked by walls or curtains. The input transformer and the direct current supply to the transistors should be protected by fuses. The danger of fire is much less with a power-line-operated transistor receiver than with a vacuum tube receiver since transistors require no heater supply and so produce much less heat.

Radioactivity

The dramatic discovery and early studies of radioactivity —*i.e.*, the property exhibited by certain types of matter of emitting energy and subatomic particles spontaneously --at the end of the 19th century ushered in an unprecedented period of exciting advances in man's knowledge, first of the submicroscopic nature of matter and eventually of the enormous energy sources that supply the Sun and stars.

Discovery of radioactivity

Radioactivity was discovered by Henri Becquerel, a French physicist, in 1896, only a few months after the discovery in Germany of X-rays. The fact that X-ray tubes showed visible fluorescence (*i.e.*, re-emitted the energy as light) of the glass during X-ray production first led Becquerel to suppose that there might be some close relation between fluorescence in the form of visible light and the emission of X-rays. Some of the uranium salts are fluorescent; hence, Becquerel concentrated his studies on uranium, exciting fluorescence by sunlight. During a succession of cloudy days in Paris, he left wrapped photographic plates in the dark near the uranium but found them nevertheless blackened when developed. This experiment and subsequent ones convinced him that uranium continuously emitted radiations of great penetrating power, like X-rays, and the emission proceeded independently of chemical form and of external energy sources.

This article is divided into the following sections:

I. General considerations

HISTORY AND NOTABLE MILESTONES IN RADIOACTIVITY

The history of discoveries and advancing knowledge of radioactivity is too long and varied to be treated in detail here. Table 1 presents a chronology of notable events.

NUCLEAR STRUCTURE

To understand the phenomena of radioactivity, a knowledge of the structure of atoms is useful (see ATOMIC STRUCTURE; NUCLEUS, ATOMIC; SPECTROSCOPY; ISOTOPES; PARTICLES, SUBATOMIC; ELECTROMAGNETIC RADIATION; only a brief overview can be given here).

The known elements, over 100 in number, are composed of atoms consisting of a massive nucleus carrying one or more positive charges, surrounded by a cloud of negatively charged electrons equal in number to the charge of the nucleus, called the atomic number (conventionally designated Z). The nucleus consists of two kinds of more massive particles, neutrons without electrical charge and protons each with a single positive charge, the two kinds of particles having about the same mass, respectively 1,836.1 and 1,838.63 times the mass of an electron. The sum of the numbers of protons and neutrons (called nucleons collectively) in the atomic nucleus is the atomic mass number (*A*).

Definition of half-life

The exact masses of nuclei and neutral atoms are measured in atomic mass units (amu), a scale in which the carbon-12 atom is defined as exactly 12 mass units. On this scale most atoms have masses that are nearly but not exactly whole numbers. All the atoms of any specific element have the same number of protons (the atomic number) but may have different numbers of neutrons; thus, for one atomic number (Z) there may be more than one stable atomic mass number. Nuclei with the same number of protons but different number of neutrons are called isotopes. The term nuclide refers to a particular nuclear species with its electron cloud. The nucleons are strongly bonded together by a force peculiar only to neutrons and protons, called a nucleon–nucleon force. Certain combinations of nucleons produce exceedingly stable nuclei, whereas other combinations are unstable to varying degrees. An unstable nucleus, or radioisotope, will decompose spontaneously, or decay, into a more stable configuration but will do so only in a few specific ways by emitting certain particles or certain entities (quanta) of electromagnetic energy, called photons. Radioactive decay is a property of several naturally occurring elements as well as of artificially produced isotopes of the elements. The rate at which a radioactive element decays is expressed in terms of its half-life; *i.e.*, the time required for one-half of any given quantity of the isotope to decay. Half-lives range from those too long to measure (greater than 1,000,000,000 [10^9] years for some nuclei) to those too short to measure (less than 10^{-9} second; see below Rates of radioactive transitions). The product of a radioactive decay process (called the daughter of the parent isotope) may itself be unstable, in which case it, too, will decay. The process continues until a stable nuclide has been formed.

The symbolization of a particular nuclide consists of the symbol for the element—say, C for carbon—with the atomic number (Z) as a prefix subscript and the atomic mass (*A*) as a prefix superscript $_Z^AC$; thus, the notation $_6{}^{12}C$ means one atom of the carbon isotope that has six protons and six neutrons; this isotope is referred to as carbon-12. The isotope carbon-14 has eight neutrons and is symbolized $_6{}^{14}C$. Sometimes the number of neutrons is affixed as a subscript; *e.g.*, $_6{}^{14}C_8$ (ordinarily this means the number of these atoms in a molecule).

On the submicroscopic scale of the nucleus the manifestations of quantum mechanics are dominant; *i.e.*, a nuclear system can exist only in certain discrete energy states. Each energy state has particular properties besides its unique energy, the important properties being the spin (more correctly, total angular momentum), magnetic dipole moment, and electric quadrupole moment. The spin is, as the word implies, the mechanical angular momentum of rotation, expressed as an integral (0, 1, 2, . . .) or half-integral ($\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$, . . .) number, the units being $\hbar$, Planck's constant, h, divided by 2π. The magnetic moment, symbolized by the Greek letter mu, μ, is the measure of the strength of magnetism along the spin direction and is measured in units of the nuclear magneton ($e\hbar/2m_pc$, e representing the elementary unit of charge, m_p the mass of the proton, and c the speed of light). The spectroscopic quadrupole moment, Q_{spec}, is the measure of the nonsphericity of the charge distribution of the nucleus with respect to the spin axis. A positive value of Q_{spec} denotes a cigar-shaped nucleus; a zero value denotes a spherical nucleus; and a negative value denotes a doorknob-shaped nucleus. The usual unit of Q_{spec} is the barn, an area unit equal to 10^{-24} square centimetre, comparable to the cross-sectional area of nuclei. A further property, the parity, concerned with the symmetry of a quantum-mechanical wave equation that describes it, is denoted by a + (even) or − (odd) sign following the spin number.

II. The general phenomena of radioactivity

THE NATURE OF RADIOACTIVE EMISSIONS

Positive and negative beta particles

The emissions of the most common forms of spontaneous radioactive decay are the alpha (a) particle, the beta (β) particle, the gamma (γ) ray, and the neutrino. The alpha (a) particle, or ray, is actually the nucleus of a helium-4 atom, with two positive charges $_2{}^4He$. Such charged atoms are called ions. The neutral helium atom has two electrons outside its nucleus balancing these two charges. Beta particles may be negatively charged (beta minus, symbol e−), also called a negatron, or positively charged (beta plus, symbol e^+), also called a positron. (The beta minus [β^-] particle is actually an electron created in the nucleus during beta decay without any relationship to the orbital electron cloud of the atom.) The positron is regarded as the antiparticle of the negatron, because the two particles when brought together will mutually annihilate each other. Gamma rays are electromagnetic radiations like radio waves, light, and X-rays. Beta radioactivity also produces particles called the neutrino and antineutrino, with no charge and no rest mass, symbolized by the Greek letter nu, ν and $\bar{\nu}$, respectively. The energies associated with these particles are usually expressed in terms of the work required to move a unit electrical charge through a potential of one volt; the unit is the electron volt, or eV (an MeV is 1,000,000 electron volts and is equal to 1.6 × 10^{-13} joule; one kilo-electron volt [keV] is 1,000 electron volts). In the less common forms of radioactivity there may be emitted fission fragments, neutrons, or protons. Fission fragments are themselves complex nuclei with usually between one-third and two-thirds the charge Z and mass A of the parent nucleus. The neutrons and protons, as mentioned above, are the basic building blocks of the complex nuclei, having approximately unit mass on the atomic scale and having zero charge or unit positive charge, respectively. The neutron cannot long exist in the free state. It is rapidly captured by nuclei in matter; otherwise, in free space it will undergo beta-minus decay to a proton, a negatron, and an antineutrino with a half-life of 12.8 minutes. The proton is the nucleus of ordinary hydrogen and is stable.

TYPES OF RADIOACTIVITY

The early work on natural radioactivity associated with uranium and thorium ores identified two distinct types of radioactivity: alpha and beta decay.

Alpha decay. In alpha decay, an energetic helium ion (alpha particle) is ejected, leaving a daughter nucleus of atomic number two less than the parent and of atomic mass number four less than the parent. An example is the decay (symbolized by an arrow) of the abundant isotope of uranium, uranium-238, to a thorium daughter plus an alpha particle. The energy released (*Q*) in million electron volts (MeV) and the half-life ($t_{1/2}$) will be stated for this reaction and those that follow. It should be noted that in every reaction the charges, or number of protons, shown in subscript are in balance on both sides of the arrow, as are the atomic masses, shown in superscript.

$$^{238}_{92}U \longrightarrow {}^{234}_{90}Th + {}^4_2He \qquad \begin{array}{l} Q_\alpha = 4.268 \text{ MeV} \\ t_{1/2} = 4.51 \times 10^9 \text{ years} \end{array}$$

Beta-minus decay. In beta-minus decay, or negatron emission, an energetic negative electron is emitted, producing a daughter nucleus of one higher atomic number and the same mass number. An example is the decay of the uranium daughter product thorium-234 into protactinium-234.

$$^{234}_{90}Th \longrightarrow {}^{234}_{91}Pa + e^- + \bar{\nu} \qquad \begin{array}{l} Q_{\beta^+} = 0.263 \text{ MeV} \\ t_{1/2} = 24.1 \text{ days} \end{array}$$

In the above reaction for beta decay, $\bar{\nu}$ represents the antineutrino, an uncharged particle with zero rest mass. (In the accepted relativistic theory a particle has a total mass m, given by Einstein's famous equation E = mc^2, in which c is the speed of light, and E is the total energy. Most particles have a characteristic rest mass, m_0, their mass when they are not moving. Neutrinos and antineutrinos have zero rest mass; hence, they must always have the speed of light.)

Gamma rays—photon emission

Gamma decay. A third type of radiation, gamma radiation, usually accompanies alpha or beta decay. Gamma rays are photons, the elementary packets of electromagnetic radiation, and are without rest mass or charge. Alpha or beta decay may simply proceed directly to the

Table 1: Notable Events in Understanding of Nuclei and Radioactivity

researcher	year	event
Wilhelm Konrad Rontgen	1895	discovery of X-rays
Henri Becquerel	1896	discovery of radioactivity of uranium
Joseph John Thomson	1897	discovery of electron as constituent of atoms
Marie Sktodowska-Curie and Pierre Curie	1898	discovery of highly radioactive elements polonium and radium in uranium ores
Ernest Rutherford	1899	discovery of radioactive gaseous emanation from thorium
Pierre Curie	1900	classification of two different kinds of radiation, alpha and beta rays, from radium
Paul-Ulrich Villard	1900	discovery of third type of radiation, gamma rays
André-Louis Debierne	1900	discovery of actinium
William Crookes	1900	discovery of radioactive UX_1 (thorium-234)
Max Planck	1901	proposal that electromagnetic radiation comes in packets (quanta)
Ernest Rutherford and Frederick Soddy	1902	recognition that nuclear changes (transmutations) accompany radioactive emissions
William Ramsay and Frederick Soddy	1903	discovery that helium is formed by decay of radium
Albert Einstein	1905	theory of equivalence of mass and energy ($E = mc^2$)
Egon Ritter von Schweidler	1905	formulation of statistical laws of radioactive decay
Otto Hahn	1905	discovery of radioactive thorium (thorium-228)
Norman Robert Campbell and A. Wood	1906	discovery of radioactivity in natural potassium and rubidium
Bertram Borden Boltwood	1907	discovery of ionium (thorium-230)
Johannes Wilhelm Geiger	1908	experiments on alpha-particle scattering by thin foils
Frederick Soddy	1910	originated concept of radioactive isotopes—that a given element can consist of different nuclear species
Ernest Rutherford	1911	proposal that positive charge and most of mass of atoms is concentrated in tiny central nucleus
Niels Bohr	1913	quantum-mechanical theory of planetary atom
Otto Hahn and Lise Meitner	1918	discovery of protactinium
Ernest Rutherford	1919	first artificial transmutatron of nuclei (alpha particles on nitrogen)
Francis William Aston	1919	mass-spectrograph construction and mass measurement of isotopes
Louis de Broglie	1924	proposal that moving particles have wavelike nature
Werner Heisenberg, Erwin Schrodinger. P.A.M. Dirac, Wolfgang Pauli, Max Born, and others	1924–27	formulation of the new quantum mechanics
George Gamow, Ronald Gurney, and Edward Uhler Condon	1928	quantum-mechanical tunnelling theory of rates of alpha decay
Wolfgang Pauli	1931	neutrino hypothesis in beta decay
Harold Urey	1932	discovery of heavy hydrogen (deuterium)
James Chadwick	1932	discovery of neutron
Carl David Anderson	1933	discovery of positron
Frédérick Joliot-Curie and Irbne Joliot-Curie	1934	first artificially produced radioactivity, discovery of positron beta decay
Enrico Fermi	1934	first production of radioactivity by neutron capture, formulation of beta decay rate theory
Hideki Yukawa	1935	meson theory of nuclear forces
Hideki Yukawa and Shoichi Sakata	1936	theoretical proposal of orbital electron capture beta decay
Niels Bohr	1936	compound nucleus model of nuclear reactions
Gregory Breit and Eugene Wigner	1936	single-level resonance formula for nuclear states
C. Perrier and Emilio Segrè	1937	discovery of technetium, element 43
D. Bayley and Horace Richard Crane	1937	discovery of beta-delayed alpha emission
Louis W. Alvarez	1938	experimental discovery of electron capture decay
Hans Bethe	1939	proposal of nuclear mechanisms for energy production in Sun and stars
Otto Hahn and Fritz Strassmann	1939	discovery of nuclear fission
Lise Meitner and Otto R. Frisch	1939	calculation of the huge energy release expected in fission
Niels Bohr and John Archibald Wheeler	1939	comprehensive theory of fission
Richard B. Roberts, R. C. Mayer, and P. Wang	1939	discovery of beta-delayed neutron emission after fission
Georgy Nikolayevich Flerov and Konstantin Antonovich Petrzhak	1940	discovery of spontaneous fission
Martin David Kamen and Samuel Ruben	1940	discovery of carbon-14
Edwin M. McMillan and Philip H. Abelson	1940	discovery of first transuranium element, neptunium, element 93
Enrico Fermi and others	1942	first continuous chain-reacting fission reactor operated
Glenn T. Seaborg, Edwin M. McMillan, Arthur Charles Wahl, and Joseph W. Kennedy	1946*	synthesis of plutonium, element 94
Jacob A. Marinsky. Lawrence E. Glendelii, and Charles D. Coryell	1946*	synthesis of promethium, element 61

*Work done during World War II and kept secret until publication year listed. Discovery of plutonium was in 1941. curium in 1944, americium in 1945.

ground (lowest energy) state of the daughter nucleus without gamma emission, but the decay may also proceed wholly or partly to higher energy states (excited states) of the daughter. In the latter case, gamma emission may occur as the excited states transform to lower energy states of the same nucleus. (Alternatively to gamma emission, an excited nucleus may transform to a lower energy state by ejecting an electron from the cloud surrounding the nucleus. This orbital electron ejection is known as internal conversion and gives rise to an energetic electron and often an X-ray as the atomic cloud fills in the empty orbital of the ejected electron. The ratio of internal conversion to the alternative gamma emission is called the internal-conversion coefficient.)

Isomeric transitions. There is a wide range of rates of half-lives for the gamma-emission process. Usually dipole transitions (see below ***Gamma transitiort rates),*** in which the gamma ray carries off one $\hbar$ unit of angular momentum, are fast, less than nanoseconds (one nanosecond equals 10^{-9} second). The law of conservation of angular momentum requires that the sum of angular momenta of the radiation and daughter nucleus is equal to the angular momentum (spin) of the parent. If the spins of initial and final states differ by more than 1, dipole radiation is forbidden, and gamma emission must proceed more slowly by a higher multipole (quadrupole, octupole, etc.) gamma transition. If the gamma-emission half-life exceeds about a nanosecond, the excited nucleus is said to be in a metastable, or isomeric, state (the names for a long-lived excited state), and it is customary to classify the decay as another type of radioactivity, an isomeric transition. An example of isomerism is found in the protactinium-234 nucleus of the uranium-238 decay chain:

$$^{234m}_{91}\text{Pa} \longrightarrow {}^{234}_{91}\text{Pa} + \gamma \qquad Q_\gamma = 0.0698 \text{ MeV} \quad t_{1/2} = 1.17 \text{ min}$$

The letter *m* following the mass number stands for metastable and indicates a nuclear isomer.

Beta-plus decay. In the 1930s, new types of radioactivity were found among the artificial products of nuclear reactions: beta-plus decay, or positron emission, and electron capture. In beta-plus decay an energetic positive electron is created and emitted, along with a neutrino, and the nucleus transforms to a daughter, lower by 1 in atomic number and the same in mass number. For instance, carbon-11 ($Z = 6$) decays to boron-11 ($Z = 5$) plus one positron and one neutrino:

$$^{11}_{6}\text{C} \longrightarrow {}^{11}_{5}\text{B} + e^{+} + \nu \qquad Q_{\beta^+} = 0.97 \text{ MeV} \quad t_{1/2} = 20.4 \text{ min}$$

Electron capture. Electron capture is a process in which decay follows the capture by the nucleus of an orbital electron. Electron capture (EC) is similar to positron decay in that the nucleus transforms to a daughter of one lower atomic number. Electron capture differs in that an orbital electron from the cloud is captured and annihilated by the nucleus with subsequent emission of an atomic X-ray as the orbital vacancy is filled by an electron

from the cloud about the nucleus. An example is the nucleus of beryllium-7 capturing one of its inner electrons to give lithium-7:

$$^{7}_{4}\mathrm{Be} + e^- \longrightarrow {}^{7}_{3}\mathrm{Li} + \nu \qquad Q_{\mathrm{EC}} = 0.8616\ \mathrm{MeV} \qquad t_{1/2} = 53\ \mathrm{days}$$

The main features of radioactive decay of a nuclear species are often displayed in a decay scheme. Figure 1 shows the decay scheme of beryllium-7, taken from the *Table of Isotopes* (first corrected printing, 1965) of C. Michael Lederer, Jack M. Hollander, and Isadore Perlman. The scheme shows the half-life of the parent and that of the excited daughter state as well as its energy, 0.4774 MeV. The spins and parities of all three states are indicated on the upper left-hand side of the level. The multipolarity of the gamma ray (magnetic dipole, M1, plus 0.005 percent electric quadrupole, E2) is indicated above the vertical arrow symbolizing the gamma transition. The slanted arrows symbolize the electron-capture (EC) decay with labels giving the percentage of decay directly to ground state (89.7 percent) and the percentage' of electron-capture decay going via the excited state (10.3 percent). The boldface numbers following the percentages are so-called log ft values, to be encountered below in connection with beta-decay rates. The overall energy release, Q_{EC}, is indicated below. The Q_{EO} is necessarily a calculated value, because there is no general practical means of measuring the neutrino energies accompanying EC decay. With a few electron-capturing nuclides it has been possible to measure directly the decay energy by measurement of a rare process called inner bremsstrahlung (braking radiation). In this process the energy release is shared between the neutrino and a gamma ray. The measured distribution of gamma-ray energies indicates the total energy release. Usually there is so much ordinary gamma radiation with radioactive decay that the inner bremsstrahlung is unobservable.

From C.M. Lederer, J.M. Hollander, and I. Perlman, *Table of Isotopes*

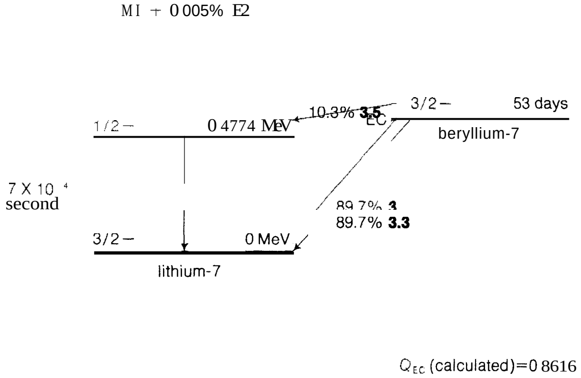

Figure 1: Radioactive decay of beryllium-7 to lithium-7 by electron capture (EC; see text).

Inner bremsstrahlung

Spontaneous fission. Yet another type of radioactivity is spontaneous fission. In this process the nucleus splits into two fragment nuclei of roughly half the mass of the parent. This process is only barely detectable in competition with the more prevalent alpha decay for uranium, but for some of the heaviest artificial nuclei, such as fermium-256, $_{100}{}^{256}\mathrm{Fm}$, spontaneous fission becomes the predominant mode of radioactive decay. Kinetic energy releases from 150 to 200 MeV may occur as the fragments are accelerated apart by the large electrical repulsion between their nuclear charges. The reaction is as follows:

$$\begin{array}{ll} {}^{256}_{100}\mathrm{Fm} \longrightarrow {}^{140}_{54}\mathrm{Xe} + {}^{112}_{46}\mathrm{Pd} + 4n & Q = 150\text{-}200\ \mathrm{MeV} \\ \quad +\text{other fission products} & t_{1/2} = 2.7\ \text{hours} \end{array}$$

Only one of several product sets is shown. A few neutrons are always emitted in fission of this isotope, a feature essential to chain reactions. Spontaneous fission is not to be confused with induced fission, the process involved in nuclear reactors. It is a property of uranium-235, plutonium-239, and other isotopes to undergo fission after absorption of a slow neutron. Other than the requirement of a neutron capture to initiate it, induced fission is quite similar to spontaneous fission regarding total energy release, numbers of secondary neutrons, and so on.

Proton radioactivity. Proton radioactivity, discovered in 1970, is exhibited by an excited isomeric state of cobalt-53, $^{53m}\mathrm{Co}$, 1.5 percent of which emits protons.

$$\begin{tikzcd}[row sep=small] & {}^{52}_{26}\mathrm{Fe} + p & Q_p = 1.57\ \mathrm{MeV} \\ {}^{53m}_{27}\mathrm{Co} \arrow[ur, "1.5\%"] \arrow[dr, "98.5\%"'] & & \\ & {}^{53}_{26}\mathrm{Fe} + e^+ + \nu & t_{1/2} = 0.243\ \mathrm{sec} \end{tikzcd}$$

In addition to the above types of radioactivity, there is a special class of rare beta-decay processes that gives rise to heavy-particle emission. In these processes the beta decay partly goes to a high excited state of the daughter nucleus, and this state rapidly emits a heavy particle.

Special beta-decay processes. ***Beta-delayed neutron emission.*** An example of this type of beta decay is the following reaction:

$$\begin{tikzcd}[row sep=small] {}^{17}_{7}\mathrm{N} \arrow[r] & \overset{*}{{}^{17}_{8}\mathrm{O}} + e- + \bar{\nu} \arrow[dr] & & Q_{\beta^-} = 8.68\ \mathrm{MeV} \\ & & {}^{16}_{8}\mathrm{O} + n & E_{max\ n} = 1.81\ \mathrm{MeV} \\ & & & t_{1/2} = 4.16\ \mathrm{sec} \end{tikzcd}$$

(Note: the asterisk denotes the short-lived intermediate excited states of oxygen-17, and $\boldsymbol{E_{max}}$ ▪ denotes the maximum energy observed for emitted neutrons.) There is a small production of delayed neutron emitters following nuclear fission, and these radioactivities are especially important in providing a reasonable response time to allow control of nuclear fission reactors by mechanically moved control rods.

Beta-delayed alpha emission. Among the positron emitters in the light-element region, a number beta decay partly to excited states that are unstable with respect to emission of an alpha particle. Thus, these species exhibit alpha radiation with the half-life of the beta emission. Both the positron decay from boron-8 and negatron decay from lithium-8 are beta-delayed alpha emission, because ground (unexcited) as well as excited states of beryllium-8 are unstable with respect to breakup into two alpha particles. Another example, sodium-20 (^{20}**Na**) to give successively neon-20 (^{20}**Ne**; the asterisk again indicating the short-lived intermediate state) and finally oxygen-16 is listed below:

$$\begin{tikzcd}[row sep=small] {}^{20}_{11}\mathrm{Na} \arrow[r] & {}^{20}_{10}\mathrm{Ne} + e^+ + \nu \arrow[dr] & & Q_{\beta^+} = \mathbf{13.0\ MeV} \\ & & {}^{16}_{8}\mathrm{O} + \alpha & E_{max\ \alpha} = 4.44\ \mathrm{MeV} \\ & & & t_{1/2} = 0.39\ \mathrm{sec} \end{tikzcd}$$

Beta-delayed proton emissions. In a few cases, positron decay leads to an excited nuclear state not able to bind a proton. In these cases proton radiation appears with the half-life of the beta transition. The combination of high positron-decay energy and low proton-binding energy in the daughter ground state is required. An example is given below, in which tellurium-111 (^{111}**Te**) gives successively antimony-111 (^{111}**Sb**) and then tin-110 (^{110}**Sn**):

$$\begin{tikzcd}[row sep=small] {}^{111}_{52}\mathrm{Te} \arrow[r] & \overset{*}{{}^{111}_{51}\mathrm{Sb}} + e^+ + \nu \arrow[dr] & & Q_{\beta^+}\ \text{uncertain} \\ & & {}^{110}_{50}\mathrm{Sn} + p & E_{max\ p} = 3.7\ \mathrm{MeV} \\ & & & = 19.5\ \mathrm{sec} \end{tikzcd}$$

OCCURRENCE OF RADIOACTIVITY

Some species of radioactivity occur naturally on Earth. A few species have half-lives comparable to the age of the elements (about **6** × **10**^{9} years), so that they have not decayed away after their formation in stars. Notable among these are uranium-238, uranium-235, and thorium-232, the basis of the atomic energy industry. Also there is potassium-40, the chief source of irradiation of the body through its presence in potassium of tissue. Of lesser significance are beta emitters vanadium-50 (^{50}**V**), rubidium-87 (^{87}**Rb**), indium-115 (^{115}**In**), tellurium-123 (^{123}**Te**), lanthanum-138 (^{138}**La**), lutetium-176 (^{176}**Lu**), and rhenium-187 (^{187}**Re**), and the alpha emitters cerium-142 (^{142}**Ce**), neodymium-144 (^{144}**Nd**), samarium-147, 148 ($^{147,\ 148}$**Sm**), gadolinium-152 (^{152}**Gd**), dysprosium-156 (^{156}**Dy**), hafnium-174 (^{174}**Hf**), platinum-190 (^{190}**Pt**), and lead-204 (^{204}**Pb**). Besides these approximately 109-year species, there are the shorter-lived daughter activities fed by one or another of the above species; *e.g.*, by various nuclei of the elements between lead (Z = 82) and thorium (Z = 90).

Cosmic ray bombardment

Another category of natural radioactivity includes species produced in the upper atmosphere by cosmic ray bombardment. Notable are 5,720-year carbon-14 and 12.3-year tritium (hydrogen-3), 53-day beryllium-7, and 2,700,000-year beryllium-10. Meteorites are found to contain additional small amounts of radioactivity, the result of cosmic ray bombardments during their history outside the Earth's atmospheric shield. Activities as short-lived as 35-day argon-37 have been measured in fresh falls of meteorites. Nuclear explosions since 1945 have injected additional radioactivities into the environment, consisting of both nuclear fission products and secondary products formed by action of bomb neutrons on surrounding matter.

The fission products encompass most of the known beta emitters in the mass region 75–160. They are formed in varying yields, rising to maxima of about 7 percent per fission in the mass region 92–102 (light peak of the fission yield versus atomic mass curve) and 134–144 (heavy peak). Two kinds of delayed hazards caused by radioactivity are recognized. First, the general radiation level is raised by fallout settling to Earth. Protection can be provided by concrete or earth shielding until the activity has decayed to a sufficiently low level. Second, ingestion or inhalation of even low levels of certain radioactive species can provide a special hazard, depending on the half-life, nature of radiations, and chemical behaviour within the body.

Some of these internally hazardous products of nuclear explosions are listed in Table 2 below.

Nuclear reactors also produce fission products but under conditions in which the activities may be contained. Containment and waste-disposal practices should keep the activities confined and eliminate the possibility of leaching into groundwaters for times that are long compared to the half-lives. A great advantage of thermonuclear fusion power over fission power, if it can be practically realized, is not only that its fuel reserves, heavy hydrogen and lithium, are vastly greater than uranium, but also that the generation of radioactive fission product wastes can be avoided. In this connection it may be noted that a major source of heat in the Earth's interior and the Moon's interior is provided by radioactive decay. Theories of the formation and evolution of Earth, Moon, and planets must take into account these large heat production sources.

Desired radioactivities other than natural activities and fission products may be produced either by irradiation of certain selected target materials by reactor neutrons or by charged particle beams or gamma ray beams of accelerators.

Table 2: Fall-out Activities Posing Ingestion Hazards

nucleus	formation process	half-life	remarks
^{90}Sr (strontium-90)	fission (5 percent yield)	29 years	long-term deposition in bones, irradiating marrow, the site of red blood cell formation; moves through food chain in milk
^{137}Cs (cesium-137)	fission (6.5 percent)	30 years	body eliminates over several months; localized in the soft tissues
^{89}Sr (strontium-89)	fission (5 percent)	51 days	same remarks as above for ^{90}Sr, but less hazardous since shorter lived
^{131}I (iodine-131)	fission (3 percent)	8 days	short-lived, but can concentrate in food chain, via milk to thyroid gland
^{14}C (carbon-14)	formed by neutrons on atmospheric nitrogen	5,720 years	atmospheric $^{14}CO_2$ incorporated into green plant, then animal material
3H (tritium)	formed by neutrons on lithium-6; released in thermonuclear explosions	12 years	incorporated into living material via tritiated water (^3H_2O); radiations are soft (18.6 keV maximum) and short-ranged

III. Interaction of radiation with matter

The operation of radiation-detection instruments, absorption and shielding materials, and biological effects are all dependent on the interactions of radiation with matter. The types of interaction are described briefly in this article.

For additional details, refer to the articles RADIATION DETECTION AND CHARACTERIZATION; RADIATION EFFECTS ON MATTER; NUCLEUS, ATOMIC; ATOMIC STRUCTURE; X-RAYS; RADIATION, BIOLOGICAL EFFECTS OF; RADIATION INJURY.

Several types of radiation are associated with radioactivity, and a presentation of their interactions calls for recognition of the following types of radiation: charged particles (*a*, *β*, p, fission fragments); photons (y, X-rays); neutral heavy particles (n); and neutrinos.

CHARGED PARTICLES

Role of ionization

Electrically charged particles at the energies occurring in radioactive decay slow down in passage through matter mainly by ionization (ejection of bound electrons) of the electron clouds of the atoms near which they pass. The rate of loss of kinetic energy is thus greater the higher the charge of the particle and indeed is proportional to the square of the charge. The rate of loss is greater the slower the speed (for energies up to about twice the rest mass energy, $2m_0c^2$, at which relativistic effects reverse the trend), because the slower moving particle spends more time close to an atom of the medium and therefore has a greater chance to ionize it. The rate of loss is greater in a medium with lower ionization potential than in one with higher.

Closely related to stopping rate is specific ionization. In a gas and in some insulators and semiconductors, the ionized electrons (those removed from atoms) move far enough from the positively charged parent ions that the electric charge may be collected on electrodes. The number of ion pairs produced per unit path length is thus measurable. A plot of this specific ionization versus path length is called a Bragg curve.

The tracks of alpha particles and fission fragments may be registered in photographic emulsions or in cloud chambers (vessels containing supersaturated vapour, which, rapidly expanded, provides a medium in which the trails of the particles can be traced by trails of visible droplets), and they are seen to be essentially straight paths. Because they move in straight lines and lose energy essentially continuously in a large number of ionizations, heavy charged fragments of a given energy possess a definite range. Ranges may be expressed in distance units but are usually given in terms of mass (mg/cm^2, milligrams per square centimetre of absorber). The straight-line behaviour is a consequence of the fact that alpha and fission-fragment masses exceed by several thousandfold the masses of the electrons slowing them down. The ranges of alpha particles of energies encountered in radioactivity are exceedingly small. For example, the 5.157-MeV alpha particles of plutonium-239 have a range of 4.45 mg/cm^2 of air or 3.75 centimetres (1.5 inches) of dry air at 25° C (77" F) and one atmosphere pressure. The ranges in mass per unit area for other stopping materials are similar.

Beta particles (electrons of both signs), compared to alpha particles and fission fragments, are observed to follow more erratic wandering paths as they slow down in matter, particularly near the ends of their paths. The ionization process is still dominant in slowing down, but the electrons being ionized are of equal rest mass; hence, like a billiard ball colliding with balls of equal mass, the fast electron will usually undergo large deflections in slowing down. These abrupt deflections of beta particles in matter also lead to a conversion of part of their energy into photons by the bremsstrahlung (braking-radiation) process; acceleration or deceleration of charged particles can lead to energy loss by electromagnetic radiation.

Ranges of beta particles

The maximum ranges of beta particles of energies encountered commonly in radioactivity are much longer than for alpha particles, mentioned above. For example, in strontium-90 and yttrium-90 fission-product decay, beta particles are emitted up to a maximum of 2.27 MeV energy. For beta energies between 0.6 MeV and 15 MeV the following simple range relationship was proposed by Norman Feather, a British physicist, for aluminum, and it holds for most other materials as well: the range (R) is proportional to the beta-particle energy (E), or R $= 0.543E - 0.160$. The range (R) is in grams per square centimetre of absorber, and E is in MeV. Thus, for the strontium–yttrium-90 example, the range is 1.07 g/cm^2. The range in distance units is obtained by dividing the density. For water or living tissue with density near unity, the range is 1.07 centimetres.

ELECTROMAGNETIC RADIATION

In contrast to charged-particle stopping, the electromagnetic photons (gamma rays and X-rays) are not gradually slowed down, because they must travel with the speed of light if they survive an encounter. They interact with matter in three kinds of discrete events, described below, in which they disappear or are converted into photons of lower energy.

The photoelectric *effect*. In this type of encounter with orbital electrons of absorber atoms, the photon disappears and gives up its entire energy to the ionization of an orbital electron in the matter. Elements of high atomic number, such as lead or uranium, are far more effective than light elements for the absorption of gamma-ray energies in the 0.1–1 MeV range encountered in radioactivity. The photoeffect probability goes as approximately the fifth power of the atomic number of the absorbing material. The photoeffect probability increases with decreasing photon energy but drops as the energy falls below binding energies of particular electron orbitals.

The Compton effect. In this type of encounter with an electron of the medium, the photon is converted to a lower energy photon that may go off in any direction, the energy and momentum differences being taken up by the electron. The Compton effect is more weakly dependent on atomic number and photon energy than the photoeffect.

Pair production. Gamma rays of energy greater than 1.02 MeV, which is twice the rest mass, m_0c^2, of an electron, may on encountering matter disappear, creating an electron–positron pair. This process rises with photon energy past the 1.02 MeV energetic threshold.

Concept of half-thickness

Absorption calculations. Because gamma-ray absorption is by discrete all-or-nothing events (rather than a slowing down, as with charged particles), gamma rays do not possess definite ranges in matter. The absorption is instead characterized by a half-thickness, the amount of absorber reducing the gamma-ray flux to half its incident value (*i.e.*, half the number of photons). Twice this thickness will cut the flux down to a fourth, three half-thick-

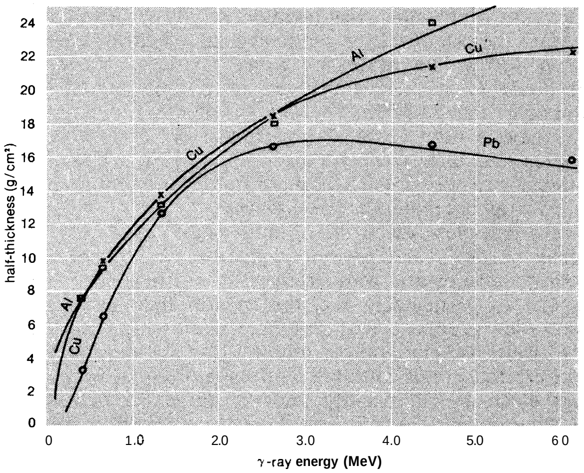

Figure 2: Gamma-ray absorption in aluminum (Al), copper (Cu), and lead (Pb) as a function of energy.

From G. Friedlander, J.W. Kennedy, J.M. Miller Nuclear and Radiochemistry, 2nd ed. (copyright 1964); *used by* permission *of john* Wiley & *Sons,* Inc.

nesses to an eighth, and so on. The combined effect of the three absorption processes gives the half-thickness curves shown in Figure 2 for three materials, aluminum (Al), copper (Cu), and lead (Pb), for gamma-ray energies up to 6 MeV. Lead is the most effective of the three absorbers at all energies, though the differences among materials are small, in the neighbourhood of 1.7 MeV.

As an example of the use of Figure 2, consider the beta emitter cobalt-60, widely used for cancer radiation therapy and for radiation research generally; the important radiations in this regard are the two gamma rays of 1.173 MeV and 1.332 MeV. It is required to ascertain the thickness of lead shielding for a cobalt-60 shipping container to reduce the gamma-ray flux of the 1.332-MeV photon by a factor of 1,024 ($= 2^{10}$, or ten half-thicknesses). One half-thickness value (about 12 g/cm^2) may be read from the curve for lead for an energy of 1.3 MeV. Then the required ten half-thicknesses are 120 g/cm^2 of lead, or, dividing by the density of 11.3 grams per cubic centimetre, a thickness of 10.6 centimetres is obtained.

NEUTRONS AND NEUTRINOS

Shielding problems for neutrons do not arise in the handling of radioactivity, except for the heaviest materials, such as californium-252, for which there is spontaneous fission with its concomitant emission of fast (about one-MeV) neutrons. Neutron slowing down and absorption, however, is a subject of great importance for the operation of fission reactors and the shielding around nuclear accelerators.

Neutrons, having no charge, do not slow down by ionization. They slow down (are moderated) by a series of collisions with nuclei of the medium (called the moderator). The most effective moderator is ordinary hydrogen, because this nucleus, of all nuclides, is of nearly equal mass to the neutron and can thus take up, on the average, the most energy per collision. The slowing down goes on until the neutrons are thermalized; that is, possess the same average thermal kinetic energy as atoms of the moderator. Before and after thermalization, neutrons are subject to capture by various nuclei, some with large probabilities (usually expressed as an effective cross section in barn units, one barn being 10^{-24} cm^2). Water, paraffin, and concrete are employed commonly for neutron shielding because of their large hydrogen contents. This shielding may be combined with materials containing boron or cadmium for more effective capture of the thermalized neutrons.

To a first approximation, neutrinos do not interact with matter, and therefore shielding cannot be used, nor need there be concern about biological radiation effects. Unusually large and specialized detectors have been built for neutrino study, which have detected a few neutrinos through a process of reverse beta decay.

IV. Energetics and kinetics of radioactivity

ENERGY RELEASE IN RADIOACTIVE TRANSITIONS

Consideration of the energy release of various radioactive transitions leads to the fundamental question of nuclear binding energies and stabilities. A much-used method of displaying nuclear-stability relationships is an isotope chart, those positions on the same horizontal row corresponding to a given proton number (Z) and those on the same vertical column to a given neutron number (N). Such **a** map is shown in Figure **3.** The irregular bold line surrounds the region of presently known nuclei. The area encompassed by this is often referred to as the valley of stability, because the chart may be considered a map of a binding energy surface, the lowest areas of which are the most stable. The most tightly bound nuclei of all are the abundant iron and nickel isotopes. Near the region of the valley containing the heaviest nuclei (largest mass number A; that is, largest number of nucleons, N + Z), the processes of alpha decay and spontaneous fission are most prevalent; both these processes relieve the energetically unfavourable concentration of positive charge in the heavy nuclei.

Along the region which borders on the valley of stability on the upper left-hand side are the positron-emitting and electron-capturing radioactive nuclei, with the energy release and decay rates increasing the farther away the nucleus is from the stability line. Along the lower right-hand border region, beta-minus decay is the predominant process, with energy release and decay rates increasing the farther the nucleus is from the stability line.

The grid lines of the graph are at the nucleon numbers corresponding to extra stability, the "magic numbers," to be treated in the section below on ***Nuclear*** *models.* The circles labelled "deformed regions" enclose regions in which nuclei should exhibit cigar shapes; elsewhere the nuclei are spherical. Outside the dashed lines nuclei would be unbound with respect to neutron or proton loss and would be exceeding short-lived (less than 10^{-19} second).

From Proceedings of the International Conference on Properties of Nuclei Far from the Region of Beta-Stability, Leysin, 1970, (CERN 70-30)

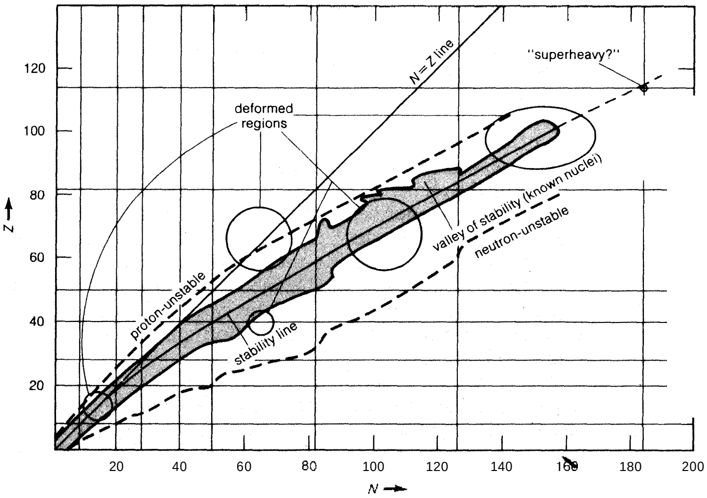

Figure 3: Map of the nuclei.
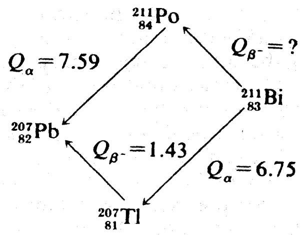
The coordinates are number of neutrons N and number of protons Z. The bold line encloses the region of known nuclei. The dashed lines are estimated limits for barely binding nucleons. The stability line gives the locus of nuclei most stable with respect to beta decay. Nuclei within the circular regions are cigar-shaped; otherwise the nuclei are spherical. The grid line intersections of the graph indicate the closed shell "magic numbers" of extra stability. A possible region of undiscovered longer lived nuclei is indicated as "superheavy?"

Calculation and measurement of energy. By the method of closed energy cycles, it is possible to **use** measured radioactive-energy-release (Q) values for alpha and beta decay to calculate the energy release for unmeasured transitions. An illustration is provided by the cycle of four nuclei below:

Closed energy cycles



In this cycle, energies from two of the alpha decays and one beta decay are measurable. The unmeasured beta-decay energy for bismuth-211, Q_{β^-}(Bi), is readily calculated, because conservation of energy requires the sum of Q values around the cycle to be zero. Thus, Q_{β^-}(Bi) + 7.59 − 1.43 − 6.75 = 0. Solving this equation gives Q_{β^-}(Bi) = 0.59 MeV. This calculation by closed energy cycles can be extended from stable lead-207 back up the chain of alpha and beta decays to its natural precursor uranium-235 and beyond. In this manner the nuclear binding energies of a series of nuclei can be linked together. Because alpha decay decreases the mass number *A* by 4, and beta decay does not change *A*, closed *α–β*-cycle calculations based on lead-207 can link up only those nuclei with mass numbers of the general type *A* = 4n + 3, in which n is an integer. Another, the 4n series, has as its natural precursor thorium-232 and its stable end product lead-208. Another, the 4n + 2 series, has uranium-238 as its natural precursor and lead-206 as its end product.

In the earlier research on natural radioactivity the classification of isotopes into the series cited above was of great significance, for they were identified and studied as families. Newly discovered radioactivities were given symbols relating them to the family and order of occurrence therein. Thus, thorium-234 was known as UX_1, the isomers of protactinium-234 as UX_2 and UZ, uranium-234 as U_{II}, etc. These original symbols and names are sometimes encountered in more recent literature but are mainly of historical interest. The remaining 4n + 1 series is not naturally occurring but comprises well-known artificial activities decaying down to stable thallium-205.

To extend the knowledge of nuclear binding energies it is clearly necessary to make measurements to supplement the radioactivedecay energy cycles. In part, this extension can be made by measurement of Q values of artificial nuclear reactions (see NUCLEUS, ATOMIC). For example, the neutron-binding energies of the lead isotopes necessary to link the energies of the four radioactive families together can be measured by determining the threshold gamma-ray energy to remove a neutron (photonuclear reaction); or the energies of incoming deuteron (nucleus hydrogen-2, denoted by d, of the heavy hydrogen isotope deuterium) and outgoing proton in the reaction, symbolized *d*, p, can be measured to provide this information.

Further extensions of nuclear-binding-energy measurements rely on precision mass spectroscopy (see MASS SPECTROMETRY, PRINCIPLES OF). By ionizing, accelerating, and magnetically deflecting various nuclides, their masses can be measured with great precision. A precise measurement of the masses of atoms involved in radioactive decay is equivalent to direct measurement of the energy release in the decay process. The atomic mass of naturally occurring but radioactive potassium-40 is measured to be 39.964008 amu (atomic mass units). Masses are usually given as the mass of the electrically neutral atom (nucleus plus orbital electrons) on a scale fixed by the carbon-12 atomic mass being'defined as exactly 12 units. Potassium-40 decays predominantly by P-emission to calcium-40, having a measured mass 39.962589. Through Einstein's equation, energy is equal to mass (*m*) times velocity of light (c) squared, or E = *mc*², the energy release (Q) and the mass difference, *Am,* are related, the conversion factor being one amu, equal to 931.478 MeV. Thus, the excess mass of potassium-40 over calcium-40 appears as the total energy release Q_β in the radioactive decay Q_{β^-} = (39.964008 − 39.962589) × 931.478 MeV = 1.31 MeV. The other neighbouring isobar (same mass number, different atomic number) to argon40 is also of lower mass, 39.962384, than potassium-40. This mass difference converted to energy units gives an energy release of 1.5 MeV, this being the energy release for electron-capture decay to argon-40. The maximum energy release for positron emission is always less than that for electron capture by twice the rest mass energy of an electron ($2m_0c^2$ = 1.022 MeV); thus, the maximum positron energy for this reaction is 1.5 − 1.02, or 0.48 MeV.

Energy–mass conversions

To connect alpha-decay energies and nuclear mass differences requires a precise knowledge of the alpha-particle (helium-4) atomic mass. The mass of the parent minus the sum of the masses of the decay products gives the energy release. Thus, for alpha decay of plutonium-239 to uranium-235 and helium-4 the calculation goes as follows:

M (^{239}Pu)	239.05216
−*M* (^{235}U)	−235.04393
−*M* (^{4}He)	− 4.00260
	0.00563 × 931.478

Q_α = 5.24 MeV

By combining radioactive-decay-energy information with nuclear-reaction Q values and precision mass spectroscopy, extensive tables of nuclear masses have been prepared. From them the Q values of unmeasured reactions or decay processes may be calculated.

Alternative to the full mass, the atomic masses may be expressed as mass defect, symbolized by the Greek letter delta, A (the difference between the exact mass M and the integer *A*, the mass number), either in energy units or atomic mass units.

Absolute nuclear binding energy. The absolute nuclear binding energy is the hypothetical energy release if a given nuclide were synthesized from *Z* separate hydrogen atoms and *N* (equal to *A* − *Z*) separate neutrons. An example is the calculation giving the absolute binding energy of the stablest of all nuclei, iron-56.

26 × M (^{1}H)	26 × 1.007825 =	26.20345
30 × *M* (*n*)	30 × 1.008665 =	30.25995
M (^{56}Fe)		− 55.93493

binding energy = 0.52847 × 931.478 = 492.58 MeV

average binding energy per nucleon of ^{56}Fe = 492.58/56 = 8.796 MeV

A general survey of the average binding energy per nucleon (for nuclei of all elements grouped according to ascending mass) shows a maximum at iron-56 falling off gradually on both sides to about 7 MeV at helium-4 and to about 7.4 MeV for the most massive nuclei known. Most of the naturally occurring nuclei are, thus, not stable in an absolute nuclear sense. Nuclei heavier than iron would gain energy by degrading into nuclear products nearer to iron, but it is only for the elements of greatest mass that the rates of degradation processes such as alpha decay and spontaneous fission attain observable rates. In a similar manner, nuclear energy is to be gained by fusion of most elements lighter than iron. The coulombic (electrostatic) repulsion between nuclei, however, keeps the rates of fusion reactions unobservably low unless the nuclei are subjected to temperatures of greater than 10⁷° C. Only in the hot cores of the Sun and stars or in thermonuclear bombs or controlled fusion plasmas are these temperatures reached and nuclear-fusion energy released.

NUCLEAR MODELS

The liquid-drop model. The average behaviour of the nuclear binding energy can be understood with the model of a charged liquid drop. In this model, the aggregate of nucleons has the same properties of a liquid drop, such as surface tension, cohesion, and deformation. There is a dominant attractive-binding-energy term proportional to the number of nucleons *A*. From this must be subtracted a surface-energy term proportional to surface area and a coulombic repulsion energy proportional to the square of the number of protons and inversely proportional to the nuclear radius. Furthermore, there is a symmetry-energy term of quantum-mechanical origin favouring equal numbers of protons and neutrons. Finally, there is a pairing term that gives slight extra binding to nuclei with even numbers of neutrons or protons.

The pairing-energy term accounts for the great rarity of odd-odd nuclei (the terms odd-odd, even-even, even–odd, and odd–even refer to the evenness or oddness of proton number, *Z*, and neutron number, N, respectively) that are stable against beta decay. The sole examples are deuterium, lithium-6, boron-10, and nitrogen-14. A few other odd–odd nuclei, such as potassium-40, occur in nature, but they are unstable with respect to beta decay. Furthermore, the pairing-energy term makes for the larger number of stable isotopes of even-Z elements, compared to odd-Z, and for the lack of stable isotopes altogether in element 43, technetium, and element 61, promethium.

Mirror nuclei

The beta-decay energies of so-called mirror nuclei afford one means of estimating nuclear sizes. For example, the neon and fluorine nuclei, ${}_{10}{}^{19}\mathrm{Ne}_9$ and ${}_{9}{}^{19}\mathrm{F}_{10}$, are mirror nuclei, because the proton and neutron numbers of one of them equal the respective neutron and proton numbers of the other. Thus, all binding-energy terms are the same in each except for the coulombic term, which is inversely proportional to the nuclear radius. Such calculations along with more direct determinations by high-energy electron scattering and energy measurements of X-rays from mu-mesic atoms (hydrogen atoms in which the electrons are replaced by negative mu mesons, a type of fundamental particle) establish the nuclear charge as roughly uniformly distributed in a sphere of radius 1.2 $A^{1/3} \times 10^{-13}$ centimetre. (The length unit 10^{-13} centimetre occurs so commonly in nuclear physics that it has a special symbol, fm, and is known as the fermi, honouring the great pioneer of nuclear science Enrico Fermi.) That the radius is proportional to the cube root of the mass number has the great significance that the average density of all nuclei is nearly constant.

Careful examination of nuclear-binding energies reveals periodic deviations from the smooth average behaviour of the charged-liquid-drop model. An extra binding energy arises in the neighbourhood of certain numbers of neutrons or protons, called "magic numbers." These numbers are 2, 8, 20, 28, 50, 82, and 126. Nuclei such as ${}_2{}^4\mathrm{He}_2$, ${}_8{}^{16}\mathrm{O}_8$, ${}_{20}{}^{40}\mathrm{Ca}_{20}$, ${}_{20}{}^{48}\mathrm{Ca}_{28}$, and ${}_{82}{}^{208}\mathrm{Pb}_{126}$ are especially stable species, doubly magic, in view of their having both proton and neutron numbers magic. These doubly magic nuclei are situated at the intersections of grid lines on Figure 3.

The shell model. In the preceding section the overall trends of nuclear binding energies were described in terms of a charged-liquid-drop model. Yet there were noted periodic binding-energy irregularities at the magic numbers. The periodic occurrence of magic numbers of extra stability is strongly analogous to the extra electronic stabilities occurring at the atomic numbers of the noble-gas (helium, neon, argon, krypton, xenon, and radon) atoms (*i.e.*, 2, 10, 18, 36, 54, 86). The explanations of these stabilities are quite analogous in atomic and nuclear cases as arising from filling of particles into quantized orbitals of motion. The completion of filling of a shell of orbitals is accompanied by an extra stability. The nuclear model accounting for the magic numbers is known as the shell model. The shell model in its simplest form can account for the occurrence of spin zero for all even-even nuclear ground states; the nucleons fill pairwise into orbitals with angular momenta cancelling. The shell model also readily accounts for the observed nuclear spins of the odd-mass nuclei adjacent to doubly magic nuclei, such as ${}_{82}{}^{208}\mathrm{Pb}$. Here, the spins of ½ for neighbouring ${}_{81}{}^{207}\mathrm{Tl}$ and ${}_{82}{}^{207}\mathrm{Pb}$ are accounted for by having all nucleons fill pairwise into the lowest energy orbits and putting the odd nucleon into the last available orbital before reaching the doubly magic configuration (the Pauli exclusion principle dictates that no more than two nucleons may occupy a given orbital, and their spins must be oppositely directed); calculations show the last available orbitals below lead-208 to have angular momentum ½. Likewise, the spins of 9/2 for ${}_{82}{}^{209}\mathrm{Pb}$ and ${}_{83}{}^{209}\mathrm{Bi}$ are understandable, because spin-9/2 orbitals are the next available orbitals beyond doubly magic lead-208. Even the associated magnetization, as expressed by the magnetic dipole moment, is rather well explained by the simple spherical-shell model.

The spherical-shell-mode1 orbitals are labelled in a notation close to that for electronic orbitals in atoms. The orbital configuration of calcium-40 has protons and neutrons filling the following orbitals: $1s_{1/2}$, $1p_{3/2}$, $1p_{1/2}$, $1d_{5/2}$, and $1d_{3/2}$. The letter denotes the orbital angular momentum in usual spectroscopic notation, in which the letters s, p, d, *f*, g, *h*, *i*, etc. represent integer values of *l* running from zero for *s* (not to be confused with spins) through six for *i*. The fractional subscript gives the total angular momentum j with values of $l + ½$ and $l - ½$ allowed, as the intrinsic spin of a nucleon is ½. The first integer is a radial quantum number taking successive values 1, 2, 3, etc., for successively higher energy values of an orbital of given *l* and *j*. Each orbital can accommodate a maximum of 2j + 1 nucleons. Table 3 lists the orbitals comprising each shell, the exact order of various orbitals within a shell differing somewhat for neutrons and protons. The parity associated with an orbital is even (+) if *l* is even (*s*, d, g, i) and odd (—) if *l* is odd (p, *f*, *h*).

Table 3: Spherical-Shell-Model Orbitals

shell closure number	
2	$1s_{1/2}$
8	$1p_{3/2}$, $1p_{1/2}$
20	$1d_{5/2}$, $2s_{1/2}$, $1d_{3/2}$

The ground and lowest excited states of lead-209 are to be associated with occupation by the 127th neutron of the lowest available orbitals above the closed shell of 126. From the last line of Table 3 it is to be noted that there are available $g_{9/2}$, $d_{5/2}$, and $s_{1/2}$ orbitals with which to explain the ground and first two excited states. Low-lying states associated with the $i_{11/2}$ and $j_{15/2}$ orbitals are known from nuclear-reaction studies, but they are not populated in the beta decay.

The 2.13-MeV state that receives the primary beta decay is not so simply interpreted as the others. It is to be associated with promotion of a neutron from the

$3p_{1/2}$ orbital below the 126 shell closure. The density (number per MeV) of states increases rapidly above this excitation, and the interpretations become more complex and less certain.

Doubly magic nuclei

By suitable refinements, the spherical-shell model can be extended further from the doubly magic region. Primarily, it is necessary to drop the approximation that nucleons move independently in orbitals and to invoke a residual force, mainly short-range and attractive, between the nucleons. The spherical-shell model augmented by residual interactions can explain and correlate around the magic regions a large amount of data on binding energies, spins, magnetic moments, and the spectra of excited states.

The unified model. For nuclei more removed from the doubly magic regions, the spherical-shell model encounters difficulty in explaining the large observed electric quadmpole moments indicating cigar-shaped nuclei. For these nuclei a hybrid of liquiddrop and shell models, the unified model, has been proposed. (See the circular regions of Figure 3 for occurrence of cigar-shaped nuclei.)

Nucleons can interact with one another in a collective fashion to deform the nuclear shape to a cigar shape. Such large spheroidal distortions are usual for nuclei far from magic, notably with 150 $\lesssim A \lesssim$ 190, and 224 $\lesssim A$ (the symbol $<$ denotes less than, and $\sim$ means that the number is approximate). In these deformed regions the unified model prescribes that orbitals be computed in a cigar-shaped potential and that the relatively low-energy rotational excitations of the tumbling motion of the cigar shape be taken into account. The unified model has been highly successful in correlating and predicting nuclear properties in the deformed region. An example of a nuclear rotational band (a series of adjacent states) is provided by the decay of the isomer hafnium-180*m* (^{180m}Hf), Figure 4, through a cascade of gamma rays down the ground rotational band (see below ***Gamma transition rates*** for explanation of M2, E1, E2, and *E3).*

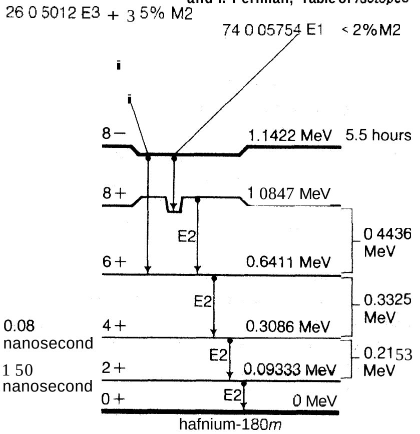

Figure 4: The decay scheme of hafnium-180*m* (^{180m}Hf). See text.

RATES OF RADIOACTIVE TRANSITIONS

There is a vast range of the rates of radioactive decay, from undetectably slow to unmeasurably short. Before presenting detailed consideration of the factors governing particular decay rates, it is well to review the mathematical equations governing radioactive decay and to consider general methods of rate measurement in different ranges of half-life.

Exponential-decay law. Radioactive decay occurs as a statistical exponential rate process. That is, the number of atoms likely to decay in a given infinitesimal time interval (dN/dt) is proportional to the number (N) of atoms present. The proportionality constant, symbolized by the Greek letter lambda, λ, is called the decay constant. Mathematically, this statement is expressed by the first-order differential equation

$$-\frac{dN}{dt} = AN. \tag{1}$$

This equation is readily integrated to give

$$N(t) = N_0 e^{-\lambda t}, \tag{2}$$

in which N_0 is the number of atoms present when time equals zero. From the above two equations it may be seen that a disintegration rate, as well as the number of parent nuclei, falls exponentially with time. An equivalent expression in terms of half-life $t_{1/2}$ is

$$N(t) = N_0(½)^r; r = t/t_{1/2}.$$

It can readily be shown that the decay constant, A, and half-life $(t_{1/2})$ are related as follows: $A = \log_e 2/t_{1/2} = 0.693/t_{1/2}$. The reciprocal of the decay constant λ is the mean life, symbolized by the Greek letter tau, τ.

For a radioactive nucleus, such as potassium-40, that decays by more than one process (89 percent β^-, 11 percent electron capture), the total decay constant is the sum of partial decay constants for each decay mode. (The partial half-life for a particular mode is the reciprocal of the partial decay constant times 0.693.) It is helpful to consider a radioactive chain in which the parent (generation 1) of decay constant λ_1 decays into a radioactive daughter (generation 2) of decay constant λ_2. The case in which none of the daughter isotope (2) is originally present yields an initial growth of daughter nuclei followed by its decay. The equation giving the number (N_2) of daughter nuclei existing at time t in terms of the number $N_1(0)$ of parent nuclei present when time equals zero is

$$N_2(t) = \lambda_1 N_1(0)\,\frac{e^{-\lambda_1 t} - e^{-\lambda_2 t}}{\lambda_2 - \lambda_1}, \tag{3}$$

in which e represents the logarithmic constant 2.71828.

Radio-active decay chain

The general equation for a chain of n generations with only the parent initially present (when time equals zero) is as follows:

$$N_n(t) = N_1(0)\,(C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t}$$
$$+ \ldots .\, C_n e^{-\lambda_n t})\lambda_1\lambda_2 \ldots \lambda_{n-1}, \tag{4}$$

in which ***e*** represents the logarithmic constant 2.71828.

$$C_1 = 1/(\lambda_2 - \lambda_1)\,(\lambda_3 - \lambda_1) \ldots (\lambda_n - \lambda_1),$$

$$C_2 = 1/(\lambda_1 - \lambda_2)\,(\lambda_3 - \lambda_2) \ldots (A_{,,} - \lambda_2),$$

$$C_n = 1/(\lambda_1 - \lambda_n)\,(\lambda_2 - \lambda_n) \ldots (\lambda_{n-1} - \lambda_n)$$

These equations can readily be modified to the case of production of isotopes in the steady neutron flux of a reactor or in a star. In such cases the chain of transformations might be mixed with some steps occurring by neutron capture and some by radioactive decay. The neutron-capture probability for a nucleus is expressed in terms of an effective cross-sectional area. If one imagines the nuclei replaced by spheres of the same cross-sectional area, the rate of reaction in a neutron flux would be given by the rate at which neutrons strike the spheres. The cross section is usually symbolized by the Greek letter sigma, σ, with the units of barns (10^{-24} cm^2) or millibarns (10^{-3} b) or microbarns (10^{-6} b). Neutron flux is often symbolized by the letters nv (neutron density, n, or number per cubic centimetre, times average speed, v) and given in neutrons per square centimetre per second.

The modification of the transformation equations merely involves substituting the product $nv\sigma_i$ in place of λ_i for any step involving neutron capture rather than radioactive decay. Reactor fluxes nv even higher than 10^{15} neutrons per square centimetre per second are available in several research reactors, but usual fluxes are somewhat lower by a factor of 1,000 or so. Tables of neutron-capture cross sections of the naturally occurring nuclei and some radioactive nuclei can be used for calculation of isotope production rates in reactors.

Measurement of half-life. The measurement of half-lives of radioactivity in the range of seconds to a few years commonly involves measuring the intensity of radiation at successive times over a time range comparable to the half-life. The logarithm of the decay rate is plotted against time, and a straight line is fitted to the points. The time interval for this straight-line decay curve to fall by a factor of 2 is read from the graph as the half-life, by virtue of equations (1) and (2). If there is more than one activity present in the sample, the decay curve will not be a straight line over its entire length, but it should be resolvable graphically (or by more sophisticated statistical analysis) into sums and differences of straight-line exponential terms. The general equations (4) for chain decays show a time dependence given by sums and differences of exponential terms, though special modified equations are required in the unlikely case that two or more decay constants are identically equal.

Decay curve for two or more activities

For half-lives longer than several years it is usually not feasible to measure sufficiently accurately the decrease in counting rate over a reasonable length of time. In such cases a measurement of specific activity may be resorted to. That is, a carefully weighed amount of the radioactive isotope is taken for counting measurements to determine the disintegration rate, D. Then by equation (1) the decay constant λ_i may be calculated. Alternately, it may be possible to produce the activity of interest in such a way that the number of nuclei, N, is known, and again with a measurement of D equation (I) may be used. The number of nuclei, N, might be known from counting the decay of a parent activity or from knowledge of the production rate by a nuclear reaction in a reactor or accelerator beam.

Half-lives in the range of 100 microseconds to one nanosecond are usually measured electronically in coincidence experiments. The radiation giving birth to the species of interest is detected to provide a start pulse for an electronic clock, and the radiation by which the species decays is detected in another detector to provide a stop pulse. The distribution of these time intervals is plotted semi-logarithmically, as discussed for the usual decay-rate treatment, and the half-life is determined from the slope of the straight line.

Half-lives in the range of 100 microseconds to one second must often be determined by special techniques. For example, the activities produced may be deposited on rapidly rotating drums or moving tapes, with detectors positioned along the travel path. The activity may be produced so as to travel through a vacuum at a known velocity and the disintegration rate measured as a function of distance, but this method usually applies to shorter half-lives in or beyond the range of the electronic circuit.

Species with half-lives shorter than the electronic measurement limit are not considered as separate radioactivities, and the various techniques of determining their half-lives will hence not be cited here.

Decay-rate considerations for various types of radioactivity will now be given in the same order as listed above in the section *Types of radioactivity.*

Alpha ***decay.*** Alpha decay, the emission of helium ions, exhibits sharp line spectra when spectroscopic measurements of the alpha-particle energies are made. For even–even alpha emitters the most intense alpha group or line is always that leading to the ground state of the daughter. Weaker lines of lower energy go to excited states, and there are frequently numerous lines observable. The alpha spectrum of curium-242 is shown in Figure 5.

The main decay group of even–even alpha emitters exhibits a highly regular dependence on the atomic number, ***Z,*** and the energy release, Q. (Total alpha energy release, ***Q,,*** is equal to alpha-particle energy, E_{α}, plus daughter recoil energy needed for conservation of momentum; $E_{recoil} = (m_{\alpha}/[m_{\alpha} + M_d])E_{\alpha}$, with m, equal to the mass of the alpha particle and M_d the mass of the daughter product.) As early as 1911, the German physicist Johannes Wilhelm Geiger, together with the British physicist John Mitchell Nuttall, noted the regularities of rates for even-even nuclei and proposed a remarkably successful equation for the decay constant, log $\lambda = a +$ b log r, in which r is the range in air, b is a constant, and ***a*** is given different values for the different radioactive series. The decay constants of odd alpha emitters (odd ***A*** or odd Z or both) are not quite so regular and may be much smaller. The values of the constant b that were used by Geiger and Nuttall implied a roughly 90th-power dependence of λ on Q_{α}. There is a tremendous range of known half-lives from the 2 × 10^{15} years of $_{60}{}^{144}$**Nd** (neodymium) with its 1.83-MeV alpha-particle energy (E,) to the 0.3 microsecond of $_{84}{}^{212}$**Po** (polonium) with E, = 8.78 MeV.

Geiger–Nuttall law

From I. Perlman, F. *Asaro,* and *S.G.* Thompson, *Physical Review,* vol. 92, p. **694** (1953)

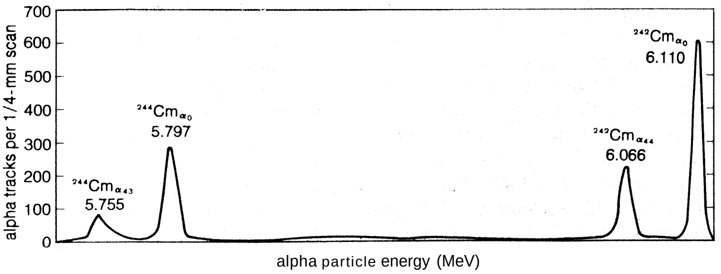

Figure 5: Spectrum of curium-242 and curium-244, showing relative peak intensities for principal alpha particle groups. Ground state alpha groups are labelled α_0.

The theoretical basis for the Geiger–Nuttall empirical rate law remained unknown for 17 years, until the formulation of wave mechanics. A dramatic early success of wave mechanics was the quantitative theory of alpha-decay rates. One of the curious features of wave mechanics is that particles may have a nonvanishing probability of being in regions of negative kinetic energy. In classical mechanics a ball that is tossed to roll up a hill will slow down until its gravitational potential energy equals its total energy, and then it will roll back toward its starting point. In quantum, or wave, mechanics the ball has a certain probability of tunnelling through the hill and popping out on the other side. For objects large enough to be visible to the human eye, the probability of tunnelling through energetically forbidden regions is unobservably small. For submicroscopic objects like alpha particles, nucleons, or electrons, however, quantum mechanical tunnelling can be an important process—as in alpha decay.

The logarithm of tunnelling probability on a single collision with an energy barrier of height B and thickness D is a negative number proportional to thickness D, to the square root of the product of B and particle mass *m.* The size of the proportionality constant will depend on the shape of the barrier and will depend inversely on Planck's constant h (see the article MECHANICS, QUANTUM).

Tunnelling of alpha particles

In the case of alpha decay, the electrostatic repulsive potential between alpha particle and nucleus generates an energetically forbidden region, or potential barrier, from the nuclear radius out to several times this distance. The maximum height (B) of this alpha barrier is given approximately by the expression $B = 2Ze^2/R$, in which Z is the charge of the daughter nucleus, *e* is the elementary charge in electrostatic units, and R is the nuclear radius. Numerically, B is roughly equal to $2Z/A^{1/3}$, with ***A*** the mass number and B in energy units of MeV. Thus, although the height of the potential barrier for $_{84}{}^{212}$**Po** decay is nearly 28 MeV, the total energy released is Q, = 8.95 MeV. The thickness of the barrier (***i.e.,*** distance of the alpha particle from the centre of the nucleus at the moment of recoil) is about twice the nuclear radius of 8.8 × 10^{-13} centimetre. The tunnelling calculation for the transition probability (P) through the barrier gives approximately

$$P = \exp\left[\left(-\frac{\sqrt{2MB}\,R}{\hbar}\right)\left(\frac{\pi B^{1/2}}{Q^{1/2}} - 4\right)\right], \qquad (5)$$

in which M is the mass of the alpha particle and ***A*** is Planck's constant ***h*** divided by 2π. By making simple assumptions about the frequency of the alpha particle striking the barrier, the penetration formula (5) can be used to calculate an effective nuclear radius for alpha decay. This method was one of the early ways of estimating nuclear sizes. In more sophisticated modern techniques the radius value is taken from other experiments, and alpha-decay data and penetrabilities are used to calculate the frequency factor.

The form of equation (5) suggests the correlation of decay rates by an empirical expression relating the half-life ($t_{1/2}$) of decay in seconds to the release energy (Q_α) in MeV:

$$\log t_{1/2} = \frac{a}{\sqrt{Q_\alpha}} + b. \qquad (6)$$

Values of the constants a and b that give best fits to experimental rates of even–even nuclei with neutron number greater than 126 are given in Table 4. The nuclei with 126 or fewer neutrons decay more slowly than the heavier nuclei, and constants a and b must be readjusted to fit their decay rates.

Table 4: Semi-empirical Constants*

	a	*b*

84 polonium (Po)	129.35	–49.9229

*From correlation of ground-state decay rates of even–even nuclei with N > 126. See equation (6) in text.

The alpha-decay rates to excited states of even-even nuclei and to ground and excited states of nuclei with odd numbers of neutrons, protons, or both may exhibit retardations from equation (6) rates ranging to factors of thousands or more. The factor by which the rate is slower than the rate formula (6) is called the hindrance factor. The existence of uranium-235 in nature rests on the fact that alpha decay to the ground and low excited states exhibits hindrance factors of more than 1,000. Thus, the uranium-235 half-life is lengthened to 7 × 10^8 years, a time barely long enough compared to the age of the elements in the solar system for uranium-235 to exist in nature today.

The alpha hindrance factors are fairly well understood in terms of the orbital motion of the individual protons and neutrons that make up the emitted alpha particle. The alpha-emitting nuclei heavier than radium are considered to be cigar-shaped, and alpha hindrance factor data have been used to infer the most probable zones of emission on the nuclear surface—whether polar, equatorial, or intermediate latitudes.

Alpha-decay rates are also a sensitive measure of the tendency of nucleons to pair or cluster in nuclei, and a considerable amount of information about pairing has been deduced therefrom.

The weak interaction

Beta decay. The processes separately introduced at the beginning of this article as beta-minus decay, beta-plus decay, and orbital electron capture can be appropriately treated together. They all are processes whereby neutrons and protons may transform to one another by what is called weak interaction. In striking contrast to alpha decay, the electrons (minus or plus charged) emitted in beta-minus and beta-plus decay do not exhibit sharp, discrete energy spectra but have distributions of electron energies ranging from zero up to the maximum energy release, Q_β. Furthermore, careful measurements of heat released by beta emitters (most radiation stopped in surrounding material is converted into heat energy) show a substantial fraction of the energy, Q_β, is missing. These observations, along with other considerations involving the spins or angular momenta of nuclei and electrons, led an Austrian physicist, Wolfgang Pauli, in 1931 to postulate the simultaneous emission of the neutrino. The neutrino, as a light and uncharged particle with nearly no interaction with matter, was supposed to carry off the missing heat energy. Today, neutrino theory is well accepted with the elaboration that there are four kinds of neutrinos, the electron neutrino and mu neutrino and corresponding antineutrinos of each. The electron neutrinos are involved in nuclear beta-decay transformations, and the mu neutrinos are encountered in decay of muons (mu mesons) to electrons (see further PARTICLES, SUBATOMIC).

Although in general the more energetic the beta decay the shorter is its half-life, the rate relationships do not show the clear regularities of the alpha-decay dependence on energy and atomic number.

The first quantitative rate theory of beta decay was given by Fermi in 1934, and the essentials of this theory form the basis of modern theory. As an example, in the simplest beta-decay process, a free neutron decays into a proton (p), a negative electron (*e*-), and an antineutrino (symbolized by the Greek letter nu with a superior bar; $\bar{\nu}$): $n \rightarrow p + e^- + \bar{\nu}$. The weak interaction responsible for this process, in which there is a change of species (*n* to *p*). by a nucleon with creation of electron and antineutrino, is characterized in Fermi theory by a universal constant, g. The sharing of energy between electron and antineutrino is governed by statistical probability laws giving a probability factor for each particle proportional to the square of its linear momentum (defined by mass times velocity for speeds much less than the speed of light and by a more complicated. relativistic relation for faster speeds). The overall probability law from Fermi theory gives the probability per unit time per unit electron energy interval, *P*(W), as follows:

$$P(W) = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7}\, W(W^2-1)^{1/2}(W_0-W)^2, \qquad (7)$$

in which W is the electron energy in relativistic units ($W = 1 + E/m_0c^2$) and W_0 is the maximum ($W_0 = 1 + Q_\beta/m_0c^2$), m_0 the rest mass of the electron, c the speed of light, and h Planck's constant. This rate law expresses the neutron beta-decay spectrum in good agreement with experiment, the spectrum falling to zero at lowest energies by the factor W and falling to zero at the maximum energy by virtue of the factor $(W_0 - W)^2$.

In Fermi's original formulation the spins of an emitted beta and neutrino are opposing and so cancel to zero. Later work showed that neutron beta decay partly proceeds with the ½$\hbar$ spins of beta and neutrino adding to one unit of *A* (Planck's constant divided by 2π). The former process is known as Fermi decay (F) and the latter Gamow–Teller (GT) decay, after the Russian–born George Gamow and the Hungarian–born Edward Teller, the physicists first proposing it. The interaction constants are determined to be in the ratio $g_{GT}^2/g_F^2 =$ 1.4. Thus, g^2 in equation (7) should be replaced by $(g_F^2 + g_{GT}^2)$.

Gamow–Teller decay

The scientific world was shaken in 1957 by the measurement in beta decay of maximum violation of the law of conservation of parity. The meaning of this nonconservation in the case of neutron beta decay considered above is that the preferred direction of electron emission is opposite to the direction of the neutron spin of ½$\hbar$. (The direction of nuclear spin is an arrow upward in the direction of the thumb of one's right hand, in which the extended fingers point in the direction of rotation). By means of a magnetic field and low temperature it is possible to cause neutrons in cobalt-60 and other nuclei, or free neutrons, to have their spins set preferentially in the up direction perpendicular to the plane of the coil generating the magnetic field. The fact that beta decay prefers the down direction for spin means that the reflection of the experiment as seen in a mirror parallel to the coil represents an unphysical situation: conservation of parity, obeyed by most physical processes, demands that experiments with positions reversed by mirror reflection should also occur. Further consequences of parity violation in beta decay are that spins of emitted neutrinos and electrons are directed along the direction of flight, totally so for neutrinos and partially so by the ratio of electron speed to the speed of light for electrons.

The overall half-life for beta decay of the free neutron, measured as 12 minutes, may be related to the interaction constants g^2 (equal to $g_F^2 + g_{GT}^2$) by integrating (summing) probability expression (7) over all possible electron energies from zero to the maximum. The result for the decay constant is

$$\lambda = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7}\left\{(W_0^2-1)^{1/2}\left(\frac{W_0^4}{30}-\frac{3W_0^2}{20}-\frac{2}{15}\right)+ \right.$$
$$\left. +\frac{W_0}{4}\ln[W_0+(W_0^2-1)^{1/2}]\right\}, \qquad (8)$$

in which W_0 is the maximum beta-particle energy in relativistic units ($W_0 = 1 + Q_\beta/m_0c^2$), with m_0 the rest mass of the electron, c the speed of light, and h Planck's constant. The best g value from decay rates is approximately 10^{-49} erg centimetre^3. As may be noted from equation (8), there is a limiting fifth-power energy dependence for highest decay energies.

Beta spectra decay

In the case of a decaying neutron not free but bound within a nucleus, the above formulas must be modified. First of all, as the nuclear charge Z increases, the relative probability of low-energy electron emission increases by virtue of the coulombic attraction. For positron emission, which is energetically impossible for free protons but can occur for bound protons in proton-rich nuclei, the nuclear coulomb charge suppresses lower energy positrons from the shape given by equation (7). This equation can be corrected by a factor $F(Z,W)$ depending on the daughter atomic number Z and electron energy W. The factor can be calculated quantum mechanically. The coulomb charge also affects the overall rate expression (8) such that it can no longer be expressed as an algebraic function, but tables and graphs are available for analysis of beta decay rates. The rates are analyzed in terms of a function $f(Z,Q_\beta)$ calculated by integration of equation (7) with correction factor $F(Z,W)$. The β^- and β^+ spectra of copper-64 are shown in Figure 6.

From G. Friedlander, J.W. Kennedy. J.M. Miller. *Nuclear and Radiochemistry*, 2nd ed. (copyright 1964); used by permission of John Wiley & Sons. Inc.

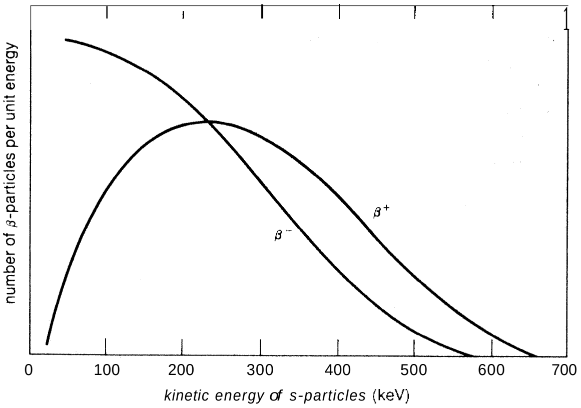

Figure 6: β^- and β^+ spectra cf copper-64.

Approximate expressions for the f functions usable for decay energies Q between 0.1 MeV and 10 MeV, in which Q is measured in MeV, and Z is the atomic number of the daughter nucleus, are as follows (the symbol ≈ means approximately equal to):

$$f_{\beta^-} \approx 6.0Q^{4-0.005(Z-1)}\cdot 10^{Z/50},$$

$$f_{\beta^+} \approx 6.2Q^4/10^{0.007Z}\cdot 10^{0.009Z(\log 1/3Q)^2}.$$

For electron capture, a much weaker dependence on energy is found:

$$f_{EC} \approx (Z+1)^{3.5}Q/4\times 10^5 .$$

The basic beta decay rate expression obeyed by the class of so-called superallowed transitions, including decay of the neutron and several light nuclei. is

$$\lambda_\beta = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7} f_\beta \qquad (9)$$

Like the ground-to-ground alpha transitions of even–even nuclei, the superallowed beta transitions obey the basic rate law, but most beta transitions go much more slowly. The extra retardation, as with alpha hindrance, is explained in terms of mismatched orbitals of neutrons and protons involved in the transition. For the superallowed transitions the orbitals in initial and final states are almost the same. Most of them occur between mirror nuclei, with one more or less neutrons than protons; *i.e.,* beta minus decay of hydrogen-3, electron capture of beryllium-7 and positron emission of carbon-11, oxygen-15, neon-19, . . . titanium-43.

The nuclear retardation of beta decay rates below those of the superallowed class may be expressed in a fundamental way by multiplying the right side of equation (9) by the square of a nuclear matrix element (a quantity of quantum mechanics), which may range from unity down to zero depending on the degree of mismatch of initial and final nuclear states of internal motion. A more usual way of expressing the nuclear factor of the beta rate is the log ft value, in which f refers to the function $f(Z,Q_\beta)$. Because the half-life is inversely proportional to the decay constant λ, the product $f_\beta t_{1/2}$ will be a measure of (inversely proportional to) the square of the nuclear matrix element. For the log ft value, the beta half-life is taken in seconds, and the ordinary logarithm to the base 10 is used. The superallowed transitions have log ft values in the range of 3 to 3.5. Beta log ft values are known up to as large as —23 in the case of indium-115. There is some correlation of log ft values with spin changes between parent and daughter nucleons, the indium-115 decay involving a spin change of four, whereas the superallowed transitions all have spin changes of zero or one. Various classifications according to spin change may be made for beta decay (allowed, first forbidden, second forbidden, etc.).

Beta *ft* values

Gamma transition. The nuclear gamma transitions belong to the large class of electromagnetic transitions, encompassing radio frequency emission by antennas or rotating molecules, infrared emission by vibrating molecules or hot filaments, visible light, ultraviolet light, and X-ray emission by electronic jumps in atoms or molecules. The usual relations apply for connecting frequency ν, wavelength λ, and photon quantum energy E with speed of light c and Planck's constant h, namely, $\lambda = c/\nu$ and $E = h\nu$. It is sometimes necessary to consider the momentum (p) of the photon given by $p = E/c$.

Classically, radiation accompanies any acceleration of electrical charge. Quantum mechanically there is a probability of photon emission from higher to lower energy nuclear states, in which the internal state of motion involves acceleration of charge in the transition. Thus, purely neutron orbital acceleration would carry no radiative contribution.

A great simplification in nuclear gamma transition rate theory is brought about by the circumstance that the nuclear diameters are always much smaller than the shortest wavelengths of gamma radiation in radioactivity. That is, the nucleus is too small to be a good antenna for the radiation. The simplification is that nuclear gamma transitions can be classified according to multipolarity, or amount of spin angular momentum carried off by the radiation. One unit of angular momentum in the radiation is associated with dipole transitions (a dipole consists of two separated equal charges, plus and minus). If there is a change of nuclear parity, the transition is designated electric dipole (E1) and is analogous to the radiation of a linear half-wave dipole radio antenna. If there is no parity change, the transition is magnetic dipole (M1) and is analogous to the radiation of a full-wave loop antenna. With two units of angular momentum change the transition is electric quadrupole (E2), analogous to a full-wave linear antenna of two dipoles out-of-phase, and magnetic quadrupole (M2), analogous to coaxial loop antennas driven out-of-phase. Higher multipolarity radiation also frequently occurs with radioactivity.

Multipolarities are experimentally measured by angular dependence of radiation or by ratios of orbital electron ejection to photon emission (internal conversion).

Transition rates are usually compared to the single-proton theoretical rate, or Weisskopf formula, named after a United States physicist, Victor Frederick Weisskopf, who developed it. Table 5 gives the theoretical

Table 5: Gamma Transition Rates*

transition type	partial half-life *t* (seconds)	illustrative t_γ valuer for $A = 125, E = 0.1$ MeV (seconds)
E1	$5.7 \times 10^{-15} E^{-3} A^{-2/3}$	2×10^{-13}
E2	$6.7 \times 10^{-9} E^{-5} A^{-4/3}$	1×10^{-6}
E3	$1.2 \times 10^{-2} E^{-7} A^{-2}$	8
E4	$3.4 \times 10^{4} E^{-9} A^{-8/3}$	9×10^{7}
E5	$1.3 \times 10^{11} E^{-11} A^{-10/3}$	1×10^{15}
M1	$2.2 \times 10^{-14} E^{-3}$	2×10^{-11}
M2	$2.6 \times 10^{-8} E^{-5} A^{-2/3}$	1×10^{-4}
M3	$4.9 \times 10^{-2} E^{-7} A^{-4/3}$	8×10^{2}
M4	$1.3 \times 10^{5} E^{-9} A^{-2}$	8×10^{9}
M5	$5.0 \times 10^{11} E^{-11} A^{-8/3}$	1×10^{17}

*The energies *E* are expressed in MeV. The nuclear radius has been taken as 1.3 fermis. It is tu be noted that t_γ is the partial half-life for γ emission only; the occurrence of internal conversion will always shorten the measured half-life.

reference rate formulas in their dependence on nuclear mass number ***A*** and gamma ray energy Eγ (in MeV).

It is seen for the illustrative case of gamma energy 0.1 MeV and mass number 125 that there occurs an additional factor of 10^7 retardation with each higher multipole order. For a given multipole, magnetic radiation should be a factor of 100 or so slower than electric. These rate factors generally ensure that nuclear gamma transitions are nearly purely one multipole, the lowest permitted by the nuclear spin change. There are numerous exceptions, however; mixed M1–E2 transitions are common, because E2 transitions are often much faster than the Weisskopf formula gives and M1 transitions are generally slower. All E1 transitions encountered in radioactivity are much slower than the Weisskopf formula. The other higher multipolarities show some scatter in rates, ranging from agreement to considerable retardation. In most cases the retardations are well understood in terms of nuclear model calculations.

Electric monopole transitions

Though not literally a gamma transition, electric monopole (EO) transitions may appropriately be mentioned here. These may occur when there is no angular momentum change between initial and final nuclear states and no parity change. For spin-zero to spin-zero transitions, single gamma emission is strictly forbidden. The electric monopole transition occurs largely by the ejection of electrons from the orbital cloud in heavier elements and by positron–electron pair creation in the lighter elements.

V. Applications of radioactivity

MEDICAL APPLICATIONS

Radioisotopes have found extensive use in medical therapy. Radium-226 and its radon daughter have been used since early days of radiology as radiation sources to arrest development of cancer. These isotopes are now largely replaced by cobalt-60. Many medical applications use isotopes not as radiation sources but as tracers localizing in particular organs and giving diagnostic information. In a 1969 speech, U.S. nuclear chemist Glenn T. Seaborg, then chairman of the U.S. Atomic Energy Commission, summarized the status of medical applications noting that cobalt-60 (and to some extent cesium-137) was used to treat cancer and as a suppressant of the immune reaction occurring after the transplanting of human organs; iodine-131 (and in some cases other radioactive iodine isotopes, such as iodine-125) was used to diagnose various thyroid disorders, treat hyperthyroidism and functional metastatic thyroid cancer, diagnose kidney and liver disorders and make tests of the functioning of these organs, screen for pulmonary emboli by lung scans, locate tumours, and make blood-volume and cardiac-output studies; carbon-14 was used to study abnormalities of metabolism that underlie diabetes, gout, anemia, and acromegaly; gallium-68, strontium-85, strontium-87*m*, fluorine-18, and calcium-47 were used for bone scanning in suspected metabolic disorders and malignancies; chromium-51, to measure cell mass; arsenic-74, to locate brain tumours; yttrium-90, for treating pituitary gland disorders; gold-198, as a palliative in lung cancer; mercury-197 and mercury-203, for renal function tests; selenium-75 (selenomethionine), to scan the pancreas for cancer detection; sodium-22 and sodium-24, to measure exchangeable sodium and diagnose circulatory disorders; phosphorus-32, to treat the blood disorders polycythemia vera and chronic leukemias, and in some cases even bone cancer; iron-59 and iron-55, to measure the rate of formation of red-cell mass, red-cell survival times, and intestinal absorption rates; and cobalt-57 (and cobalt-60), for vitamin B_{12} absorption tests. Combinations of radioisotopes are used in many applications, such as the measurement of red blood cells and plasma volume for the control of blood transfusions. Seaborg also noted the uses of six-hour technetium-99*m*, widely used for its nearly ideal properties in diagnosing thyroid, liver, brain, and kidney diseases.

As more hospitals acquire low power isotope production reactors or cyclotrons, the medical use of a wide range of short-lived isotopes is increasing. Table 6 lists some medically useful short-lived isotopes.

Table 6: Some Medically Useful Short-lived Gamma-emitting Isotopes

	isotope	half-life (hours)
Sodium	^{24}Na	15.0
Magnesium	^{28}Mg	21.0
Silicon	^{31}Si	2.6
Potassium	^{42}K	12.5
Calcium	^{47}Ca	113.0
Manganese	^{56}Mn	2.6
Nickel	^{65}Ni	2.6
Zinc	^{69m}Zn	13.8
Gallium	^{72}Ga	14.0
Arsenic	^{76}As	26.0
Bromine	^{82}Br	36.0
Strontium	^{87m}Sr	2.8
Molybdenum	^{99}Mo	67.0
Technetium	^{99m}Tc	6.0
Iodine	^{123}I	13.0
Iodine	^{130}I	12.5
Barium	^{137m}Ba	0.043
Lanthanum	^{140}La	40.0
Praseodymium	^{142}Pr	19.2
Dysprosium	^{165}Dy	2.3
Tungsten	^{187}W	24.0
Mercury	^{197}Hg	65.0

Positron diagnostics

Positron emitters offer special possibilities in diagnostic scanning of radioactive tracer movement in the body, for positrons rapidly annihilate with electrons in matter. The annihilation is usually accompanied by emission of two penetrating (0.51 MeV) gamma rays in opposite directions. Two counters on opposite sides of the body recording coincidences (simultaneous arrival of two gammas) can more sharply and efficiently locate the position of the tracer activity than can scanners based on measurement of a single gamma ray. Positron emitters generally cannot be produced in reactors and require charged particle accelerators such as cyclotrons. A table of medically useful positron emitters is given in Table 7.

Table 7: Some Medically Useful Positron Emitting Isotopes Produced by Cyclotrons

	isotope	half-life
Carbon*	^{11}C	20 minutes
Nitrogen	^{13}N	10 minutes
Oxygen	^{15}O	2 minutes
Fluorine*	^{18}F	1.9 hours
Sodium	^{22}Na	2.6 years
Chromium	^{49}Cr	42 minutes
Iron	^{52}Fe	8.3 hours
Cobalt	^{55}Co	18.2 hours
Copper*	^{64}Cu	12.8 hours
Gallium	^{68}Ga	1.1 hours
Arsenic	^{72}As	1.1 days
Arsenic	^{74}As	17.5 days
Technetium	^{94}Tc	54 minutes
Iodine	^{124}I	4.5 days

*Can also be produced in a reactor.

INDUSTRIAL APPLICATIONS

Foremost in applications is the nuclear energy industry based on release of fission energy of uranium through neutron chain reacting reactors. This application is extensively treated in other articles (see NUCLEAR FISSION and NUCLEAR REACTOR).

There are many industrial applications of radioisotopes in measurements of thickness of metal or plastic sheets by absorption of radiation, or in density measurements by backscattering of radiation. Radioisotopes may be used in place of large X-ray machines for X-ray examinations of manufactured metal parts.

Rapid nondestructive analysis of solid materials for the elements composing them can be quickly made by X-ray fluorescence analysis for all but the five lightest elements. The material is exposed to low-energy gamma radiation and the resulting X-rays from the material are detected by an energy-sensitive detector like lithium-drifted silicon or germanium. The elements are measured by the intensity of their characteristic X-rays.

A highly sensitive method of analysis for a number of elements is neutron activation analysis. The material is irradiated with neutrons and the resulting radioactivities are identified as a measure of the elements present in the sample.

OTHER APPLICATIONS

Radioactive isotopes are mixed with fluorescent paints in order to provide the energy for luminous signs or watch dials. Tritium is increasingly being used because of its lack of gamma radiation; it is rapidly replacing radium and thorium.

Because of the constancy in half-life, radioactivities can serve as clocks for a wide variety of scientific deductions. In geochronology and cosmochronology various radioactivities have served to determine the ages of various minerals, the age of the Earth itself, and the time that has passed since the stellar formation of the elements (see DATING, RELATIVE AND ABSOLUTE).

Radioactive isotopes alone can provide small and compact sources of electrical power. The 86-year alpha emitter, plutonium-238, has served as a compact heat source, with negligible radiation outside thin shielding, generating electricity through thermoelectric junction circuits. The 18-year curium-244 and strontium-90 are also promising in these applications.

(J.O.R.)

Radio-Frequency Heating

Radio-frequency heating is the process of heating materials by exposing them to the output of a radio-frequency generator operating at frequencies above 70,000 cycles per second (hertz). This type of heating can be generated exactly where desired to the exclusion of other areas, making the technique essentially efficient.

Radio-frequency heating can be broken down into two groups: inductive heating, which is used for heating metals and other materials that are good conductors of electricity, and dielectric (capacitance) heating, which is used for materials that are poor conductors of electricity, such as insulators. Both techniques have broad applications in industry.

INDUCTION HEATING

Operating principles. Induction-heating technology is based on the fact that electromagnetic energy can be transmitted very efficiently over relatively short distances (up to a few centimetres) without benefit of conductors. Investigative work on this phenomenon was begun in 1935, and studies undertaken at that time provided the foundation for several efficient heating methods now used extensively in various technological processes.

In induction heating, the material to be heated, which must be a fairly good conductor of electricity, is placed in a high-frequency electromagnetic field generated by a conductor or coil (usually called the inductor) connected to a high-frequency generator. This field causes electrical currents (eddy currents) to be excited or induced in the regions of the material located within the field of the inductor. These eddy currents heat up the material; the amount of heat produced depends on the magnitude of the induced currents, the resistance of the material to the flow of electrical current, and the length of time the material is in the field.

During heating, the inductor, usually made of copper tubing, is kept cool by passing water through it. The heated object is located a fraction of a centimetre to several centimetres from the inductor, depending on the technological requirements and the shape of the product, and nowhere does it make contact with the inductor.

"Skin effect"

A phenomenon known as the "surface effect," or "skin effect," causes uneven distribution of alternating current over the cross section of the object being heated and must be allowed for in induction-heating technology. As the frequency of the generator is increased, the induced currents tend to crowd to the surface of the heated material and drop off very rapidly towards the interior. The heat developed in the material follows the same pattern, as the heating is a direct result of the eddy currents.

For practical calculations a procedure based on several assumptions, although slightly reducing the accuracy of the results, is used extensively in high-frequency heating technology. The calculation is based on the equation:

$$p = 5.03 \,.\, 10^4 \sqrt{\rho/\mu f} \text{ millimetres} \qquad (1)$$

in which p is a factor indicating the depth of current penetration, p the electrical resistivity, μ the magnetic permeability of the material with respect to air or vacuum, and f the operating frequency in cycles per second.

As temperature increases p and μ change markedly, and this in turn results in an increase in the depth of penetration of the current. The specific resistance p of steel increases during heating; for example, in the 20"–1,000" C (70°–1,800° F) temperature range, the specific resistance of low-alloy steel increases nearly tenfold. Magnetic permeability μ of steel depends on the intensity of the electromagnetic field created by the inductor and the chemical composition and structure of the steel. Magnetic permeability drops sharply at a critical temperature known as the Curie point and remains close to unity with any further increase in temperature. For example, the Curie point of carbon eutectoid steel containing 0.83 percent carbon is 729° C (1,344" F), while the magnetic properties of pure iron vanish at 768° C (1,414" F). Nonmagnetic steels of the austenite class, which have a constant $\mu = 1$ that does not depend on temperature, are exceptions.

Curie point

As can be seen from Equation 1, the increase in resistivity and the decrease in permeability as the temperature increases both contribute to an increase in the depth of penetration. The depth of penetration for low-alloy structural steel, for example, increases nearly 30-fold in the 20"–1,000" C temperature range.

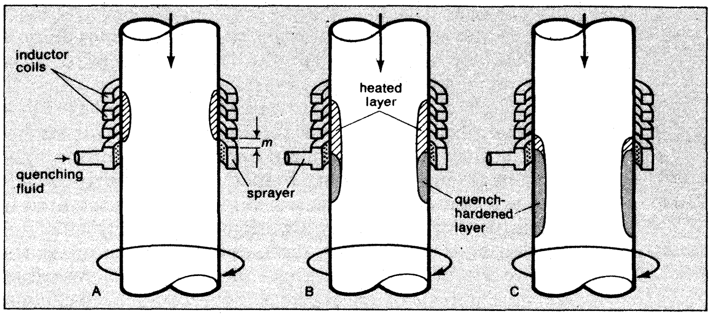

Figure 1: Induction heating and quench hardening of the surface of a rotating cylindrical shaft (see text).

Adapted from M.G. Lorinskii, *Industrial Applications* of *Induction Heating* (1970); Pergamon Press Ltd.

Applications. Induction heating permits the efficient completion of such technological tasks as: (1) case hardening of the working surfaces of steel products; (2) through heating (heating clear through the material as opposed to surface heating) of billets or individual zones of bars for stampings and forgings; (3) heating for soldering with hard and soft solder, permitting manufacture of complete assemblies from individual parts; (4) tempering and annealing of selected portions of a part or component; (5) fusion of metals and production of high-quality alloys.

Surface ***and zonal*** *hardening.* Induction heating makes it possible to reduce manyfold the production time of parts requiring heat treatment for hardening because in most cases heating requires only a few seconds. Moreover, surface hardening can be carried out directly on the production line, leading to total automation of all heating and hardening processes, uniform quality of all processed products, and substantial improvement in working conditions.

There are three basic heating methods for surface hardening: simultaneous, when the entire surface to be processed is subjected at once to heating and subsequent hardening; sequential, the successive heating for hardening of individual areas of the same part; and continuous-sequential heating and hardening, during which the processed object is moved continuously through the zone of influence of the inductor, heating the desired surface layer to the hardening temperature and then to the coolant, where hardening takes place. Greatest productivity can be achieved using the simultaneous heating method, but in this case the generator power must be sufficient to ensure heating of the entire area to be processed at once.

Optimal frequency

The optimal frequency for the induction-heating process, which can be found from empirical formulas, depends on the configuration of the products to be treated and the thickness of the layer to be hardened.

For heating parts with simple shapes (bodies of revolution, planes), the minimum frequency will be

$$f \cong 50{,}000/S^2 \text{ hertz} \qquad (2)$$

in which δ is the thickness of the layer to be heated in millimetres.

For heating parts with complex configurations (with protuberances and depressions in the processed zone), the optimal frequency is about ten times higher, and for heating gear teeth with a magnetic permeability of between four and ten the frequency is still higher.

The time required for heating a cylindrical surface of thickness δ from one to four millimetres can be calculated using the following formula:

$$t \cong \delta^2/2 \text{ seconds.} \qquad (3)$$

The generator power can be approximated by using the relation

$$p_g = \Delta QS/t \text{ kilowatts} \qquad (4)$$

in which ΔQ is the average power required for heating the material, including radiation loss, and S is the area to be heated. For a layer approximately two millimetres thick, Q is 2.5 kilowatt-seconds per square centimetre. Thus for a heating time of two seconds and an area of 100 square centimetres, the generator power must be 2.5 × 100/2 or 125 kilowatts.

The sequential, or successive, method of hardening individual portions of a part, a variation of the simultaneous heating method, is used in production of internal-combustion-engine crankshafts, with the individual journals of the shafts alternately heated and hardened; gear cogs, with sequential hardening "cog by cog"; and other objects.

In many cases, particularly when high productivity is not required, as in processing large parts, a continuous-sequential "feed" method is employed (Figure 1). Figure 1A illustrates the moment at which heating begins. The piece to be processed (in this case a cylindrical shaft) is fed, for instance, from top to bottom through an inductor. When this method is used, feed can also be horizontal or at various angles to the vertical.

In addition to the sequential motion, the shaft is also rotated around its axis to ensure uniform heating of the layer being hardened regardless of the accuracy of positioning relative to the inductor walls. The rate of rotation is usually between 100 and 300 revolutions per minute.

The layer that is heated to hardening temperature is shown by the heavy diagonal shading. At a distance *m* from the inductor, usually about five times the thickness of the heated layer, is situated a sprayer (water or emulsion shower). The coolant emerges through holes 1.O–1.2 millimetres in diameter bored on the inside of the sprayer surface. The height of the sprayer is about ten times the depth of penetration.

The process of hardening the heated layer is illustrated in Figure 1B. The hardened layer is shown in black on the shaft section. If the high-frequency current generator is turned off at the moment shown in Figure 1C, then the shaft must be fed downward for a certain additional distance to harden the heated zone then in the inductor.

For hardening layers of thickness $\delta = 1$–5 millimetres on parts made of structural steel, the minimum feed rate can be calculated by using the empirical formula:

$$v_{\min} = 5/\delta \text{ millimetres per second.} \qquad (5)$$

The maximum feed rate is limited only by the generator power. As generator power increases, the inductor height can be increased. Feed rate on lines for continuous-sequential hardening usually runs between 0.2 and 2.0 centimetres per second.

In cases in which the thickness of the layer to be hardened is greater than the depth of penetration of the eddy currents into the steel, the remaining thickness is heated essentially by thermal conduction from the heated to the unheated region.

The inductor height is selected as a function of the available power and workpiece diameter.

The use of the continuous-sequential heating and hardening method for processing large parts, because of the lower productivity, permits a substantial reduction in generator power capacity.

Inductor configuration

The inductor configuration is one of the most important elements in designing equipment for heating specific areas of parts of varying configurations.

The size of the zone to be heated depends on the shape of the inductor and its location in relation to the part

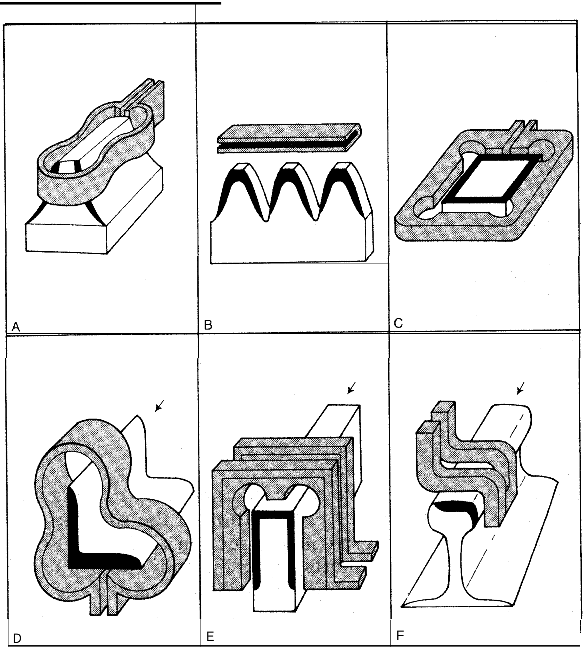

Figure 2: Representative inductor configurations for heating steel bodies of various shapes (see text).

being treated. The air gap between the inductor surface and the treated area is usually about two to five millimetres. When a vacuum-tube generator is used, a smaller gap can result in electrical breakdown between the inductor and the part being treated, due to thermionic emission (emission of electrons), which takes place at hardening temperatures.

An increase in the air gap results in increased losses as a result of diffusion of the electromagnetic field around the inductor and, other conditions being equal, reduces the intensity of induction heating.

Figure 2 indicates several characteristic inductor shapes for heating and tempering steel components of different configurations. The top three (A,B,C) are used for simultaneous heating and the bottom three (D,E,F) for heating parts while they are moving through the inductor field.

The cost of surface hardening depends largely on the required hardened layer thickness, type of apparatus, and degree of automation in the feeding of the processed parts. In the U.S.S.R., for example, the cost of hardening one square centimetre of surface to a depth of three millimetres can vary between 0.1 and 1 kopeck. The cost of heating a uniform mass-produced item is lower because of mechanization and the automation of all processes. Surface hardening of individually produced parts is more expensive than that of mass-produced parts, since the specific cost of preparatory operations (manufacture of inductor and equipment for holding the parts, time spent in readjustment, etc.) must be higher.

Through heating. High-frequency electrothermics—induction heating of billets (blocks of metal) for stamping and forging—is a standard operation in industry. The advantages include a sharp reduction of the heating cycle to a few minutes as compared to long heating required in fossil-fuel furnaces, thus lowering losses due to the formation of scale. Further, the method nearly doubles the service life of dies and reduces the margin on the subsequent treatment of the forgings. Moreover, the technique makes it possible completely to automate the preparation of billets for forging and, consequently, to produce uniform high-quality products. Another valuable feature is the possibility of reducing by up to 50 percent the floor area required in the production areas of the forging mills because of acceleration of the heating cycle and because the high-frequency equipment requires much less area than large furnaces. The power consumption needed in the prolonged process of heating up the furnaces is also eliminated, and a substantial improvement in the working conditions of the forging and heating workers is achieved.

A graph for the approximate determination of the frequency range for through induction heating for stamping and forging structural steel billets measuring between 10 and *200* millimetres in diameter is given in Figure **3.**

The induction method can also be used successfully for heating billets of nonferrous metals such as aluminum, copper alloys, etc. In these uses, heating efficiency will be less than for steel, and the optimum frequency will be lower. For a given frequency, the diameter of an aluminum billet would, thus, be much smaller than that of a steel billet.

The approximate time required for the through induction heating to forging temperature of carbon steel varies from *20* seconds for a ten-millimetre-diameter billet to five minutes for one of 100-millimetre diameter. For alloyed structural steel, the time is about 20 percent greater.

Losses due to radiation from the heated surface increase very rapidly as the temperature is increased; therefore, in selecting the heating regime, the shortest duration possible of the heating cycle must be achieved to reduce radiation losses.

The average power consumption for heating one kilogram of steel is approximately one-half kilowatt-hour. The required generator power can be determined with the formula:

$$P_g = 30\,G/t \text{ kilowatts} \qquad (6)$$

in which G is the weight of the billet, and t, the heating time in minutes.

Adapted from M.G. Lozinskii, *Industrial Applications of Induction Heating* (1970); Pergamon Press Ltd.

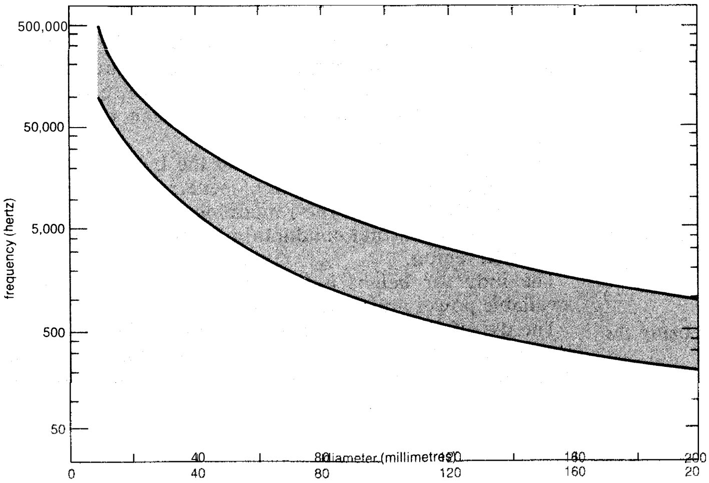

Figure 3: Recommended frequency ranges for heating solid cylindrical steel billets of various diameters.

Heating for soldering and brazing. Joining of steel parts after induction heating by means of high-speed soldering is a widely employed technique. Such soldering, when carried out with hard solders, retains and even increases the strength of the parts being joined while substantially reducing the consumption of materials for their production.

For through heating for soldering solid cylindrical parts, the choice of frequency is the same as for stamping and forging heating. Correct frequencies for cases in which it is necessary to heat a part of a hollow cylindrical steel product for soldering are shown in the graph in Figure 4.

The strength of the joint made by high-frequency soldering depends largely on the cleanness of the soldered surfaces, the gap between them, correct choice of heating routine (duration of the process and heating temperature), quality of the solder and flux (the material that cleans and prepares the surface for soldering), and subsequent heat treatment.

Flux

The quality of the flux is of great importance in high-frequency soldering. Calcined (anhydrous) borax, finely pulverized and mixed with solvent to a pasty consistency, is widely used. The use of pastry flux instead of powder permits precise dosing and preparation of the parts to be joined long before soldering.

The soldering of both hard alloy plates and high-speed (heat-resistant) steel plates to tool mounts and milling cutter bodies is employed extensively in industry.

Copper is usually used for soldering hard alloys and a flux consisting of 50 percent pulverized ferromanganese and 50 percent powdered glass is used in soldering high-speed steel plates. In the latter case the heating temperature is about 1,300"–1,350" C (2,360"–2,450" F), which makes it possible to follow the soldering operation with the hardening of the soldered plates (the haidening temperature of high-speed steels falls within the above-specified temperature range).

Tempering** of **steel. Local tempering to reduce residual stresses and also to decrease the hardness of the steel can be carried out successfully after local surface hardening by the use of high-speed induction heating. Short-term (for a few seconds) heating of the zone to be treated up to a temperature of, for example, 500" C will produce the same results as two hours of tempering in an oven at 150°–180° C.

In many cases, "self-tempering" can be achieved after surface hardening. For this purpose the heat intensity and duration of cooling are both determined in such a way that the heat remaining in the part after termination of cooling will be sufficient to lower the residual stresses and hardness of the hardened zone to within the required limits.

Adapted from M.G. Lozinskii, *Industrial Applications of Induction Heating* (1970); Pergamon Press Ltd.

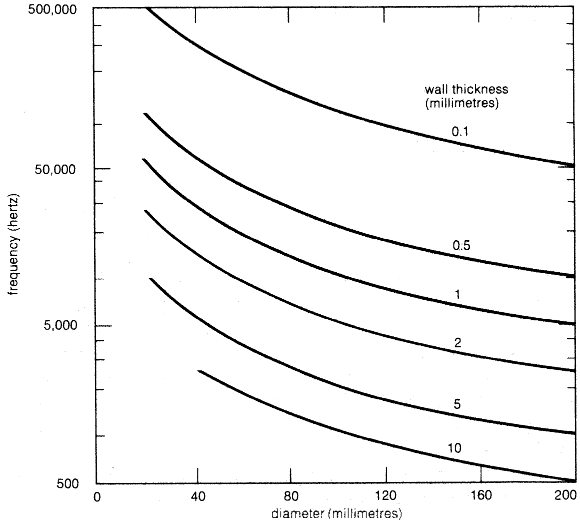

Figure 4: Optimum frequencies for heating hollow steel cylinders of various diameters and wall thicknesses preparatory to soldering.

The same inductors that are employed for hardening are also used for tempering. Heating regimes for tempering and the duration of the cooling process in hardening with subsequent self-tempering are determined by experimentation.

Induction furnaces. Metallurgy is the oldest branch of the comparatively new induction heating technology. The production of magnetic and heat-resistant alloys, and of other alloys with various special properties in an induction furnace, is an important part of metallurgy.

The shape of the induction heating coils and the frequency requirements for an induction furnace are similar to those used for through heating of billets. The average specific power consumption for furnaces with a capacity of 150–200 kilograms and more of steel is about 0.6 kilowatt-hours per kilogram and increases somewhat for smaller furnaces.

DIELECTRIC HEATING

Basic principles. The dielectric ("capacitance") heating method is based on the utilization of heat created in materials that are poor electrical conductors, when placed in high-frequency electromagnetic fields. The heat is formed as a result of losses that occur in a material located between metal walls that form a sort of capacitor connected to the high-frequency generator. The amount of the loss is a characteristic of the material called its loss factor, or "loss angle."

"Loss angle"

In contrast to induction heating, in which nonuniform heating is possible, capacitance heating provides comparatively uniform through heating of objects made of various dielectrics (wood, plastic, rubber, food products, etc.), which are located in the high-frequency field of the capacitor.

The dielectric heating method has been successful in solving problems in which it was necessary to heat poor conductors. Depending on the structure and physical properties of these poor conductors, it is quite possible to select the optimal frequency and applied voltage for heating them.

Heating insulating materials and poor conductors usually requires substantially less specific power than heating metals. Thus, to heat a layer of metal of a thickness, for example, of 3 millimetres for surface hardening, a thousand or more watts of high-frequency energy are required for each square centimetre of surface. For the high-frequency drying of large volumes of wood, on the other hand, the average power is usually less than one watt per square centimetre. But because of the high electrical resistance of the insulators, generating the necessary heat requires much higher frequencies than in the induction heating of metals.

At low frequencies even high voltage does not ensure the required power. Therefore, the frequencies used for dielectric heating vary from hundreds of thousands of hertz to many gigahertz (1,000,000 hertz).

A type of electron tube known as the magnetron is widely used in industry to generate high-frequency power in the gigahertz range. Developed about 40 years ago, magnetrons were used during World War II in radar generators, combining high output powers with extremely high frequencies (see also ELECTRON TUBE). At the present time there are magnetrons capable of continuous operation with effective power outputs of the order of several kilowatts at frequencies in the 3,000 to 30,000 gigahertz (and even higher) range.

Applications. Of many industrial applications of dielectric heating, only a few will be discussed.

Drying of wood. The average power consumption in evaporating one kilogram of water from wood is about 2.5 kilowatt-hours. To determine the parameters of the apparatus, it is necessary to determine the weight of the water to be removed during drying on the basis of the job specifications.

High-frequency drying is normally used only for the final processing of lumber that has been seasoned in kilns, containing, for example, 20 percent moisture. The final moisture content in such cases is usually about 10 percent. Thus, the power and time requirements for a drying operation are directly related to the amount of moisture represented by this drop from 20 percent to 10 percent.

Cracking

The duration of the drying process, however, is controlled by the danger of cracking the lumber due to the formation of steam and the rupture of the fibres. In general, the time will be around one hour per ten millimetres of thickness of the boards. For example, a board 40 millimetres thick should dry in not less than four hours, and a board 20 millimetres in thickness may be dried in two hours.

Heating of ceramic products. Many ceramic firms employ dielectric heating of ceramic products during their production cycles. Capacitor-type heaters are used with the ceramic products placed between the plates of the capacitor. In many cases a conveyer belt is used to transport the products between the plates of the capacitor, thus making it possible to automate the process.

Confectionery and culinary industries. One of the relatively new applications of the dielectric heating technique is in the confectionery and culinary industries. In these applications the product is placed between capacitor plates connected to a radio-frequency generator. The heated products never come into contact with the conductors; the heat generated within them is proportional to the frequency and depends on their physical properties.

Baking and preparing roasted meat dishes by no means exhaust the culinary possibilities of this technique; it is widely used in the food industry, and equipment is available for both restaurants and homes.

Melting glass and other dielectrics. Many materials that are good dielectrics at room temperature become conductors when heated. Glass, for example, heated close to its melting point, about 800" C, becomes a comparatively good conductor.

Radio-frequency heating can be used successfully for melting glass and glasslike materials (including various types of rocks), but the process is not effective until the temperature is increased to a point at which the material becomes conducting. Thus to start melting, a small portion of the material must be heated close to the melting point by some other heat source, such as gas burners. The high-frequency power is then switched on and the preheated conducting zone begins to increase its temperature and goes into the liquid state.

A valuable feature of the above-described method is the possibility of enlarging or reducing the dimensions of the molten zone, depending on the amount of generator power. A dynamic equilibrium is established; there is a certain minimum power below which the process does not take place, and the molten material hardens. In this regard the heating of glass differs substantially from the high-frequency heating of metals, which may be heated as much or as little as desired.

Radioisotopes, Applications of

Isotopes are atoms of an element that are slightly different structurally from each other but have the same chemical properties. For example, the element tin has ten different stable isotopes of varying atomic weight. Some isotopes are stable; that is, they retain their character in all normal circumstances. Certain isotopes, however, are unstable, or radioactive, because the ratio of neutrons to protons is either too low or too high for stability; that is, they tend to break down spontaneously into entirely different elements, giving off radiation in the process. Isotopes of all of the elements heavier than bismuth are radioactive; for a detailed discussion see RADIOACTIVITY.

Radioactive isotopes, or radioisotopes, have proved to be valuable tools in the laboratory, in industrial plants, and in agriculture. The radiation they give off, called alpha, beta, and gamma rays, can be readily detected by such detectors as Geiger counters, scintillation counters, and the like. Since the rates of emission of the rays and their penetrating abilities are known and since their intensities are reduced when they travel through materials, they can be used in making highly accurate scientific measurements, in testing the operation of mechanical systems without disassembling, in tracing flow in pipes, in measuring nutrient intake of plants, and in innumerable other applications.

Radiation doses must be controlled within amounts judged safe to the personnel involved in manufacturing processes and to the consumers of the products having residual radiation.

Residual radiation in products

In the United States, federal government approval has customarily been granted by the Atomic Energy Commission (AEC) to specific products whose radiation does not exceed that of cane sugar sold in stores. The AEC has ruled that products are considered safe for release to the public when radiation does not exceed the concentration established many years ago for water.

Disposal of radioactive waste into sewers or the atmosphere may come under government regulation in the future.

Potential health hazards are discussed fully in the article RADIATION INJURY.

EXPERIMENTATION

First use

The first experimental use of radioisotopes occurred in Austria in 1913 just ten years after the award of the Nobel Prize to Henri Becquerel and to Pierre and Marie Curie for the discovery of radioactivity. Hungarian physicist George Charles de Hevesy, working in the Vienna Institute for Radium Research, used what was then known as "radium D," actually an isotope of lead (lead-210), to study the solubility in water of lead sulfide and lead chromate. A little later he used "thorium B (lead-212) to study the uptake of lead by growing plants.

For the next several years a variety of experiments were carried out with naturally occurring radioisotopes in biology and medicine. The invention of the cyclotron in the early 1930s brought a new source of isotopes, but they became plentiful only with the development of nuclear reactors in the 1950s. Measurement and control systems based on radioisotopes were then devised, and new fields of application for the radiations opened up: food processing, medical-supply sterilization, and sources of yower and heat. In the early 1970s tracer applications were increasing steadily; food processing and other process-radiation applications also were expanding.

Naturally occurring radioisotopes. About 55 radioactive isotopes can be found in nature and about 20 more radioactive-decay products are always associated with some of them. They range from traces of carbon-14 and potassium-40 in the body to radium, thorium, and uranium, which are mined commercially. Table 1 lists these nuclides or atoms of a specific isotope with their half-lives (the time required for half the atoms in a given quantity of material to decay) and natural abundances. Most naturally occurring radioisotopes are insignificant as sources of radioactivity either because they are not abundant or because they have low activities as a result of their long half-lives. The exceptions are radium, used in medical therapy, and uranium and thorium, used in the nuclear industry as fuel and in "breeder" reactors, *i.e.*, reactors that produce more fissionable material than they burn.

Table 1: Naturally Occurring Radioactive Isotopes

isotope	abundance (percent)	half-life (years)	isotope	abundance (percent)	half-life (years)
^{14}C	trace	5.8 X 10^{3}	^{149}Sm	13.83	4 × 10^{14}
^{40}K	0.012	1.3 X 10^{9}	^{152}Gd	0.20	1.1 X 10^{14}
^{48}Ca	0.18	>2 X 10^{16}	^{159}Tb	100	5 × 10^{16}
^{50}V	0.24	6 × 10^{14}	^{165}Ho	100	6 × 10^{16}
^{64}Zn	48.89	1 × 10^{15}	^{169}Tm	100	5 × 10^{16}
^{70}Zn	0.62	1 × 10^{15}	^{175}Lu	97.41	1 × 10^{17}
^{76}Ge	7.76	2 × 10^{16}	^{176}Lu	2.60	2.1 X 10^{10}
^{82}Se	9.15	1 X 10^{17}	^{174}Hf	0.18	4.3 X 10^{15}
^{87}Rb	27.85	4.7 X 10^{10}	^{180}Ta	0.012	I × 10^{13}
^{96}Zr	2.80	3 × 10^{17}	^{180}W	0.14	3 × 10^{14}
^{92}Mo	15.84	4 X 10^{18}	^{182}W	26.41	2 × 10^{17}
^{100}Mo	9.13	3 × 10^{17}	^{183}W	14.40	1 × 10^{17}
^{113}Cd	12.26	1 X 10^{15}	^{186}W	28.41	6 X 10^{15}
^{116}Cd	7.58	1 × 10^{17}	^{187}Re	62.93	7 × 10^{10}
^{115}In	95.72	6 X 10'4	^{192}Os	41	1 × 10^{14}
^{124}Sn	5.94	2 × 10^{17}	^{190}Pt	0.013	7 × 10^{11}
^{123}Sb	42.75	I × 10^{16}	^{192}Pt	0.78	1 X 10^{15}
^{123}Te	0.87	1.2 × 10^{13}	^{198}Pt	7.21	1 × 10^{15}
^{130}Te	34.48	8 × 10^{20}	^{196}Hg	0.146	1 × 10^{14}
^{138}La	0.09	1.1 X 10^{11}	^{209}Bi	L00	1 X 10^{14}
^{136}Ce	0.193	3 X 10^{11}	^{222}Rn	from ^{226}Ra	3.8 days
^{142}Ce	11.07	5 × 10^{15}	^{226}Ra	from ^{230}Th	1622
^{141}Pr	100	2 X 10^{16}	^{230}Th	from ^{234}U	8 × 10^{4}
^{144}Nd	23.85	5 X 10^{15}	^{232}Th	100	1.4 × 10^{10}
^{150}Nd	5.62	1 × 10^{16}	^{234}U	0.006	2.5 X 10^{5}
^{147}Sm	14.97	I X 10^{11}	^{235}U	0.72	7.1 X 10^{8}
^{148}Sm	11.24	1.2 × 10^{13}	^{238}U	99.27	4.5 X 10^{9}

Manufactured radioisotopes. When atoms of uranium-235 or plutonium-239 are bombarded with neutrons in a controlled chain reaction, a series of fission fragments is produced (see also NUCLEAR REACTOR). Many of these particles are themselves radioactive and continue to decay. Some, either stable or with very long half-lives, remain in the fission products; and the individual elements can be separated from the rest of the fission products.

The fission products are by analogy the ashes from the burning of nuclear fuels. Finding uses for them is extremely important because as nuclear wastes they must be disposed of. Table 2 lists some important fission products along with their abundances and half-lives. The first artificial radioisotopes were identified in the early 1930s as a result of transmutations (nuclear reactions changing one chemical element into another). By 1935 the University of California cyclotron, the earliest type of charged-particle accelerator, was being used to make a number of radioisotopes. After World War II, neutron-produced radioisotopes became available. Since then, production of radioisotopes has increased enormously.

Table 2: A Few Important Fission Products

nuclide	half-life	fission yield (percent)	nuclide	half-life	fission yield (percent)
^{85}Kr	10.4 years	0.3	^{106}Ru	1 year	0.38
^{89}Sr	50.4 days	4.6	^{131}I	8.05 days	2.8
^{90}Sr	28 years	5.3	^{133}Xe	5.27 days	4.5
^{91}Y	57.5 days	5.9	^{137}Cs	30 years	5.9
^{95}Zr	65 days	6.4	^{140}Ba	12.8 days	6.1
^{95}Nb	35 days	6.4	^{144}Ce	285 days	6.1
^{99}Tc	2.1 X 10^{5} years	6.1	^{147}Pm	2.5 years	2.6
^{129m}Te	33 days	0.19			

First identification of artificial radioisotopes

Target atoms to be bombarded with neutrons may be sealed in quartz vials that are welded into aluminum containers and lowered into the core of a nuclear reactor. After bombardment the products are processed to a form suitable for ultimate use. This processing may involve simply dissolving the irradiated material or may require a more complex treatment. In all cases handling is carried out remotely in hot cells to protect workers from radiation (see Figure 1).

BY courtesv of Oak Ridge National Laboratory, Oak Ridge, Tennessee

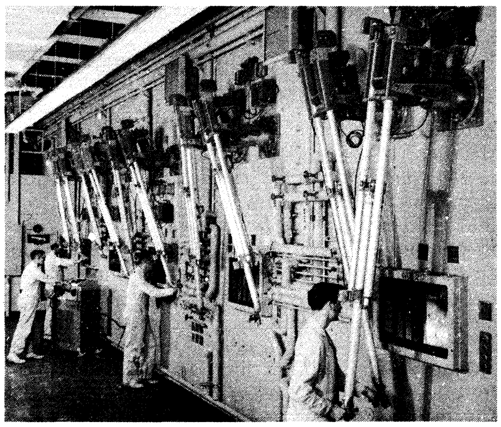

Figure 1: Hot cells at the Oak Ridge National Laboratory for processing fission products.

Reactors produce only a limited number of isotopes with a low ratio of neutrons to protons; charged-particle accelerators are a more efficient means of producing such isotopes. Energies of the accelerators can be varied over wide ranges, and the nuclear reaction can be controlled.

Because most elements contain several isotopes, their bombardment often results in mixtures containing undesirable radioisotopes. Targets are therefore usually enriched with a specific isotope, resulting in the production of a very high proportion of the desired radioisotope.

ISOTOPIC TRACERS

All uses of radioisotopes depend upon the radiations that result from the decay of the unstable nuclei. When a radioisotope, or radioactive element, is added in small smounts to relatively large amounts of the stable element, it will behave chemically exactly the same as the stable species, but it can be tracked or traced by a Geiger counter or other device. This characteristic leads to the largest variety of radioisotope applications, including studies of wear, tracing of fluid flow and locating leaks in pipes and hydraulic systems, analyzing metabolism of foods and drugs, and studying fertilizer uptake by plants.

In agriculture and animal husbandry. In the mid-1930s radioisotopes began to be used in studies to trace the uptake of fertilizer. The addition of phosphorus-32 to phosphate fertilizers allowed the study of rate of fertilizer uptake and its distribution in the plant. As a result, it was discovered that application of nutrients on leaves is about 95 percent efficient but application on roots is only about 10 percent efficient.

Radioisotopic tracers have been used to help evaluate the effects in plants of growth stimulators, such as auxins and gibberelins, the function of certain proteins and nucleic acids, and the effects of plant-growth regulators. Thousands of plant metabolic studies have been carried out on amino acids and proteins, sulfur, nitrogen, and phosphates. One of the most significant early applications, involving carbon-14, assisted by the stable isotope oxygen-18, was in the study of photosynthesis, at the University of California, beginning about 1948. These studies revealed that none of the oxygen released during photosynthesis comes from the carbon dioxide, but instead from the water.

Photosynthesis studies

In the evaluation of insecticides, pesticides, and weed killers, it is desirable to follow the life cycles of organisms to determine specific effects of the chemical on the biological system. Such isotopes as carbon-14, sulfur-35, phosphorus-32, and iodine-131 have been useful in this work.

Many radioisotopes have been involved in investigating the body processes and habits of animals. Weight gain as related to types of feed and to hormones, the significance of trace elements and vitamins in diets, and the effect of tranquillizers in reducing weight loss during shipment have all been studied with isotopes.

Radioisotopes also are used to tag insects, animals, and fish for study of their life cycles; migratory patterns and ranges; mating and feeding habits; and identification of parasites, hosts, and prey.

In medicine. Some of the earliest uses of radioisotopes were as tracers in medical diagnosis and in metabolic research. More than 100 radioisotopes have been used in medicine since about 1945, though five have been used for diagnosis much more than the others: chromium-51, iodine-131, phosphorus-32, iron-59, and technetium-99*m*. Chromium-51 is used for measurement of total volume and residence time of red blood cells; measurement of total volume of plasma and blood; measurement of cardiac output; location of the exact position of the placenta in expectant mothers; determination of amount and location of bleeding from the gastrointestinal tract. Iodine-131 is used for determination of blood volume, cardiac output, plasma volume, liver activity, fat metabolism, thyroid-cancer metastases, brain tumours, and particularly the size, shape, and activity of the thyroid gland. Phosphorus-32 can help identify tumours because cancerous cells tend to concentrate phosphates more than do healthy cells. Iron-59 is used for measurement of the rate of formation of red blood cells, their lifetime, and their volume; and for measurement of absorption of iron by the digestive tract to evaluate the effectiveness of various iron compounds in revitalizing blood. Technetium-99*m* is extremely valuable for diagnosis of brain tumours using scanning devices.

Other radioisotopes used frequently in medicine are sodium-24 in circulatory studies; cobalt-58 and cobalt-60 added to vitamin B_{12} in diagnosis of pernicious anemia; arsenic-74 and copper-64 in locating tumours; hydrogen-3 (as tritiated water) in measuring total body water.

In the pharmaceutical field, isotopes are used in studying the reactions involved in making new compounds.

In industry. During chemical or physical processing, the radioisotopes retain their chemical identities, and the process streams can be followed regardless of changes in the system or its components. Radioisotopes are widely used in industry to trace the flow of materials; *e.g.*, the flow of a lubricant in a sealed engine; often there is no other way to do this. In the 1970s, the continuous use of safe but detectable amounts of radioisotopes promises to become routine for many industrial processes and products.

In blast-furnace operations, iron-59 has been used to study distribution of constituents and their residence times in a number of metallurgical processes. The use of radioisotopes results in improvements in mixing during formation of alloys.

Wear studies

Tracers yield information about the rate of tool wear in punching and machining operations and on the wear of gear trains and similar moving parts, permitting evaluation of the characteristics of alloys and the stability of cutting oils. Automobile manufacturers can test such components as engine cylinders and pistons, piston rings, bearings, and lubricating oil by irradiating piston rings and cylinder liners (iron-59) or bearings (copper-64 and zinc-65) and noting the change in radioactivity in the lubricant. In contrast to other wear-measuring techniques, radioisotopes can be used to test the system while operating without disassembling, so that effects of idling, acceleration, speed, starting, stopping, coolant temperature, and the viscosity and composition of the lubricant can be related directly to friction and wear.

One of the original applications of radioisotope tracing was the location of obstructions in underground pipelines. An isotope source, mounted in a small rubber ball or other suitable carrier, is introduced into the blocked pipe. It moves along until it reaches the obstruction, where it stops. It can then be located exactly from above ground by use of a radiation detector, and the blocked section can be replaced without costly searching. Leak testing is extremely important in industry; in underground piping, iodine-131, bromine-82, and sodium-24 are used; in heat exchangers, hydrogen-3 (tritium) is used; in telephone cables, krypton-85.

Other typical industrial tracer applications include measurement and control of the time a chemical remains resident in a solution, uniformity of mixing components, catalyst flow, and efficiency of separation, as in distillation. Important information about hydrodynamic relationships in oil-bearing geological formations and about flow patterns in subterranean rock formations may be obtained by using hydrogen-3 and iodine-131 tracers. This information is useful because. oil yields can be increased by water-flooding of wells. Tracers are used in transcontinental oil lines to identify the boundaries between different types of oil being pumped through the line.

In environmental and ocean studies. Tracers are widely used in studies of air pollution from smokestack-gas effluents and of water pollution in lakes and rivers and are also used to measure deepwater currents in lakes and oceans.

Sand and silt labelled with the isotopes gold-198 or xenon-133 are being used to study drift and transport of sand and silt in waterways, thus making the maintenance and restoration of beaches and harbours more efficient.

Carbon dioxide with carbon-14 is used to study photosynthesis in marine algae, providing information important to long-range sea-farming plans.

Snow-management research

Radioisotopes have been used in gauges to monitor snow density and as tracers to study water movements in snowpacks; snow-management research is designed to provide ways for delaying snow melt, measuring snow-water content, and increasing total-water content from snow- and watersheds. Sediment density in rivers and streams can be measured continuously with radioisotopes. A nuclear sediment-density gauge has been developed to give a continuous measurement of suspended matter in rivers and streams, thereby providing data as to what happens during and immediately after heavy rainfall.

Tracers are also used in many other areas of research, such as the kinetics of reactions, reaction mechanisms, diffusion, permeability of membranes, sorption on surfaces, vapour pressures of metals, and the mechanism of passivity, which makes metals resistant to certain environments.

USE OF DIRECT RADIATION

Direct application of penetrating radiation from radioisotopes has found increasing applications in medical therapy, in agriculture for pest-control purposes, and in industry.

In medicine and biology. The therapeutic uses of X-rays—and now of radioisotopes—are based upon the facts that these radiations cause ionization of the matter through which they pass and that malignant or otherwise diseased cells are usually more affected by this radiation than are healthy cells. Diseased cells may be killed by the radiations, while nearby healthy cells, although damaged, usually recover. Cobalt-60, iridium-192, and cesium-137 have been used primarily to replace X-ray therapeutic units, with the advantage that rotational isotope units that minimize damage to the skin and other healthy cells are less cumbersome than similar X-ray machines. A more subtle advantage of radioisotopes is that they can be used on localized areas or organs. For example, iodine concentrates in the thyroid and can be tagged with radioactive iodine for radiation in the thyroid to reduce the activity of that gland. Phosphate containing phosphorus-32 concentrates in tissues that utilize phosphates in their metabolism, including the blood-forming tissues. This concentration provides a treatment for *polycythemia vera*; the hematopoietic, or actively forming, cells are sensitive to radiation and are selectively destroyed. Gold-198 in the form of a colloid (finely distributed in a liquid) has been used in palliative treatment to control the accumulation of excess fluid in the chest and abdominal cavities from their linings as a result of the growth of some types of malignant tumours. The treatment is not curative, but it is not as dangerous or uncomfortable as frequent surgical drainage. Beads and needles containing, or made of, cobalt-60, yttrium-90, or gold-198 can be implanted directly in tumours to increase the effectiveness of radiation and to cut down on peripheral cell damage.

Medical sterilization

Biocidal uses. A major use of gamma radiation is in the medical- and hospital-supply business for sterilizing bandages, surgical sutures, plastic blood-donor kits, rubber gloves, disposable hypodermic syringes, catheters, surgical blades, needles, and other instruments. This method of sterilization eliminates the need for boiling, autoclaving, or chemical treatment, and materials can be packaged before sterilization instead of aseptically afterward. The process for the sterilization of catgut sutures is particularly complicated when heat treatment is used but simple with gamma radiation.

One of the world's largest cobalt-60 irradiation facilities, located at Dandenong, Australia, is used for the disinfestation of goat hair. The radiation destroys the anthrax spores but does not harm the fibres.

For insect eradication. Ionizing radiations may be used to eradicate insects by sexual sterilization. The classic application concerns the elimination of the screwworm fly, indigenous to large parts of the southern U.S., the Caribbean, and Mexico. The fly lays its eggs in the navels of newborn animals or in open wounds of livestock; the resulting maggots burrow into the animals, killing them. In the southeastern U.S., the annual loss varied from $25,000,000 to $50,000,000. In the pupal stage, these insects may be sexually sterilized by low doses (2,500 roentgens) of radiation. Sterile males compete on a par with normal males for mates, and females mate only once. Saturation of an area with up to 50,000,000 sterilized males at a time rapidly reduced to zero the number of eggs that hatched from the normal native flies. Over a period of a year and a half, during which more than 2,000,000,000 sterilized male flies were released, the screwworm fly was completely eliminated.

Industrial uses. Radioisotopes can be used as a source of gamma rays for radiography. The principle is the same as in conventional X-radiography: the radiations of short wavelength can penetrate materials opaque to ordinary light, shadowing the more dense parts on photographic film to produce the image, or radiograph.

Radioisotopes have certain advantages over conventional X-ray sources: portability, freedom from external power supplies, applicability to odd and complex shapes, and the capability for inside-out exposures. The large number of available isotopes provides a wide range of energies. A disadvantage is that the radioisotope source cannot be turned off. Point radioisotope sources yield radiographs with good resolution.

Portable radioisotope units can be used for taking radiographs of an accident victim on the scene before deciding whether or not he should be moved; one such iodine-125 unit weighs only two pounds.

Neutron radiography was discovered about 1930, but the practical applications became significant only in the late 1960s. The X-rays or gamma rays used to make conventional radiographs interact with orbital electrons, but neutrons react with the nucleus; and the radiographs made by the two methods show quite different details.

In luminescent devices. Just as electrons are used to excite the phosphors in a television tube, isotopic beta emitters are used in luminescent devices such as exit signs in aircraft and runway markers. The original application was in radium-activated luminescent watch dials. Some compasses have isotope-activated luminous dials. Illuminants such as tritium, krypton-85, and promethium-147 are independent of external power supplies and have a lower maintenance cost than conventional systems.

The radiations from radioisotopes are reduced in intensity when they travel through materials, the amount of the reduction depending on the thickness and density of the materials. This principle, involving a radioisotopic source and a radiation detector, is used to determine and control the thicknesses and densities of various substances and to locate and control levels of liquids and solids. Radiation detectors provide continuous, nondestructive measurements and can be used along with an automatic-control system for regulating thickness and density of manufactured products.

In gauging. The material being processed is assumed to have uniform density, so that any change in radiation intensity measures a change in thickness. An increase in radiation intensity indicates a decrease in thickness and vice versa. The radiation-detector signal may be used to adjust and control a thickness-regulating device, such as a roller setting. The method can be applied to metal, paper, plastic, or coatings. A technique known as backscattering may also be used to measure thickness, weight, or density. When radiation enters a material, some is reflected, or backscattered, and the amount can be related directly to thickness or density. This technique is particularly effective in estimating the extent of corrosion of boiler shells, pipe walls, and ships' hulls.

Radioisotope gauges are used in agriculture to measure eggshell thickness. The breakage of eggs during shipment is decreased by selection of thick-shelled eggs.

In gauging density, the dimensions of the material are kept constant so that changes in radiation intensity are caused by density changes. Densities of liquids, powders, granular solids, and slurries may be estimated by placing a source and detector on opposite sides of a pipe or container.

Isotope gauges are used in agriculture to measure silage density and to control the density of condensed milk and the air content of ice cream.

Level gauging

In gauging a level, the radiation detector senses the change that occurs when material is or is not in the container at the prescribed level. More radiation is transmitted through the container when the level of material is below the radiation source than when it is above and the radiation must pass through it. A practical application is the automatic coatrol of liquid filling devices such as are used in agriculture for filling milk cans and cartons. The detector is placed at the level to which the container is to be filled, and when the product reaches this level, the change in radiation intensity can be used to shut off the filling device.

As an inspection-control mechanism, a detector may be set at a level just below that to which the containers must be filled; any container that does not meet the minimum-fill specifications will allow a surge in radiation that can be used to activate a reject mechanism.

Polymerization reactions

In chemical processing. In one of the first commercial applications of ionizing radiations from a radioisotope source to initiate a chemical reaction, cobalt-60 has been used since 1962 to produce ethyl bromide by the reaction between ethylene and bromine. Later, a radiation-induced sulfoxidation of hydrocarbons produced biodegradable detergents that break down without leaving a pollution residue. Cobalt-60 can be used in a continuous industrial chemical process for polymerizing ethylene to yield a basic raw material for packaging, laboratory tubing, and many other uses. Radiation can induce chemical cross-linking (bonding) in polymers (chemical compounds consisting of repeated structural units); polyethylene cross-linked by radiation shows increased mechanical strength at elevated temperature, and irradiated stretched tubing can be shrunk by heating to give adherent insulation.

Organic monomers (compounds that may become a structural unit in a polymeric compound) may be polymerized within the structure of wood to give wood plastics. Wood is placed under vacuum, the pores are filled with a monomer such as monomethylmethacrylate, and the combination is exposed to gamma radiation from a radioisotope source. Not only is the monomer polymerized, but some of it is apparently grafted to the cellulose of the wood, forming a new product with improved abrasion and water resistance, dimensional stability, and shear- and static-bending strength. These wood-polymer combinations are particularly suited for use as veneers, in certain types of furniture, parquet flooring, and such specialty products as golf club heads, billiard cues, and rifle stocks. A similar treatment gives concrete-polymer combinations that have improved qualities over untreated concrete. A possible use of this technique would be to form lightweight building blocks from compacted refuse–polymer composites, a process that might help solve the solid-waste-disposal problem.

In chemical analysis. Radioisotopes may be used as a source of radiations in devices for chemical analysis of samples. Such a device carried by the space satellite Surveyor 5 used alpha particles from curium-242 and reported on the composition of the surface of the moon.

Use in establishing age of artifacts

Oil paintings can be identified as to the composition of the paint used by a technique called activation analysis, in which they are exposed to a neutron beam and then placed on one photographic film after another for short periods of time. Since the radiations emitted from different elements within the painting have different properties and decay at different rates, they may often be distinguished by the varying images they induce in the chronological series of photographic films.

Pieces of ancient pottery, ancient coins, and other objects can also be identified chemically by activation analysis: the object is exposed to neutrons and the radioisotopes formed from the materials present, including any trace of impurities, usually give a positive identification of the composition of the original object.

The fact that extremely small amounts of certain elements can be detected and identified nondestructively by the activation-analysis technique has been used by law enforcement agents in various ways. Human hair contains small traces of metallic elements, but the quantities vary from person to person. The actual quantities can be determined by activation analysis. A murder conviction in Canada was based partly on activation-analysis evidence that a hair found in the hand of the murder victim matched the suspect's hair with respect to the proportion of metallic elements. Activation analysis of wipings taken from a suspect's hands indicates not only if he has fired a gun recently but also the number of bullets fired and the type of ammunition used. In another case, activation analysis of soil specimens from the scene of a crime and soil residue on a vehicle in the possession of a criminal suspect established a link with the site of a crime 1,000 miles away.

OTHER USES

Carbon dating. Dating, the determination of the age of objects from their radioactivity, is treated fully in the article DATING, RELATIVE AND ABSOLUTE. The use of naturally occurring carbon-14, an excellent method of estimating ages of objects up to about 50,000 years, was developed by U.S. physicist Willard Libby about 1946 and is based on the assumption that natural carbon dioxide in the air contains traces of cosmic-ray-produced carbon-14, but in rather fixed amounts determined by the rate of production of carbon-14 from nitrogen and the rate of decay of carbon-14 already in existence. Because plant life grows by photosynthesis of atmospheric carbon dioxide and animals feed on the plants, living organic matter is also in equilibrium with the carbon-14 in the atmosphere. Once organic matter has ceased to grow, however, there is no replenishment of the carbon dioxide, and the amount of carbon-14 gradually decreases as it decays. Thus the amount of residual carbon-14 when compared to the carbon-14 in living matter permits an estimation of the date at which the object died, as, for example, when a tree was cut.

Plant mutation. Radiation can be used to change the molecular structure of plant genes, inducing mutations in the plants. Successful mutations are rare, but experimentation in this area is simple. Studies since the early 1930s have yielded results throughout the world in producing millions of hectares of superior crops. Nearly 50 new varieties of plants so produced were released to growers in the late 1960s. Crop varieties have been improved and shortages caused by disease have been averted by using radiation to induce mutations. The technique is proving valuable to breeders of flowers and ornamental plants as well as in agriculture.

In Japan the higest yielding rice variety, the Reimei, has been produced by treating dry seeds with gamma rays from cobalt-60. The success of this technique has opened the possibility of improving even high-yielding crop varieties. Radiation-induced mutations may alleviate some population-growth problems.

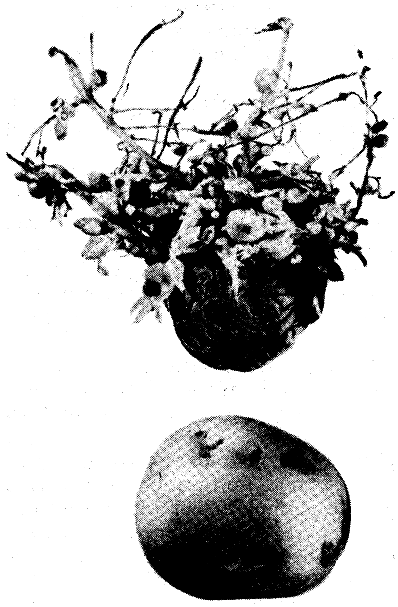

Figure 2: Sprout inhibition of potatoes by gamma irradiation using cobalt-60. (Top) Not treated. (Bottom) Exposed to 20,000 rads of gamma radiation. Photograph taken after both were stored for 16 months.

Pasteurization

Food processing. Beta and gamma radiation may be used to pasteurize, sterilize, and preserve foods. Food irradiation is discussed fully in the article FOOD PRESERVATION. Radiation treatment can be applied to inhibit the sprouting of potatoes and onions (see Figure 2), to disinfest grain and grain products, and to extend shelf life of fruits, meats, and seafoods. Radiation treatment of foods is relatively cheap, rapid, and effective and requires no heat.

Heat and power. When radiation is slowed down or stopped by matter, the kinetic energy is converted to heat. By using suitable isotopes and shielding materials heat and power can be produced. The heat generated by radioactive decay may be used directly as was done in the lunar missions to keep equipment warm during the cold lunar nights; or the heat may be converted into electrical or mechanical energy. The advantage of isotopes as power sources lies in their long lives that make energy available over long periods without recharging. Many SNAP (Systems for Nuclear Auxiliary Power) devices involving radioisotopes are commercially available and can be used to power navigational lights and buoys or remote and unmanned weather stations. Units have also been carried to the moon to provide electricity for various scientific experiments.

In medical therapy. ***Heart pacemakers.*** The newest application of radioisotopes in the life sciences is as a source of power for cardiac support devices, in particular, for the cardiac pacemaker and the artificial heart involved in programs supported by the U.S. Atomic Energy Commission and the National Heart Institute of the National Institutes of Health. In the pacemakers, plutonium-238 is the isotope source, the heat from it being converted to electricity by means of thermoelectric junctions. In one case, the four-ounce unit supplies 160 microwatts of electric power, sufficient to shock the heart 70 times per minute for a minimum of ten years. The obvious advantage is that replacement of the pacemakers through implantation surgery will have to occur only once in ten years in contrast to every two years for ordinary battery-powered devices.

Circulatory-assist devices, the ultimate of which is a completely implantable artificial heart, involve the heat from radioisotopes to power a Stirling or Rankine-cycle engine that simulates the pumping action of the heart. British surgeons have successfully implanted radioisotope-powered pacemakers, and the French have implanted an isotope-powered artificial heart in animals.

Heat for life-support systems. A potential use of isotopic heat and power is in an integrated life-support system for aerospace application. The design of this unit anticipates the handling of human waste and spacecraft debris for a 180-day mission and includes a waste incinerator, a high-temperature urine-vapourizing unit, and a catalytic oxidizer–incinerator.

GROWTH OF THE RADIOISOTOPE INDUSTRY

National vroduction and consumption

The radioisotope industry is continually growing. In France the vroduction and sale of radioisotopes increased rapidly throughout the 1960s. In 1967 total sales were valued at more than 14,000,000 francs ($3,000,000), excluding taxes, nearly half of which were to other countries.

In East Germany, from 1958 until 1968, the radioisotope centre at Rossendorf made more than 30,000 deliveries of radioactive products, of which almost half were exports. This material represents a total radioactivity of 1.3 kilocuries, valued at 8,000,000 marks. The centre is a leading supplier of radioactive materials in Europe.

In Argentina, from 1954 until 1968, consumption of radioisotopes increased from about 8 curies to 85 curies. In Brazil consumption increased at approximately the same rate. Argentina may soon produce all its own radioisotope requirements, except for high-intensity radiation sources, and may also export radioisotopes to other Latin-American countries.

In Australia, in fiscal 1969, the total income from sales of Australian-produced radioisotopes was $236,000 (U.S. equivalent $260,000), more than double that for 1968. Demand increased particularly for medical products.

In India there has been a steady growth in the use of radioisotopes since 1958. In 1968 about 18,000 consignments of radioisotopes valued at 2,200,000 rupees (U.S. equivalent $300,000) were supplied to 325 institutions, mainly for work in medicine, agriculture, industry, and hydrology.

In Japan the total number of establishments licensed to use radiation increased from 50 in March 1959 to 1,540 in March 1968; the greatest percentage increase was accounted for by hospitals and industry.

In the United States the program for applications of radioisotopes began about 1946, and the overall growth has levelled off to about 15 percent per year. Originally the AEC supplied essentially all of the domestic isotopes, but for a number of years it has been withdrawing from the sale of isotopes that can be produced in commercial facilities. As a result, except for the fission products, the AEC produces only a small proportion of the isotopes used in the United States.

About 100 private U.S. firms produce radioisotopes or convert them into products for medicine, science, and industry. Total sales of these companies are estimated at $53,000,000 annually, consisting of about $8,000,000 in basic radioisotope materials, $16,000,000 in radiochemicals, $25,000,000 in radiopharmaceuticals, and $4.000.000 in radiation sources. In addition, sales of devices in which radioisotopes are employed total about $40,000,000 a year. If the sales of products produced by radiation processing, auxiliary materials, and services related to radioisotopes and radiation uses are included, the total commercial activity in the United States is at a level of several hundred million dollars annually. The cyclotron isotopes account for about $3,000,000 in sales each year. At the end of 1969, 57 Industrial accelerator irradiation units and 18 industrial isotope irradiation units were in operation. Most of the isotope users must be licensed.

Table 3: Global Savings from Radioisotope Use
($000,000)

applications	24 countries, 1961–63	U.S., 1963	U.S.S.R., 1961	total
Gauging	26.7–43.4	35.2–50.4	100*	162–194
Radiography	12.1–28.9	4.0–7.6	22	38–58
Ionization	1–2	†	†	1–2
Tracing	10–40	27-48:	58*	95–146
Total	49–104	66–106	180	296–400

*The exact distribution of savings in certain gauging and tracing is not known. †Included in other groups.
‡Includes also certain gauging and ionization applications.

Table 3 lists savings experienced by some countries through the use of radioisotopes in various applications.

Radiology

Radiology is a branch of medicine that originally dealt with the use of X-rays in the diagnosis of disease and the use of X-rays, gamma rays, and other forms of ionizing radiation (*e.g.*, radiation that causes formation of positive and negative ions in the substance penetrated) in the treatment of disease. In more recent years radiology has also come to include diagnosis by a method of organ scanning with the use of radioactive isotopes and also with nonionizing radiation, such as ultrasound waves. Similarly, the scope of radiotherapy has extended to include, in the treatment of cancer, such agents as hormones and chemotherapeutic drugs.

The topics discussed in this article include the profession of radiologist and the ancillary professions, types of radiation and the radiation sources used, radioactive isotopes, other forms of radiation used in diagnostic and therapeutic radiology, new developments, and needed future developments.

History and associated specialties

DEVELOPMENT OF RADIOLOGY

X-rays were discovered by Wilhelm Conrad Rontgen, a German professor of physics, in his laboratory in the University of Wurzburg on November 8, 1895. It is probable that other workers had produced X-rays previously in their laboratories without realizing their significance, but Rontgen immediately set about a complete analysis of the properties of this phenomenon. Seven weeks later, on January 1, 1896, he published a model exposition of his work, to which little in basic knowledge has been added even to the present day, although multitudinous fringe advancements of knowledge have occurred, and developments in the techniques of the use and applications of X-rays continue to the present time. Within days of his publication there was speculation in newspapers in Germany, Austria, the United States, and England as to the possible medical applications of this new discovery, and so, one of the greatest revolutions in the evolution of modern medicine was started.

In radiodiagnosis use was made early of three of the properties of X-rays—their ability to penetrate the tissues, their photographic effect, and their ability to cause certain substances to fluoresce. In penetrating the tissues, the radiation is absorbed differentially, depending on the densities of the tissues that are being penetrated. The radiation

Introduction of contrast media

emerging from tissues thus produces on a photographic film or a fluorescent screen an image of the structures of differing densities within the body. The limiting factor is the similarity between the densities of adjacent soft tissues within the body, with a resultant failure to produce a contrast between the images of adjacent structures or organs. During the first two decades following their discovery, X-rays were used largely for the diagnosis and control of treatment of fractures and for the localization of foreign bodies, such as bullets, during World War I. Early, the physicians using these methods introduced artificial contrast agents, such as a paste consisting of barium sulfate, which is inert and nontoxic when taken by mouth. When it is taken by mouth or introduced by enema, the various parts of the alimentary tract can be demonstrated and examined. Refinements of this technique continue to the present day, and radiological examination of the alimentary tract is an elegant and precise aid to diagnosis. Later, other contrast media were produced that could be injected into blood vessels. The media could thus be used either to demonstrate those vessels, whether arteries or veins, or after their selective concentration and excretion by the kidneys, to show the urinary tract. Within the first few months after Rontgen's discovery, attempts were made to produce films of moving objects; thus, it was soon realized that radiology might be able to depict function and so demonstrate dynamic physiological functions rather than just static anatomy. Technical difficulties and the hazards of a high dose of radiation to the patient prevented the proper development of this technique. In the 1950s, an electronic method was devised to intensify the image, the so-called image intensifier, which made possible the overcoming of the technical difficulties, and now cineradiography is routinely performed in many departments. During the whole period of development, photographic techniques were also continually improved. Single-coated photographic plates were used at first, and then double-coated photographic films; photographic emulsions have now been developed to such a point that high speed can be provided with good definition and little intrusion of photographic grain into the image. Similarly, processing methods have been improved; automatic processors now can deliver a fully processed dry film in 90 seconds.

Emergence of the radiobiologist

In radiotherapy, use is made of the biological effects of ionizing radiations. The early workers noted that large doses of radiation would cause, after some delay, reddening of the skin, which might lead on to blistering and ulceration. Even small repeated doses, if occurring often enough, might produce serious skin lesions. It was argued, then, that a phenomenon producing such damage to normal tissues might be directed toward abnormal and undesirable tissues, such as cancer. Research into the fundamental nature of the biological action of radiation continues to the present day, and a new race of scientist, the radiobiologist, has emerged. About the same time as the uses of X-rays were first being applied to medicine, radium was discovered, and also the importance of the time factor as a modifier of the reaction of tissue to radiation was established. Thus was born the art of radiotherapy, at first based entirely on an empirical approach. It was soon noted that ionizing radiations also have the effect of alleviating pain, and so in the period of development of this form of treatment it was used rather extensively in the treatment of painful forms of arthritis, swellings of the salivary glands, herpes zoster or shingles, overgrowth of adenoids in children, and several other benign conditions. As knowledge of the possible harmful effects of radiation has grown, many of these applications have been discarded, except in special circumstances and under strict supervision.

The vast bulk of the practice of radiotherapy has to do with cancer, and it is here that the great advances have been made. The first step was to establish a unit of measurement. Since the early days physicians practicing treatment with ionizing radiations have worked in close collaboration with physicists, and much of the fundamental research has been undertaken by radiation physicists working alongside their medical colleagues. The establishment of an internationally accepted unit of measurement at Stockholm in 1925, the roentgen unit, enabled physicists to undertake similar calibration in different centres and provided a means of devising a system of dosimetry.

THE PROFESSIONS ASSOCIATED WITH RADIOLOGY

The radiologist and radiographer

A radiologist is a physician who has specialized in radiodiagnosis or radiotherapy, or both. During the evolution of radiology most physicians in this branch of medicine practiced both forms of the specialty, and in certain parts of the United States, in France, Germany, and some other parts of southern Europe, in South America, and in India, it is still common to practice both. Since the end of World War II, however, in the United Kingdom, the Scandinavian countries, The Netherlands, Australia and New Zealand, and the major cities in the United States, the two have been completely separated, with separate training programs. This is a natural development as equipment and techniques have become more sophisticated and as each branch has tended to absorb more fringe activities, such as the use of ultrasound techniques in diagnostic radiology and the use of chemotherapeutic agents in the treatment of cancer in therapeutic radiology.

In most Western countries now, for a physician who wishes to specialize in radiology, after qualifying as a physician, the training period is four years. The majority of radiologists practice in hospitals. Equipment is now so exotic and the facilities required so demanding that it is usually possible to produce the financial requirements and the supporting staff only within an institution. It is usually also only in large institutions with private or public financial backing that significant research can be undertaken and advances made. Nevertheless, in all countries throughout the world, there is always a demand for private facilities, and these exist at a high level of work for all but the more sophisticated techniques in most countries. The radiologist is the medical practitioner probably most often consulted by other medical practitioners. In radiodiagnosis he has a clinical problem referred to him; he investigates it either by a simple examination, such as for a fracture, or by a more complex technique, such as the introduction of a catheter (tube) into a renal (kidney) artery and showing the renal circulation by injecting a contrast medium; he then interprets the results to the referring physician. The surgeon, the orthopedist, the internist, the gynecologist, the pediatrician, and the general practitioner all refer problems to him. In radiotherapy he again is a man with problems referred to him—*e.g.*, the patient with cancer for advice on treatment. This treatment he takes over and conducts and continues to review in collaboration with his colleagues. In the Western world, with the increasing expectation of life, and therefore the increasing incidence of cancer, he is becoming more and more a key figure in the satisfactory treatment of a major human problem.

Radioactive isotopes are unstable forms of elements that emit radiation in the process of breaking down into other elements. With the growth of the use of these isotopes for diagnosis and therapy, a new branch of medicine is developing—that of the specialist in nuclear medicine. Some of the investigations carried out by such specialists lie outside the normal scope of radiodiagnosis; many of them are more related to physiology and clinical biochemistry. Thus, nuclear medicine exists with part of its frontier overlapping radiology; many radiologists practice nuclear medicine, and also many of those who practice nuclear medicine are drawn from such other disciplines as endocrinology, gynecology, and biochemistry.

The radiologist is supported by a radiographer or radiological technician. These highly trained technicians in most Western countries undergo a two-year period of training and carry out most of the day-to-day conduct of patient investigation or treatment under the guidance or supervision of the radiologist. In many less developed countries, where the need for radiology as an aid to diagnosis is far greater than the ability of the government to provide radiologists, it is essential that technicians be trained and sent to outlying places in order to carry out the technical aspects of such examinations.

In places in which radiotherapy exists on any substantial scale, physicists are needed and in most instances are provided. Medical physics has developed or grown alongside the growth of radiotherapy. Now that medical physicists exist, they provide a service to a greater clientele than radiotherapists; with the increasing need for an awareness of radiation hazards and the constant monitoring of all radiation workers including radiographers, the diagnostic radiologists also receive a service from them.

Radiation: types, sources, and hazards

TYPES AND SOURCES OF RADIATION

X-rays. X-rays form part of the broad spectrum of electromagnetic waves of which radio waves, microwaves, infrared rays, visible light, ultraviolet rays, and cosmic rays are also component parts. These waves are energy waves, the various parts of the electromagnetic spectrum differing in wavelength; whereas the wavelength of radio waves is measured in metres, that of X-rays is measured in angstrom units. (The vast difference in size thus indicated is difficult to grasp: there are 10,000,000,000 angstrom units in a metre.) X-rays have various physical and biological properties that are made use of in both diagnostic and therapeutic radiology. In diagnostic radiology, use is made of their penetrating property, of the fluorescent effect that they have on certain substances, and of their photographic effect. In therapeutic radiology, use is made of their penetrating property and their biological effect.

X-ray production

Production of X-rays is brought about when electrons travelling at high speed collide with matter in any form. The usual method of producing them is by means of an X-ray tube, an electronic device consisting of an evacuated glass tube containing two electrodes to which is applied an alternating current of many thousands of volts. The high voltage is produced by an X-ray generator.

X-ray generators are in fact step-up transformers. The normal domestic or industrial electric supply of alternating current is fed into the transformer and stepped up to the required voltage—in the diagnostic field ranging from 25 to 150 kilovolts or occasionally 200 kilovolts, and in the field of radiotherapy ranging from 10 to 300 kilovolts. Obviously, at the differing kilovoltage levels, the transformers differ considerably in complexity, size, weight, and manoeuvrability. At the lower kilovoltages in some machines, the X-ray tube itself, being a valve, acts as a rectifier (a device for changing alternating to direct current), no current passing from cathode to anode (negative to positive electrode) during half the cycle, the other half being utilized—a process called half-cycle rectification. In the more modem type of machine, full-wave rectification is achieved by inserting four electronic or solid-state rectifiers in the generator between the high-voltage terminals of the transformer and the terminals of the X-ray tube. In the extremely sophisticated machines, a means of producing what amounts to straight-line current across the tube has been achieved by the use of six such rectifiers. At this point the needs and design of sources and other factors for diagnostic radiology and radiotherapy differ.

Description of X-ray tube

X-ray tubes consist of an evacuated diode (electronic tube containing a cathode and an anode) surrounded by a metal casing that is lined with lead except for a small port or window through which the useful beam emerges. The space between the casing and the glass insert is filled with insulating oil, which also has the property of being a good conductor of heat. The cathode houses a filament within a focussing cup, which is supplied with current from a low-voltage transformer within the generator. The filament can thus be heated to incandescence, providing a halo of electrons. The anode consists of copper, a good conductor of heat, with a small block of tungsten (which has a high melting point), called the target, about one-half inch square, set in the anode face. When an extremely high current is applied to the cathode and the anode, the available electrons are attracted to the anode along a path in the vacuum, striking the target with tremendous energy. This impact creates two products—heat and X-rays. The face of the anode is angled in such a way that the maximum beam of X-rays is directed through the port in the tube casing. Only about 1 percent of the energy directed at the anode results in the formation of X-rays, the remainder being wasted by heating of the target. Tube manufacturers have devised various means of preventing the melting of the target—*e.g.*, uses of a metal of high melting point and an anode that is a good heat conductor; oil circulation around the tube insert and anode terminal; and rotation of the anode during exposure so as to expose a changing surface of the target to the stream of electrons.

The higher the current in the cathode filament, the more electrons there are available to join the stream to the anode, and so the greater is the intensity of the X-ray beam. The higher the potential difference (*i.e.*, kilovoltage) between the cathode and the anode, the greater is the speed of the electrons striking the target, which results in producing X-rays of a shorter wavelength and therefore of greater penetrating power. The controls for varying filament current and for varying kilovoltage are within the generator and are manipulated from the control table on the X-ray unit. One further factor influences the quantity of X-radiation produced, the time during which the current, measured in milliamperes, passes across the tube. Intensity of the X-ray beam, therefore, is expressed as the product of tube current and time—*i.e.*, as milliampere seconds.

Radiographic quality is the term used to describe the photographic image produced on photographic film and is dependent on a number of factors. Photographic factors affecting quality are described in a later section, but some physical factors also have an affect and are properly described here. The shorter the wavelength of the radiation used, the greater is the penetrating power. The interpretation of radiographic images depends on producing shadows of adjacent structures. X-radiation is absorbed differentially by tissues of different densities, the resulting photographic image portraying this differential absorption. It is necessary to use X-rays of greater penetrating power to produce satisfactory radiographs (X-ray pictures) of the skull, for example, than of the soft tissues of the leg. Similarly, the photographic blackening of a film depends on the intensity of the beam, which must be strictly controlled.

The X-ray beam emerging from a small target on the X-ray tube acts like a point source of light and produces a sharp image, whereas the beam from a broad target produces a penumbra effect (*i.e.*, a grayish margin). Because a small target cannot be subjected to so intense a bombardment of electrons, however, a compromise must be achieved.

X-radiation is absorbed in air as the square of the distance. Thus, the greater the distance of the object and the film from the source, the less the intensity of the beam will be; the nearer to the source the object and film are placed, the greater will be the geometrical distortion of the image. Thus, optimum conditions for radiographic procedures are essentially a compromise.

Use of grids to reduce X-ray scatter

One further feature is involved. If a photon (an amount of energy) of X-radiation strikes an atom and dislodges an electron and is of greater energy than the energy required to dislodge the electron, the residual energy continues as a photon of scattered radiation in a different direction. The greater the intensity of an X-ray beam and the thicker or denser the part being penetrated, the greater is the scattered radiation. Scattered radiation may produce fogging and blurring of the image. Therefore, instruments known as grids are interposed between the patient and the film. Grids consist of an assembly of lead strips interspaced with strips of wood or plastic or other radiolucent material (material partially penetrable to radiation). The relation of the depth to the width is called the grid ratio; the greater the ratio the greater is the efficiency to absorb scattered radiation. Grids may be stationary or moving, the latter being synchronized with the X-ray exposure, the movement being either unidirectional or oscillating.

X-ray tubes for therapy machines are, in principle, mostly the same as for diagnostic radiology, differing only in detail. Target size is not so critical as for diagnostic tubes so long as excessive penumbra is avoided. Cooling of the anode may be achieved by a variety of means; for example, having the copper anode in metallic connection with a number of metallic fins or sheets outside the tube, which can be cooled by a flow of oil or other suitable material past them. For low-voltage X-ray equipment, the target must be placed close to the skin, and the window must be as thin as possible, so that excessive filtration of the beam is avoided. In supervoltage machines a transmission target is used in which the useful X-ray beam is taken from the target in the same direction as the incident electron stream, so that the emergent beam is filtered by the target material itself.

Dosimetry is the science of the measurement and calculation of dose distribution in the tissues and of depth of dose. The units of dose have been redefined from time to time.

Three types of units for measuring ionizing radiation are in common use: the roentgen, which is the unit for absorption in air; the rad (radiation absorbed dose), which is the unit of absorbed dose; and the rem (roentgen equivalent man), the quantity of any ionizing radiation that has the same effect as one rad of X-rays (of 200–250 kilovolts).

The roentgen is the quantity of X-radiation or gamma radiation that produces in 0.001293 gram of air (one cubic centimetre of dry atmospheric air at 0° C [32° F] and at a pressure of 760 millimetres of mercury—the standard atmospheric pressure at sea level) one electrostatic unit of positive or negative electricity. The rad is the amount of radiation that delivers energy equivalent to 100 ergs to a gram of irradiated tissue.

Several instruments have now been devised for dose measurement. So important is the accurate calculation and planning of dose delivery that the existence of sophisticated physics support—with physicists, physics technicians, and physics workshops—is now regarded as an essential for any centre at which radiotherapy is practiced. The applications of this in clinical practice are considered in more detail in a later section.

Gamma rays and X-rays compared

Gamma rays. Gamma radiation, the wave radiation that arises in the nucleus of a radioactive atom, may occur naturally, as from uranium and radium, or may be produced artificially, as from the radioactive isotopes cobalt-60 and iodine-125. (A radioactive isotope is an unstable variant of a substance that has a stable form; during the process of breaking down, the unstable form emits radiation.) Gamma rays and X-rays have similar characteristics, and differ only in their wave length and their origin. The energies of the gamma-ray quanta given off by a particular radioactive element are characteristic of the nucleus from which they come. Gamma rays from the isotope cobalt-60, for example, are confined to two wavelengths, 10.5 X.U. and 9.3 X.U. (an X.U., or X unit, is approximately 0.00000000001 centimetre). Similarly, the spectrum from radium is complicated but still consists of a number of discrete wavelengths. By comparison, an X-ray beam as generated in a conventional X-ray tube is heterogeneous, consisting of radiation of many wavelengths. The penetration of gamma rays is measured by the half-value layer—the thickness of suitable material that is required to reduce the intensity of the radiation by one-half. Ten millimetres (0.4 inch) of lead or ten centimetres (four inches) of tissue is needed, for example to reduce the radiation of isotope lead-214 by one-half; only two centimetres (0.8 inch) of tissue is required for isotope iodine-125, which has low penetrating power.

Radioactive isotopes. Radioactive isotopes have already been considered in relation to gamma radiation; in later sections their clinical uses in both diagnostic and therapeutic fields are discussed. Here mention need only be made of isotopes as a source of radiation. Radioactivity is the property, possessed by some isotopes, of emitting ionizing radiations spontaneously. These radiations are emitted from the nucleus of atoms when the nucleus is unstable because of its structure. Radioactive isotopes are indistinguishable chemically from the stable form of the element. The radiations emitted consist usually of charged particles, nearly always accompanied by gamma radiation. These radiations, in addition to gamma rays, may consist of: (1) alpha particles, which are positively charged helium atoms travelling with high energy and high velocity; they have little penetrating power but can cause local biological damage. (2) Beta particles, which are negatively charged electrons; they have high energy and high velocity and are relatively easily absorbed. (3) Positrons, which are the same as beta particles except that they carry a positive charge; the range of a positron is small, and on coming to rest it combines with an electron, producing a pair of gamma photons. The radioactive isotopes used in clinical practice are mostly gamma emitters, though some beta emitters are used in both branches of radiology.

Ultrasound waves. Ultrasound waves, produced by a device called a transducer and of about 1,500,000 to 5,000,000 hertz, or cycles per second, are able to pass through body tissues in straight lines until they encounter an interface, or common boundary, between two types of tissue. At this point the waves are reflected as echoes. The echoes, received back at the transducer, can be converted into electrical impulses and shown as waves on the fluorescent screen of an oscilloscope. Two types of scanning with ultrasound waves, known as the **A** scan and the compound B scan, are used to determine the depths of the reflecting interfaces within the body. These diagnostic techniques, analogous to the use of echo sounders to chart the ocean floor, are mentioned further in a later section.

Infrared rays. Thermography, the use of infrared rays diagnostically, is a relatively new diagnostic measure. It represents a spin-off from military advances and rocketry fields. A thermograph is a graphic record of the infrared radiation emitted from the skin. The record is obtained by scanning the skin's surface, and it indirectly relates to cutaneous blood supply. The method is simple, harmless, and relatively inexpensive.

The infrared radiations are concentrated and focussed by a system of mirrors, the area of skin being scanned somewhat as a motion picture camera records the changing events in a scene. The beam of heat radiation is then focussed on a highly sensitive crystal, usually composed of indium and arsenic salts, which is cooled on one surface by liquid nitrogen to below —160" C (—256" F) to increase its sensitivity. The crystal converts the heat energy into units of electrical energy, and the latter can then be displayed on a television monitor. Permanent records of the display can be obtained with Polaroid films. Various modifications can be employed. Thus, isotherms can be drawn, lines connecting points within a given temperature range. A variety of instruments is available. One widely employed unit can record thermographs in the range 0"–1,000" C (32"–1,800" F) when used commercially in blast furnace control, but when adapted to clinical use in accurate to 0.2" C (0.4" F).

RADIATION HAZARDS

Mention has already been made of the dangers of exposure to ionizing radiation. These dangers may be immediate and in the form of a burn, just as a burn may be caused by other forms of electromagnetic radiation, such as visible light or ultraviolet rays, except that in the case of ionizing radiations the bum **may** affect deeper tissues. In radiodiagnosis with modem apparatus, the doses administered, even under prolonged screening procedures, are so small as to be far below the range at which such an effect is likely or possible. In radiotherapy with modem apparatus, the control of beam direction, of field of application, and of depth within the tissues of dosage also practically eliminates this possibility.

Types of remote danger

Remote dangers may be either (1) malignant; *i.e.*, leading to a localized cancer, such as a skin cancer, or to a generalized cancer, such as leukemia; or (2) genetic; the genetic effect results from a genetic mutation, of which the individual is unaware but which may affect future generations, as the affected individuals continue to reproduce.

With regard to malignancy, the doses administered in radiodiagnostic investigations are regarded as being safe, though it is thought that in the early period of the development of the technique of cardiac catheterization (introduction of a tube into a vein and along the vein into the heart) before apparatus had become as refined as it is today and when some of these procedures were not in the hands of radiologists or under their supervision, large bone-marrow doses may have been administered that could subsequently have led to leukemia. It is virtually impossible to prove such a course of events. Similarly, in radiotherapy, dose and beam control are now so highly developed that the possibility of causing cancer is highly unlikely. It is a fact, however, that in the 1930s wide-field radiotherapy was a standard practice in treatment of ankylosing spondylitis, a form of arthritis of the spine occurring often in young men. Follow-up 20 years later of a large group of persons thus treated showed a higher incidence of leukemia than in the ordinary population.

With respect to genetic effect, the doses administered in radiodiagnostic procedures could be significant, especially those involving the lower part of the trunk and the upper part of the thighs. All radiologists and all radiographers in their training receive instruction and guidance about the importance of filtration of the beam, limitation of beam size, sex-gland protection, especially in young persons, and departmental discipline. It is considered that no unnecessary X-ray examination should ever be carried out, and that the physician requesting an investigation should always consider that the medical needs and advantage likely to accrue from the examination are clear and outweigh the admittedly small potential danger. Provided that protective devices are available, that the technicians are protection-conscious, that departmental discipline is good, and that the requesting physician is circumspect, dangers are unlikely to arise. In radiotherapy, dose and beam control render genetic effects unlikely except in certain unavoidable cases. Similarly, the age group and type of condition being predominantly treated often render the likelihood of further procreation small.

Similar effects do not occur with nonionizing radiations.

The practice of radiology: techniques and equipment

DIAGNOSTIC RADIOLOGY

In modem medicine one of the basic essential aids to diagnosis is the science of radiodiagnosis, using X-rays, radioactive isotopes, or ultrasound as a means of demonstrating normal or abnormal anatomy and function.

X-ray techniques. ***Exposure and timing.*** When X-rays are generated by means of a low kilovoltage, the radiation has a long wavelength and a relatively low penetrating power. Radiations produced in the five- to 20-kilovolt range are used mostly for laboratory work. From 25 to 45 kilovolts, one of the few clinical applications is X-ray examination of the breast. Radiations of 50 to 100 kilovolts are used for many of the day-to-day routine examinations--of the skeleton, the chest, the alimentary tract, the urinary tract, and so forth. X-rays generated by means of a kilovoltage above 100 kilovolts have a short wavelength and high penetration. In the diagnostic range it is rare to use a kilovoltage either above or even as high as 200 kilovolts. The greatest field of application is in the range from 100 to 125 kilovolts, with some techniques that make use of up to 150 kilovolts.

Elimination of movement

Wavelength, and therefore penetration, is dependent on the generating kilovoltage, but this is not the only factor concerned in the production of a satisfactory radiograph. Intensity of radiation is a factor, this being dependent on the current passing between the cathode and the anode of the X-ray tube during an exposure and on the length of the exposure. In routine work it is essential to eliminate movement so as to obtain the greatest possible sharpness of image. This is achieved by stabilizing the part under examination, such as a limb, with sandbags, or by inducing the person being examined to hold the breath, and always by using the shortest time exposure possible. Not all movement can be stopped, however, and cardiac (heart) movement can cause blurring. In order to overcome this, timing devices have been designed to give exposures of as little as 1/120 of a second or even shorter, but this in turn has made it necessary to build generators that will provide a greater milliamperage. In conventional diagnostic work, most generators work in the 200 to 500 milliamperage range, but generators have been built that will deliver up to 1,000 milliamperes.

Films and intensifying screens. X-radiation produces a photographic effect on photographic film, but not as great an effect as visible light. X-radiation also causes certain substances, mainly barium platinocyanide, calcium tungstate, and zinc sulfide, to fluoresce, producing visible light. As it is always desirable to keep time exposures to a minimum and also to deliver the least amount of radiation to the subject under examination, use is made of both these features. Double-coated film, with a silver halide photographic emulsion on a cellulose acetate or polyester base, is used for the purpose, so as to achieve maximum film blackening from any exposure. Film cassettes are used that contain a pair of intensifying screens made of fluorescent material between which the film is pressed. Good contact between screens and film is essential to prevent blurring. The major effect on the film, therefore, is due to visible light. Because the grain size of the crystals of fluorescent material can subtract from the sharpness of the image, for examinations in which minute detail is essential (*e.g.*, of hands or feet), the photographic effect of X-rays rather than of visible light is used.

Rapid film processors

Processing of X-ray films. Processing of X-ray films is the same in principle as any photographic processing and is carried out in a darkroom. In many departments this is done manually; it consists of developing, rinsing, fixing, and washing, followed by drying. This must be carried out according to a strict regimen, temperature and time control being of the greatest importance. Development at 68° F (20" C) for five minutes produces a wet film for scrutiny after complete washing in 30 or more minutes. In recent years automatic processors have become available, which, still using standard film, produce a dry film in 11 minutes or as little as seven minutes. These processors have now been introduced into most major departments. More recently, rapid processors have been designed that produce a dry film in 90 seconds. This has been brought about by raising the temperature of development to somewhere in the region of 100" F (about 40° C), by introducing a hardener into the gelatin of the emulsion (so as to prevent melting), and by modifying the sensitivity of the silver halide in the emulsion. Some increased photographic graininess is considered in many busy departments to be more than compensated for by the speed with which dry films can be produced.

Some special procedures. Tomography, also called body-section roentgenography, is a procedure for demonstrating selected planes within the subject under examination. A conventional radiograph is a two-dimensional representation of a three-dimensional subject, all structures lying in the direction of the X-ray beam being superimposed. In tomography a plane in the line of the beam is selected, and the shadows of all structures above and below that plane are blurred. Thus, the shadows of unwanted structures are blurred, leaving in focus those shadows in the selected plane. This is achieved by moving the source of the X-rays (*i.e.*, the tube) in one direction over the subject, and the film in the opposite direction under the subject during the exposure, the tube and film having a connecting link that rotates about the fulcrum at the level of the selected plane. The movement of tube and film are thus at all times opposite and with velocities proportional to one another. This technique, devised in the early 1930s, now has a wide field of application. The apparatus can be simple, but sophisticated apparatus is also now available for this purpose.

Stereoscopy is a method of taking two films of a selected area, the films and subject remaining in identical spatial relationship but the tube being shifted slightly between the two exposures. The shift used is usually six centimetres (2.4 inches), this being the average distance between the pupils of an observer's eyes. The right shift is then viewed with the observer's right eye, and the left with the left eye, special binoculars being available for this purpose; the resultant image is a three-dimensional picture.

Macroradiography is an enlargement technique that can be performed with X-ray tubes having very small targets. If the effective target of the tube is 0.3 millimetre (0.01 inch), this will act as a point source producing little or no penumbra. In conventional radiography the part under examination is placed as close as possible to the film so as to preserve sharpness of the image. With a 0.3-millimetre target the subject can be placed at a distance from the film and enlargements made as great as to twice the original size that show a degree of sharpness comparable to that achieved by conventional procedures. In certain fields of work, scrutiny of such macroradiographs enables interpretation and demonstration to be made more satisfactorily.

Microradiography is a laboratory technique for examining thin sections of specimens. By means of a generator that produces X-rays in the five-kilovolt to 20-kilovolt range—thus of low penetration—images of extremely thin sections can be obtained. Some such machines with a molybdenum target and a beryllium window can produce an almost homogeneous beam of X-rays. Film having a single coat of extremely fine grain or maximum resolution plates are used; the exposed films or plates can subsequently be examined under the microscope by magnification up to X60 without interference from photographic grain.

Contrast media for special procedures. The procedures in which contrast media are used are described in some detail in the section on clinical applications. Contrast is defined as the difference in density between adjacent objects or structures or the difference in light transmission by the shadows of these structures or objects. The whole of radiological interpretation is dependent on the quality of contrast and the quality of sharpness. Into some structures, which do not create a shadow differing in density from the adjacent structures, artificial contrast media are introduced in order to make detailed examination of the structures feasible. Three main groups of contrast media are employed: gas (air, oxygen, or carbon dioxide), barium sulfate, and organic iodine compounds. Because gases absorb less radiation than the surrounding tissues, shadows with increased blackening result. Barium and iodine atoms absorb more radiation than the surrounding tissues, thus causing denser shadows. Gases are used for examination of the ventricular system of the brain (the brain cavities), for intra-abdominal problems, and in some examinations of the alimentary (digestive) tract. There are many and varied organic iodine compounds, with different chemical structures, different degrees of viscosity, and dealt with in different physiological ways by the organs or systems to which they are directed. By use of them the biliary tract, the urinary tract, renal (kidney) function, the vascular system, the chambers of the heart, the spinal canal, the female genital tract, and many other areas can be demonstrated. The essential features of contrast media are that they produce adequate contrast, are simple to handle, and are nontoxic.

Types of contrast media

Fluoroscopy. In fluoroscopy use is made of the fluorescent effect of X-rays. X-rays penetrating the subject under examination impinge on a fluorescent screen; the radiologist observes the image so created and is able to see motion and to move the subject in various directions so as to examine all sides and aspects of a particular structure. There are, however, radiation hazards to subject and operator; because of the increased time required to observe motion, the time factor is long, and tube current is kept low, thus providing only a dim image. To make maximum use of the dim image the operator must be fully dark-adapted. No permanent record of the screen image remains, and the screen image itself is too dim to photograph. Most machines, therefore, are fitted with devices for sliding a film between the subject and the screen and making a conventional X-ray exposure. This cannot be performed simultaneously with observation of the screen image, though many simple and many elaborate devices have been designed to cut down the time interval between the two events. This method was the standard procedure for examination of the alimentary tract for more than three decades.

Image intensifiers, photofluorography, and television. Electronic amplification of the screen image became a reality during the late 1950s and the 1960s. X-rays are used to produce an electron image of the subject. The electron image is then accelerated by a high-voltage field aided by electron lenses and mirrors, and the enhanced electron image is then converted to a visible image. This is the principle of the image intensifier. This image can be observed visually through a mirror system, it can be photographed (this process is called photofluorography), or a television camera can be fitted to an aperture on the intensifier outlet and the image observed on a monitor.

Photofluorography and television observation can take place simultaneously by means of separate apertures, and thus observation of what is being photographed is achieved. The television image can be stored on a videotape recorder and subsequently viewed repeatedly and at leisure. If the image is to be photographed, either a 100-millimetre camera or a 70-millimetre camera is used. The 100-millimetre cameras are commonly used to produce single-frame pictures (for example, of the chest); 70-millimetre cameras are used either for single-frame exposures or for exposures of up to six per second (as in alimentary tract work). By use of a 16- or 35-millimetre motion-picture camera, rapid serial sequences can be made; joint movements, micturition (urination) studies, and the swallowing mechanism are all fields of application, but the most common field is in the study of the heart, using a contrast medium (angiocardiography). The motion pictures are usually taken at 32 frames per second, but recent developments favour high-speed cineradiography (200 frames per second) in the investigation of some cardiac conditions.

Ward and operating-theatre radiography. Portable and mobile X-ray machines of considerable output have now been designed, some of conventional design, some battery-operated, and some using a condenser-discharge mechanism that can be used outside the X-ray department. There is a growing demand for X-ray work in the wards, with the development of intensive care units, and in the operating theatres, where radiographic control of surgical procedures is becoming more exacting.

Clinical applications of X-rays. *The skeletal system.* Among the first applications of X-rays for diagnostic purposes was visualization of bones. In fractures, the actual break in continuity of a bone can be portrayed, as well as its site, extent, and type, together with important features such as shortening or comminution (shattering into small fragments). The satisfactory reduction of the fracture and the progress of bony union can be demonstrated. In disease processes the radiological changes lag behind the clinical state so that the diagnosis usually cannot be made early—for example, in an acute infection such as osteomyelitis (inflammatory infection of bone). In a chronic disease, however, such as tuberculosis or chronic arthritis (inflammation of a joint), in which the onset is usually more gradual and unnoticed and the progress slower but more inexorable, changes in either the bone or the joint can often be demonstrated in minute detail. Normal bone consists of the cortex, which shows as a dense shell on the outside, and the medulla, which shows as fine honeycombed meshwork of bony plates, or trabeculae. Joint cartilage does not cast a shadow; thus a joint appears as a space between two bone ends. Changes in this space and in the underlying bone are an indication of joint disease, and on the character of these changes the type of joint disease can often be diagnosed. Thus, in addition to infections, long-standing conditions, such as rheumatoid arthritis and ankylosing spondylitis; degenerative disease, such as osteoarthritis and Paget's disease; deficiency diseases, such as scurvy and rickets; benign and malignant tumours; congenital malformations and hereditary congenital diseases, such as hemophilia, can all be demonstrated. Occasionally, in order to demonstrate the extent of a disease process or an injury within a joint, a contrast medium is injected into the joint cavity, and films are taken; this is the technique of arthrography.

Observation of fractures and of chronic disease

Usefulness of chest X-rays

The respiratory system. Viewing of the lungs and the other structures within the chest is the most widely used application of X-rays in clinical medicine. Air in the lungs absorbs little or no radiation, and so the blood vessels in the lungs appear on the radiograph as branching linear shadows, and abnormalities in the lungs appear as distinct shadows contrasted against the background of the air content of the surrounding area. Similarly, changes in the shape of mediastinal structures (the structures between the two lungs) appear as abnormal, projecting out against the air contrast of the adjacent lung. Thus, lung diseases (such as pneumonia, tuberculosis, pneumoconiosis, and cancer) can be diagnosed. In many Western countries, in the campaign that has been successfully waged against pulmonary tuberculosis, one of the two most important tools has been chest radiography, the other, of course, being the development of anti-tuberculous drugs. In the lungs, the air content is mostly in the alveolar spaces (the minute air sacs), and it may not be possible to detect changes in the respiratory passages—the bronchi and bronchioles. The technique of bronchography has therefore been devised: a radiopaque contrast medium is run into the bronchial tree, and minute changes in this structure are shown with great anatomical accuracy. Similarly, during a routine chest examination it may not always be possible to define the shape and limits of a lesion because of the superimposition of the shadows of overlying structures. Tomography, which eliminates these unwanted shadows, is widely used in the investigation of intrathoracic disease (disease of structures in the chest).

The cardiovascular system. Perhaps the greatest strides have been made in recent years in the investigation of the system of arteries and veins. The two contributory factors to this progress have been the development of highly sophisticated apparatus enabling the taking of high-speed motion pictures and the introduction of catheter techniques. By the introduction of a catheter, or tube, into a vein in the arm and threading it through until ıts tip reaches the heart chambers, or even until the tip has passed through the heart and into the pulmonary arteries, detailed investigation of the heart can be carried out. Pressures can be determined at different points along this course; blood can be withdrawn at various sites for analysis of oxygen saturation; finally, a contrast medium can be injected to demonstrate the size and shape of heart chambers and valves, and also any defects in chamber walls because of congenital lesions. Expertness in this procedure progressed rapidly after World War II, but the real revolution occurred in the 1950s when a catheter was developed with a shaped or curved end and with a central guide wire that could subsequently be withdrawn in order to allow the injection of contrast medium. Many variations on this have been developed; it is now possible to introduce a catheter into almost any artery or vein of reasonable size in the body by threading it from a puncture site in the leg or arm to the desired point for injection. Thus, it has become possible to examine the chambers in the left side of the heart as well as the right side, and the investigation of cardiac disease has become an extremely refined procedure. Similarly, it is possible to carry out coronary arteriography (X-raying of the coronary arteries), and, as a result, surgery of the coronary arteries is developing. It is possible to show the vessels of the liver or the alimentary tract, the renal circulation, or the pelvic vessels. In the pelvis, the placental circulation in a pregnant woman can be shown and thus the placental site can be localized in suspected cases of placenta praevia (abnormal location of placenta, so that it tends to precede the child during birth). The vessels of the limbs can be shown, and the whole field of vascular surgery, in addition to cardiac surgery, has grown up as a result. Another field that has recently developed in vascular work is the demonstration of the lymph vessels (lymphangiography). In this technique a contrast medium is injected into the .fine peripheral lymph vessels, and its progress through the meshwork of lymph vessels and glands is followed radiographically.

Use of catheter in investigation of blood vessels

The central nervous system. Investigations of the brain and spinal cord have reached an advanced stage; the subspecialty of neuroradiology is now recognized. The bony anatomy of the skull and spine can be demonstrated in considerable detail by conventional techniques. Skull radiography is a precise technique requiring accurate knowledge of the anatomical landmarks on the part of the radiographer. He must take immense care in the positioning of the patient, have angulation of the patient's head and of the X-ray tube precisely accurate, and use an X-ray exposure exactly suited to the investigation. Fractures of the skull and facial bones can be demonstrated, as can their relationship to other structures, such as the air sinuses. Infections in the paranasal and mastoid air sinuses (bony cavities alongside the nose and behind the ear) can be shown, as can destruction of bone in the skull by tumours. Changes due to long-standing increase in intracranial pressure may be seen. Changes of a similar nature may be detected in the spine.

By injection of a contrast medium into an artery in the neck--either the carotid artery or the vertebral artery—part of the cerebral circulation can he shown, and by injection in turn into the arteries on both sides of the neck the total intracranial circulation can be investigated. Such conditions as aneurysms (an aneurysm is a dilation and thinning of a vessel wall at a weak point), degenerative vascular changes, and brain tumours can be diagnosed. Another technique, known as encephalography, is to inject air into the subarachnoid space in the spine (the space between the middle and the inner covering of the spinal cord) and allow it to rise into the cerebral ventricles (the cavities in the brain), thus demonstrating their site and size; displacements due to atrophy or tumours can thus be shown.

Lesions in the spinal canal causing disease due to pressure on either the spinal cord or the nerve roots can be shown by the technique termed myelography; a radiopaque contrast medium is injected into the spinal canal and, under fluoroscopic control, is allowed to run up and down the canal while suitable radiographs are taken.

The alimentary tract. One of the first fields in which contrast media were used was that of examination of the alimentary tract. A barium sulfate mixture is used either by mouth to examine the esophagus (gullet), stomach, and small intestine, or by enema to examine the large intestine. Various refinements have been introduced, such as a combination of barium and air contrast to improve the sharpness of the depiction of anatomical details and so enable the radiologist to detect smaller and earlier evidence of disease. In the hands of an experienced radiologist, diagnosis of diseases of the alimentary tract is now a highly accurate procedure, though it is important to realize its limitations and the great need for close cooperation between physician and radiologist.

The biliary tract. For examination of the gallbladder and biliary tract a contrast medium can be given orally or introduced into a vein, or it can be injected directly into the biliary tract during or after a surgical operation. The contrast medium given orally is an organic iodine compound that is secreted by the liver along with bile. The gallbladder absorbs water from the bile containing the contrast medium; thus, the medium becomes concentrated and casts a radiographic shadow. Stones within the gallbladder can be shown by this method; the ability of the gallbladder to contract, a normal function, can be assessed by having the subject swallow a substance that normally causes such contraction. A clearer demonstration of the system of bile ducts can usually be obtained if an organic iodine compound is injected into a vein; this method is particularly useful if the gallbladder has been removed or has failed to concentrate substances given orally. Finally, when operating to remove the gallbladder, the surgeon may wish to make certain that there are no residual stones remaining in the common bile duct. This is accomplished by injecting a contrast medium into the system of bile ducts under direct vision, a technique called operative cholangiography.

Assessment of gall bladder function

The urinary tract. With the development of techniques for X-ray studies of the blood vessels, it is now possible to demonstrate the arterial, capillary, and venous phases of renal (kidney) blood circulation. Reduction in the toxicity of contrast media and advances in techniques have enabled radiologists to test with certainty the excretory efficiency of the kidneys, thus allowing earlier diagnosis of chronic renal disease and also showing the anatomy of the excretory and collecting system—the renal calyxes and pelvis (the cavities in which urine collects before passing by way of the ureter into the bladder), the ureter, and the bladder. For investigating the excretory efficiency of the kidney, a catheter technique is used, the contrast medium being injected directly into a renal artery. By this means, vascular abnormalities, such as aneurysms and infarcts (sections of dead tissue), can be shown, scarring due to chronic infection can be seen, and renal tumours diagnosed. To show the anatomy of the excretory and collecting system, an organic iodine compound that is selectively concentrated and excreted by the kidney is injected into a vein. By this means, chronic infection, obstructive lesions, stones, and tumours may be diagnosed, and indications suggestive of vascular lesions and some other conditions observed. The lower urinary tract, the urethra, and the bladder can be examined most effectively by the injection of a contrast medium directly into the outer opening of the urethra.

Other applications. Many other aspects of human anatomy and function are routinely examined by radiological means. The female genital tract can be investigated, especially in cases of infertility, by injection of a contrast medium, to show the cavity of the uterus and to investigate whether the Fallopian tubes are open. The salivary glands can be demonstrated by injection of contrast medium into their ducts. The lachrymal system can similarly be defined by injection into the tear duct. Foreign bodies in the eye or any other part of the body can be accurately localized. The mechanism of swallowing can be depicted and analyzed. .The female breast can be examined (the technique is called mammography), and in many cases lumps not perceptible by touch can be detected and diagnosed as cancer; in other instances, masses that can be felt can be diagnosed as cysts or nonmalignant lesions. With the growth of this branch of medicine, greater specialization has occurred. There are now individual departments dealing solely with pediatric radiology, urological radiology, skeletal radiology, and so on, and there are radiologists who devote their time and skill entirely to one or another of these fields.

Scanning techniques. *Isotope scanning.* In isotope scanning, radioactive isotopes are introduced into the body and their distribution is then determined by observations of their radioaction. By a process of comparison of the distributions so determined, it is often possible to recognize the presence, shape, and size of abnormalities. A radioactive material is administered, usually by way of the veins, and becomes concentrated to different amounts in different organs and systems. Different isotopes are used for different organs and are usually emitters of gamma rays only. Technetium-99, for example, is used in one compound (a pertechnate) for brain scans and in another (technetium sulfur colloid) for liver scans. The radiation emitted is detected by a scintillation counter, which is moved to and fro over the organ at the part of the body being scanned; these messages can then be electronically recorded as marks on paper or as a photographic image. Various scanning devices have now been elaborated, the most recent, the gamma camera, having the advantage of producing a picture four times more rapidly than conventional scanners and so being capable of screening a larger number of patients. Within the abdomen, scanning of the spleen can show the exact site and size of that organ. Liver scanning can distinguish localized lesions, such as cancer, from diffuse disease, such as cirrhosis. Similarly, the pancreas and tumours within it can be shown. The flow of blood through the kidney blood vessels can be demonstrated and abnormalities of function detected. Lung scans are useful in the diagnosis of pulmonary infarction. Brain scans may show localized lesions. The investigation of thyroid function by the use of iodine-131 is now routine.

Detecting and recording scintillations

Ultrasonic scanning. In ultrasonic scanning mechanical vibrations with a frequency of several million cycles per second—far above the range of human hearing—are used. These frequencies can be confined within a narrow beam. The diagnostic procedure is based on the reflection of ultrasonic waves at interfaces between different tissues. The echo amplitudes thus created can be detected by a sensitive receiver. Energy not reflected travels on and is available for reflection by deeper interfaces. Because ultrasound is absorbed rapidly by bone, application of the technique lies mainly at soft-tissue interfaces. The echoes collected by the receiver, as the transducer (the source of the sound) is moved across the surface of the subject, may be displayed on the screen of a cathode ray tube, or photographic records may be made.

In clinical diagnosis the technique is being used increasingly. In the brain it is used for localization of midline structures, especially after a head injury. Similarly, it can be used to determine whether a structure is solid or cystic or to localize foreign bodies in the eye. The progress of cirrhosis of the liver can be assessed in this way without the need for an operation. It is of value in obstetrical diagnosis, in diagnosing cysts and tumours in the pelvic cavity, cysts in the kidney or tumours in the bladder, and in assessing the function of heart valves in cardiac disease. It seems likely that the techniques of scanning organs by means of radioactive isotopes and ultrasound will evolve not as competitive but as complementary methods.

Thermographic scanning. Thermography has been widely used in clinical practice, although its precise status is still uncertain. Alterations in the heat of the forehead skin correlate with blood flow in the brain. The skin over and above the middle part of the eye is supplied almost exclusively by an artery that arises as a branch from the main artery to the brain within the cranium. Thus, reduced blood flow through the latter artery is reflected by reduced heat emission in this skin area.

A wide variety of inflammatory and cancerous conditions in bone, muscle, and other parts of the body can be detected by this means. Similarly, incompetent (malfunctioning) perforating veins in the calf of the leg (they are called perforating because they pass through the membrane connecting the two bones of the lower leg) can be recognized; warm blood from the deep veins can flow to superficial veins if the valves of the communicating channels are not efficient; this is useful information to the surgeon contemplating surgery in patients with varicose veins. Breast cancer can be detected and topographically mapped out by this method, and extensions of the tumour can be noted.

THERAPEUTIC RADIOLOGY

Radiotherapy is the treatment of disease by ionizing radiations; by far the most important group of conditions that respond to such treatment are cancers. As radiotherapists became expert in the treatment of malignant disease, it was a logical development for them to embrace other nonoperative techniques, such as hormone therapy and cytotoxic chemotherapy (attacking cancers with chemicals that destroy cells). Radiotherapy, however, is also used in certain skin diseases and in some other conditions.

Techniques. In the treatment of malignant disease both X-radiation and gamma radiation are used. It will be remembered that X-rays are produced when targets are bombarded by electrons, whereas gamma rays are ionizing radiations with similar properties that come from radioactive materials. In recent years equipment has been developed for producing X-rays of great penetrating power, at least equal to and often greater than that of gamma rays. The equipment designed to produce X-rays of great penetrating power does so by generating an intense beam of fast-moving electrons that strike a target; it can be arranged for the electrons to avoid striking the target and to escape from the accelerating chamber through a thin window. They can be used directly as a beam of therapeutic value. Similarly, some radioactive materials give off a spontaneous emission not only of

Types of ionizing radiation

gamma rays but also of alpha particles and beta particles. Alpha particles have little penetrating powei and are easily absorbed, though they have the property of producing intense ionization in theii path. The penetrating power of the beta particle is considerably greater and its ionizing effect less. Beta-radiation emitters have certain therapeutic values.

X-ray production. Grenz rays (X-rays of long wave and less ability to penetrate) are generated by use of a step-up transformer at voltages as low as ten kilovolts but rising occasionally to 40 kilovolts. With this type of radiation, the modern tube is fitted with a beryllium window that allows a broad beam of X-rays to pass through; the beam can be limited by applicators.

Superficial and medium therapy is achieved in the range of 50 to 140 kilovolts, usually by means of a step-up transformer. The amount is usually transformed into direct current by means of vacuum tubes, thus allowing a greater use of the current. The X-ray tube is usually oil-immersed to promote cooling; this cooling may be supplemented by the use of circulating water. The tube has an inherent filtration, absorbing some of the radiation, and additional filters can be used to control the quality of radiation emitted.

Deep therapy is produced usually with a voltage in the region of 240 to 300 kilovolts with a step-up transformer. With a current of 15 milliamperes, this type of unit can produce a dose of 90 roentgens per minute. The tube is, again, usually immersed in oil, with cooling assisted by water circulation. A variety of filters can be attached to the tube window to control the quality of radiation.

The linear accelerator is a supervoltage therapy machine now in common use. In this device, electrons are accelerated in a straight line by using extremely short radio waves of about ten centimetres' wavelength. The electrons are produced from a thermionic emitter (an apparatus that emits electrons and ions from white-hot materials) and are injected into the accelerator chamber in pulses, so that they are in step with that part of the radio wave in which the electric field will accelerate the electron along the chosen axis, and are directed onto a heavy gold target. By this means X-ray beams of energy from four to 15 million electron volts can be generated. In this type of apparatus it is possible to allow the electrons to escape by changing the solid gold target for a thin window, though at this level of megavoltage their therapeutic value is not great.

The betatron is another apparatus in current use in which electrons can be given enormous energy. In this the electrons are made to travel around and around in a circular path inside a suitably shaped vacuum chamber, and during the time they travel they are made to move with continually increasing energy; the energy either is emitted as an electron beam or is allowed to strike a target with an energy equal to 20 to 42 million electron volts. X-rays produced with this energy level have been found to have particularly useful properties in therapy.

Gamma-ray production. Mention has already been made of the fact that gamma rays may occur naturally in some substances, such as radium, or occur as part of the decay process of artificially produced radioactive isotopes. Several of these are used for therapeutic purposes.

Cesium and cobalt isotopes

Radioactive cesium units are available for gamma-ray therapy. The radioactive isotope of cesium—cesium-137—has a half-life of 33 years (that is, it takes 33 years for half of the cesium atoms to disintegrate). The physical properties of this form of radiation give it certain advantages over deep therapy, and the casing for housing can be relatively small, though protective walls must be much heavier than are required with X-ray units. Cesium-137 is present in substantial quantities in the fission products from uranium and is thus a waste product of chain-reacting piles.

Radioactive cobalt units are also now available. The development of nuclear reactors with high-neutron flux (high emission of neutron particles) has made possible the production of the very active isotope cobalt-60. In these units, the source is permanently mounted in the middle of a large sphere of lead that may weigh as much as a ton; consequently, the design of this type of apparatus produces engineering problems, such as the need to provide heavy concrete protective walls. This type of unit is the most usual in use for gamma radiation.

Radium is a naturally occurring element having chemical properties similar to barium and emitting ionizing radiation. It disintegrates with the emission of an alpha particle, forming another element, radon, in the process. Radium has an atomic number of 88 and an atomic weight of 226. The emitted alpha particle carries away from the nucleus a charge of two units and a mass of four units, so that the radon nucleus has a charge of 86 and a mass of 222. Radon, an inert gas similar to neon and argon, is important for therapy. Radon is also radioactive; it decays with a half-life of 3.82 days and gives off an alpha particle. The resultant atom is known as radium-A, itself an alpha-emitting body giving a product known as radium-B. Radium-B and the next product, radium-C, decay rapidly, giving off a beta particle. The series then continues through four more unstable radioactive products; finally, an atom of atomic number 82 and atomic weight 206 results. This is a normal stable lead atom; at this point the radioactive transformations cease. Such a series is known as a radioactive family. Radium itself is the product of a small series of disintegrations starting with uranium as the parent.

Radium sealed in a container so that the radon and subsequent products cannot escape reaches a stage of radioactive equilibrium and can be used for therapeutic purposes.

Radioactive isotopes of other elements also are used for therapeutic purposes. Radioactivity is a property that some isotopes of all elements possess. It can be produced artificially when slight modifications are made to the nuclear structure of the naturally existing isotopes. Strontium-90, for example, which occurs in the products arising from the fission of uranium, has a half-life of 28 years and has therapeutic uses.

Technical aids. It is important for a radiotherapist, who is to use a beam of ionizing radiation, to have adequate information about the distribution of dose that the beam will produce within the body.

Work of radiation therapist

Radiation physics is the science that has grown up in this context. The work of calibrating equipment, mapping the doses of radiation administered, and protecting patients and radiation workers from unwanted radiation is the work of graduate physicists. Modern treatment centres usually require a team of such physicists.

By the use of applicators the field to which a beam is applied can be defined and limited. By the use of filters the intensity and penetrating power of a beam can be varied, and so the depth of a dose assessed. Dose measurement must thus be carefully planned; this will often require a considerable number of measurements and tests before a particular treatment can be carried out. Similarly, routine checks must be carried out from time to time by the physicists after calibrations have been calculated.

This type of physics department requires elaborate laboratories and workshops. Equipment and instruments for the type of delicate measurement undertaken must be readily available. When carrying out measurements the physicist often uses models (which he calls phantoms) of wax or other substances of absorbing and scattering power similar to those of the part of the body to be irradiated. When detailed planning is proceeding it may be necessary to build molds and jigs in order to plan and deliver dose accurately.

Plaster shells may be made to fit on the part of the body under treatment so as to enhance accuracy of beam direction. All such devices are usually manufactured on the spot in associated workshops.

It is the responsibility of the radiotherapist to judge as closely as possible the location and size of the lesion, the amount and delivery rate of radiation likely to be effective, and the tolerance of neighbouring uninvolved tissues. When this has been done, the physicist determines the penetration, intensity, geometry, and aiming of the single or multiple beams best suited to deliver the radiation in the amounts and at the points stipulated. The technician or radiographer then administers the treatment under the supervision of the radiotherapist.

Clinical application. Growth is a fundamental property of living things, the reproduction of cells occurring by the process of division called mitosis. Growth does not cease entirely even in adults, for the normal replacement of tissues is by the reproduction of normal cells. Most such growth is strictly controlled in the interests of the body as a whole; however, some new growths are not thus controlled and are known as tumours, or neoplasms, and these may be benign or malignant. Malignant growths, known as cancers, spread either locally by invading adjacent tissues or to remote parts of the body through the blood or lymphatic channels. These remote lesions are known as secondary growths, or metastases. Malignant growths always inflict some degree of harm on the host, depending on a variety of factors, such as site of origin, type of tissue from which they arise, rate of growth, age of host, spread, and so forth. In the fight against cancer, radiation therapy, either alone or in conjunction with other forms of treatment, including surgery, is in the forefront.

The effect of radiation on tissues, whether normal or cancerous, is essentially the same, but since cancer cells usually grow more rapidly than normal cells, they are more seriously damaged by the beam. Radiation has the effect of arresting cell growth and division, and this effect can be permanently secured throughout a cancerous growth. Some growths and tissues are more sensitive than others to radiation; some are relatively resistant. Inevitably, adjacent normal tissues are also damaged. Some normal tissues, such as the blood-forming tissues and the reproductive organs, are sensitive to radiation. The training and experience of a radiotherapist enable him to assess all these different factors in planning and conducting the treatment and judging its results in the great variety of conditions that come his way.

A great many cancers can now be cured by means of radiation therapy, alone or in conjunction with other types of therapy. In some conditions, though cure may not be effected, arrest of the progression of the growth may be achieved, while in others, though cure or arrest is not achieved, radiation therapy has a palliative effect. Among the more common cancers treated are those of the breast, esophagus, bladder, brain, skin, uterus, larnyx (voice box), and tongue. Cancers of the blood-forming organs and bone also are treated in this way.

Use of oxygen in tumour therapy

The radiotherapist and his other clinical colleagues have a considerable choice of methods, often influenced by the stage that a cancer has reached by the time that they see it. In some, such as in cancer of the breast or some forms of hone cancer, radiation therapy may be used as an adjunct to surgical treatment. Tumours well supplied with blood vessels and well supplied with oxygen tend to respond more readily to radiation; hence in certain instances the oxygen concentration is artificially raised by having the patient inhale a high-oxygen concentration—about three times atmospheric pressure—from specially constructed chambers or tanks. Certain tumours can be treated with hormones with some effect, so that this is another method that the radiotherapist uses as experience dictates. Cancers of the breast, prostate, thyroid, and uterus may be influenced by hormone therapy. Similarly, some chemical agents, called cytotoxic drugs, are known to inhibit growth and to have an effect on tissue cells, especially cancer cells. Most cytotoxic drugs are administered intravenously; they may be used as an alternative to radiation therapy or in conjunction with it; occasionally they are used alternately with radiation therapy.

Radiation therapy is also useful in the treatment of a variety of skin diseases. Grenz rays have been found efficacious, the depth dose being very small. Similarly, some forms of rheumatism, some forms of inflammation, and some gland conditions can be safely and satisfactorily treated with medium or deep therapy.

Radioactive isotopes are also used as therapeutic agents in this field of work. Iodine-131, which is used in tracer doses in the investigation of thyroid disease, is successfully used in the treatment of thyrotoxicosis (the effects of an overactive thyroid). Similarly, phosphorus-32 and gold-198 have clinical uses in treatment. Strontium-90, which is a pure beta emitter, is successful in the treatment of some eye conditions, such as corneal ulcer.

NEW DEVELOPMENTS

Radiology is the most expensive branch of medicine in any institution, and the development stage in the design of any apparatus is always costly. The manufacturers of apparatus, therefore, must be convinced of the likely outcome of any design project before being prepared to tie up capital in its development.

Use of computers

The use of computers as a new tool in this field is still being explored, though used on an increasing scale. In therapeutic radiology, computer-assisted planning and dose calculation are already developing. This has necessitated, so that procedures and results from different centres can be compared, the building up of a computer language or terminology so that the data stored will be in similar terms. In diagnostic radiology, data storage and retrieval are already practiced in a few centres. In some actual radiological reporting can be made directly into an on-line computer and retrieved or displayed at a number of points in a hospital. A remote point, far from the reporting centre, can recall, and display reports whenever required. Similarly, the analysis of work flow in a department by use of a computer model can be carried out and contribute to efficient management. Both branches of radiology now are increasingly using computers for data analysis in large series and with a much larger number of components than was possible by previous methods. All these matters require careful planning and the establishment of a terminology.

In diagnostic radiology, the development of high-speed rotating anodes is just beginning to have effect. This permits higher tube loading and enables the practice of such procedures as high-speed cineradiography. The technique of xeroradiography, which employs charged selenium plates instead of X-ray films, is in the process of being rediscovered and may yet realize its potential both as a simple procedure and as a means of conserving the use of film in a world that is already concerned about the supply of silver.

In the developing countries, maintenance of apparatus, including the replacement of simple component parts, is often difficult and can take many months. The development of simple, hardy apparatus, easy to maintain, for use in such countries is a new development: the World Health Organization has taken an interest in this problem and has drawn up specifications for such apparatus; in the United States, a simple battery-operated machine has recently been designed for use in remote places where the electrical supply is unreliable. Further, in developing countries, the shortage is often not of doctors but of technicians to operate the machines. Efforts have been made recently to establish the basic requirements for entry into training and the minimum requirements in training such operators, so that in poorly served places the maximum use can be made of this essential diagnostic aid without exposing the population to unnecessary radiation hazards. In the field of education, in the programmed training of radiologists, audiovisual programs are being increasingly prepared and used, so that trainees, while working in a teaching environment, may have greater access to self-teaching facilities.

In therapeutic radiology, the main effort in new developments has been applied to the refinement of existing procedures and techniques. The delivery of dose and the regulation of beam direction have now been refined to such an extent that in many cases it is possible to extirpate the tumour with little or no damage to the surrounding tissues. Similarly, research is being done into increasing the sensitivity of the cancer by the use of oxygen under pressure.

Immunosuppressive effect of radiation

One last feature is of considerable interest. Radiation is known to have an immunosuppressive effect, as in reducing the rejection of tissue transplants. During the 1960s the surgery of organ transplantation advanced considerably, but rejection of the transplanted organ remained a problem. The immune response is closely interconnected with the function of lymphocytes in the blood and blood-forming tissues. Radiation is among the immunosuppressive agents that work by the destruction of the lymphocytes and the suppression of new lymphocyte production. The radiation may be administered either as total body radiation or locally. The latter may be either to the site prior to transplant or as external radiation of the transplant itself. Many techniques have been used, with varying degrees of success, in humans, and experimentally in animals, but much work remains to be done in this field.

NEEDED FUTURE DEVELOPMENTS

In diagnostic radiology, improvements in film speed without coarsening film-grain size are needed in order to reduce the patient's exposure to radiation.

Contrast media are needed that are less toxic and that coat the surfaces of hollow structures rather than filling them, since this would contribute to a more precise and detailed examination. Catheter techniques for the exploration of small vessels and for introduction of contrast media into them must be refined. The developing fields of isotope scanning and ultrasound scanning need further development.

In therapeutic radiology, it seems most likely that the application of the electron beam and of beams of fast neutrons will be explored in greater depth. Mention has been made earlier of the fact that electron beams, as produced in the betatron, have been found to have certain therapeutic values. This may open up a whole new area in this field of work. Similarly, work has recently been recommenced on the use of fast-neutron beams. Such a beam is produced in a cyclotron by bombarding a beryllium target. The neutrons thus produced have a wide spectrum of energy up to about 20 million electron volts, with an output of about 40 rads per minute. This type of beam appears to have a diminished effect on the skin, and at the present time it appears that there is a favourable tumour response. Much work remains to be done, and undoubtedly will be done, in this field.

BIBLIOGRAPHY. The historical description of the discovery of X-rays and the actual text (in English) of Rontgen's first papers are given in OTTO GLASSER, Dr. *W.C. Rontgen* (1945). For a detailed and comprehensible presentation of the physics of ionizing radiations and their applications, see W.J. MEREDITH and J.B. MASSEY, *Fundamental Physics of Radiology* (1968). The hazards involved in this field of work and a rational discipline are succinctly described in KATHARINE WILLIAMS, C.L. SMITH, and H.D. CLARKE, *Radiation and Health* (1962). The unbelievably vast scope of diagnostic radiology and its clinical applications are admirably introduced in DAVID SUTTON (ed.), *A Textbook of Radiology* (1969). Greater detail of the field of isotope scanning is given in L.M. FREEMAN and P.M. JOHNSON (eds.), *Clinical Scintillation Scanning* (1969); and of ultrasonic scanning in C.C. GROSSMAN *et al.* (eds.), *Diagnostic Ultrasound* (1966). *A* comprehensive, authoritative account of radiotherapy that is intelligible to the layman is J. WALTER and H. MILLER, *A Short Textbook of Radiotherapy for Technicians and Students,* 3rd ed. (1969).

(J.H.M.)

Radio Sources, Astronomical

Every object in the universe, with the theoretical exception of bodies frozen at absolute zero, emits radiant energy at least feebly. The visible stars emit electromagnetic waves in the optical range, and some emit detectable signals in other ranges that may include radio wavelengths. Radio waves, which may be produced by several processes, are sometimes strong enough to permit study of their emitting objects by radio, as well as optical, telescopes. The existence of some astronomical objects has been detected only by their radio emission. The first detection of radio signals from outside the Earth's atmosphere was made in 1932 by the American radio engineer Karl Jansky, whose discoveries led to the development of radio astronomy. During an investigation of the origin of atmospheric static signals, in addition to the static which originated in distant thunderstorms, he heard a background hiss on the loudspeaker attached to his receiver and antenna system. Significantly, this background hiss, or radio noise, reached a maximum intensity every 24 hours. More detailed study showed that the radio noise occurred whenever the Milky Way passed through the beam of the antenna, and Jansky concluded correctly that radio waves were being generated in the Milky Way and, further, that the most intense emission was coming from the centre of the Milky Way (the galactic centre).

Discovery of extra-terrestrial radio signals

Hearing of these results, Grote Reber, an Illinois engineer with an amateur interest in radio and astronomy, built a 31-foot- (9-metre-) diameter parabolic reflector antenna at his home, searched for the galactic emission at shorter wavelengths, and made the first radio map of the Milky Way; the resolution of his map—that is, the least angular distance apart at which two objects could be distinguished—was 12 degrees.

Although the Sun was the first astronomical object investigated (in 1900 by Sir Oliver Lodge in England) for radio emission, no solar radio signal was found until 1942, when radar systems situated around the English coast picked up an intense new form of interference that was, at first, thought to be enemy jamming but that on further investigation turned out to be radiation from the Sun. In the same year radio emissions from the Sun were detected in the United States.

PRINCIPLES OF RADIO RECEPTION

The range of radio frequencies used in Earth-based studies of the universe is limited only by the screening effect of the atmosphere. Normally, wavelengths from one centimetre to 30 metres can penetrate the atmosphere without undue absorption by the atoms and molecules present in it. The short-wavelength end of the spectrum has been extended down to about one millimetre by the use of high mountain sites, and the long-wavelength end has been successfully extended to 300 metres by observations from artificial Earth satellites.

Most of the radio energy falling on the Earth is in the form of a continuous spectrum—that is, radiation is received over the whole range of wavelengths with the intensity changing gradually across the whole range. Different types of radio sources have different spectra, and the shape of this continuous spectrum gives important clues about the physical conditions in a radio source.

Functions of radio telescopes

Types of receivers. Radio telescopes have two main functions. The first is to collect the weak radio signals, and the second is to separate details of the structure of radio sources. The angular degree to which such details can be distinguished from one another is called the angular resolution of the telescope. Commonly, parabolic reflectors, whose shape ensures that the signals are brought together into a good focus, are used to gather radio waves from a distant radio source together in a focal area to be fed into a radio receiver. The larger the reflector, the more sensitive it becomes-either it can detect more distant radio sources or it can survey the nearer sources more rapidly. The largest radio telescopes operating at metre or decimetre wavelengths have resolutions much worse than the unaided eye, which can normally distinguish between objects 0.1 millimetre (0.004 inch) apart at a distance of 25 centimetres (ten inches), a resolution of a little more than one minute of arc; an optical telescope does better still with a resolution of a fraction of a second of arc. In order to achieve the even better resolutions necessary for proper investigation of many classes of radio sources, the radio outputs from two or more telescopes are combined into what is called an interferometer.

Types of emission. ***Free–free emission.*** Radio emission, like light, is produced when a charged particle, generally an electron, is made to accelerate. One class of astronomical radio sources consists of clouds of hot ionized gas—that is, a gas whose atoms and molecules have absorbed enough energy to lose their electrons and become positively charged ions. Such a cloud emits radio waves by the process known as free–free emission. In this process, the free electrons are attracted toward positively charged ions as they pass each other; the acceleration produces a pulse of radiation. The sum of such pulses originating in a large number of such encounters between electrons and positive ions gives a continuous spectrum in which the power (energy per unit of time) radiated per unit frequency interval is constant with frequency. Radio sources that emit by the free–free process include the outer tenuous layers of the Sun and the ionized hydrogen regions of interstellar space. A similar process is that known as blackbody radiation, in which the emitting region is so compact or deep that the only emission that can escape comes from the near side. In this case, the power radiated increases as the square of the frequency. Measurements of the emitted radio power give a direct estimate of the temperature of the source. The planets belong to this class of source.

Synchrotron radiation. Among emission processes in radio astronomy, the most important is the synchrotron process, in which electrons moving at speeds very close to that of light (called relativistic speed) spiral around magnetic fields emitting radiation that is polarized—that is, which vibrates more strongly in a direction perpendicular to the magnetic field. This radiation was first found in the beams from synchrotron particle accelerators. The electrons may be a part of the energetic cosmic ray background flux in the Milky Way or may be produced in some violent event in the radio source itself. The precise shape of the continuous spectrum of synchrotron radiation depends, among other things, on the energy spectrum of the electrons.

Emission from neutral hydrogen. Line radiation (that is, radiation strongly concentrated toward a particular wavelength) at the 21.1-centimetre wavelength was first detected from clouds of neutral atomic hydrogen in the Milky Way in 1951. This radiation provides a very useful tool for studying the motion of many components of the Milky Way and of external galaxies. Motion in the line of sight toward or away from the observer is calculated from measurements of the Doppler shift—*i.e.*, a change in wavelength caused by the motion of the source—and measured from the 21-centimetre and other lines discovered later. Many interstellar spectral lines have now been detected from atoms and molecules that radiate in the radio range. Of these lines, the 21-centimetre line of neutral hydrogen, which appears in many parts of interstellar space, is very important because hydrogen is widely distributed in the universe as the building material for element formation in the interiors of stars.

THE SUN AS A RADIO SOURCE

The dominant radio source in the sky, the Sun is a huge and complex sphere of hot gas heated from inside by thermonuclear reactions (fusion of atomic nuclei). Lying above the surface that is seen with the naked eye are regions of tenuous gas and magnetic fields in which intense radio signals are generated. These vary from the highly variable emission characteristic of metre wavelengths, in which the intensity changes by factors of up to 10^3 in a few minutes, to a steady signal of about ten centimetres wavelength recorded from the so-called quiet Sun.

Radio emission from the quiet Sun. At times when there are no active areas (sunspots, flares, and prominences on the Sun), radio emission known as the quiet Sun component may be picked up. This emission originates in two layers already known optically: the chromosphere, which lies immediately above the photosphere, the visual surface, and extends for several tens of thousands of kilometres; and the corona, which is at a temperature of 1,000,000" K and extends upward outside the chromosphere to about 1,000,000 kilometres (a height above the surface equal to the Sun's radius). Radio radiation at long wavelengths is unable to escape to the Earth from the cooler chromosphere, and maps of the Sun at wavelengths of about three metres represent the radio appearance of the corona, with a diameter about twice that of the visual solar disk and a brightness temperature of about 10^6° K. At shorter wavelengths, about three centimetres, the radiation can escape from the chromosphere, and the diameter of the radio Sun at three centimetres is only a little larger than the optical disk, the brightness temperature being about 10^4° K. At intermediate wavelengths, the dimensions and brightness temperatures lie within these limits (see Figure 1).

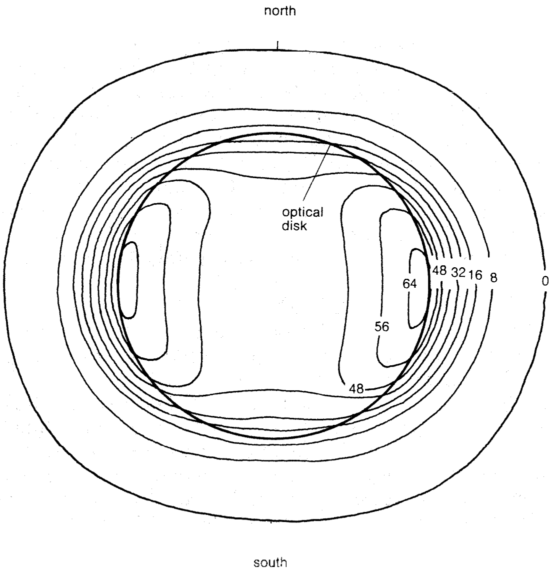

Figure 1: The quiet radio Sun at a wavelength of 20 cm showing contours of equal temperature in units of 1,000" K. Note the characteristic brightening at 20 cm wavelength on the east and west limbs, and the size of the radio Sun, which extends far beyond the optical disk (photosphere) into the chromosphere and corona.

Varying radio signals from the Sun. ***The so-called slowly varying component.*** A second part of the Sun's emission is the slowly varying component. This changes over the rotation period of the Sun, approximately 27 days, the rate at which sunspots also rotate. The slowly varying radio emission comes from extended regions larger in section than the sunspots, lying 10,000 to 50,000 kilometres (about 6,000 to 30,000 miles) above the spots and intimately connected with the bright areas called plages. Most of the radio emission is thermal radiation corresponding to the amount and distribution expected at a temperature of 10^6° to 10^7° K. Observations at centimetre wavelengths suggest an origin in magnetic fields with a strength of about 1,000 gauss (a gauss is the unit of magnetic field), which must reach to these heights from the sunspots (for comparative purposes, the strength of the Earth's dipole field is about one gauss as measured at the surface).

Eruptive, sudden, or catastrophic radio signals. Active regions of the Sun, usually near a sunspot, are the sites of solar flares, seen as a brightening in the red light emitted by hydrogen. These active regions are also the breeding grounds of more violent (catastrophic) radio events that are associated in some way with solar flares. Flares are accompanied by the outward ejection of material, and sometimes pre-existing arches of bright solar material are also induced to erupt. The simultaneous emission of X-rays causes immediate excess ionization—that is, breakup of atoms and molecules into charged particles (ions and electrons) in the low ionosphere of the Earth—and solar protons travelling at speeds near the speed of light reach the Earth's surface several hours later. Slower moving streams of particles that are also emitted reach the Earth about 30 hours later and produce auroras and magnetic storms. The total energy released in a solar flare may be as much as 10^{32} ergs (an erg is a unit of energy equal to one dyne centimetre; a man climbing a flight of stairs expends several million ergs) mainly in the form of light, X-rays, and protons. This energy is generally believed to come from the annihilation of part of the magnetic field lying above the sunspot group.

The eruptive component of the Sun's activity varies markedly with wavelength. At metre wavelengths the events are intense; individual bursts may last only seconds or minutes, while noise storms may last from hours to days. At centimetre wavelengths the activity is less intense, and the characteristic durations are from minutes up to an hour. Understanding of the eruptive component has come mainly from measurements of the changes in the spectrum—that is, the distribution over different wavelengths with time.

Sequence of radio outburst events

A large radio outburst will begin at the same time as the flare with a group of the so-called type III bursts; bursts of this type individually last about ten seconds and characteristically show a rapid increase in wavelength through the duration of the burst as the causative disturbance moves out rapidly through the solar atmosphere to levels from which the longer wavelengths can escape. These disturbances typically move at speeds about one-fifth to one-half that of light. Often, type III bursts occur simultaneously at pairs of wavelength bands separated in frequency by a factor of 2. Such a harmonic relationship suggests that this type of burst is generated by the solar plasma (a mixture of electrons and positive ions) by a process in which the plasma oscillates at a frequency that is dependent upon the electron density. Coincident with this group of metre wave bursts is a smooth microwave burst generated through the synchrotron process (see above) by the escaping stream of electrons moving at speeds near that of light in the sunspot magnetic field; this is accompanied by a burst of X-rays. Type III bursts are sometimes followed by a short period of continuum (spread continuously through all radio wavelengths) radiation called type V.

Typically, after a lapse in activity for several minutes, an intense type II burst begins. This type shows sharp band structure and generally has the harmonics attributed to plasma oscillations. The increase in wavelength and, consequently, the outward speed is about 100 times slower than for the type III bursts. The type II burst is believed to be caused by a shock wave originating at the same time as the fast electrons that give the type III burst but moving at only 1,000 kilometres (about 600 miles) per second.

Another type of eruption, called type IV, merges with and follows the type II bursts; it may last for several hours. This emission is quite different in character from the types II and III radiation. The radiation from all levels is spread over a broad band of wavelengths and is believed to be mainly synchrotron emission. It comes from a region several minutes of arc in diameter that moves outward at about 1,000 kilometres per second and may reach heights equivalent to several solar radii. This type IV emission is very complex, and several kinds of emission process are at work. The outward motions of the types II and IV bursts are comparable with those of streams of particles that produce magnetic storms and are probably different aspects of the same phenomenon (see Figure 2).

RADIATION FROM THE MOON AND PLANETS

The Moon. The planets are, on the whole, rather weak radio sources, and intensive studies have been necessary to derive their radio brightnesses. Radio measurements are particularly important in that they give the temperature at depth in the solid surface or in the atmosphere, which cannot be observed at optical wavelengths. The radio emission from the Moon's surface at any wavelength comes from a depth of ten times that wavelength (*e.g.*, from 100 cm at a wavelength of 10 cm). The uppermost surface layers at the centre of the lunar disk vary in temperature from 150" to 370" K (—200" to 200" F) between lunar night and day. At one-centimetre (radio) wavelength, the variation is 200" to 160" K (—100" to —170" F). It is clear, however, that solar heating does not penetrate to a depth of more than one metre (three feet) into the surface material of the Moon, because at 20-centirnetres wavelength, where the radiation from this depth is recorded, it is essentially constant at 230" K (—45" F).

Mercury. Mercury, nearest to the Sun and one of the most difficult planets to observe, has an overall temperature of 400" K (260" F) measured at three-centimetres wavelength. Early radio measurements indicated a change of no more than from 250" to 450" K between night and day on Mercury. This was something of a surprise because it had long been thought that Mercury always turned the same face to the Sun, and that the dark side, since it would never be directly heated, would be at a

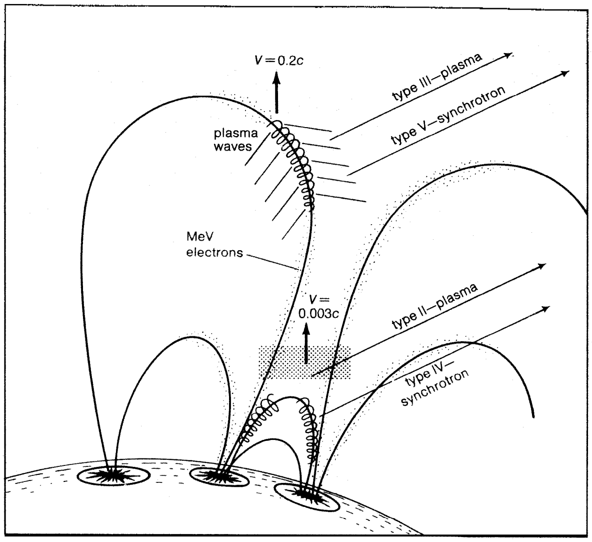

Figure 2: Origins *of* various types of radio *burst* activity on the ***Sun.***
The curves represent typical magnetic lines of force beginning and ending in surface areas (shown dark) related to flares. Type 11, III, and V originates in disturbances moving outward from the optical flare at speed V about 0.003 times the velocity of light, c, for Type II and at 0.2 times the velocity of light for Types III and V. Type IV is generated by relativistic electrons gyrating in the intense magnetic fields near the surface of the Sun.

Adapted from H.P. Palmer, *el al.* (eds.), *Radio Astronomy Today* (1963); Harvard University Press and Manchester University Press

temperature close to 0° K (—459" F). Radar observations resolved the discrepancy by demonstrating that Mercury rotates in 59 (±3) days, which is ⅔ of its orbital period of 88 days. This faster rotation makes the dark and light sides more nearly equal in temperature; at sufficiently long wavelengths, radiation would come from very deep layers, to which the day heating and night cooling does not penetrate, and the measured temperatures would be the same, as they are on the Moon.

Venus. One of the first surprises in radio studies of the planets occurred in the case of Venus and caused an important change in plans for spacecraft exploration. Measurements at wavelengths shorter than one centimetre indicated temperatures of 300" to 400° K (80° to 260" F), significantly above the infrared temperature of 240" K (—30" F). When these measurements were extended to wavelengths longer than three centimetres, the brightness temperature was found to be close to 600° K (620" F) at all wavelengths, indicating that the temperature of the solid surface is near 600" K, and the upper layers of the atmosphere are measured in the infrared, at 240" K. Temperatures between these values, from measurements at millimetre wavelengths, represent intermediate depths within the atmosphere of Venus. Radio measurements during a flyby by a spacecraft have confirmed these results obtained by ground-based radio telescopes. Other measurements from craft entering the Venerean atmosphere have shown that the pressure on the surface of Venus is about 100 times the atmospheric pressure on Earth. Herein lies the reason for the high surface temperature of Venus; the dense atmosphere, and particularly its carbon dioxide content, produces an intense greenhouse effect at the surface, trapping solar heat like a glassed-in enclosure. The observed radio temperatures and the measured density of the atmospheric constituents are consistent with this explanation.

Mars. The planet Mars has a mean infrared temperature of 217" K (—69" F) averaged over the light and dark hemispheres, and radio observations at the three-centimetre wavelength are consistent with this value. Nevertheless, the temperature calculated from measurements at shorter wavelengths is at 170" ±10° K, (—150" ±20° F), significantly lower. There is, as yet, no explanation of this difference. All these measurements refer to the surface layer of Mars and cannot be much affected by

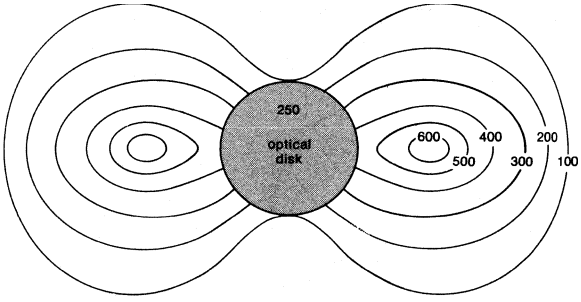

Figure 3: Radio emission (schematic) from Jupiter at 20 cm. At this wavelength, radiation from the Van Allen belts dominates with a maximum brightness temperature of about 600" K. The emission associated with the optical disk contributes less, and the temperature is only 250" K.

the Martian atmosphere as the surface pressure is about 1 percent of that on Earth.

The components of radio emission from Jupiter

Jupiter. Radio emission from Jupiter is interesting in that it has three distinct components. One is the emission from the dense atmosphere that makes up most of the visible disk of the planet. Its temperature, 140° K (—210" F), is the same at all wavelengths. The second component increases in temperature with wavelength and is produced well outside the optical disk (see Figure 3). This emission is strongly linearly polarized (*i.e.*, the radiation vibrates more strongly in some directions than in others) and originates in the strong magnetic field of Jupiter. Electrons of high energy are present within the field as they are in the Van Allen belts of high energy particles surrounding the Earth. These electrons emit radiation by the synchrotron process. Since the axis of Jupiter's magnetic field is inclined at nine degrees to the rotation axis of Jupiter, the intensity and polarization of the emission change as the planet rotates. These changes can be used to derive a very accurate period for the rotation of the planet's solid core, which is presumably responsible for the magnetic field. This value is nine hours, 55 minutes, 29.83 seconds (±0.26 seconds), compared with nine hours, 55 minutes, 40.6 seconds (±0.26 seconds) found for the rotation of the visible markings in the temperate zone. The third type of emission from Jupiter is restricted to wavelengths between eight and 30 metres and consists of sporadic bursts of high intensity. These bursts appear to be fixed at several longitudes on Jupiter for periods of years at a time and have a rotation period of nine hours, 55 minutes, 29.37 seconds. There is evidence for changes in the period of this long-wavelength radiation relative to that of the magnetic field, which indicates that the active centres of metre-wavelength emission are moving slightly in the atmosphere of Jupiter. The emission process of these bursts is not understood, but there is clearly an efficient mechanism that releases about 10^{18} ergs in each pulse. A remarkable modulation effect is connected with Jupiter's satellite Io, which has the power to turn off this emission even though Io is 420,000 kilometres (260,000 miles) from Jupiter. The cause of this effect is not clear, but it is possible that it is due to some interaction between Io and the magnetosphere of Jupiter.

Saturn, Uranus, and Neptune. Optically, Saturn is very similar to Jupiter, but at radio wavelengths the only similarity is the thermal emission from the gaseous disk, for which the temperature measured at a wavelength of several centimetres is 130" K (—225" F). A small but significant increase in emission temperature at longer wavelengths is restricted to the disk and is not like the Van Allen belt emission on Jupiter. No sporadic emission has been detected from Saturn, and no emission has so far been detected from its well-known rings. For comparison, the temperature of Saturn is 93° K (—290" F) measured in the eight-to-14-micron wavelength infrared band. Uranus and Neptune both have temperatures that rise gradually from about 100° K (—280" F) at three-millimetre wavelength to 170° K (—150° F) at three centimetres. In both cases, this radio brightness temperature, even at the shortest wavelength, is greater than the temperature expected from solar heating alone. The longer radio wavelengths come from greater depths within the clouds surrounding Saturn, Uranus, and Neptune, and it is conjectured that temperatures are higher because heat is generated within the planets.

RADIO_OBSERVATIONS_OF_THE_MILKY_WAY

Early radio sky maps

The earliest radio sky maps were relatively crude. They have since been systematically improved to give high-resolution surveys of the entire Milky Way over a wide range of frequencies. The surveys have shown the Presence of discrete radio sources both inside and outside the Milky Way, and a general background of emission covering the whole sky but strongly concentrated to the plane of the Milky Way, also called the galactic plane. The general appearance of the radio sky observed at a frequency of 200 megahertz is illustrated in Figure 4 which has been plotted in galactic coordinates. (Galactic longitude is measured around the galactic equator from the galactic centre, and latitude is measured toward the galactic poles from the equator). The highest brightness temperatures are found in the galactic centre region and the lowest at or near the galactic poles. A ridge of strong emission following the galactic plane has two components—one is thermal emission from ionized hydrogen and the other nonthermal synchrotron emission.

Thermal emission from the galactic plane. The thermal emission from the galactic plane is concentrated in a disk extending out about four kiloparsecs (one kiloparsec equals about 3,260 light-years, or 19.16 × 10^{15} miles) from the galactic centre. It lies in a slab extending about 200 parsecs from the galactic plane. The gas responsible for this emission is hydrogen in a state of high excitation at a temperature of 10,000" K. Excitation at this level is probably produced by a substratum of young stars that heat and ionize the hydrogen. Alternatively, however, it could be produced by the explosive events that occurred in the recent history of the Milky Way; these will be

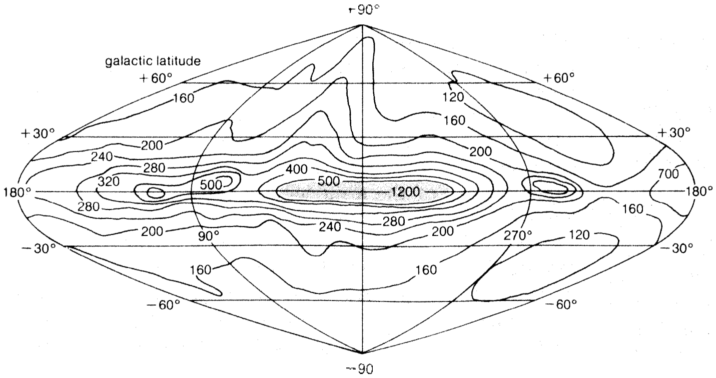

Figure 4: The radio sky at 200 megahertz plotted in galactic coordinates, with galactic equator dissecting the Milky Way. The strongest radiation is concentrated on the galactic equator: the highest radio brightness temperatures (about 1,200" K) are found near the galactic centre.

discussed in the next section. In this region of thermal emission the average ionized hydrogen density is about 0.2 atoms per cubic centimetre. The region contains about 4 × 10' times the mass of the Sun, compared with the total mass of the Milky Way of 1 × 10'' solar masses.

Presence of cosmic rays and magnetic fields

Nonthermal emission from the galactic plane. Studies of the latitude and longitude distribution of the nonthermal radio emission near the galactic equator indicate that it comes from a disk with a thickness perpendicular to the galactic plane of 0.7 kiloparsec and a radius of about nine kiloparsecs; on this scale the Sun lies ten kiloparsecs from the galactic centre. The discovery of this nonthermal emission component provided a new means of studying the cosmic ray electrons and the magnetic fields that thread through the Milky Way and that are responsible for the synchrotron emission from the disk. The radio spectrum of the synchrotron emission is identical with. that expected from the observed cosmic-ray energy spectrum. The observation of this radio emission shows conclusively that the cosmic rays are not a phenomenon existing only in the Sun's region of the Milky Way but are widespread. Radio observations of neighbouring galaxies indicate that cosmic rays are produced there too.

The radiation from the spiral arms. There is strong indication that some synchrotron emission is produced in the galactic spiral arms. This is certainly true of the Andromeda Nebula (a galaxy quite similar to the Milky Way), where the optical and radio spiral arms coincide.

The radiation from the halo. Another component of the nonthermal emission from the Milky Way is called the halo, which is difficult to distinguish from the disk component because of the presence of elongations, called spurs, that extend from many parts of the galactic plane, as can be seen in Figure 4. In all probability there is a weak halo of emission with a radius in the galactic plane of about 15 kiloparsecs and a thickness perpendicular to the plane of half this amount. If this is so, then magnetic fields and cosmic rays extend far beyond the confines of the galactic disk.

The 21-centimetre hydrogen emission. The richest increase in understanding of the Milky Way that has resulted from radio studies has come from measurements of the radiation produced at the 21-centimetre wavelength by cold clouds of interstellar neutral (*i.e.*, not ionized) hydrogen. In 1945, when radio astronomy was still in its infancy, a Dutch astronomer, H. van de Hulst, predicted that this emission should be detectable. Although the transition that produces a 21-centimetre photon from an atom of hydrogen is likely to occur in any particular atom only once every 11,000,000 years, van de Hulst believed that there would be so many hydrogen atoms, between 10^{20} and 10^{22} in a column a centimetre square extending in a line of sight through the Milky Way, that the emission would be detectable. This hope was realized in 1951, when the 21-centimetre line was first observed at a number of radio observatories. Observations pieced together over the whole sky show that the neutral hydrogen producing 21-centimetre radiation is distributed on a remarkably thin layer only several hundred parsecs thick and extending for about 15 kiloparsecs from the galactic centre. The neutral hydrogen is concentrated in long features that appear to be very similar to spiral arms seen in photographs of external galaxies. Optical studies of the spatial distribution of stars and regions of ionized hydrogen suggest that the optically visible constituents of spiral arms agree in position with these neutral hydrogen spiral arms.

Clouds of hydrogen

A wealth of additional structure is found in the neutral hydrogen distribution. High-resolution studies demonstrate that the spiral arms are composed of clouds ranging in size from rather less than one parsec to several tens of parsecs. A typical cloud may have a diameter of ten parsecs, a density of ten hydrogen atoms per cubic centimetre, and a temperature of 100" K (— 280" F). A line of sight through the Milky Way intercepts about ten such clouds per kiloparsec.

Clouds of molecules

Characteristic radio signals from molecules. The first radio observations of interstellar molecules were made in 1963 when the radiation of the hydroxyl (OH) radical was detected at a wavelength of 18 centimetres. Although the OH was found only in absorption against background sources, and the signals were weak compared with those from atomic hydrogen, it was immediately obvious that a new method was now available for studying the interstellar medium. Densities of OH in interstellar clouds were generally between 10^{-4} and 10^{-7} of those of atomic hydrogen. The greater OH abundances were in small clouds near the galactic centre, which also contain remarkably high abundances of other molecules (see below). This region appears to have the most ideal conditions of any discovered for the formation of molecules. Further study of the interstellar medium at 18 centimetres showed hydroxyl emission from dense dust clouds some distance from the galactic plane. These are believed to be regions of high gas density in which atoms and molecules coalesce to produce large aggregates in the form of dust grains. Hydroxyl emission from such clouds is therefore not surprising.

An entirely unexpected development in the hydroxyl story was the discovery (1965) of intense emission with unexpected properties from a new class of hydroxyl sources situated near ionized hydrogen regions, commonly called H II regions, such as the Orion Nebula and the nebula known as NGC 6334. The emission had such unusual features that it was at first called mysterium. Characteristically this anomalous emission has high intensities and spectral lines much narrower than expected; and, further, the ratios of the intensities of the four component lines of the.18-centimetre hydroxyl transition were not in agreement with theory. Additional peculiarities not seen previously in hydrogen-line studies were strong polarization (that is, the strength of the ratio signal depended on direction) and, in some cases, time variability. These characteristics have been investigated in many OH sources. Measurements with interferometers showed that one of these sources near the H II region known as W3 could be resolved into a number of separate bright patches scattered over an area two seconds of arc in diameter. Features of W3 ranging in size from 0.01 to 0.005 seconds of arc were distinguished. These were much smaller than could have been resolved with an optical telescope. The corresponding brightness temperatures of the emitting features are $10^{10\circ}$ to $10^{13\circ}$ K. The overall dimensions of the hydroxyl-emitting region correspond to those expected at a late stage of contraction of a gas cloud on its way to becoming a star.

Maser actions in interstellar gas

The anomalous hydroxyl emission is believed to arise as a result of the so-called maser process (maser stands for microwave amplification by stimulated emission of radiation), which has the property of amplifying background radiation at the wavelength of the masering atom or molecule by very large factors. This property is used in the operations of masers (at radio frequency) and lasers (at optical frequencies). Furthermore, the emitted spectral line is narrower than the normal line emission from the gas. What is not yet clear is how the hydroxyl molecules in interstellar space are "pumped" or "energized" so that there are more molecules in the upper state of the 18-centimetre level than in the lower state, a situation that must arise before the maser can operate. Some excitation of the molecules to a third, much higher state by a radiative or collisional process is thought to be responsible; the molecules would then fall from this "pumped" level, overpopulating the upper of the two levels involved in the 18-centimetre emission. Other groups of radio-frequency lines have been observed from OH that also appear to be a result of masering.

The year 1968 saw the beginning of a rapid increase in the discovery of new interstellar molecules by radio methods following on from the detection of hydroxyl radical (see also 'INTERSTELLAR MEDIUM). The discovery of formaldehyde (H_2CO) in 1969 was surprising, however, because this molecule contains both carbon and oxygen, each of which is about 10^{-4} of the abundance of hydrogen in interstellar space. There was no obvious way of telling which other molecules would be readily detectable, particularly since, if they masered, their emission would be considerably enhanced above that expected on the basis of abundance alone. Six new molecules were discovered in 1970. Each had two or more of the elements carbon, nitrogen, and oxygen. All the molecules detected at radio wavelength in the interstellar medium up to the end of 1970 are listed in the article INTERSTELLAR MEDIUM.

Of the recently discovered molecules, water vapour and formaldehyde have been studied in most detail. Water vapour has only been detected in the masering form; it shows very strong signals that come from small regions comparable in size to those found for the hydroxyl sources. Most water vapour sources come from the regions of anomalous hydroxyl emission. Evidently, the processes that lead to a concentration of hydroxyl also give a high abundance of water molecules, H_2O.

Probable inverse maser action

Formaldehyde is interesting in that it is widely distributed and is always recorded in absorption, even in regions of the sky where there is no continuum source to intercept the radiation and thus produce the absorption. In these regions it is apparently in absorption against the universal 3° K background radiation (see below). This means that formaldehyde can somehow come to a temperature beneath not only that of its surroundings but also beneath the temperature of the radiation field in which it is immersed. It is conjectured that this interstellar formaldehyde refrigerator is an inverse maser in which the lower energy level in the two responsible for the formaldehyde line emission is overpopulated relative to the upper level. The process of this population inversion is not yet clearly understood.

Radio observations of these molecules provide the basis for an entirely new branch of astronomy, interstellar chemistry. Attempts to understand the way in which the molecules are formed and the study of the role that these molecules may have had in providing building blocks for the origin of life on the Earth are important parts of this subject.

Radio observations of discrete sources. ***Radio details at the galactic centre.*** The Galaxy contains a large number of discrete radio sources, emitting both thermal and nonthermal radiation, scattered around the galactic equator and lying mainly within ten degrees of the galactic plane. At the centre of the Milky Way is a complex of many radio sources. The most intense of these, called Sagittarius A because it was the first discrete source discovered in the constellation Sagittarius, is about three minutes of arc in diameter and is believed to be the nucleus of the Milky Way; its position has been used along with other data to define the zero longitude point of the galactic coordinate system mentioned above. Sagittarius A is a nonthermal source presumably emitting by the synchrotron process. At the distance of the centre of the Galaxy, its angular diameter corresponds to a linear dimension of ten parsecs. Around the nucleus are a number of thermally emitting sources over a distance covering about 40 seconds of arc. These are ionized hydrogen with a mass of 10^5 times the mass of the Sun; the gas density is 20 atoms per cubic centimetre. Further out again is a radiating region, a nuclear bulge covering about four degrees in diameter along the galactic plane and one degree perpendicular to the plane. The radio signal from this region is synchrotron emission, and it is the strongest emission from the galactic centre region at longer wavelengths (about three metres).

Mixed with the ionized hydrogen and cosmic ray electrons are pockets of neutral gas. The absorption regions of neutral hydrogen, hydroxyl, and formaldehyde contain the largest known concentrations of these molecules. Most of the molecules so far discovered have also been recorded by their emissions in several regions within one degree of the nucleus. Ammonia, for example, is only found here near the galactic centre. It is evident that this limited volume of the Milky Way is very effective in producing molecules.

The motion of neutral hydrogen gas further outside this nuclear region has a strong circulation (see Figure 5). Out to a distance of two degrees (400 parsecs) there lies a thin disk which rotates in the plane of the Galaxy at a speed of rather more than 200 kilometres per second (120 miles per second). Around this lies a ring with a radius of 700 parsecs rotating at a similar speed. The neutral hydrogen density in these features is from one to three atoms per cubic centimetre, and its total mass is 5 × 10" solar masses. Further out still from the centre, at a distance of four kiloparsecs, is a dominating feature that is expanding outward at 50 kilometres (30 miles) per second, as well as taking part in galactic rotation. The existence of this feature known as the four-kiloparsec arm is a major enigma in the understanding of the Milky Way. It has a mass of 3×10^7 solar masses, and a considerable amount of energy will have been needed to give it an outward speed of 50 kilometres per second; further, its existence implies a large circulation of material through the central regions of the Milky Way. Another phenomenon that some astronomers consider may be related to the outflow of gas in the galactic plane from the centre is the infall of neutral hydrogen clouds towards the galactic plane at velocities of up to 200 kilometres per second in the vicinity of the Sun.

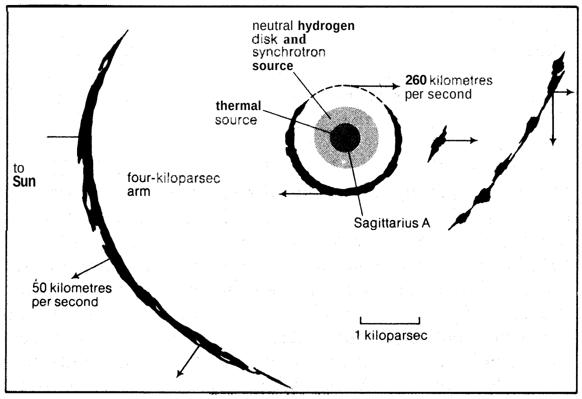

Figure 5: The distribution of neutral hydrogen in the galactic centre region.
The Sun is 10 kiloparsecs to the left of centre. The outer neutral hydrogen features show evidence for expansion from the centre. The central rotating disk contains an extended synchrotron source, a thermal source, and the small-diameter source Sagittarius A.

Many theories have been proposed to explain the phenomena just described in the central regions of the Milky Way. Broadly they fall into two classes: in one, flow of gas is considered as a part of a general circulation of material in the Milky Way, though no convincing source of the material has been proposed; in the other, the outward motion is thought to be the result of the recent explosion or series of explosions in the galactic centre. It is known from other measurements that about 10^9 solar masses of material lie within 100 parsecs of the centre, probably in the form of stars. Considerable activity must have occurred recently, or must still be happening, to produce the electrons moving at nearly the speed of light that are responsible for the two nonthermal sources in the centre. Such fast electrons can exist only for periods of about 10^6 to 10^7 years, a very short time compared with the age of the Milky Way (10^{10} years).

Radio signals from supernovae remnants. One of the two most abundant types of discrete radio source found in the Milky Way are the supernovae remnants. These are the remains of stars that have violently exploded into supernovae, undergoing a sudden tremendous brightness increase and sending out an expanding volume of gas at speeds of several thousand kilometres per second. Embedded in this volume are the very fast moving (relativistic) electrons that emit strong radio signals in the ambient magnetic fields. The first supernova remnant to be identified as a radio source was the Crab Nebula. In the year 1054 a supernova in the position of the Crab Nebula was seen to explode. It became so bright that it could be seen in the daytime. The wisps of glowing gas resulting from this explosion were first noted in 1731, but the true nature of this nebulosity was not realized until the 20th century. The present expansion velocity of the nebula is 1,150 kilometres (715 miles) per second; its

*Minutes of arc. †Watts m^{-2}Hz^{-1} × 10^{26}.

diameter is about three parsecs, corresponding to an angular diameter of six minutes of arc at a distance of 1,700 parsecs. Radio emission is generated throughout the Crab Nebula by relativistic electrons (moving at very fast speeds, near that of light) some of which were produced at the time of the supernova explosion and have been continually produced since that time. Relatively strong magnetic fields (compared to the interstellar fields) of about 10^{-4} gauss are deduced from the measured intensity of the optical and radio synchrotron emission.

The brightest radio supernova remnant is Cassiopeia A (Cas A) in the constellation of Cassiopeia. Its shell structure is more typical of supernova remnants than is the centrally filled Crab Nebula. Although the optical object lies behind dense dust clouds, the outlines of a filamentary shell two minutes of arc in radius can be discerned. Its expansion speed is 7,000 kilometres (about 4,000 miles) per second, and estimates of its age calculated from the expansion velocity suggest that the Cas A supernova outburst occurred in AD 1702 (&14). The simple shell structure of Cas A implies that all the material now confined in a thin outer shell was emitted in a single explosion. Because of the gradual expansion of the shell, the radio luminosity is expected to decrease with time. Such a decrease has, in fact, been detected and amounts to 1.1 percent per year.

Estimate of radio wave-length energies in brightest supernova source

The kinetic energy in the shell of the Cas A supernova explosion is estimated at 10^{51} ergs. Kinetic energy is energy of motion. The energy in cosmic rays and electrons is now about 10^{49} ergs, and the total that has been radiated since the initial outburst at all wavelengths from radio to X-rays is approximately 10^{47} ergs. These energies must be compared with the total nuclear energy available from conversion of hydrogen to helium in the original star of about 10'' ergs. Evidently, about 1 percent of this energy has been released into the expanding remnant.

Three other supernova explosions have been seen in the Milky Way: the supernovae of AD 1006, Tycho's supernova (AD 1572), and Kepler's supernova (AD 1604). All are shell-like sources of radio energy. The expansion velocities calculated for Tycho's and Kepler's supernovae exceed 10,000 kilometres (6,000 miles) per second, appreciably greater than those found in the Crab Nebula.

About 100 radio sources believed to be supernovae remnants have been found. Some, like the Cygnus Loop, IC 443, and S147, were later identified with optical nebulosities, but most lie in obscured parts of the Milky Way where no optical identification is possible. The last mentioned radio sources are considered to be supernova remnants because they have a nonthermal, presumably synchrotron, spectrum and, in many cases, a shell-like structure. Most of these supernova remnants are older than the bright compact remnants described in previous paragraphs. The oldest remnants that are still distinguishable at optical and radio wavelengths have ages of about 10" years; after this, the expanding gas becomes tenuous and merges with the rest of the interstellar medium. Some of the better known supernova remnants are listed in Table 1 above.

Analysis of the number and lifetimes of supernova remnants indicates that the rate of supernova explosions in the Milky Way is one every 30 years, a rate comparable to that found in similar external galaxies. A supernova is not seen to erupt once every 30 years, however, because most must occur behind the dense dust clouds in the plane of the Milky Way.

Pulsed radio signals. A class of galactic radio sonrces believed to be closely related to the supernova remnants comprises the pulsars, sources that emit their radio waves in periodic pulses. They appear, like the H II regions and nonthermal disk radiation, to be concentrated to the galactic plane in a layer several hundred parsecs thick. About 50 of these sources are now known (see the article PULSARS).

Radio signals from individual nebulae. Individual emission nebulae, concentrations of ionized hydrogen glowing by their own light, form another group of galactic radio sources. Such objects include the great nebula in Orion (M42), the Rosette Nebula (NGC 2237–46), and the Omega Nebula (M17). All of these ionized hydrogen regions, usually called H II regions, are dense clouds of hydrogen gas in which bright (young) stars have recently formed. These stars emit intense ultraviolet light of sufficiently short wavelength to ionize much of the hydrogen clouds. The ionized clouds then produce thermal radiation at radio wavelengths that can penetrate the complete depth of the Milky Way and give valuable information about regions that are optically invisible.

The Orion Nebula at radio wave-lengths

The Orion Nebula, in the "sword" of the constellation Orion, is one of the most extensively studied H II regions. Although faint optical nebulosity can be traced out 30 minutes of arc from the centre, the most light and radio emission comes from a central region about four minutes of arc in diameter, which corresponds to 0.4 parsec at its distance of 400 parsecs. The average density in the central regions of the Orion Nebula is 2,000 atoms per cubic centimetre, and its total mass is 100 solar masses. This is about 10 percent of the mass of the cluster of young stars called the Trapezium that has condensed from the nebula and now heats it to its equilibrium temperature of 10,000" K (18,000" F). Two bright regions near the centre of the nebula have densities of 10,000 atoms per cubic centimetre. This high central concentration in the nebula and the presence of very young stars at its centre indicate that the Orion Nebula is less than 10^4 years old, very young in the astronomical time scale.

The Rosette Nebula at radio wave-lengths

A much older H II region (the Rosette Nebula) is found in the constellation Monoceros. Its linear diameter is about 16 parsecs (52 light-years), and its mean density is 20 atoms per cubic centimetre. The Rosette Nebula is a shell object having a broad central hole in distinction to the centrally bright Orion Nebula. Estimates of its age range between 10" and 10' years. Radio studies of nebulosities are particularly valuable in giving a clear picture of the distribution of emission throughout the entire depth of the region, in contrast to optical studies, which can be severely limited by obscuration. Most H II regions contain large quantities of dust mixed with the gas. Some of the brighter ionized hydrogen regions are listed in Table 2 below.

The planetary nebulae, often elliptical in shape, sur-

The planetary nebulae at radio wavelengths

rounding extremely hot central stars, form a quite distinct class of H II regions. The nebulosity has been ejected from the star and has a temperature higher than that of ordinary H II regions. The central stars of planetary nebulae are believed to be near the final stages of evolution, whereas the stars associated with normal H II regions are in the earliest stages of evolution.

The final class of galactic radio sources to be described is that of flare stars. These are red dwarf stars just beginning their long lifetimes; from time to time they produce flares that are much more intense than those that may be seen on the Sun and that may increase the star's brightness over a short period (usually minutes or hours) by a factor of two or more. The flares are accompanied by nonthermal radio outbursts that can be detected weakly at the Earth. The prototype star of this group is UV Ceti, about three parsecs distant. Radio bursts that accompany the optical flare can last for several tens of minutes.

RADIO SOURCES BEYOND THE MILKY WAY

In 1951 only about 100 radio sources were known; as of the early 1970s, about 20,000 had been cataloged, most of them lying outside the Milky Way. Of those whose angular sizes have been measured, the majority are found to have diameters less than a few minutes of arc and half have diameters between three and 30 seconds of arc. A few percent of the sources, or at least significant components within them, may have diameters of a few hundredths or thousandths of a second of arc. From a wealth of data some clear-cut patterns have emerged. The extragalactic radio sources can be divided into two classes—those associated with optically recognizable galaxies and those identified with remote starlike (quasi-stellar) objects. At the present time only about 300 of all the extragalactic radio sources are identified with optical objects with measured red shifts (a reddening of light proportional to distance), and it is possible that other classifications may emerge when all the radio sources are investigated optically.

Radio galaxies. Neutral hydrogen has been detected in more than 100 galaxies extending to distances of 40 megaparsecs (40 × 10^6 parsecs). A clear pattern emerges in the relationship between the neutral hydrogen content of a galaxy and its morphological type. Irregular galaxies, such as the Magellanic Clouds, contain several tens of percent of their mass in neutral hydrogen, while spirals contain a few percent and elliptical galaxies less than a few tenths of a percent, if any at all. This pattern is believed to be the result of the different rates of evolution of the different morphological types—the ellipticals evolved rapidly, using up their supply of hydrogen in an early phase of star formation, while the spirals have evolved more slowly and still possess some hydrogen that can be used in future star formation.

The nearby spiral galaxies, all of which have constituents similar to those of the Sun's galaxy (*i.e.*, contain both young and old stars and include at least several percent of their mass in gas and dust), give detectable radio emission, comparable in total intensity to that emitted by the Milky Way and amounting on average to 10^{38} ergs per second integrated over all radio frequencies. These are called "normal" galaxies in distinction to the giant radio galaxies that emit 10^{40} ergs per second and the quasi-stellar radio sources that emit 10^{44} to 10^{46} ergs per second. Among the normal galaxies those with elliptical shapes, which contain little gas and dust and few young stars, are the weakest radio emitters.

Radio studies cf the Andromeda Nebula. The Andromeda Nebula (often referred to by its number in the catalog of the 18th-century French astronomer Charles Messier as M31) is the nearest spiral galaxy and is particularly well placed for detailed study. It has a structure very similar to that of the Milky Way, and many comparisons are useful. Its continuous radio emission has been detected between wavelengths of ten metres and three centimetres, and its integrated emission (that is, the total signal from the whole galaxy) shows a nonthermal spectrum that is presumably generated by fast-moving electrons in an interstellar magnetic field. This nonthermal emission comes from an area measuring six degrees by four degrees with its long axis parallel to the major axis of M31. The outer optical envelope may be traced over an area measuring only four degrees by one degree. The greater extent of the radio source is direct evidence for a halo surrounding M31 and is more convincing than is the case for a halo in the Milky Way described above.

In a high resolution map of M31 at 75-centimetres wavelength details four minutes of arc apart can be distinguished, and the spiral arm radiation can be seen; it is strongest at the position of the dominant optical spiral arms lying between 30 and 80 minutes of arc from the centre along the major axis. A source with a small angular diameter (80 seconds of arc = 200 parsecs) is found at the centre of M31, coincident with its optical nucleus. This source is comparable in intrinsic brightness to the extended component at the nucleus of the Milky Way; but there is no compact source at the nucleus of M31 similar to the bright source Sagittarius A at the centre of the Galaxy.

Like the Milky Way, M31 produces strong 21-centimetre-wavelength emission from its neutral hydrogen. This radiation is strongest in the vicinity of the major spiral arms but lacking in the central regions of the galaxy. The neutral hydrogen extends farther out from the centre than the stars or H II regions. A detailed comparison with the optical data shows that the young stars and their associated H II regions lie in the area of greatest neutral hydrogen density at 40 to 80 minutes of arc (eight to 16 kiloparsecs) from the centre. It appears that the hydrogen in the central regions has already condensed into stars and that the neutral hydrogen density in the outermost regions is too low to permit star formation at the rate found at intermediate positions. Such direct comparisons between the neutral hydrogen and optical data are valuable in understanding the processes by which stars form in the interstellar gas.

The Virgo A and Centaurus A radio galaxies. Only the nearby normal galaxies can be detected in either 21-centimetre-line emission or continuum emission; *i.e.*, radiation spread continuously over a wide range of radio wavelengths. The discovery of anomalously bright radio galaxies extended by a factor or 50 or so the depth to which the universe could be examined at radio wavelengths. Among the first galaxies in this class to be identified were Virgo A, the brightest radio source in the constellation Virgo, and Centaurus A, the brightest in the constellation Centaurus. These sources both happen to be close by and outshine normal galaxies by a factor of 100 or more, in absolute brightness at radio wavelengths. Virgo A has been identified with the giant elliptical galaxy known by its Messier catalog number M87; M87 is the brightest member of the Virgo cluster of galaxies at a distance of 12 megaparsecs. The main radio emission has an extent similar to that of the optical object. Short-exposure photographs show that the object is very unusual in having a bright blue jet that extends a kiloparsec from the nucleus. Radio measurements reveal a compact component, radiating a few percent of the total flux, coincident with the jet. The presence of this jet indicates that the nucleus of M87 is still active. Many astrophysicists have proposed that the main radio source was produced by a similar central explosion but on a vaster scale.

Centaurus A has been mapped over a region ten degrees in diameter, which at its distance corresponds to one megaparsec (10^6 parsecs, or 3.26 × 10' light-years) in overall extent, the largest linear size of any known radio source. It has two outer components of low surface brightness and two intense compact central components embedded in the outer envelope of the galaxy NGC 5128. This is also a peculiar elliptical galaxy, being crossed by a dark band of absorbing material that is a very unusual feature in an elliptical galaxy. The dark material and peculiar velocities found optically in NGC 5128 are again indicative of some central explosion that is presumably also responsible for the ejected radio plasma. In this galaxy two explosions appear to have occurred; one produced the outer diffuse emission, and a more recent explosion produced the compact inner components. Centaurus A was one of the first extragalactic radio sources in which linearly polarized radio emission was detected. Radiation from the outer components of the source is as much as 20 percent polarized. Synchrotron emission is evidently responsible.

Cygnus A

Very distant radio galaxies. By the early 1950s much more distant radio galaxies of even greater intrinsic radio luminosity were discovered. The brightest extragalactic source in the sky, Cygnus A, was identified with a peculiar double galaxy that displayed a red shift in its light equivalent to a speed of recession of 16,000 kilometres (10,000 miles) per second. The presently accepted relationship between red shift and distance is roughly 100 kilometres (60 miles) per second per megaparsec; accordingly, the distance of Cygnus A is 160 megaparsecs. Cygnus A was at first thought to be a pair of galaxies in collision in which the energy of the radio emission came in some way from the energy of motion of the two colliding galaxies. It became evident, however, that, in this system and other double systems, the collisional hypothesis was inadequate to account for the estimated energy and that an explanation in terms of some central explosion was more promising. In Cygnus A the presumed explosion has produced optical radiation in two adjacent volumes, while the two plasma clouds containing the relativistic (fast) electrons moving near the speed of light and magnetic fields responsible for the radio emission were ejected to much greater distances and were now separated by 80 seconds of arc (60 kiloparsecs). The rate of radio emission from Cygnus A is 10^{44} ergs per second, and the estimated value for the energy in the relativistic electrons and magnetic fields to 10^{60} to 10^{61} ergs. This is a minimum estimate of the total energy at the present time stored in this galaxy. This amount of energy is about 10^{-4} of the Einstein rest mass (Mc^2 in which M is the mass and c is the velocity of light) of the entire galaxy—a radio emission so inexplicably large that it poses one of the major problems of astrophysics at the present day.

The Seyfert galaxies

The observed properties of the radio galaxies can be summarized briefly. They are often double or multiple sources in which the radio components are situated on either side of the parent optical galaxy. The associated optical galaxies tend to be surprisingly alike in absolute luminosity, with an average magnitude of —21 (4 × 10^{10} times the intrinsic brightness of the Sun). One group of radio galaxies is identified with the Seyfert galaxies (named after Carl Seyfert, the American astronomer who first studied them), which are spirals with particularly active nuclei. The radio luminosity increases from its lowest value in the irregular galaxies, through the giant ellipticals (*e.g.*, Virgo A) to dumbbells (double galaxies —*e.g.*, Cygnus A) to the D galaxies, which are single galaxies each in an extensive envelope, and N galaxies, which have a bright nucleus in a faint envelope. Many pose the energy problem described for Cygnus A. The most distant radio galaxy discovered so far is 3C295, whose red shift indicates that it is receding at 0.46 times the speed of light. It is ten times further away than Cygnus A but is similar in all other properties.

Quasi-stellar radio sources. Quasi-stellar objects are discussed fully in QUASI-STELLAR SOURCES. A summary of their properties sufficient for the present purpose follows. Quasi-stellar radio sources (quasars) are identified with certain optical objects that produce starlike images on photographs. These are believed to be not stars belonging to the Galaxy but extragalactic objects photographically unresolved. The associated radio sources, on the other hand, are generally not so small and they have sizes and shapes similar to those of radio galaxies. Radio measurements alone, therefore, cannot distinguish whether a particular object is a radio galaxy or quasar. There are, however, some statistical differences between the two groups. The extragalactic nature of the quasi-stellar radio sources was established from observation of the nearest one, number 3C273 in the third Cambridge catalog of radio sources. A compact component in 3C273 coincides with a starlike object, and an extended component 20 seconds of arc away is situated at the end of an optical jet directed away from the "star." Recent radio studies have shown that the compact source (called component B) has several more or less concentric components, the smallest of which has an angular diameter of 0.0003 seconds of arc. This corresponds to a linear diameter of one parsec if it is assumed that the object's red shift is caused by distance and that the usual rules for finding the distances of galaxies apply. The radio emission from component B is variable over periods of years; an examination of photographs made since 1890 demonstrates that the quasi-stellar object has varied also in optical intensity by more than a factor of two with characteristic time scales generally of about ten years but sometimes in a period of a few months. These latter variations imply that some optical components must be smaller than a few light-months (*i.e.*, 0.1 parsec) in diameter. This is of an order of size similar to that of the radio measurements of size mentioned previously. Clearly, vast quantities of energy are being released in 3C273. A typical outburst of this type releases about 10^{58} ergs of energy in the form of relativistic (fast) electrons and magnetic fields.

About 150 quasi-stellar objects associated with radio sources have been studied in some detail, and their red shifts, presumably a measure of their distances, have been determined. The quasi-stellar radio sources as a group show flatter radio spectra than the radio galaxies. Many seem to emit less energy at low frequencies, indicating sufficiently large numbers of fast-moving electrons and magnetic fields to produce synchrotron self-absorption; that is, the energy produced by the accelerating electrons is re-absorbed by other electrons nearer the observer. Those sources with flat spectra have observable components with the smallest angular diameters—in some cases as small as 0.001 second of arc. A few radio galaxies also have this characteristic. Other quasi-stellar radio sources produce extended radio emission spread over ten kiloparsecs or more; this is considered to be the result of some explosion that occurred millions of years ago. In such cases, the related central optical object has continued to emit. Some, like 3C273 with several high and low brightness components, show evidence for multiple explosions. One major difference between radio galaxies and quasi-stellar radio sources is the greater rate of optical and radio emission from the quasi-stellar sources. Since the energy in magnetic fields and fast-moving electrons is comparable in the two types of object, the quasi-stellar radio sources must have shorter lifetimes than galaxies by a factor of ten to 100; typically, their age is several times 10^6 years. Their density in space is considerably less than that of the radio galaxies. Evidence suggests that there are approximately 10' radio galaxies for every quasi-stellar radio source in the nearby region of the universe.

The distribution of very distant radio sources. The methods of measuring distance that have been developed by optical astronomers can be used to derive distances for those radio sources that are identified with a galaxy. Such methods can measure distances to the nearby galaxies with an accuracy of between 10 and 20 percent. In the case of a more distant galaxy, apparent brightness can be used as a distance indicator so long as its absolute brightness can be assessed from its morphological type or spectrum.

In radio and optical astronomy it is now possible to investigate objects at very large distances; consequently, the properties of these objects are assessed as they were a long time ago when light and radio waves set out on their journey to the Earth. Assuming that their red shifts are true distance indicators, many of the quasi-stellar sources are so far away that the emission received from them set out when the universe was less than half its present age. Some astronomers, however, have argued that the red shift may be a gravitational effect in objects at intermediate distances, claiming that the expected correlation between red shift and apparent magnitude for quasi-stellar sources does not exist.

The understanding of the evolution of the universe does not have to rely only on those radio galaxies and quasi-stellar sources whose distances are known. The problem can be approached statistically. If it is supposed that the universe is uniformly filled with a population of radio sources of the same absolute luminosity, then in counting all the sources out to some distance (*R*), at which the apparent luminosity is proportional to R^{-2}, the number of sources will be proportional to R^3. It can be seen then that the number of sources, N, down to some limiting apparent luminosity, S, is proportional to the inverse three-halves power of S—that is, to S-%.This is true even if the sources are not all of the same absolute brightness but are nevertheless mixed in space. Many such counts of radio sources have been made and reliable data is now available down to very low apparent brightness levels. A plot of the logarithm of N versus the logarithm of S taken from the Cambridge surveys is shown in Figure 6. In a uniform universe the slope of this plot should be the power of *S* shown above; that is, —1.5. Figure 6 and similar plots using different sample source counts indicate that the slope for the brighter sources (the bottom right-hand end of plot) is close to —1.8 and is definitely steeper than —1.5, and the results are interpreted as indicating an excess density of apparently weaker and therefore more distant sources. This higher density is then taken to be characteristic of the earlier epochs in the evolution of the universe. Such a decrease of source density from those early stages to the present is precisely what is expected in an expanding universe and is at variance with any simple steady-state model of the universe. At the very faint end of the log N–log *S* plot the number of radio sources falls well below the expected 1.5 slope. This has been explained as the effect of a low rate of formation of radio sources in the first few tens of percent of the age of the universe; at these early epochs conditions were presumably not favourable for the formation of radio sources.

Adapted from *Annual Review of Astronomy and Astrophysics* (1968)

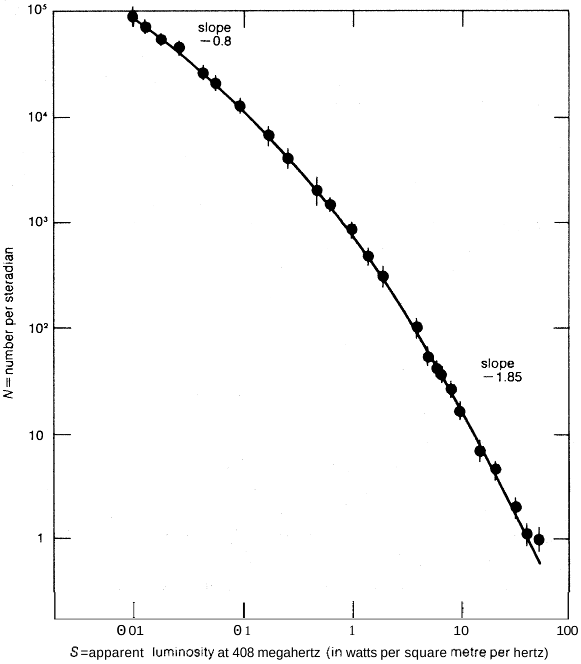

Figure 6: Observed relationship between number of radio sources (N) as a function of limiting apparent luminosity (S) plotted on a logarithmic scale.

The correct interpretation of the log N–log S plot is not entirely clear. There is no reasonable doubt that it can be fitted to a model of an evolving ("big-bang") model as described in outline above. There may be other explanations—for example, in terms of an oscillating model. Indeed, proponents of the steady-state models claim that the data can be fitted to their theories with appropriate modifications to their original concepts. Many astronomers feel uneasy about interpreting log N–log *S* data that include a significant fraction of quasi-stellar sources whose nature is still not clear.

There is one more piece of observational data that radio astronomy has contributed to the cosmological argument: the 3° Kelvin universal blackbody (thermal) radiation. This radiation, which appears to come impartially from all directions, has a brightness temperature at all wavelengths of about 3° K; more accurate recent measurements indicate a value of 2.7" K (—454.8" F). The integrated radiation from the estimated background (of unresolved radio sources) has been allowed for in the measurements. At wavelengths shorter than 10 centimetres this contribution is considerably less than 2.7" K radiation, in any case. In evolutionary cosmologies this radiation is explained as a residual glow from the expanding radiation field generated at the time of the "big bang." Steady-state cosmology has no explanation for it.

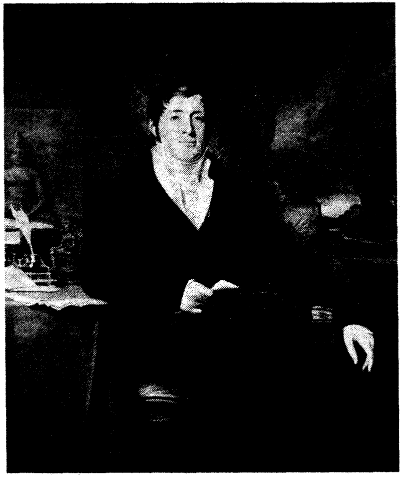
Raffles, Sir Stamford

Sir Thomas Stamford Raffles, as employee of the British East India Company, was one of the founders of Britain's empire in the Far East. In 1819 he founded Singapore, which was to become the vital link in the China trade.

Early life and the beginning of East India service

Born to an improvident. merchant captain and his wife on July 6, 1781, during a homeward voyage from the West Indies, Raffles grew up in an atmosphere of debt. Forced to cut short his schooling at the age of 14, he entered the service of the East India Company as a clerk in order to support his mother and four sisters. Although his formal education was inadequate, he studied the sciences and several languages at his own leisure and conceived an interest in natural history that was to earn him a distinguished reputation. Both in and out of office hours, his industry won him such notice that at the age of 23 he was appointed assistant secretary to the newly formed government of Penang, a hitherto inconspicuous island at the northern entrance to the Strait of Malacca.

In Penang, established in order to give England a foothold in the Dutch-held East Indies, Raffles shaped his career by an intensive exploration into the language, the history, and the culture of the Malayan peoples scattered over the islands of the archipelago. This unique study



Raffles, oil painting by G.F. Joseph, 1817.

caught the attention of Lord Minto, governor general of India, at a time of crisis, when Napoleon was using Java as a springboard for the destruction of England's slow and lumbering ships, the Indiamen, on the long haul to China. Determined to remove Java from French influence, Minto appointed Raffles his agent to prepare the way for a naval invasion.

Entrusted with an independent authority that aroused jealousy in Penang, Raffles established his headquarters in Malacca. Rewarded for his extraordinary work by an appointment to Minto's staff, Raffles sailed with him to Java, where the expeditionary force landed without mishap on August 6, 1811, and, after a short and sharp engagement with the Dutch–French forces, occupied the island. Minto gave considerable credit for the success to Raffles. Having already described him as "a very clever, able, active and judicious man," he now recognized his intellectual and administrative ability and his humanism and concern for the Javanese, and on September 11 he proclaimed him lieutenant governor of Java. Shortly afterward Minto sailed for Calcutta, leaving Raffles at the age of 30 to rule not only Java but an archipelagic empire of several million inhabitants.

Reforms of the Dutch system in Java

Raffles inaugurated a mass of reforms aimed at transforming the Dutch colonial system and improving the condition of the native population. His reforms, however, proved too costly to a trading company primarily concerned with profit and were short-lived. After four and a half years in Java, suffering from increasing ill health and shattered by the death of his wife, he was recalled. Left vulnerable to personal attack by the death of Minto, he sailed for England on March 25, 1816, thoroughly out of favour with the court of directors of the East India Company.

He never regained their full confidence. Despite a dazzling London success in both fashionable and learned society that culminated in his election as a fellow of the Royal Society and the award of knighthood, he resumed his Eastern service in a situation of reduced and restricted authority, as lieutenant governor of the dilapidated, fever-ridden pepper port of Bengkulu on the west coast of Sumatra. Yet it was from Bengkulu, as he watched the Dutch regain possession of the archipelago and enforce a policy of complete commercial monopoly, that he made his next move to extend British influence in southeast Asia.

In a voyage to Calcutta, which all but ended in shipwreck, he employed his wide knowledge of Eastern affairs and his powers of persuasion to convince Lord Hastings, then governor general of India, that immediate and forceful action was essential to safeguard British trade. On December 7, 1818, he sailed from Calcutta, bearing Hastings' qualified authority to establish a fortified post eastward of the Straits of Malacca and so placed as to wedge open the gateway to the China seas. On the morning of January 29, 1819, he landed on the shore of a sparsely populated island off the southern tip of Malaya and, risking imminent collision with the Dutch, established by treaty the port of Singapore. Although he returned to his post at Bengkulu for three years, he went back to Singapore in October 1822, when he reorganized the various branches of the administration. His regulations of January 1823 stated,

Establishment of the free port of Singapore

> the Port of Singapore is a free Port, and the trade thereof is open to ships and vessels of every nation . . . equally and alike to all.

By a treaty of March 17, 1824, the Dutch relinquished all claim to Singapore. For Raffles, however, this was a time of rapidly deteriorating health, characterized by headaches of increasing ferocity, and he sailed for England, arriving there on August 22, 1824. In London his vast collections illustrating natural history and Malayan lore won him acclaim as an Orientalist, and he assisted in founding the London Zoo, of which he was elected the first president. He died of a brain tumour on July 5, 1826.

BIBLIOGRAPHY. C.E. WURTZBURG, ***Raffles of the Eastern Isles*** (1954), is a comprehensive work of great industry, excellently edited by CLIFFORD WITTING, and includes a comprehensive bibliography; MAURICE COLLIS, ***Raffles*** (1966), is a later and briefer work presenting a clear picture of the man behind the facts.

(H.F.P.)

Railroads and Locomotives

A railroad (or railway) is a mode of land transportation in which freight-goods- and passenger-carrying vehicles, or cars, with flanged wheels move over two parallel steel rails. The guideway, or track, consists of the parallel rails laid on crossties, or sleepers, and anchored in a bed of crushed rock or other ballast. The cars usually are pushed or pulled by a locomotive, although they may be self-propelled. The track gauge (the distance between inside faces of the rails) varies from country to country and sometimes among railroads within the same country. The predominant gauge among railroads of the world, however, is the so-called standard gauge, which is four feet 8.5 inches (1.435 metres).

The development of railroads is one of the great landmarks in the progress of civilization. From early in the 19th century, railroads provided an element that helped greatly to realize the potential of the Industrial Revolution in the form of a reliable, low-cost, high-volume system of land transportation.

Basic principle of the railroad

The railroad's basic principle, flanged steel wheels rolling on steel rails, is what gives this mode its unique capability for heavy-duty transportation. The flanges on the insides of the wheels guide the locomotives and cars, causing them to follow the line of the rails; and the rolling friction of the wheels on the rails is extremely low. In fact, if a 40-ton (36,000-kilogram) railroad freight car of a standard United States type were set rolling on level track at 60 miles (about 100 kilometres) per hour, it would travel five miles (8 kilometres) or more before coming to a stop. By contrast, a motor truck of similar weight set free on a level highway at the same speed would roll only about one mile (1,600 metres).

Because of this self-guiding characteristic and the low rolling friction, a locomotive of relatively modest horsepower can pull a long train of cars. This, basically, is the reason for the economy of railroad transportation. A freight train of 5,000 tons (4,500,000 kilograms) gross weight (*i.e.,* weight of cars and freight) can be hauled with a locomotive of about 5,000 horsepower, depending on terrain and desired operatihg speeds, or approximately one horsepower per gross ton. Typical truck tractor-trailer combinations for intercity highway freight service are powered at about ten horsepower per gross ton. The railroad also has roughly the same 10 to 1 advantage in fuel economy and in employee productivity.

Almost from its inception, the railroad became the dominant all-purpose land carrier of both freight and passengers. It still performs that role in many countries, especially those that are in earlier stages of industrialization. The growth of automotive highway, air, pipeline, and modem water transport, however, has resulted in a changed and more specialized role for the railroads of many countries. In the United States, for example, highway and air services have almost completely taken over the transportation of passengers, except in urban areas and on short- to medium-distance (up to 300 miles [500 kilometres]) intercity runs. In freight transportation, highway trucks perform most of the service at distances of less than 300 miles, and pipelines carry most of the petroleum products, as well as other commodities. Yet United States railroads still produce a substantially greater volume of intercity freight transportation than any other mode; in recent years their freight volume consistently set new records as the economy of the country grew. Similar trends are evident in other highly industrialized nations.

This article is divided into the following sections:

A general survey, from a historical viewpoint, of all forms of transport is presented in the article TRANSPORTATION, HISTORY OF. Forms of urban rail transport are described in TRANSPORTATION, URBAN.

I. History

DEVELOPMENTS TO 1850

Origins. The railroad as it is known today originated in England in the first quarter of the 19th century. Much earlier, however, crude "wagonways" were used in mines both in England and on the European continent. A narrow-gauge railroad in the mines at Leberthal, Alsace, was illustrated in ***Cosmographioe universalis*** by Sebastian Miinster in 1550. In his treatise ***De re nzetallica,*** printed at Basel in 1556, Georgius Agricola (Georg Bauer) described and illustrated a small mining wagon that ran on a wooden track and was guided by an iron prong, or pin, running in a narrow gap between the rails.

Early mine railroads

In the mid-16th century, such mining railroads seem to have been quite generally used in the mines of central Europe. One mining wagon, with flanged wooden wheels and track, is in the Verkehrs und Bau Museum, Berlin. It was used in the gold mines of northwestern Transylvania.

Mining railroads were apparently introduced into England from Germany early in the 17th century. The first written mention of a railroad in Britain is in a manuscript account of an estate near Nottingham, in 1603 or 1604. In the early years of the 17th century, numerous lines, some quite lengthy, were built from mining pits to rivers. **A** notable example was the Tanfield Wagon Way, Durham, England, a portion of which was built possibly as early as 1632. About 1726 this line was considerably expanded; one of its branches required a 103-foot (31-metre) stone-arch bridge. The Tanfield line continued in operation as a mineral railroad until 1964. By the end of the 18th century, there was a considerable network of railroads, or wagonways, extending back into the country from both sides of the Tyne and Wear rivers. These mining railroads were essentially privately operated adjuncts to the mining operations. Horses supplied the motive power.

The early mining railroads used two methods of guiding the vehicles along the track. Earliest practice, apparently, was to use vehicles with special flanged wheels, such as are used today, although the flanges could be on either the outside or inside of the wheel tread, running on "edge rails." Later, "plateways" were introduced, iron angles laid end to end; the vertical flanges on these angles served to guide the wagons, which had ordinary flat-tread wheels. The advantage of the plateway was that wagons did not require special wheels, although the distance between wheels (*i.e.*, the wheel gauge) had to fit that of the plates. Thus, the same wagons could use both ordinary roads and plateways. Many plateways were built, mostly between 1795 and 1815 (one survived as a public plateway until 1917). The plateway, or flanged-rail system, eventually gave way to the flanged-wheel system, at least partly because of the difficulty of devising a workable switch, or turnout, for the former.

Plateways for wagons

Mining railroads were used in Wales and Scotland, as well as in England. The first railroad authorized by an act of Parliament was the Middleton to Leeds colliery line of 1758 (a section of this line is still in operation).

In 1801 the Surrey Iron Railway was incorporated. This was the first public freight-carrying railroad; it opened from Wandsworth to Croydon on July 26, 1803.

Early railroad development. The development of mechanical traction to replace horsepower may be said to mark the emergence of the modern railroad. Thereafter, railroads spread rapidly in Britain and then in other parts of the world. But, because of differing conditions, railroads developed quite differently in Britain, on the continent of Europe, and in North America.

Britain. The "New Castle," a locomotive built by the English engineer Richard Trevithick (Figure 1), ran on a Welsh tramroad in 1804 but, like a number of the early steam locomotives, was too heavy for the rails. The first practical and successful locomotive was built in 1812 to the instructions of John Blenkinsop, an inspector at the Middleton colliery near Leeds. It ran on cast-iron rails and had two vertical cylinders driving two shafts geared to a toothed wheel that engaged a rack rail.

In 1813 the English inventor William Hedley built the "Puffing Billy," a simple adhesion locomotive that relied on friction between the wheels and the rails, dispensing with the toothed rack rail (the rack-rail system is now used only on a few mountain railroads with extremely steep gradients). Like John Blenkinsop's locomotives, "Puffing Billy" was used for hauling coal wagons between a mine and wharves, as was George Stephenson's first locomotive, the "Blücher," completed in 1814.

In 1823 Stephenson, one of the great pioneer railroad and locomotive builders, was invited to build and equip a railroad from Stockton to Darlington. The ceremonial opening of this landmark line took place on September 27, 1825. The Stockton and Darlington Railway was the first public railroad in the world to use locomotive traction and the first built to carry both freight and passengers. At first steam locomotives were used only for freight service; passenger service was provided by a contractor who used horse-drawn coaches. The first locomotive on the Stockton and Darlington was George Stephenson's "Locomotion." It and similar locomotives proved unreliable and expensive to maintain. They were suitable only for hauling low-speed mineral trains; their weight and tractive effort were limited by the relatively weak track. At times the railroad reverted to horses, but the situation was improved in 1827 with the introduction of the "Royal George," a six-coupled locomotive designed by Timothy Hackworth.

First public locomotive traction railroad

But the railroad era really began with the opening, on September 15, 1830, of the Liverpool and Manchester

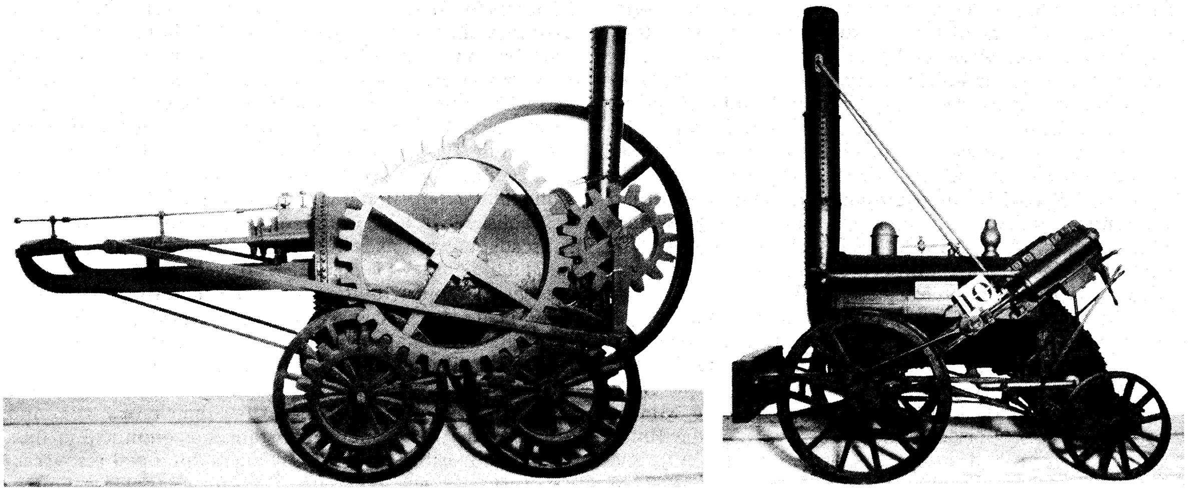

Figure 1. (Left) The "New Castle," built by Richard Trevithick in 1803, the first locomotive to do actual work. (Right) The "Rocket," built by George Stephenson, it won the 1829 trials by the Liverpool and Manchester Railway, England.

By courtesy of the Baltimore and Ohio Railroad Company

Railway. The Liverpool and Manchester incorporated all the features of modern public railroads. It was a public carrier of both passengers and freight. with all business handled directly by the company itself: it used mechanical traction for all traffic.

George Stephenson's "Rocket"

Previous to its opening in 1829, the Liverpool and Manchester held a contest to determine the best type of motive power. The trials took place on the Rainhill level (Lancashire) from October 6 to 14, 1829. Three steam locomotives took part: George Stephenson's "Rocket" (Figure 1), Timothy Hackworth's "Sans Pareil," and the "Novelty," built by John Braithwaite and John Ericsson. On the last day of the trials the "Rocket" was awarded the £500 prize. The "Rocket's" superiority was due mainly to its use of a multiple fire-tube boiler rather than the single-flue boilers previously used. About this time, too, John Birkinshaw developed the fish-bellied (bellying out on the underside), rolled-iron edge rail. This was much stronger than the cast-iron rails previously used and enabled heavier locomotives to be run.

After the Rainhill trials, the steam locomotive became the dominant form of railroad motive power and was to remain so for over a century. The success of the Stockton and Darlington and the Liverpool and Manchester lines touched off widespread railroad building in Great Britain. In 1836 the London and Greenwich Railway opened, bringing the first public passenger service to London. In 1838 the London and Birmingham Railway was opened for its full length, and in 1840 the line from London to Southampton was completed. The Great Western Railway's line from London to Bristol was opened in 1841. By that time there were over 1,300 miles (2,100 kilometres) of rail line in the United Kingdom, and between 1844 and 1846 Parliament authorized the construction of more than 400 new lines, representing the height of the "railway mania" in Great Britain.

Unlike the other early British railroads, which used the four-foot-8.5-inch (1.435-metre) gauge, the Great Western line was built to a seven-foot (2.1-metre) gauge. The directors of the road adopted this broad gauge at the instigation of the line's brilliant chief engineer, Isambard Kingdom Brunel. There were, and still are, sound technical reasons for using a wide gauge; by 1835, however, when the Great Western directors adopted Brunel's seven-foot, it was already too late. The necessity for individual railroads to work together as an integrated network dictated a common gauge, and the 4-foot-8.5-inch width had already become the "standard gauge"; it remains so today. The Great Western continued to use the broad gauge until 1892, when the line was converted to standard gauge.

Continental Europe. Although the beginnings of railroads occurred quite early in most European countries, subsequent extension of rail lines was much slower than in Great Britain. Continental railroad practices soon diverged from those in Britain, though not as sharply as in North America. Standard gauge (or a width so close to it as to be compatible for through running) became dominant in all continental countries except Russia and Finland, where the width is five feet (1.5 metres), and Spain and Portugal, which use five feet six inches (1.680 metres). As compared with British railroads, continental railroads are also built to a much larger loading gauge, or clearance diagram, the dimensions above and outside the rails that rolling stock or loads must not exceed. This means that continental locomotives and cars are much bigger than those in Britain.

There was also more emphasis on state planning and control in the construction of early continental railroads. There, unlike the situation in Britain (and in North America), few competing railroads were built. In some cases the governments themselves built the lines; in other cases private companies received exclusive franchises to serve specific routes.

First railroad in France

The first railroad in France, from Saint-Etienne to Andrtzieux, went into use in 1827. It used horses and carried only freight until 1832, when steam locomotives were adopted. The Saint-Etienne–Lyon line was completed in 1832. The first international line, from Strasbourg to Basel, was completed in 1841, by which time France had 350 miles (about 550 kilometres) of railroads.

The use of the steam locomotive in Germany began on December 7, 1835, with the opening of a railroad between Nürnberg and Fürth. A gauge of six feet (1.8 metres) was selected for the first public railroad in Russia, which was opened, with horse traction, in 1836. The original line in Russian Poland was of standard gauge, but Russia finally standardized on a width of five feet (1.5 metres). By 1850 there were only about 370 miles (600 kilometres) of railroad in all of Russia, but in 1851 the 404-mile (650-kilometre) link between St. Petersburg and Moscow was completed by the American engineer George Washington Whistler.

The first railroad in the Austro-Hungarian Empire, a 90-mile (140-kilometre) horse line between Linz and Budweis, was opened in 1832. By 1837, when the first steam locomotives were introduced, there were some 170 miles (270 kilometres) of horse-traction public railroads in the country.

North America. Interest in railroads in the United States developed almost as soon as in England. One of several horse-drawn tramways built early in the 19th century was Gridley Bryant's Granite Railway in Quincy, Massachusetts. This three-mile (five-kilometre) broad-gauge line carried the granite used in building the Bunker Hill Monument in Boston.

By 1813 the inventor Oliver Evans was proposing a railroad between New York and Philadelphia. Two years later, John Stevens received from the New Jersey legislature the first charter for a railroad ever granted in America. Stevens was ahead of his time: the chartered line, between the Delaware and Raritan rivers, was never built. But in 1825 he built and operated the first locomotive to run on rails in America; it ran on a half-mile circle of track at Stevens' home in Hoboken,·New Jersey.

Success of the Stockton and Darlington in England spurred interest in railroads in the United States. On February 28, 1827, the Baltimore and Ohio Railroad Company was chartered. The line began carrying revenue traffic on January 7, 1830. The first 13 miles (21 kilometres) of line, from Baltimore to Ellicott's Mills (now Ellicott City), opened on May 24, 1830.

Baltimore and Ohio Railroad

The Baltimore and Ohio was the first railroad in the United States to be chartered as a common carrier of freight and passengers. Its promoters, looking beyond local needs, envisaged a line going all the way to the Ohio River to channel the commerce of the growing Middle West through the port of Baltimore. By 1834 the Baltimore and Ohio had built to Harpers Ferry, Virginia (now West Virginia), and on December 24, 1852, it reached the Ohio River at Wheeling. Subsequently, the company expanded, both by new construction and by acquiring other railroads, until it reached Chicago, St. Louis, and the Great Lakes.

Almost simultaneously, several other American railroads came into being. Construction of the five-foot-(1.5-metre-) gauge line from Charleston to Hamburg, South Carolina, by the South Carolina Canal and Rail Road Company began in February 1829. On December 25, 1830, this line became the first in the United States to start scheduled passenger operations using a steam locomotive. When the entire line to Hamburg was completed in 1833, it was the longest (136 miles [219 kilometres]) then operating in the United States. Ultimately, this line became part of the 10,000-mile (16,000-kilometre) Southern Railway System. Several other railroad systems that later grew into giants of the United States railroad industry had their beginnings in the decade of the 1830s. By 1840 there were 2,800 miles (4,500 kilometres) of line in the United States, and the country had entered its first great era of railroad building. Twenty years later, on the eve of the American Civil War, the country had 30,000 route miles (50,000 kilometres) of track.

With few exceptions, early railroads were designed to promote the commercial interests of local communities or areas. As growth progressed, however, many of the small roads were consolidated, forming through routes that served fairly large territories, and new railroad projects became more ambitious. The Pennsylvania Railroad Company (now Penn Central) completed its line from Philadelphia to Pittsburgh in December 1852, using ten inclined planes to climb over the Allegheny Mountains. A little more than a year later, it completed an all-rail route.

The growth of Canadian railroads paralleled somewhat that of the United States. Construction of the first line, the Champlain and St. Lawrence Railroad, between Laprairie and St. John, Quebec, began in 1835; its first train operated on July 21, 1836. By 1860 there were about 2,000 miles (3,000 kilometres) of railroad line in Canada.

Social and economic consequences. The impact of the early railroads upon the societies in which they developed amounted to a social revolution. For the railroad represented the first big leap ahead in man's efforts to reduce the effects of time and distance on his travel and communications. As such, its effect on the society of the early 19th century was as profound in its day as was the effect later on of the development of the automobile, the airplane, and the radio. For the first time, farmers, manufacturers, merchants, and travellers had available a form of overland transportation that was fast, relatively inexpensive, little affected by weather conditions, and capable of moving large volumes of both goods and people.

Railroads compared to older forms of transport

The effect of the railroad upon the older forms of land transportation, the stagecoach and the canalboat, was immediate and often catastrophic. Though diehards opposed the railroads, few could afford not to use them once they were built. Typically, in 1841 a trip from London to Exeter, about 175 miles (280 kilometres), required about 21 hours by stagecoach, including meal stops. By 1846 an express train made the journey in 6½ hours at less cost than by stage. (In 1970 express trains made this trip in two hours.) Newspapers and mail soon began to move by rail with dramatic time savings. On December 11, 1849, to publicize their joint route between London and Paris, the South Eastern and Nord railways of Britain and France dispatched copies of the morning ***Times*** from London at 7:00 AM and had them in Paris by 1:30 PM.

Established freight traffic quickly shifted to the new railroads; but just as railroads produced a vast increase in the total volume of passenger travel, so did they also present new opportunities for manufacturing and trade. They made it unnecessary for some types of factories to be located on canals or rivers; railroads could carry in the raw materials and take the finished products, at low cost, to much more distant markets than previously. Farmers could find a more ready market for their crops; coal and ore could be moved longer distances economically, thus making it feasible to work previously untapped resources.

So pervasive was the railroad's impact that great pressures developed on the part of both industries and communities to be served by rail transportation. Only a few towns and cities opposed the coming of railroads, and often they regretted their obstinacy when they saw growth and prosperity going to neighbouring communities that had welcomed the new form of transport. In both Europe and the United States, community leaders pushed hard to have main lines built through their towns, and if they could not get main-line status, they tried at least to get a branch-line connection.

In the United States, Canada, and other new undeveloped countries, the railroad proved to be the means of opening up new territory. Many towns and cities in the United States and Canada originally came into being as railroad "division points," where locomotives were changed, serviced, and repaired, and where operating crews were changed.

FROM 1850 TO THE PRESENT

Railroad development: 1850–1900. The second half of the 19th century saw the railroad reach maturity and become a worldwide technical, economic, and social phenomenon. In the earlier part of the half century, railroad accidents became frequent and serious, as locomotive and car sizes grew rapidly, overstraining tracks and bridges. The first steel rails were introduced in England in 1857, and the first steel bridge was built, over the Mississippi at St. Louis, in 1867–73. Other major technological advances included automatic electric block signalling, telegraphic train dispatching, automatic coupling, and air brakes. Railroads learned to work together on common standards for brakes, couplers, and wheels, to permit interchange of equipment among different lines.

Britain. As the country where the .railroad originated, Great Britain was the first to experience intensive building. Construction of new lines peaked there during the 1840s, when some 4,500 route miles (7,200 kilometres) were laid down, and remained at a high rate during the next two decades. By 1870 Britain had about 13,500 miles (21,700 kilornetres) of railroad, largely double tracked. In the remaining three decades of the century the pace slowed down, but other important developments took place. Physical plant of the main lines was improved. In Scotland bridges were built over the two great firths of Tay and Forth. The first built over the Tay, on wrought-iron piers, was blown down in a gale (1879) and was replaced in steel. The Forth was bridged by the world's longest span bridge, a giant cantilever (1890). The world's longest underwater tunnel was driven under the Severn for the Great Western Railway (1886). First-class sleeping cars were introduced on trains between London and Scotland in 1873, and dining cars on the Great Northern's London to Leeds line in 1879. On August 22, 1895, competing trains of two lines raced from London to Aberdeen, Scotland, both completing the run at average speeds in excess of 60 miles (100 kilometres) per hour.

Railroad bridges in Scotland

The United States. Railroad construction in the United States was on an even larger scale than in Britain in the

1850s, when more than 21,000 route miles were built. Construction was slowed down by the American Civil War (the first war, incidentally, in which railroads played a major role); but it resumed on a large scale immediately afterward, reaching a peak in the 1880s: in the year 1882 alone 11,500 miles (18,500 kilometres) were built, a record exceeded in 1887 with a total of 12,800 miles (20,600 kilometres). Altogether, more than 70,000 miles were built in the decade. Construction continued at a relatively high level through the 1900–10 decade.

The major thrust of American railroad development was westward. The first locomotive in Chicago, the "Pioneer" of the Galena and Chicago Union Railroad, now the Chicago and North Western Transportation Company, made its first run on October 25, 1848. The first railroad reached the Mississippi from Chicago in 1854. On May 10, 1869, the first transcontinental route was created when, at Promontory, Utah, the Union Pacific Railroad, building west from Omaha, Nebraska, met the Central Pacific Railroad, building east from Sacramento, California. Ultimately there were about nine major routes leading from the Midwest or South to the West Coast.

Government assistance to U.S. railroads

Although the United States railroad system, like that of other countries, was essentially a product of private enterprise, it received important government assistance, in the early years from state and local governments, and after the Civil War from the federal government in the form of land grants. Such grants, totalling about 131,000,000 acres (53,000 hectares) went to 29 railroads for about 18,000 miles of line (about 8 percent of total U.S. mileage). They made it possible for the railroads to push lines across prairies and mountains almost entirely undeveloped and very sparsely settled.

Railroad building becomes worldwide. Construction in western Europe followed that in Britain. In France six principal companies emerged, Nord, Est, Paris-Orléans, Paris-Lyon-Mediterranean, Midi, and Ouest. In 1878 the state took over a group of small companies in western France, creating the *État* (State) system. By 1902 the French rail network totalled 28,400 miles (45,700 kilometres). In Germany both private companies and the individual German states built railroads, but after 1876 the privately owned systems were gradually absorbed by the states. Germany's total route mileage had reached 35,625 (57,321 kilometres) by 1909.

Meanwhile, countries in other parts of Europe and throughout the world were getting their first railroads or expanding their small beginning networks to national proportions. In Canada the Canadian Pacific Railway Company tied Canada together just as the Central and Union Pacific lines had tied the United States together. One of the terms on which British Columbia entered the confederation in 1871 was the promise of this transcontinental route, which was completed in 1885. Two other Canadian transcontinentals, built with government assistance, reached the Pacific Coast in 1914 and 1915. India's first line, the East Indian Railway Company, was registered in 1849; the first line was opened between Bombay and Thana in 1853. By 1910 there were more than 32,000 miles (51,000 kilometres) of line in what are now India, Pakistan, and Bangladesh.

This period also saw the beginnings and rapid growth of railroads in Africa, Australasia, and Japan. Railroad development was handicapped in Australia because each state laid track to the gauge it considered suitable for its own needs; as a result passengers and freight had to be transshipped from one line to another, and the railroad failed to play as strong a role in opening up the country as it did in the United States and Canada.

The Trans-Siberian Railroad

A notable achievement of this period in railroad development was the building by Russia of the Trans-Siberian Railroad, 5,787 miles (9,313 kilometres) long, linking Moscow and Vladivostok. Construction began in 1891, starting simultaneously from the east and west terminals. Originally, passengers could not make the entire journey by rail but had to travel by boat (or in winter, by sleigh) across Lake Baikal. By 1916 a line around the lake allowed the trip to be made without changing cars.

The 20th century. With the 20th century the railroad reached maturity. Railroad building continued on a fairly extensive scale in some parts of the world, notably in Canada, the Soviet Union, and in Africa. But in the more developed countries construction tapered off, except for improvements or refinements of existing systems. The technological emphasis shifted to faster operations, more amenities for passengers, larger and more specialized freight cars, safer and more sophisticated signalling and traffic-control systems, and new types of motive power. Railroads in many of the more advanced countries also found themselves operating in a new climate of intense competition with other forms of transport.

Major new construction. By mid-20th century, railroads in such countries as the United States, Britain, and Ireland, as well as in western Europe generally, were beginning to abandon secondary and branch lines that had become uneconomic. But in the Soviet Union, China, Japan, Australia, and Canada, important new lines were being built. In the Soviet Union the Trans-Siberian line was double tracked and, by 1970, had been largely electrified. At that time, additional construction had raised the Soviet system to a total of 86,691 route miles (139,511 kilometres), making it the largest single railroad system in the world. In China, a large-scale railroad building program was also launched. A recently completed trunk line links Tsining with Ulaanbaatar, the capital of Mongolia, which was already on a branch of the Trans-Siberian Railroad. Several other important Chinese lines have been built or are under construction. Some of the main lines are being double tracked and electrified. Two major bridges across the Yangtze River, one at Hankow and the other at Nanking, have been built; each is more than a mile (1,600 metres) long.

Australia's record straight-line track

In Australia, considerable progress has been made in overcoming the handicap caused by the variety of gauges. The Commonwealth Railways has built several standard-gauge lines, the most important being the transcontinental link between Port Pirie and Kalgoorlie. Crossing the Nullarbor Plain, this line has one stretch of 300 miles (500 kilometres) without a curve, the longest straight track in the world. Standard-gauge rails also now link Perth with Sydney.

As Canada entered a period of rapid economic growth, it built a number of railroad lines to open up new territory. Among them were the Great Slave Lake Railway, running from Peace River, Alberta, 432 miles (695 kilometres) to Hay River and Pine Point, Northwest Territories, and the Quebec North Shore and Labrador Railway Company, a 320-mile (510-kilometre) ore-carrying line from iron ore deposits near Schefferville, Quebec, to the St. Lawrence River at Sept Iles. The Pacific Great Eastern Railway (now the British Columbia Railway), completed from Vancouver, British Columbia, to Prince George in 1956, in 1958 reached Dawson Creek and Fort Saint John, 327 miles (526 kilometres) north of Prince George. In the 1970s it expected to complete a further extension of 250 miles to Fort Nelson, British Columbia, and another line from Fort Saint James to within 140 miles of the Yukon Territory border.

In Japan, a major new railroad was built not to open new country but to enlarge the capacity of rail transportation between Tokyo and Osaka. The New Tōkaidō Line (see below) was built to standard gauge instead of the 3-foot-6-inch (1.07-metre) gauge commonly used in Japan. It has been so successful that a 100-mile (160-kilometre) extension, from Osaka to Okayama, was added in the early 1970s. The Table summarizes the current state of railway systems in selected countries.

Technological development. In the period 1900 to about 1930, few apparent advances were made in railroad technology. Nevertheless, that period saw several developments that were later to have a profound effect on railroads everywhere. One was the first practical and reliable diesel-electric locomotive; another was the perfecting of centralized traffic control, a highly efficient system of controlling train operations; still another was the first use of continuous welded rail, a major contribution to smoother track that costs less to maintain.

Railway Systems of Selected Countries

After World War II these and other technological improvements began to take hold on many of the world's railroads. The diesel-electric locomotive completely superseded the steam locomotive in the United States in little more than a decade. The vastly improved efficiency of this type of locomotive was' a major reason why railroads in that country were able to continue under private operation.

Another important trend became evident in the 1950s and 1960s: the electrification of major trunk lines in many countries. Electrification, though it requires a very heavy capital investment, is profitable wherever the traffic is extremely dense, as in Japan, parts of the Soviet Union, western Europe, and Great Britain.

II. Modem railroad technology

LOCOMOTIVES

Modern locomotive power sources

In normal practice a locomotive is a separate unit incorporating the machinery to generate (or, in the case of an electric locomotive, to convert) power and transmit it to the driving wheels. Motive power, however, can be incorporated into a car that also has passenger, baggage, or freight accommodations. Today there are three main sources of power for a locomotive: steam, oil, and electricity. Steam, the earliest form of propulsion, was in almost universal use until about the time of World War II; since then it has been largely superseded by the more efficientdiesel and electric traction.

The steam locomotive is a self-sufficient unit, carrying its own water supply for generating the steam and coal, oil, or wood for heating the boiler. The diesel locomotive also carries its own fuel supply, but the diesel-engine output cannot be coupled directly to the wheels; instead, a mechanical, electric, or hydraulic transmission must be used. The electric locomotive normally is not self-sufficient; it picks up current from an overhead trolley wire or a third rail beside the running rails. A few small battery-driven locomotives or railcars are used for special tasks.

The only other category of locomotive in use today is the turbine locomotive; although atomic-powered locomotives have been proposed, none has actually been built.

Steam locomotives. The basic features that made George Stephenson's "Rocket" of 1829 successful—its multitube boiler and its system of exhausting the steam and creating a draft in its firebox—continued to be used in the steam locomotive (Figure 2). The number of coupled drive wheels soon increased. The "Rocket" had only a single pair of driving wheels, but four coupled wheels soon became common, and eventually some locomotives were built with as many as 14 coupled drivers. Smaller "pilot" wheels are often used ahead of the drivers. Their main function is to guide the coupled wheels around curves. Large locomotives may also have smaller wheels behind the drivers. These permit the locomotive to carry a larger, heavier firebox.

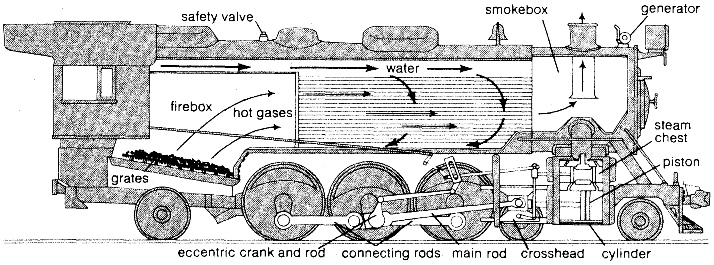

Figure 2: Cutaway diagram of steam locomotive.

Driving wheels

Steam-locomotive driving wheels are of various sizes, usually larger for the faster passenger engines. In Europe, the average was about 66- to 78-inch (1.7- to two-metre) diameter for passenger engines and 54 to 66 inches (1.4 to 1.7 metres) for freight or mixed-traffic types. Typical locomotives built in the United States just before the end of the steam era had drivers ranging from 60 to 84 inches (1.5 to 2.1 metres) in diameter.

Supplies of fuel (usually coal but sometimes oil) and water can be carried on the locomotive frame itself (in which case it is called a tank engine) or can be carried in a separate vehicle, the tender, coupled to the locomotive. The tender of a typical European main-line locomotive had a capacity of ten tons (9,000 kilograms) of coal and 8,000 gallons (30,000 litres) of water. In the Soviet Union and on some African, Asian, and Australian systems, higher capacities were common. The tender of a typical large United States steam locomotive of the World War II period was carried on 14 wheels and had a capacity of 28 tons (25,000 kilograms) of coal and 25,000 gallons (95,000 litres) of water.

In the United States the steam locomotive quickly evolved to the general type that became known as the

American Standard. It had a horizontal fire-tube boiler, a four-wheel pilot truck, and four coupled driving wheels. This type, conventionally designated 4-4-0 to reflect the number of wheels, was used for all kinds of services; it dominated American railroading until well after the Civil War period.

To meet the special needs of heavy freight traffic, other types of locomotives with more (and usually smaller) drive wheels were developed. Among them were the Mogul (2-6-o), the Consolidation (2-8-o), and the Mikado (2-8-2). The Union Pacific used a three-cylinder 4-12-2, which had 12 coupled driving wheels. Still greater tractive effort was obtained by using two separate engine units under a common boiler. The front engine was articulated, or hinge-connected to the frame of the rear engine, so that the very large locomotive could negotiate curves. The articulated locomotive was originally a Swiss invention, with the first built in 1888. The largest ever built was the Union Pacific's "Big Boy," used in mountain freight service in the western United States (Figure 3).

The articulated locomotive

By courtesy of the Unon Pacific Railroad

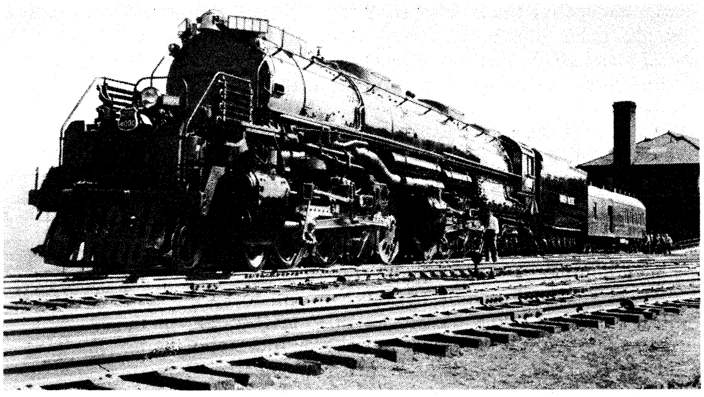

Figure 3: The "Big Boy" of the Union Pacific Railroad, built in 1941. Considered to be the largest steam locomotive ever built, it was used for hauling freight in mountainous areas.

"Big Boy" weighed nearly 600 tons (540,000 kilograms). It could exert 135,400 pounds (61,400 kilograms) of tractive force and developed more than 6,000 horsepower at 75 miles (120 kilometres) per hour.

One of the best known articulated designs is the Beyer-Garrett, which has two frames, each having its own driving wheels and cylinders, surmounted by water tanks. Separating the two chassis is another frame carrying the boiler, cab, and fuel supply. This type of locomotive is valuable on lightly laid track; it can also negotiate sharp curves. It is widely used in Africa.

In simple expansion locomotives (such as "Big Boy"), the steam from the boiler, after being used simultaneously in two (or more) cylinders, is exhausted to the atmosphere. With compound expansion, the steam goes first to one or two small high-pressure cylinders and then to two large low-pressure cylinders before being exhausted. This results in greater thermal efficiency, but with the disadvantage of higher maintenance costs.

Simple expansion locomotives with more than two cylinders were used in a number of countries; three- and four-cylinder locomotives were common in Britain. Compound locomotives were most popular in France, where for many years most locomotive designs were of this type.

Various further refinements gradually improved the reciprocating steam locomotive. Some included higher boiler pressures (up to 290–300 pounds per square inch for some of the last locomotives, compared with around 200 for earliei designs); superheating, feed-water preheating, roller bearings, and the use of poppet (perpendicular) valves rather than sliding piston valves.

Low efficiency of steam locomotives

Still, the thermal efficiency of even the best modern steam locomotives seldom exceeded about 6 percent. Incomplete combustion, heat losses from the firebox, stack, boiler, and cylinders, and other losses dissipated most of the energy of the fuel burned. For this reason the steam locomotive became obsolete, but only slowly, because it had compensating advantages, notably its simplicity and ability to withstand abuse.

By 1971 steam locomotives were virtually extinct in North America, Britain, and western Europe. They were still used to a declining extent in Africa, Asia, and Australasia. More than half the motive power in India (and in some smaller nations) was still steam, however.

Electric locomotives. Efforts to propel railroad vehicles using batteries date from 1835, but the first successful application of electric traction was in 1879, when an electric locomotive ran at an exhibition in Berlin. The first commercial applications of electric traction were for suburban or metropolitan railroads. One of the earliest came in 1895, when the Baltimore and Ohio electrified a stretch of track in Baltimore to avoid smoke and noise problems in a tunnel. One of the first countries to use electric traction for main-line operations was Italy, where a system was inaugurated as early as 1902.

By World War I a number of electrified lines were operating both in Europe and in the United States. Major electrification programs were undertaken after that war in such countries as Sweden, Switzerland, Norway, Germany, and Austria. By the end of the 1920s nearly every European country had at least a small percentage of electrified track. Electric traction was also introduced in Australia (1919), New Zealand (1923), India (1925), Indonesia (1925), and South Africa (1926). A number of metropolitan terminals and suburban services were electrified between 1900 and 1938 in the United States, and there were a few main-line electrifications. The advent of the diesel locomotive inhibited further electrification in the United States after 1938, but following World War II electrification was rapidly extended in Europe; in Switzerland 99 percent of the lines were electrified. There was also expansion of electrified operations in Africa, Asia, and Australasia. By 1972 electrified lines comprised a significant percentage of total route miles in such countries as Sweden (62 percent), Norway (57 percent), Italy (59 percent), France (26 percent), West Germany (33 percent), Soviet Union (22 percent), Japan (45 percent), and Great Britain (19 percent). By contrast, electrified route mileage in the United States was less than 1 percent.

Advantages and disadvantages. Electric traction is generally considered the most economical and efficient means of operating a railroad, provided that cheap electricity is available and that the traffic density justifies the heavy capital cost. Being simply power-converting, rather than power-generating. devices, electric locomotives have several considerable advantages. They can draw on the resources of the central power plant to develop power greatly in excess of their nominal ratings to start a heavy rrain or to surmount a steep grade at high speed. A typical modern electric locomotive rated at 4,000 horsepower has been observed to develop as much as 10,000 horsepower for a short period under these conditions. Moreover, electric locomotives are quieter in operation than other types and produce no smoke or fumes. Electric locomotives require little time in the shop for maintenance, their maintenance costs are low, and they have a longer life than diesels.

Extra power for starting and grades

The greatest drawbacks to electrified operation are the high capital investment and maintenance cost of the fixed plant—the trolley wires and structures and power substations—and the costly changes that may be required in signalling systems to make them compatible with electrified operation. A less important disadvantage is the lack of flexibility of electric locomotives, which cannot operate where there are no trolley wires.

Types of traction systems. Electric-traction systems can be broadly divided into those using alternating current and those using direct current. With direct current, the most popular line (*i.e.*, trolley or third-rail) voltages are 1,500 and 3,000, although there is a large mileage of 600 volts in southern England and several systems in the 600- to 700-volt range around New York City. The disadvantages of direct current are that expensive substations are required at frequent intervals, and the overhead wire or third rail must be relatively large and heavy.

The low-voltage, series-wound, direct-current motor is well suited to railroad traction, being simple to construct and easy to control. It was on a line electrified at 1,500 volts direct current that in 1955 two different French electric locomotives (Figure 4) achieved a speed of 205 miles (330 kilometres) per hour.

By courtesy of the French Embassy, Press and Information Division

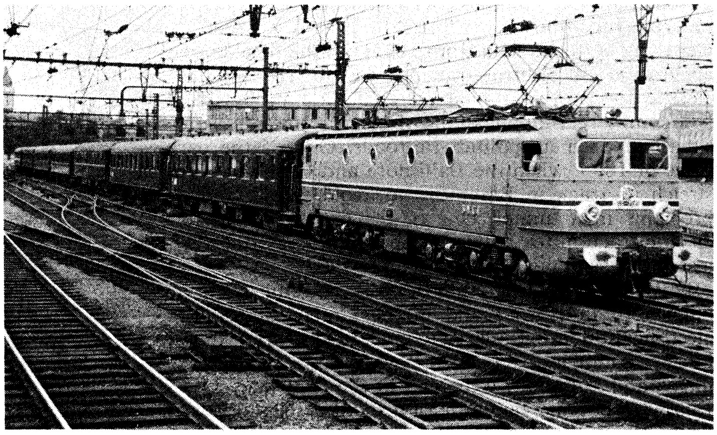

Figure 4: French C-C type electric locomotive, which operates on 1,500 volts direct current. This is one of the locomotives that set a world speed record of 205 miles (330 kilometres) per hour in 1955.

The potential advantages of using alternating instead of direct current prompted early experiments and applications of this system. With alternating current, especially with relatively high trolley-wire voltages (10,000 volts or above), fewer substations are required, and the special equipment needed to produce direct current for the locomotives is eliminated. Available alternating-current motors, however, were not suitable for operation with alternating current of the standard commercial or industrial frequencies (50 hertz [cycles per second] in Europe; 60 hertz in the United States). It was necessary to use a lower frequency (16⅔ hertz is common in Europe; 25 hertz in the United States); this in turn required either special railroad power plants to generate alternating current at the required frequency or frequency-conversion equipment to change the available commercial frequency into the railroad frequency.

Nevertheless, alternating-current trolley wires at 16% hertz are widely used on European railroads, primarily those where electrification began before World War II. Several main-line electrifications in the eastern United States were built using 25-hertz alternating current (these comprise the present Penn Central and Reading railroad systems).

Interest in using commercial-frequency alternating current on the trolley wire continued, however; and in 1933 experiments were carried out in both Hungary and Germany. The German State Railways electrified its Höllenthal branch with a trolley wire at 20,000 volts, 50 hertz.

Electrification on the French railroads

In 1945 Louis Armand, former president of the French railroads, set up a commission to study the 50-hertz operation on the Höllenthal line. As a result, the French railroads went ahead with further development of this system and converted a line between Aix-Les-Bains and La Roche-sur-Foron for the first practical experiments. This was so successful that a network of lines in northeastern France was electrified using 25,000-volt, 50-hertz alternating current.

Subsequently, the 25,000-volt, 50- or 60-hertz system has become virtually the standard for new electrification systems; it is used in a number of countries, including Britain, Turkey, Portugal, the Soviet Union, India, China, Japan, and Argentina. In 1971 several major North American railroads were studying the feasibility of electrifying key main-line segments using alternating current at 50,000 volts, 60 hertz.

With commercial-frequency, alternating-current systems, there are three ways of taking power to the locomotive driving wheels: (1) by a rotary converter or static rectifier on the locomotive to convert the alternating-current supply into direct current at low voltage to drive standard direct-current traction motors; (2) by a converter to produce variable-frequency current to drive alternating-current motors; (3) by direct use of alternating-current traction motors. The first method, using silicon rectifiers or silicon-control rectifiers (thyristers), is by far the most satisfactory. It has the advantage that the locomotive designer, if he wishes, can use the same standard direct-current traction motors that are widely used in diesel-electric locomotives.

In Europe, the problem of international operation of electric locomotives is complicated by the variety of electrification systems in use. The solution is to use locomotives designed to operate on several different voltages or frequencies or both. In the United States, equipment of the former New Haven Railroad (now Penn Central) operating into Grand Central Terminal, New York City, is designed to run on two systems: 660-volt direct current and 11,000-volt, 25-hertz alternating current.

Diesel-electric locomotives. By the end of the 1960s, the diesel-electric locomotive (or simply the diesel) had almost completely superseded the steam locomotive as the standard railroad motive power in most parts of the world, except on the electrified lines. The change came first and most quickly in North America, where, during the 25 years 1935–60 (and especially 1951–60), railroads in the United States completely replaced their steam locomotives.

What caused the diesel to supersede the steam locomotive so rapidly was the pressure of competition from other modes of transport and the continuing rise in wage costs, which forced the railroads to improve their services and adopt every possible measure to increase operating efficiency. Compared with the steam locomotive, the diesel has a number of major advantages:

1. It can operate for long periods with no lost time for maintenance; thus, the diesel can operate through on a run of 2,000 miles (3,000 kilometres) or more and then, after brief servicing, start the return trip. Steam locomotives require extensive servicing after only a few hours' operation.

2. It uses less fuel energy than a steam locomotive, for its thermal efficiency is about four times as great.

3. It can accelerate a train more rapidly and operate at higher sustained speeds with less damage to the track.

In addition, the diesel is superior to the steam locomotive because of its smoother acceleration, greater cleanliness, standardized repair parts, and operating flexibility (a number of diesel units can be combined and run by one man under multiple-unit control). With diesels, too, there is no problem of supplying large quantities of boiler feed water; there is no loss of power capability in cold weather; and there is less standby cost, since the locomotive can be completely shut down when not in use, whereas a steam locomotive must have a fire under its boiler even when on standby at the roundhouse.

Drawbacks of the diesel

The diesel-electric locomotive is, essentially, an electric locomotive that carries its own power plant. Its use, therefore, brings to a railroad many of the advantages of electrification, but without the capital cost of the power distribution and feed-wire system. As compared with an electric locomotive, however, the diesel-electric has two important drawbacks: (1) because it is a more complex mechanism than the electric, it costs more to buy and maintain and (2) since its output is essentially limited to that of its diesel engine, it can develop less horsepower per locomotive unit. Since high horsepower is required for high-speed operation, the diesel is, therefore, less desirable than the electric for high-speed passenger services and very fast freight operations.

Diesel development. Experiments with diesel-engine locomotives and railcars began almost as soon as the diesel engine was patented by the German engineer Rudolf Diesel in 1892. Attempts at building practical locomotives and railcars (for branch-line passenger runs) continued through the 1920s. The first successful diesel switch engine went into service in 1925; "road" locomotives were

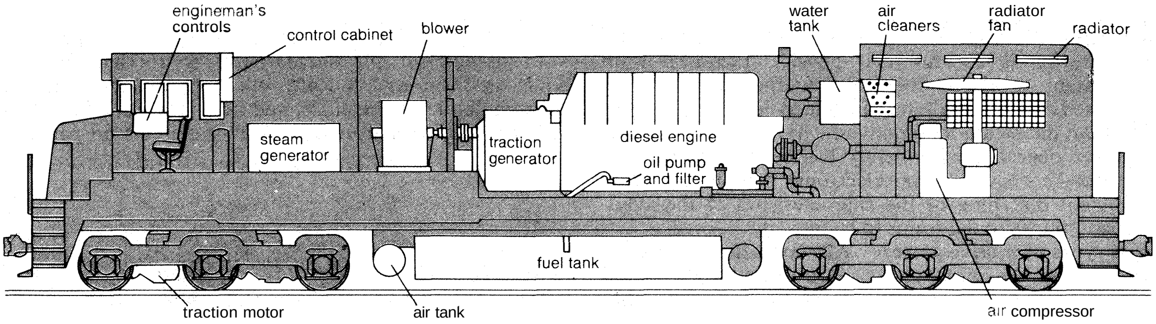

Figure 5: Cutaway of a modern diesel-electric locomotive.

delivered to the Canadian National and New York Central railroads in 1928. The first really striking results with diesel traction were obtained in Germany in 1932. There, a two-car, streamlined, diesel-electric train, with two 400-horsepower engines, began running between Berlin and Hamburg on a schedule that averaged 77 miles (124 kilometres) per hour. Diesel-electrics soon appeared elsewhere, notably in the United States.

The next step was to build a separate diesel-electric locomotive unit that could haul any train. In 1935 one such unit was delivered to the Baltimore and Ohio and two to the Santa Fe Railway Company. These were passenger units; the first road freight locomotive, a four-unit, 5,400-horsepower Electro-Motive Division, General Motors Corporation demonstrator, was not built until 1939.

By the end of World War II, the diesel locomotive had become a proven, standardized type of motive power, and it rapidly began to supersede the steam locomotive in North America. In the United States a fleet of 27,000 diesel locomotives proved fully capable of performing more transportation work than the 40,000 steam locomotives they replaced.

After World War II, the use of diesel traction greatly increased all over the world, though the pace of conversion was generally slower than in the United States. In Britain, steam-locomotive operation ended in 1968; by 1971 steam power had been largely superseded in most developed countries by diesels or by a combination of diesels and electrification.

Elements of the diesel locomotive. Although the diesel engine (Figure 5) has been vastly improved in power and performance, the basic principles remain the same: drawing air into the cylinder, compressing it so that its temperature is raised, and then injecting a small quantity of oil into the cylinder. The oil ignites without a spark because of the high temperature. The diesel engine may operate on the two-stroke or four-stroke cycle and may have cylinders arranged in line, in V-formation, horizontally opposed, or vertically opposed. Rated operating speeds vary from 350 to 2,000 revolutions per minute and rated output may be from ten to 3,600 horsepower. Railroads in the United States use engines in the 1,000-revolutions-per-minute range; in Europe and elsewhere, more compact but higher speed engines are common (see DIESEL ENGINE).

In the United States, early road units and most yard switching engines are equipped with diesels ranging from 600 to 1,500 horsepower. Road units commonly have engines ranging from 2,000 to 3,600 horsepower. Most builders use V-type engines, although in-line types are used on smaller locomotives (up to 1,200 horsepower).

Traction electrical system

With the nearly universal electric transmission, the diesel engine is directly connected to a main direct current generator that converts the mechanical energy produced by the engine into electrical energy. Through the appropriate control equipment, this is then used to drive the traction motors. The traction electrical system operates at a nominal 600-volts direct current, but the voltage varies greatly under operating conditions. The traction motors are of the series-wound type, each geared to the axle it drives (see ELECTRIC MOTOR). Most locomotives have a traction motor on each axle, although some passenger locomotives or units for light branch-line service may have six-wheel trucks (bogies) with the centre axle an idler.

In many recently built diesel-electric units, the engine drives an alternator (producing alternating current) instead of a direct-current generator. Static rectifiers convert the resulting alternating current to direct current for the traction motors. The reason for this design is that an alternator can produce more power and is less costly to maintain than an equivalent direct-current machine.

Other types of transmissions are also used in diesel locomotives. The hydraulic transmission has become quite popular in Germany. It employs a centrifugal pump or impeller driving a turbine in a chamber filled with oil or a similar fluid. The pump, driven by the diesel engine, converts the engine power to kinetic energy in the oil impinging on the turbine blades. The faster the blades move, the less the relative impinging speed of the oil and the faster the locomotive moves.

Mechanical transmission is the simplest type; it is mainly used in low-power locomotives. Basically it is a clutch and gearbox similar to those used in automobiles. A hydraulic coupling, in some cases, is used in place of a friction clutch.

Types of diesel motive power. There are four broad classes of railroad equipment that use diesel engines as prime movers:

1. The light railcar or rail bus (up to 180 horsepower) usually is four-wheeled and has mechanical transmission. It is often powered by a standard highway bus engine; it may be designed to haul a light trailer car.

2. The low-horsepower railcar (up to 1,000 horsepower) may have either mechanical or hydraulic transmission. Most railcars can haul additional trailer cars; some are designed mainly for this purpose, although they also have passenger and baggage accommodations.

3. Train sets (500 to 2,000 horsepower) are formations of more than one vehicle, usually designed to be worked from a single set of controls. The sets include one or more powered vehicles and usually have hydraulic or electric transmission.

4. Locomotives (ten to 6,600 horsepower) may have mechanical, hydraulic, or electric transmission, depending on power output and purpose. They are frequently designed to work in multiple-unit formations. Lower powered units (up to 600 horsepower) are usually designed for switching and light freight service. Medium-powered locomotives (600–1,200 horsepower) are normally used for freight, passenger, or heavy switching duties. Locomotives over 1,200 horsepower are required in main-line service in Europe and North America. In Europe locomotives in the 1,500- to 2,000-horsepower range are the most popular for express passenger work. In North America road freight units may range as high as 6,600 horsepower, and several units totalling as much as 15,000 horsepower may be used in multiple on heavy, fast trains.

Operating methods. Multiple-unit control and the operation of multiple diesel units in a train are almost universal in North America hut much less common elsewhere. A number of railroads in the United States and Canada use "slave" locomotives; these are spotted in the middle of a long freight train and controlled automatically by radio from the locomotive cab at the front end of the train. Radio-controlled slave locomotives permit easier and more efficient handling of a very long freight train, up to as many as 250 cars in regular operations.

The "slave" locomotive

To take advantage of the diesel's special characteristics, many railroads found it necessary to change both their operating techniques and their physical facilities. With diesels, many local and regional roundhouses and shops were closed, since diesels require much less frequent servicing than did steam locomotives. The scheduling of motive-power operations frequently has been centralized at the railroad's headquarters; electronic computers aid in the efficient matching of the characteristics of the available locomotives to the trains to be moved.

Other types of motive power. Although the electric locomotive and the diesel-electric are virtually the world standards, railroads continue to experiment with other types of motive power. In 1969 high-speed, passenger-train sets powered by aircraft-type turbines were placed in service between Montreal and Toronto and between New York and Boston. Though these "TurboTrains" are still in the development stage, the turbines themselves have performed well. These trains have a power unit at each end and use mechanical transmissions.

An experimental turbine-electric car built for the Long Island Rail Road in the U.S. proved sufficiently promising that additional units were planned. They are to be "dual powered" and operate from the third-rail electrification near New York City and under turbine power when outside the electrified zone.

The gas-turbine locomotive

In 1941 a gas-turbine locomotive was developed in Switzerland, and in the 1950s gas-turbine propulsion was tried in Britain and the United States. In France a two-car, gas-turbine-powered passenger train was tested at speeds up to 142 miles (228 kilometres) per hour and introduced in regular service on certain routes in 1970. British Rail was also studying gas turbines for passenger trains to operate at 150 miles (240 kilometres) per hour. The German Federal Railway used a gas turbine as a "booster" in one class of diesel-hydraulic locomotive.

Several attempts have been made to adapt the steam turbine to railroad traction. One of the first such experiments was a Swedish locomotive built in 1921. Other prototypes followed in Europe and the United States. They all functioned, but they made their appearance too late to compete against the diesel and electrification.

CARS

After the first crude beginnings, railroad-car design took divergent courses in North America and Europe, partly because of differing economic conditions and partly because of differing technological developments. Early cars on both continents were largely of two-axle design; but passenger-car builders soon began constructing cars with three and then four axles, the latter arranged in two four-wheel swivel trucks, or bogies. The trucks result in smoother riding qualities and also spread the weight of heavy vehicles over more axles.

Freight cars. European freight cars generally have two axles (four wheels), although there is a trend to two-truck, four-axle vehicles. Conventional British freight cars (goods wagons) have an average capacity of only about 13 tons, though many newer British cars are larger. On the Continent, the capacity of standard freight wagons varies from about 18 to 33 tons. The Soviet railroads use much larger, two-truck cars of up to 100 tons capacity. There is a growing trend toward higher capacity, four-axle cars in Britain and on the Continent, some capable of carrying loads up to 90 or 100 tons.

Standard American freight cars are all of two-truck design, usually with four axles though occasionally with six axles arranged in two three-axle trucks. American freight cars carry anywhere from 50 to 125 tons (45,000 to 113,000 kilograms); most new cars designed for merchandise freight have a capacity of 50 or 60 tons (45,000 to 54,000 kilograms), while new cars designed to carry bulk commodities, such as coal, ore, or chemicals, are mostly rated at 100 tons (90,000 kilograms).

There are three basic types of freight car: the open-top car, the boxcar, or house car, and the flatcar. Car builders and railroads have developed many varieties of these three basic types, plus many special types designed for efficiently carrying specific commodities.

Specialized freight cars

Among the special types of freight cars are double-deck cars for transporting automobiles (Figure 6), open cars with sliding roofs, pressurized tank cars for handling dry solids in bulk, hydraulically operating tipping cars for dumping bulk commodities, and boxcars with wide doors for easy loading and unloading of shipments on pallets.

By courtesy of the Museum of Railway Traffic. Tokyo

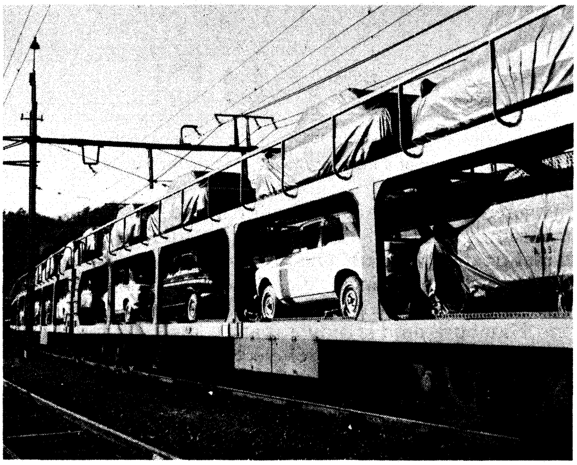

Figure 6: Japanese double-deck car, especially designed for carrying automobiles; it can load up to 12 compact cars.

Because of vertical-clearance limitations, highway trailers cannot be carried piggyback on conventionally designed flatcars on most European railroads. Ingenious special designs have overcome this problem. In France, for example, trailers are positioned on "kangaroo cars," which have pockets into which the trailer wheels are positioned, lowering the overall height. In West Germany highway trailers with their tractors are carried on certain fast intercity runs by special flatcars having small wheels to reduce the overall height.

On American railroads, in addition to the standard boxcar, the flatcar, and open-top "gondolas" and hopper cars (the latter equipped with doors for bottom unloading), the commonest specialized cars are tank cars, refrigerator cars, and livestock cars.

Automobile-parts cars

A growing trend is that of equipping cars with special internal fittings to accommodate specific products without the need for dunnage (*i.e.*, bracing or blocking of the load). Typical of these are the automobile-parts cars, which are often designed to carry certain automobile components, such as bodies, frames, or engines, of a single manufacturer. Among other special types of cars are those with "long travel" cushioned draft gear that absorb jolts and prevent damage to fragile commodities; extra-long flatcars with two- or three-level automobile racks; piggyback and container flatcars; 100- or 125-ton (90,000- or 113,000-kilogram) covered hopper cars for dry-bulk commodities; 100-ton gondolas for unit-train coal service; and 10,000-cubic-foot (280-cubic-metre) boxcars for light but bulky automobile parts.

The growing variety of specialized freight cars has complicated the problem of keeping each railroad shipper supplied with cars of the proper type. On the other hand, specialized cars usually run more miles and earn more revenue than standard cars. In the United States, so-called private car companies have played an increasing role. They acquire the cars and lease them to shippers or to the railroads themselves, a practice long followed with tank and refrigerator cars.

Passenger cars. The first passenger cars were simply road coaches with flanged wheels. Almost from the beginning, railroads in the United States began to use longer, eight-wheel cars riding on two four-wheel trucks, or bogies. In Britain and Europe, however, cars with more than six wheels were not introduced until the 1870s. Most cars of modern design, for both local and long-distance service, have an entrance at one or both ends of the car (some commuter-service cars also have additional centre doors), with centre aisle or a side corridor running the full length of the car. Flexible connections between cars give passengers access to any car of a moving train. In the United States modern passenger cars are usually 85 feet (25 metres) long and weigh from 60 to 80 tons (54,000 to 73,000 kilograms) or more. British and continental European cars are usually shorter and are always of lighter construction than cars in the United States. The standard British coach is 67 feet (20 metres) long; a modern, lightweight coach of the Swiss Federal Railways is 73 feet (22 metres) long. Recent continental designs, however, are up to 86½ feet (26 metres) in length and weigh 50 to 60 tons (45,000 to 54,000 kilograms). Narrow-gauge railroads impose weight and length restrictions. But even so, a 3.5-foot- (1.07-metre-) gauge coach of the South African Railways may be up to 63 feet five inches (19.3 metres) long and weigh up to about 48 tons (about 44,000 kilograms). Recent Australian cars follow American design and appearance.

Coaches. The interior arrangements and amenities on passenger cars vary widely. The most common type of car is the coach. In Europe the most favoured design has six- or eight-seat compartments, with the aisle, or corridor, along one side of the car. In the United States, two rows of double seats on either side of an aisle have long been standard; this design was appearing more frequently in Europe in the 1970s. Some American cars for local commuter runs have one row of triple seats and one row of double seats, with the centre aisle, permitting a 25 percent increase in the number of seated passengers. Several United States and Canadian railroads also use, for commuter runs, cars having an upper "gallery" in addition to the standard seating. These two-level coaches may seat up to 156 passengers. Luxury coaches in many countries have a small number of individual seats.

Sleeping cars. A crude sleeping car was operated in the United States as early as 1837; the first Pullman sleeper, named after its inventor and leased by the railroads, went into service in 1859. Sleeping cars were introduced in Europe and elsewhere beginning in the 1870s. Typical European sleeping cars have compartments with one, two, or more transverse beds (the trend is to more cars with single-berth compartments to meet the needs of business travellers). A typical modern American sleeping car has six bedrooms, each with two beds, and 12 "roomettes," with a single bed, giving a total capacity of 24 persons. Because the low capacity makes high fares necessary and so discourages patronage, the so-called slumbercoach was invented, with eight small double rooms and 24 single rooms, or a total capacity of 40.

"Feature" cars. Dining, or restaurant, cars became a feature of long-distance passenger trains almost from the beginning. A typical modern dining car has a kitchen at one end and tables seating 32 to 40 persons at the other. Such a car requires a large staff of waiters and kitchen personnel; thus, in recent years there has been a trend to "coffee-shop," or "lunch-counter," cars that provide limited, quick service and to food-service cars in which the passenger obtains his own food from vending machines.

The “coffee-shop" car

Another type of car often seen on long-haul trains is the lounge, or observation, car. It has a bar for beverage service and comfortable chairs for relaxation or reading. Dome cars, developed in the United States after World War II and popular on railroads having scenic routes, are also found in Canada and Europe. In a dome car passengers ride under a raised, glassed-in roof section that affords a wide-range view of the countryside.

Special types of cars. Besides the conventional freight and passenger cars already described, the world's railroads operate many special types of rolling equipment. Most numerous are the powered passenger cars and train sets mentioned previously. These may be operated by electricity on electrified railroads or have diesel engines or turbine engines mounted under the car floors. Such cars are usually designed to operate in multiple under the control of one driver and are used extensively for commuter service. The high-speed Metroliner trains (see below) operating on the electrified line between New York and Washington are of this type. Single or multiple diesel-powered passenger cars are used on light traffic lines.

Highly specialized, too, are a small number of freight cars designed to carry unusually heavy or oversized loads, such as large electrical transformers. One such car (Figure 7) carries a transformer suspended between two sets of high-capacity trucks. It has a total capacity of 375 tons (340,000 kilograms), carried on 28 wheels.

UPI Compix

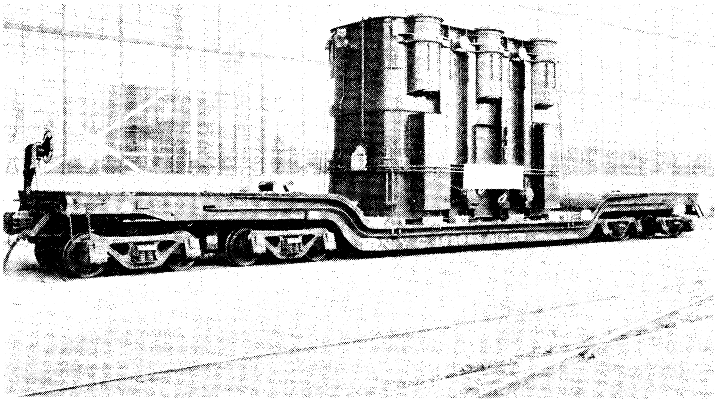

Figure 7: Specialized flatcar with low central section designed to carry electric power transformers while maintaining clearance in tunnels and under low bridges. The car is also unusual in its arrangement of eight axles.

Among the many types of railroad "service vehicles" are the so-called office, or business, cars used by company officials while on inspection tours of the line, track-measuring cars and rail "detector" cars that automatically record the condition of the track surface alignment or locate internal flaws in the rails, and various types of instructional, or personnel-training, cars. "Camp cars" are often used to house the personnel of maintenance forces engaged in major projects, such as renewing rail or constructing a new line.

Rolling-stock standardization. Much of the commercial effectiveness of the railroad has derived from the standardization of basic rolling-stock components. Each railroad builds cars suited to its own needs; but cars can be interchanged freely among railroads (assuming that they use a common track gauge) only if such elements as wheels, wheel bearings, couplers, and brakes are standardized. The knuckle type of automatic coupler was adopted in North America beginning in 1882; a similar coupler is used in several other countries, notably Australia, Japan, and the Soviet Union. Screw-and-buffer couplers are used in western Europe, but a knuckle coupler compatible with that used in the Soviet Union is under development.

There are two general types of continuous braking systems: the vacuum brake and the compressed-air brake. Of the two, the more popular is the air brake, patented in 1869 by George Westinghouse of the United States, where it was made compulsory equipment in 1893. The vacuum brake is used principally in Britain, where continuous brakes have been compulsory on passenger cars since 1889. With either system, application of the brakes on the locomotives applies the brakes throughout the entire train; and should the train become uncoupled, the brakes are automatically applied.

The Westinghouse air brake

The brake itself takes the form of a single or double shoe that presses against the wheel tread. The disk brake has also been widely applied on high-speed passenger trains and some freight cars as well.

RAILROAD TRACK AND ROADWAY

Location and construction. Ideally, a railroad should be built in a straight line, over level ground, between large centres of trade and travel. In practice, this ideal is rarely approached. The location engineer, faced with the terrain to be traversed, must balance the cost of construction against annual maintenance and operating costs, as well as against the probable traffic volume and profit.

Thus, in areas of dense population and heavy industrial activities, the railroads were generally built for heavy duty, with minimum grades and curvature, heavy bridges, and perhaps multiple tracks. Examples include most of the main-line railroads of Britain and the European continent. In North and South America, and elsewhere, the country was sparsely settled, and the railroads had to be built at minimal costs. Thus, the lines were of lighter construction, with sharper grades and curves. As traffic grew, main routes were improved to increase their capacity and to reduce operating costs.

The gauge, or distance between the inside faces of the running rails, is one of the main cost determinants. Generally, the narrower the gauge, the less costly is the line to construct and equip. This is why many of the railroads in underdeveloped, sparsely settled countries have been built to narrow gauges. On a narrow-gauge line, curvature can be more severe, less space is required, construction can be lighter, and rolling stock is less costly. Disadvantages are the limitation of speed because of reduced lateral stability and limitations on the size of locomotives and cars. About 60 percent of the world's railroad mileage is built to standard gauge, four feet 8½ inches (1.435 metres).

Eliminating adverse grades

The advent of modem high-capacity earth-moving machinery, developed mainly for highway construction, has made it economically feasible for many railroads to eliminate former adverse grades and curves through line changes. Graders, bulldozers, and similar equipment make it possible to dig deeper cuts through hillsides and to make higher fills where necessary to smooth out the profile of the track. Modem equipment has also helped improve railroad roadbeds in other ways. A number of railroads carried out ditching programs in which the drainage ditches along the roadbed were deepened. Where the roadbed is unstable, injecting concrete grout into the subgrade under pressure is a widely used technique. In planning roadbed improvements, as well as in new construction, railroads have drawn on modem soil-engineering techniques.

The first step in building a new railroad line, after the route has been surveyed and cleared of brush and trees, is to grade the right-of-way, much as is done when building a highway. Next, the crossties, or sleepers, are distributed and the rails laid and fastened to the ties. Then, ballast (usually crushed rock, slag, or volcanic ash) is applied. Finally, the track is aligned in both the horizontal and vertical planes, and the ballast is tamped, or compacted, around and under the ties.

In Canada, where much new railroad mileage was built after World War II, track-laying machines were often used (Figure 8). The machine is mounted on railcars. It feeds ties and rails ahead of the working crew, moving forward over the new track as soon as it is spiked down.

The inventors of the modern rail

Hail. The modern railroad rail has a flat bottom, and its cross section is much like an inverted T. An English engineer, Charles Vignoles, is credited with the invention of this design of rail in the 1830s. A similar design was also developed by Robert L. Stevens, president of the Camden and Amboy Railroad in the United States.

Present-day rail is, in appearance, very similar to the early designs of Vignoles and Stevens. Acutally, however, it is a highly refined product in terms of both engineering and metallurgy. Much study and research have produced designs that minimize internal stresses under the weight of traffic and thus prolong rail life. Sometimes the rail surface is hardened to reduce the wear of the rail under extremely heavy cars or on sharp curves. After they have been rolled at the steel mills, rails are allowed to cool slowly in special boxes. This controlled cooling minimizes internal shatter cracks, which at one time were a major cause of broken rails in track.

In Europe a standard rail length of 30 metres (98 feet five inches) is common. The weight of rail, for main-line use, is from about 45 kilograms per metre (about 90 pounds per yard) to 75 kilograms per metre (150 pounds per yard). British Railways uses a flat-bottomed rail weighing 55 kilograms per metre (110 pounds per yard).

Railroads in the United States and Canada have used T-rails of hundreds of different cross sections. Many of these different sections are still in use, but there is a strong trend to standardizing on a few sections. In the 1970s most new rail in North America weighed 119 or 136 pounds per yard. The standard American rail section has a length of 39 feet (about 12 metres).

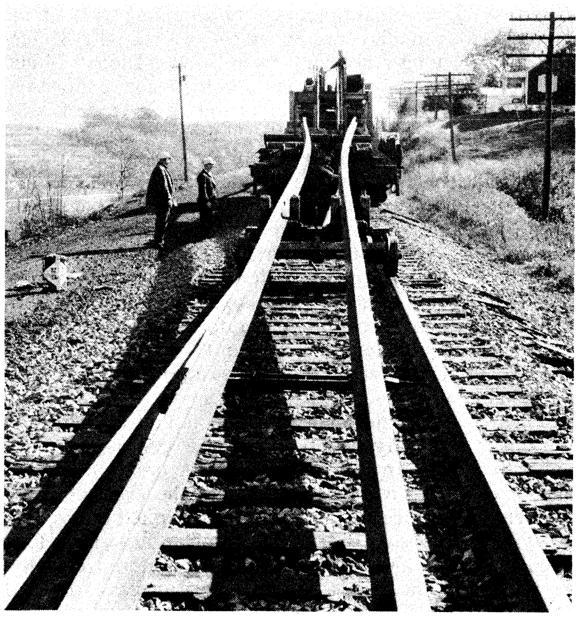

Figure 8: Moving work train laying quarter-mile lengths of continuous welded rail, which is positioned two strings at a time.

One of the most important developments is the welding of standard rails into long lengths. This continuous welded rail results in a smoother track that requires less maintenance. The rail is usually welded into lengths of about one-quarter mile (400 metres). Once laid in track, these quarter-mile lengths are often welded together in turn to form rails several miles long without a break.

Welded rail was tried for the first time in 1933 in the United States. It was not until the decade of the 1950s, however, that railroads turned to welded rail in earnest. By 1971 virtually all new rail, and much old rail taken up and relaid in new locations, was being laid in welded lengths. Welded rail was standard practice, or extensively used, in the United States, Japan, Canada, Germany, France, and Britain.

Controlling the temperature expansion of long welded rails proved not so difficult as first thought. It was found that the problem could be minimized by extensive anchorage of the rails to the ties to prevent them from moving when the temperature changes by the use of a heavy ballast section and by laying the rails when the ambient temperature is close to the mean temperature prevailing in the particular locality.

Fastening rails to crossties

Rail fittings. Whether in standard or long lengths, rails are joined to each other and kept in alignment by fishplates or joint bars. The offset-head spike is the most used and least expensive way of fastening the rails to wooden crossties, but several different types of screw spikes and clips are also used extensively on heavy-traffic lines in many countries. The rails may be attached directly to wooden crossties, but on heavy-traffic lines it is common to seat the rail in a tie plate that distributes the load over a wider area of the tie. A screw or clip fitting must be used to attach rails to concrete ties. A pad of rubber or other resilient material is always used between the rail and a concrete tie.

Crossties (sleepers). Timber has been used for railroad ties almost from the beginning, and it is still the most common material for this purpose. The modern wood crosstie is treated with preservative chemical to improve its life; the average life of crossties on main-line railroads is about 35 years. The cost of wood ties has risen steadily, creating interest in ties of other materials.

Steel ties have long been used in certain European, African, and Asian countries. Concrete ties, usually reinforced with steel rods or wires, have been gaining in popularity, as have ties consisting of concrete blocks joined by steel spacing bars. A combination of concrete ties and long welded rails produces an exceptionally solid and smooth-riding form of track. Concrete ties are extensively used in Britain, Europe, and Japan.

Tıack maintenance. Modern machinery enables a small group of men to maintain a relatively long stretch of railroad track. Machines are available to do all the necessary track maintenance tasks: removing and inserting ties, tamping the ballast, spiking rail, tightening bolts, and aligning the track. Mechanized equipment also can renew rail, either in conventional bolted lengths or with long welded lengths; cranes are used to remove the old rail and lay the new.

Prefabricated track sections

Complete sections of track—rails and crossties—may be prefabricated and laid in the track by mechanical means. Rail-grinding machines run over the track to even out irregularities in the rail surface. Track-measurement cars, under their own power or coupled into regular trains, can record all aspects of track alignment and riding quality on moving charts, so that maintenance forces can pinpoint the specific locations needing corrective work. Detector cars move over the main-line tracks at intervals with electronic-inspection apparatus to locate any internal flaws in the rails.

The mechanization of track maintenance after World War II has constituted a technologic revolution comparable to the development of the diesel locomotive and electrification. In Europe in particular, highly sophisticated maintenance machines have come into use.

Auxiliary plant. Railroad fixed plant consists of much more than the track. The New Sanyo Line, under construction in Japan in the 1970s, runs through tunnels for nearly half its total length. Railroad civil-engineering forces are concerned with constructing and maintaining thousands of buildings, ranging from switch tenders' shanties to huge passenger terminals.

Bridges. The designer of a railroad bridge must allow for forces that result from the concentrated impact that occurs as a train moves onto the bridge; the pounding of wheels, the sidesway of the train, and the drag or push effect as a train is braked or started on a bridge. These factors mean that a railroad bridge must be of heavier construction than a highway bridge of equal length.

As freight-train loads become heavier and train speeds higher, bridges need to be further strengthened. Another major objective in modem railroad-bridge construction is the need to minimize maintenance costs. The use of weathering steel, which needs no painting, all-welded construction, and permanent walkways for maintenance personnel contribute to this end. In the advanced countries there has been a widespread trend toward replacing timber trestles with concrete-slab structures or with concrete or steel-pipe culverts. The railroads also have sought ways to mechanize the maintenance of their bridges (see also BRIDGES, CONSTRUCTION AND HISTORY OF).

Buildings. Railroad buildings in the 20th century have become fewer and more functional. With paved highways running almost everywhere in the developed countries, it has become more economical to concentrate both freight and passenger operations at fewer but larger, strategically located stations. Only a few really modern passenger stations have been built. Notable among them are the highly efficient and functional stations on the New Tōkaidō Line in Japan, the new Euston station in London, and several of the new and rebuilt stations on the European continent, such as the main stations at Rome and Milan.

Diesel maintenance shops

Diesel and electric locomotives require few maintenance shops as compared with steam locomotives. Diesel shops are of three main types: small fueling, sanding, and light-maintenance centres at points where runs end or locomotives are changed; intermediate-maintenance shops, usually serving a region, that perform certain routine inspection and maintenance tasks; and heavy-repair shops, where locomotives undergo extensive repairing or rebuilding. Usually a single railroad requires only one of the latter type of shop.

Car shops, too, have been reduced in number and made more efficient through the use of process-line techniques. Terminal points and major classification yards usually have a shop for light repairs and maintenance of cars; a railroad also usually has one or more heavy-repair shops, where cars are completely overhauled or where new cars are manufactured.

It is usually more efficient to construct new shop buildings rather than convert old ones to handle modem types of rolling stock. Often, prefabricated buildings provide an economical solution to this problem. An important feature of new locomotive shops in particular is provision for collection and disposal of waste oil and other potentially polluting products of the shop or terminal operation.

Tunnels. Although very expensive, tunnelling provides the most economical means for railroads to traverse mountainous terrain or to gain access to the heart of a crowded city. Railroad tunnels, however, confront the construction engineer with some unique problems, particularly in the ventilation of tunnels on lines that are not electrified.

Some examples of famous tunnels and methods of construction are described in the article TUNNELLING AND UNDERGROUND EXCAVATION.

RAILROAD OPERATIONS AND CONTROL

Because a railroad's factory—its plant and train operations—may be spread out over thousands of miles and hundreds of communities, it has operating and service problems in some respects more complex than those of a major manufacturing installation. It is not surprising, therefore, that railroads have been among the pioneers in the use of improved methods of communication and control, from the telegraph to such present-day developments as the electronic computer and automation techniques.

Communications. Railroads were among the first to adopt the electric telegraph and the telephone, both for dispatching trains and for handling other business messages. Today, the railroads are among the larger operators of electronic communications systems.

Radio. Railroads began experimenting with radio at a very early date, but it became practical to use train radio on a large scale only after World War II, when compact and reliable very-high-frequency two-way equipment was developed. In train operations radio permits communication between the front and rear of a long train, between two trains, and between trains and the central dispatcher.

In terminals two-way radio greatly speeds yard-switching work. Through its use, widely separated elements of mechanized track-maintenance gangs can maintain contact with each other and with oncoming trains. Supervisory personnel often use radio in automobiles to maintain contact with the operations under their control.

Microwave communications

As the demand for more railroad communication lines has grown, more and more companies have begun to use broad-band radio beams (microwave) to supplement or replace the traditional lineside telegraph wires. As early as 1959, the Pacific Great Eastern Railway in western Canada began to use microwave radio for all communications, doing away almost entirely with line wires. Other railroads all over the world were turning to microwave in the 1970s.

Computers. A major reason for the growing use of microwave was the tremendously increased demand for circuits that developed from the railroads' widespread use of electronic computers.

Earlier, railroads had been among the leaders in adopting punched-card and other advanced techniques of data processing. In the 1970s there was a strong trend toward "total information" systems built around the computer. In such a system, each field reporting point, usually a freight-yard office or station, is equipped with a computer input device. Through this device, full information about every car movement (or other action) taking place at that point can be placed directly into the central computer, usually located at company headquarters. From data received from all the field reporting points on the railroad, the computer can be programmed to produce a variety of outputs. These may include train-consist reports (listing cars) for the terminal next ahead of a train, car-location reports for the railroad's customer-service offices, car-movement information for the car-records department, revenue information for the accounting department, plus traffic-flow data and commodity statistics useful in market research and data on the freightcar needs at each location to aid in distributing empty cars for loading.

Other pertinent data also may be integrated into the system so that the railroad's managers have a complete, up-to-the-minute picture of almost every phase of its operations. Such complete information and control systems promise to be a powerful tool for optimizing railroad operations and producing better service.

Signalling. Railroad signals are a form of communication designed to inform the train crew, particularly the engine crew, of track conditions ahead and to tell it how to operate the train.

The time-interval signal system

Methods of controlling train operations evolved over many years of trial and error. A common method in the early years was to run trains on a time-interval system; *i.e.*, a train was required to leave a station a certain number of minutes behind an earlier train moving in the same direction. It was common on single-track lines to program all operations in accordance with a timetable, which set up all the places trains were to meet and which could not be varied.

The development of distance-interval systems was a great improvement. In these so-called block systems, a train is prevented from entering a specific section of track until the train already in that section has left it.

The earliest form of railroad signal was simply a flag by day or a lamp at night. The first movable signal was a revolving board, introduced in the 1830s, followed in 1841 by the semaphore signal. One early signal consisted of a large ball that was hoisted to the top of a pole to inform the engineman that he might proceed (hence, the origin of the term highball).

The semaphore signal was nearly universal until the early years of the 20th century, when it began to be superseded, first by the colour-light signal and then by the searchlight type. The colour-light signal uses a separate lens and light bulb for each signal aspect, usually green, yellow, and red. The searchlight signal uses only a single, powerful lens and bulb; the different colours are displayed through the lens by means of roundels, or colour filters, that are rotated in front of the lamp. Two other types of signals are also used to a limited extent: the position light, in which rows of yellow lights duplicate the positions of semaphore arms, and the colour-position light signal, which uses coloured lights arranged in rows.

Most lines in Europe use a manual block system in which operations are controlled from wayside cabins or towers in conjunction with the wayside signals. Each tower controls a section; a train is not permitted to enter a section until the train ahead has left the section. Electric interlocking improves this system by making it impossible to give a "line clear" signal indication if the section is already occupied by a train.

The automatic block system

The basis of much of today's railroad signalling is the automatic block system, introduced in 1872 and one of the first examples of automation. It uses track circuits that are short-circuited by the wheels and axles of a train, putting the signals to the rear of the train and to the front as well as on single track at the danger aspect. A track circuit is made by the two rails of a section of track, insulated at their ends. Electric current, fed into the section at one end, flows through a relay at the opposite end. The wheels of the train will then short-circuit the current supply and de-energize the relay.

Signalling on African, Asian, and Australian systems usually follows European practice in areas of heavy traffic. On light traffic lines, control is often via the telegraph or telephone.

Operation on the basis of a timetable alone, which was common on early lines in the United States, had the disadvantage that if one train were delayed, others would also be delayed, since it was impossible to change the meeting points. By using the telegraph, and later the telephone, the dispatcher could issue orders' to keep trains moving in unusual circumstances or to operate extra trains as required. This "timetable–train order" system is still used on many lines in the United States and Canada. It is often supplemented with automatic block signals to provide an additional safety factor.

The first attempts at interlocking switches and signals were made in France in 1855 and in Britain in 1856. Interlocking at crossings and junctions prevents the signalman from displaying a clear signal for one route when he has already given clearance to a train on a conflicting route. Route-setting or route-interlocking systems are modern extensions of this principle. With them a towerman or dispatcher can set up a complete route through a complicated track area by simply pushing buttons on a control panel. This system allows a large area to be controlled from one point.

A logical development of the route-interlocking principle is centralized traffic control, a system in which trains are controlled entirely from a central point through remote operation of switches and signals (Figure 9). The operator sees the track layout in miniature on his control panel and directs the movement of trains over distances from a few miles to many hundreds of miles. Lights on the panel show the location and progress of all trains at all times.

By courtesy of the British Railways Board

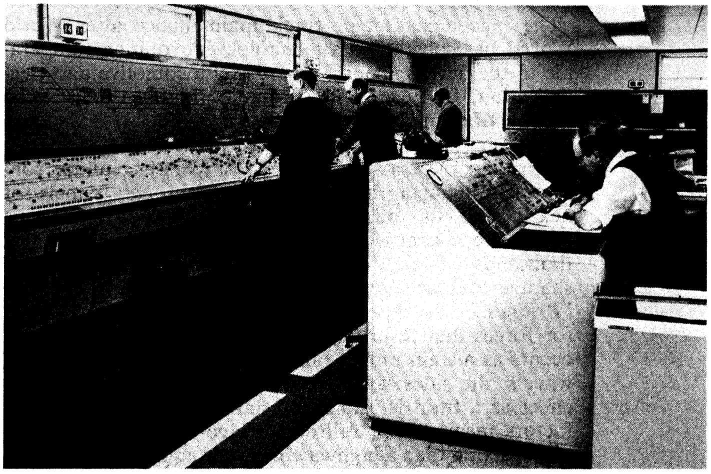

Figure 9: Computerized train control room at Bristol, England. Two panel boxes handle colour light signalling for 300 trains passing daily over the 254 track miles covered by this station.

In centralized traffic control, track circuiting is essential to ensure that the system always knows where each train is. Switches and signals are operated by coded electrical pulses that reduce the wiring required. Over long distances, centralized traffic control substantially increases track capacity by making more effective use of the trackage. Since it eliminates any need for written orders or manual operation of block signals, it permits closing telegraph or signal stations, another major economy.

The trend toward automation. A recent refinement in traffic control is to arrange the system for fully automatic operation. The machine will then set switches and clear signals for each train automatically; the dispatcher need exercise control only in unusual circumstances. This enables one dispatcher to control a still longer section of railroad. Completely automatic signalling activated by electronic program machines is used on some rapid-transit rail lines.

Automatic central traffic control

Automatic train control provides the locomotive engineman with audible (and sometimes visual) information on track conditions. Should he ignore a restrictive signal indication, the brakes are applied automatically to stop the train. A refinement of this system incorporates automatic control of train speed. A miniature signal in the cab repeats the aspects of the wayside signals (or it may take the place of wayside signals). Should train speed exceed that called for by the aspect being displayed, the brakes are applied and the speed reduced to the permissible level.

Only a slight further extension of this technique is needed to permit fully automatic operation of the train. By the early 1970s, a number of mining and industrial railroads were operated with crewless trains under full automation or remote control. On the high-speed New Tōkaidō Line in Japan, all trains operate under computerized automatic control throughout the entire 320-mile (510-kilometre) length of the line. The engineman, however, starts the trains, stops the train at station stops, and opens and closes the train doors. A similar system is used on the London Transport Victoria line, the Patco transit line in Camden, New Jersey, and the Bay Area Rapid Transit system in San Francisco.
