Most of the pitcher plants are herbaceous; stemless (acaulescent) perennials consisting of a basal cluster (rosette) of leaves arising from a short, creeping rhizome. The hollow, tubular leaves curve outward and upward with their basal portion resting on the ground (e.g., *Sarracenia purpurea*) or are erect (e.g., *S. flava*), with sheathing bases; the leaves widen gradually into pitchers. A prominent wing runs along the outer surface of the leaf from bottom to top on the side facing the centre (adaxial, or ventral, side) of the plant. At the top the wing forms a lip. On the back (dorsal) side a bladelike expansion forms a lid or hood over the mouth of the pitcher, in some cases effectively closing the opening to light and rain. The leaves of *S. purpurea* and of all the species of *Heliamphora* are open at the mouth and collect rainwater. The strikingly coloured leaves vary from yellow green to dark green suffused with red to deep red, the intensity of red depending in part on the amount of sunlight in the habitat. One species is white with red and green reticulations (netlike patterns); other species have translucent-spotted leaves.

The height of the plant usually is determined by the height of the leaves, which in most species average one to two, but may reach four feet (120 centimetres). By contrast with the North American pitcher plants, three of the six described species of *Heliamphora* are stemmed (caulescent), branched, almost shrubby perennials, which attain a height of four feet. Their pitchers vary from eight to 20 inches (20 to 50 centimetres) in length.

The inflorescence (flower cluster) of *Sarracenia* and *Darlingtonia* consists of a tall, leafless stalk (scape) with a solitary, nodding flower. The flowering scapes generally average about a foot in height but may vary from a few inches to four feet. Typically, the flowering scape more or less equals the length of the longest leaves, although in *Darlingtonia* and *Heliamphora* species the scape may be as much as twice the length of the leaves (to four feet in *Darlingtonia*). In *Heliamphora*, the inflorescence is several-flowered and one to two feet long; the flowers lack differentiated petals, the sepals being white to pink or rose purple and showy. The large flower (several inches across) of the North American species has five yellow, greenish-yellow, or pink to wine-coloured petals and five firm, green sepals, which persist long after the petals have fallen. The petals may be short or long and showy, as in *S. flava*, in which they hang down like a hound's ears. The *sarracenia*s have a unique, umbrella-like style, which has tiny stigmas on its five points.

EVOLUTION—AND CLASSIFICATION

Evolution. No fossils have been reported for the pitcher-plant order. Phylogenetic relationships must be inferred from the morphological and biological relationships of the modern species, and such considerations, not surprisingly, have led to diverse views. Most authorities now agree that the carnivorous flowering plants form a more heterogeneous group than was traditionally thought and that, therefore, carnivory must have arisen independently in several more or less unrelated evolutionary lines. No two authorities agree, however, on the number or relationships of the lines, some assigning these plants to as many as six different orders. Furthermore, different authorities place the same carnivorous species in different orders.

On the basis of floral morphology, phylogenists at present have quite different views about the origin of the order Sarraceniales. Some regard the Sarraceniales as a very specialized order that has retained some primitive features that place it near the order Ranunculales (Ran-ales), from which it and the order Papaverales are derived. Others place the pitcher-plant order next to the order Violales and derive both orders from the Theales

(Guttiferales). Still others propose different origins and alliances within the framework of their own phylogenetic systems.

Classification. Distinguishing taxonomic features. The Sarraceniales is distinguished from other orders chiefly by its distinctive, highly modified leaves and to a lesser extent by features of the inflorescence and flowers. The more important distinguishing features used to separate the three genera within the single family are presence or absence of above-ground stem, form of leaves, number and arrangement of flowers, presence or absence of petals, coloration of sepals, number of carpels (simple ovaries or sections of a compound ovary), and form of style.

Annotated classification. The order Sarraceniales, as presented here, is defined in the strictest sense and includes only the family Sarraceniaceae.

ORDER SARRACENIALES

Perennial, rhizomatous, acaulescent (stemless) or caulescent-branched, insectivorous herbs, with usually basal rosettes of tubular or pitcher-like, often winged leaves specialized for luring and trapping insects and other tiny animals. Flowers solitary, on a leafless stalk or in loose, stalked, axillary racemes (clusters arising from the angle between stem and leaf), radially symmetrical, bisexual. Perianth (sepals and petals) with 1 or 2 series; the sepals commonly 5, overlapping, often coloured and showy, persistent; the petals commonly 5 or absent, free, yellow to purple. Stamens (pollen-bearing organs) many, free; the anthers (male reproductive organs) 2-celled, opening before stigmas are receptive. Pistil (female parts—ovary, style, and stigma) 1, with 3 or 5 fused carpels, the ovary superior (positioned above the attachment point of sepals, petals, and stamens), 3- or 5-loculed (chambered). Ovules numerous. Style simple, cylindrical, with simple, slightly lobed stigma or apex expanded into large umbrella-like structure with as many lobes as carpels, each with a minute stigma beneath. Fruit a capsule, with as many locules as carpels. Seeds minute, numerous.

Family Sarraceniaceae (pitcher-plant family)

The only family, it has the characteristics of the order. Distribution disjunct in the New World in bogs, seepages, swamps, and wet savannas. Three genera (*Darlingtonia*, *Heliamphora*, and *Sarracenia*) and 13 to 16 species.

Critical appraisal. Unquestionably, the three genera named above belong in the same family. So similar is the California pitcher plant to some of the eastern species that *Darlingtonia* probably could not be defended as a separate genus if it were not for its great geographic isolation from the eastern species. The chief taxonomic problems of the family arise at two levels. First, there is no agreement about the relationship of the Sarraceniaceae to the families Droseraceae and Nepenthaceae of the order Nepenthales. Some authorities continue to hold to the older view that the three distinct families form a natural order. This view rests on the theory that the leaves of the three families represent modifications from a common type. Authors have gone so far as to propose that the families Nepenthaceae and the Sarraceniaceae should be merged into a single family because *Heliamphora* seems to bridge the gap. Other authorities place greater weight on floral and pollen morphology, both of which suggest that the Sarraceniaceae stands apart from the other two families. Increasingly, evidence indicates that these families belong in two or three perhaps widely separated orders.

Second, within the family Sarraceniaceae there has never been agreement about the number of species in the genus *Sarracenia*, even though the group has been known for 400 years. Furthermore, there is reason to suspect that a similar problem of delineating species exists in *Heliamphora*, although knowledge of this genus is scant. The most useful taxonomic features in *Sarracenia* pertain to the form and habit of the pitched leaves. The overall shape of the pitcher is generally constant and represents the single most useful feature, but colour and marking are important in some cases. Leaf size is quite variable within species and of itself is not useful. In combination, other characteristics (e.g., colour and shape of petals, odour, curvature of sepals, and presence and number of sword-like leaves) may be diagnostic. As with family relationships, specific relationships cannot be known any more definitively than they are without new lines of evidence.

Sartre, Jean-Paul

Jean-Paul Sartre, a French philosopher, playwright, and novelist and an internationally known figure in contemporary intellectual life, is the leading French exponent of Existentialism, a philosophical attitude that emphasizes the freedom and importance of individual human beings. With Sartre, the power of the subject—the self-conscious individual—comes to the fore, an emphasis that has influenced recent generations of writers all over the world; for he, more than any other philosopher, has drawn attention to individual freedom and creativity. In the eyes of some critics it may appear that the foremost Existentialist has been less cogent in his philosophy of the group and of the intersubjective themes stressed in his later work.

Gisèle Freund

Sartre, photograph by Gisèle Freund, 1968.

Early life and writings. Sartre was born in Paris on June 21, 1905. Having lost his father at an early age, Sartre grew up in the home of his maternal grandfather, Carl Schweitzer, uncle of the medical missionary Albert Schweitzer and himself professor of German at the Sorbonne. The boy, who wandered in the Luxembourg Gardens of Paris in search of playmates, was small in stature and cross-eyed. His brilliant autobiography, *Les Mots*, (Eng. trans., *The Words*), narrates the adventures of the mother and child in the park as they went from group to

group—in the vain hope of being accepted—then finally retreated to the sixth floor of their apartment "on the heights where (the) dreams dwell." "The words" saved the child, and his interminable pages of writing were the escape from a world that had rejected him but that he would proceed to rebuild in his own fancy.

Sartre went to the Lycée Henri IV in Paris and, later on, after the remarriage of his mother, to the lycée in La Rochelle. From there he went to the prestigious École Normale Supérieure, from which he graduated in 1929. Sartre resisted what he called "bourgeois marriage," but while still a student he formed with Simone de Beauvoir a union that has remained a settled partnership in life. Simone de Beauvoir's memoirs, *Mémoires d'une jeune fille rangée* (1958; Eng. trans., *Memoirs of a Dutiful Daughter*, 1959) and *La Force de l'âge* (1960; Eng. trans., *The Prime of Life*, 1962), provide an intimate account of Sartre's life from student years until his middle 50s. It was also at the École Normale Supérieure and at the Sorbonne that he met several persons who were destined to be writers of great fame; among these were Raymond Aron, Maurice Merleau-Ponty, Simone Weil, Emmanuel Mounier, Jean Hippolyte, and Claude Lévi-Strauss. From 1931 until 1945 Sartre taught in the lycées of Le Havre, Laon, and, finally, Paris. Twice this career was interrupted, once by a year of study in Berlin and the second time when Sartre was drafted in 1939 to serve in World War II. He was made prisoner in 1940 and released a year later.

During his years of teaching in Le Havre, Sartre published *La Nausée* (1938; Eng. trans., *Nausea*), his first claim to fame. This novel, written in the form of a diary, narrates the feeling of revulsion that a certain Roquentin undergoes when confronted with the world of matter—not merely the world of other people but the very awareness of his own body. According to some critics, *La Nausée* must be viewed as a pathological case, a form of neurotic escape. Most probably it must be appreciated also as a most original, fiercely individualistic, antisocial piece of work, containing in its pages many of the philosophical themes that Sartre later developed.

Sartre took over the phenomenological method, which proposes careful, unprejudiced description rather than deduction, from the German philosopher Edmund Husserl and used it with great skill in three successive publications: *L'Imagination* (1936; Eng. trans., *Imagination: A Psychological Critique*), *Esquisse d'une théorie des émotions* (1939; Eng. trans., *Sketch for a Theory of the Emotions*), and *L'Imaginaire: Psychologie phénoménologique de l'imagination* (1940; Eng. trans., *The Psychology of Imagination*). But it was above all in *L'Être et le néant* (1943; Eng. trans., *Being and Nothingness*) that Sartre revealed himself as a master of outstanding talent. Sartre places human consciousness, or no-thingness (*ne'ant*), in opposition to being, or thingness (*être*). Consciousness is not-matter and by the same token escapes all determinism. The message, with all the implications it contains, is a hopeful one; yet the incessant reminder that human endeavour is and remains useless makes the book tragic as well.

Post-World War II work. Having written his defense of individual freedom and human dignity, Sartre turned his attention to the concept of social responsibility. For many years he had shown great concern for the poor and the disinherited of all kinds. While a teacher, he had refused to wear a tie, as if he could shed his social class with his tie and thus come closer to the worker. Freedom itself, which at times in his previous writings appeared to be a gratuitous activity that needed no particular aim or purpose to be of value, became a tool for human struggle in his brochure *L'Existentialisme est un humanisme* (1946; Eng. trans., *Existentialism and Humanism*). Freedom now implied social responsibility. In his novels and plays Sartre began to bring his ethical message to the world at large. He started a four-volume novel in 1945 under the title *Les Chemins de la liberté*, of which three were eventually written: *L'Âge de raison* (1945; Eng. trans., *The Age of Reason*), *Le Sursis* (1945; Eng. trans., *The Reprieve*, 1947), and *La Mort dans l'âme*

Education

Influence
of
HusserlNovels
and
plays

(1949; Eng. trans., *Iron in the Soul*; U.S. title, *Troubled Sleep*). After the publication of the third volume, Sartre changed his mind concerning the usefulness of the novel as a medium of communication and turned back to plays.

What a writer must attempt, said Sartre, is to show people as they are. Nowhere are people more human than when they are in action, and this is exactly what drama portrays. Sartre had already written in this medium during the war, and one play now followed another: *Les Mouches* (produced 1943; Eng. trans., *The Flies*), *Huis-clos* (1944; Eng. trans., *In Camera*; U.S. title, *No Exit*), *Les Mains sales* (1948; Eng. trans., *Crime passionnel*; U.S. title, *Dirty Hands*; acting version, *Red Gloves*), *Le Diable et le bon dieu* (1951; Eng. trans., *Lucifer and the Lord*), *Nekrassov* (1955), and *Les Séquestrés d'Altona* (1959; Eng. trans., *The Condemned of Altona*). All of the plays, in their emphasis upon the raw hostility of people toward one another, seem to be predominantly pessimistic; yet, according to Sartre's own confession, their content does not exclude the possibility of a morality of salvation. Other publications of the same period include the book *Baudelaire* (1947); a vaguely ethical study on the French writer and poet Jean Genet, entitled *Saint Genet, comédien et martyr* (1952; Eng. trans., *Saint Genet, Actor and Martyr*); and innumerable articles that were published in *Les Temps Modernes*, the monthly review that Sartre and Simone de Beauvoir founded and edited. These articles were later collected in several volumes under the title *Situations*.

Political
activities

After World War II, Sartre took an active interest in French political movements, and his leanings to the left became more pronounced. He became an outspoken admirer of the Soviet Union, although he did not become a member of the Communist Party. In 1954 he visited the Soviet Union, Scandinavia, Africa, the United States, and Cuba. With the entry of Soviet tanks into Budapest in 1956, however, Sartre's hopes for Communism were sadly crushed. He wrote in *Les Temps Modernes* a long article, "Le Fantôme de Staline," that condemned both the Soviet intervention and the submission of the French Communist Party to the dictates of Moscow. Over the years this critical attitude opened the way to a form of "Sartrean Socialism" that would find its expression in a major work, *Critique de la raison dialectique* (1960; Eng. trans., of the introduction only, under the title *The Problem of Method*; U.S. title, *Search for a Method*). Sartre set out to examine critically the Marxist dialectic and discovered that it was not livable in the Soviet form. Although he still believed that Marxism was the only philosophy for the current times, he conceded that it had become ossified and that, instead of adapting itself to particular situations, it compelled the particular to fit a predetermined universal. Whatever its fundamental, general principles, Marxism must learn to recognize the existential concrete circumstances that differ from one collectivity to another and to respect the individual freedom of man. The *Critique*, somewhat marred by poor construction, is in fact an impressive and beautiful book, deserving of more attention than it gained. A projected second volume was abandoned. Instead, Sartre prepared for publication *Les Mots*, for which he was awarded the 1964 Nobel Prize for Literature, an honour that he refused.

The
biography
of
Flaubert

From 1960 until 1971 most of Sartre's attention went into the writing of a four-volume study called *Flaubert*. Two volumes with a total of some 2,130 pages appeared in the spring of 1971. This huge enterprise aimed at presenting the reader with a "total biography" of Gustave Flaubert through the use of a double tool: on the one hand, Karl Marx's concept of history and class and, on the other, Sigmund Freud's illuminations of the dark recesses of the human soul through explorations into his childhood and family relations. Although at times Sartre's genius comes through and his fecundity is truly unbelievable, the sheer volume of the work and the minutely detailed analysis of even the slightest Flaubertian dictum hamper full enjoyment. As if he himself were saturated by the prodigal abundance of his writings, Sartre moved away from his desk during 1971 and did very little writing. Under the motto that "commitment is an act, not

a word," Sartre often went into the streets to participate in rioting, in the sale of left-wing literature, and in other activities that in his opinion were the way to promote "the revolution." Paradoxically enough, this same radical socialist published in 1972 the third volume of the work on Flaubert, *L'Idiot de la famille*, another book of such density that only the bourgeois intellectual can read it.

The enormous productivity of Sartre came herewith to a close. His mind, still alert and active, came through in interviews and in the writing of scripts for motion pictures. He also worked on a book of ethics. His was no longer, however, the power of a genius in full productivity. Sartre became blind and his health deteriorated. On April 15, 1980, he died of a lung tumour. His spontaneous, peaceful, but very impressive funeral, attended by some 25,000 people, was reminiscent of the burial of Victor Hugo, but without the official recognition that his illustrious predecessor had received. Those who were there were ordinary people, those whose rights his pen had always defended.

MAJOR WORKS

PHILOSOPHY: *L'Imagination* (1936; *Imagination: A Psychological Critique*, trans. by Forest Williams, 1962); *Esquisse d'une thorie des émotions* (1939; *Sketch for a Theory of the Emotions*, trans. by Philip Mairet, 1962); *L'Imaginaire: Psychologie phénoménologique de l'imagination* (1940; *The Psychology of Imagination*, 1950); *L'Être et le néant* (1943; *Being and Nothingness*, trans. by Hazel E. Barnes, 1956); *L'Existentialisme est un humanisme* (1946; *Existentialism and Humanism*, trans. by Philip Mairet, 1948); *Question de méthode* (1960; *The Problem of Method*, trans. by Hazel E. Barnes, 1963; U.S. title, *Search for a Method*); *Critique de la raison dialectique* (1960).

NOVELS: *La Nausée* (1938; Eng. trans. by Lloyd Alexander, 1949); *L'Âge de raison* (1945; *The Age of Reason*, trans. by Eric Sutton, 1947); *Le Sursis* (1945; *The Reprieve*, trans. by Eric Sutton, 1947); *La Mort dans l'âme* (1949; *Iron in the Soul*, trans. by G. Hopkins, 1950; U.S. title, *Troubled Sleep*, 1950); and *Drôle d'amitié* (1949, unfinished). The novels are collectively known as *Les Chemins de la liberté*.

PLAYS: *Les Mouches* (first performed 1943; *The Flies*, trans. by Stuart Gilbert, 1946); *Huis-clos* (1944; *In Camera*, trans. by Stuart Gilbert, 1946; U.S. title, *No Exit*, 1946); *La Putain respectueuse* (1946; *The Respectful Prostitute*, 1949); *Les Mains sales* (1948; *Crime passionnel*, trans. by Kitty Black, 1949; U.S. title, *Dirty Hands*; acting version, *Red Gloves*, 1949); *Le Diable et le bon dieu* (1951; *Lucifer and the Lord*, trans. by Kitty Black, 1953); *Nekrassov* (1955; Eng. trans. by S. and G. Leeson, 1956); *Les Séquestrés d'Altona* (1959; *Loser Wins*, trans. by S. and G. Leeson, 1960; U.S. title, *The Condemned of Altona*, 1961).

OTHER WORKS: *Le Mur* (1939; *Intimacy*, trans. by Lloyd Alexander, 1956), short stories; *Les Jeux sont faits* (1947; *The Chips Are Down*, 1949), film script; *Qu'est-ce que la littérature?* (1947; *What is Literature?*, trans. by Bernard Frechtman, 1949); *Baudelaire* (1947; Eng. trans. by Martin Turnell, 1949); and *Saint Genet, comédien et martyr* (1952; *Saint Genet, Actor and Martyr*, trans. by Bernard Frechtman, 1963), all essays; *Les Mots* (1963; *Words*, trans. by I. Clephane, 1964), autobiography; *L'Idiot de la famille: Gustave Flaubert, 1821-1857*, 3 vol. (1971-72).

(W.De.)

Saskatchewan

Saskatchewan is one of only two Canadian provinces without a saltwater coast, and the only one whose boundaries are wholly artificial. It lies between the 49th and 60th parallels of latitude and is bounded on the west by longitude 110 degrees west of Greenwich, and its eastern limit, with minor adjustments, is longitude 102. Its southern half is largely an extension of the Great Plains of central North America, rarely rising 2,000 feet above sea level, and its northern half, **most** of which lies in the ancient rock mass of the Precambrian Shield, is sparsely populated bush country with many lakes and tundra. Its area is 251,700 square miles (651,900 square kilometres), of which 31,518 are water; and it measures 760 miles from south to north, tapering from a width of 393 miles where it abuts Montana and North Dakota, to 277 where it meets the Northwest Territories. In areas, Saskatchewan is Canada's fifth largest province, and in population, its sixth. Economically, the province has always been heavily dependent on the exportation of its agricultural and mineral products, and is thus peculiarly sensitive to fluctuations in world markets beyond its own or even Canada's control.

HISTORY

Since Saskatchewan became a full member of the Canadian federation only in 1905, much of the area's historical interest depends on events vastly older than the province. Dinosaur and mammoth finds have been common. The first known human inhabitants were Indians of several linguistic groups who were present at least 5,000 years ago, and possibly much before that; they were mainly hunters, particularly of the buffalo. With the coming of the white man, they became trappers involved in the fur trade. The first white man known to see the Saskatchewan River was Henry Kelsey, who in 1691 explored part of the plains for his employer, the Hudson's Bay Company, which received its charter in 1670 and is still extant. Fur traders and buffalo hunters, variously Indian, Métis (of mixed racial origin), French, British, and explorers and missionaries, comprised the bulk of the area's inhabitants until the second half of the 19th century.

The area from which Saskatchewan is carved was first granted to the Hudson's Bay Company and then, in 1868, surrendered by the Rupert's Land Act back to the British crown, in order that it could be turned over to the newly formed Dominion of Canada, which was done in 1870. Canada administered its newly acquired western territories almost as if they were colonies, and, in 1873, created the North West Mounted Police to maintain law and order. In 1885 the national authorities sent out troops to quell the second Riel Rebellion, an uprising in which a large number of Métis, by now deprived of their main sustenance, the buffalo, sought to establish their rights to western lands in the face of growing settlement. Constitutionally, the territories in 1875 were granted an executive council with a promise of an elected assembly, and by 1897 they had won responsible parliamentary government on the British model.

Saskatchewan, created by the Saskatchewan Act (a Canadian statute) in 1905, entered confederation with its present boundaries and the status of a province equal to the others except that, as with its sister province Alberta, the federal government retained control of its natural resources, paying a subsidy in place of the revenues the resources might have yielded. (The resources were assigned to the province in 1930.) The new provincial government, after a good deal of rivalry among the towns, chose Regina, the former territorial capital, as its centre of operations, and the first premier appointed was Walter Scott (1867–1938), a believer in partisan politics, as opposed to those who favoured a continuation of the kind of cooperative effort that had led up to the creation of Saskatchewan as a separate province. A member of the party in federal power at the time, the Liberal Scott was the first of several able politicians who have kept the party in power in Saskatchewan except in 1929–34 and 1944–64, and after 1971. The 1944–64 period was unique in North

American history: during it the Cooperative Commonwealth Federation (CCF), successively led by T.C. Douglas (1904–) and Woodrow Lloyd (1913–), established the first avowedly Socialist government on the continent, and the party won international attention in 1962 when it implemented the continent's first compulsory medical care program, accompanied by a doctors' strike.

Regardless of which political party has been in power at any given time, the Saskatchewan environment has always demanded much governmental intervention in the economy. The provincial telephone company and the power and gas utility, for example, are publicly owned, but neither was created by a Socialist government. The cooperative movement has been encouraged by all parties and has been influential in a wide range of service, retail, and wholesale activities that include large credit unions and an oil refinery. In the handling of grains, the backbone of the province's economy, the Saskatchewan Wheat Pool, also a cooperative, has been a dominant influence. The co-ops helped many individuals survive the desperate drought and depression of the 1930s, when Saskatchewan society, according to an official investigation, sustained setbacks as severe as any to which comparable communities were exposed during that time. In the decades following World War II, the province attained a major development in mineral exploitation and industrial growth, and its diversified base, combined with new farming techniques, made a repetition of the 1930s appear unlikely.

THE NATURAL AND HUMAN LANDSCAPE

Although familiarly known as one of the "prairie provinces," Saskatchewan has little true prairie; a large proportion of its productive acreage (barely half the province) is rolling ranch and parkland, both of which offer immense vistas from their higher points. There is not a single mountain in the province, although the term is loosely used to identify several landmarks. The Cypress Hills, in the southwest corner of Saskatchewan, include the provincial summit: 4,567 feet (1,392 metres) above sea level. The Hills are unique in that they constitute the only part of the area to escape glaciation and contain unique plant and animal life. Wood Mountain (3,275 feet [998 metres]) and the Vermilion Hills (2,500 feet [760 metres]) are the province's other major departures from the rolling plains topography. Cut into the plains are many spectacular river valleys, the most notable being those of North and South Saskatchewan and the Qu'Appelle.

Saskatchewan drains from west to east, its great rivers (which provided the first transportation routes) rising in the Rocky Mountains and emptying ultimately into Hudson Bay. The soils through which the rivers flow are predominantly chernozemic (dark-coloured grassland) and podzolic (light-coloured forest) with extensive deposits of poorly drained mineral and peat soils in the north. The climate alone keeps much land out of production. Only in the southern half of the province are there even as few as from 80 to 100 frost free days annually. Temperature variations are extreme; January temperatures have exceeded -65°F (-53°C) in settled parts, and in July temperatures upward of 105°F (41°C) have often been recorded. The normal mean daily reading for the arable regions ranges from -5°F (-21°C) to 10°F (-12°C) in January, and from 55°F (13°C) to 65°F (18°C) in July. Precipitation generally is not high, averaging from ten to 20 inches each year; snowfall ranges from 30 inches in the southwest to over 60 inches in the northeast.

The vast unsettled parts of Saskatchewan support a large wildlife population of great variety. Grizzly bear and mountain lion are now rare, but brown bear, moose, deer, and antelope are common, together with enormous numbers of smaller mammals. Coyote, fox, and lynx, together with the gophers, rabbits, and other creatures they prey on, are abundant, and the northern portion of the province still supports a considerable amount of trapping. Saskatchewan is on the main western flyway of waterfowl, songbirds, hawks, and owls, many of which nest in the

Early
explora-
tion

Climatic
factors

province. The extensive water resources maintain both commercial and game fish in quantity. Northern Saskatchewan, particularly, is one of the world's last frontiers for the hunter and angler.

The lack of heavy industry and of metropolitan areas keeps Saskatchewan relatively free of the kinds of pollution associated with high population density and manufacturing, but the extensive agrizultural development subjects it to those connected with weed killers and insecticides. Significant amounts of mercury have been found in fish and birds, and continuing research suggests that the amount of contamination in wildlife may be larger than had been apparent. The sources of the major rivers also subject Saskatchewan to upstream pollutants from areas over which it has no control; but prevailing winds do not come from heavily polluted regions, and the air is generally clean, though an occasional northern forest fire casts a pall over thousands of square miles to the south.

Saskatchewan's landscape makes its inhabitants conscious of the sky; and the changing patterns of light and shadow on clouds, which commonly offer magnificent sunrises and sunsets, are as much a part of the scenery as any contour of the earth. All of Saskatchewan is further north than any of the most densely populated parts of Canada, and the province's own north is largely inaccessible except by air, with the result that few citizens are familiar with it. The provincial university, at its Saskatoon campus, maintains an Institute for Northern Studies and an Institute of Space and Atmospheric Studies that has done extensive research on the aurora borealis. When a resident thinks of Saskatchewan's chief regions, he is less likely to think of the north than of the province's main agricultural and recreational areas: the wheat belt, the ranching country, the Qu'Appelle Valley, the Cypress Hills, Waskesiu Lake; or, if he is historically minded, of the old fur-trading routes and trails, and their inevitable forts, or the sites of Saskatchewan's few battles. To the untrained eye the relative uniformity of the rolling plains is not conducive to thinking in terms of regions as such. Nor is Saskatchewan dominated by any metropolitan centres. Unlike many Canadian provinces, Saskatchewan has in effect two capitals: Regina, the official capital, in the central south, and Saskatoon 160 miles to the north, both of them among the most rapidly growing cities in North America, with populations exceeding 140,000 and 125,000 respectively, by the start of the 1970s. The next largest cities were Moose Jaw (32,000) and Prince Albert (28,000). Each city (there were three others above 10,000) has its "constituency," the surrounding area for which it provides goods and services, but although the seven largest communities contain well over one-third of the population, none is typical of the most obvious settlements. The most striking man-made feature of the landscape is the grain elevator, and the typical town is a cluster of houses around three or four elevators, surrounded by enormous fields. The towns are rarely more than a dozen miles apart on the railways and highways, and their original locations were settled largely by the amount of track that a railway maintenance crew could cover with a hand-propelled "jigger" cart. Technological development having reduced the necessity for many of them, Saskatchewan's rural and small town population was, by the 1970s, generally in a state of decline.

THE PEOPLE

In numbers, the people of Saskatchewan have remained much the same for over 40 years: the population was 921,785 in 1931, and up to 926,242 in 1971, having dipped to a low of 831,728 in 1951. In almost every other way, however, the population has changed markedly during the area's history. It was originally exclusively Indian, to which French and British elements were added early. Then other European groups—German, Austrian, Ukrainian, Scandinavian, Russian, and Polish, among others—were attracted, some by generous homestead grants, and some in part by a desire to avoid compulsory military service in their own countries. The period of heaviest immigration was before 1920, when the population rose suddenly from less than 100,000 in 1901 to

nearly 700,000. The population of British origin was, by the 1970s, less than 40 percent. Many of these groups, including the British, settled in separate communities where they could use their own language and continue their own religion and customs, and Saskatchewan contains many settlements readily identifiable as Ukrainian, French Canadian, German, etc. Provincial law permits the use of languages other than English in schools for specific purposes, and widespread advantage has been taken of the law. Ethnic variety is matched by that found in religious affiliation: although individual communities may be predominantly of one persuasion, in the provinces as a whole the largest church, the United Church of Canada, had, by the 1970s, only 30% of the population as adherents, followed by the Roman Catholic (26%), Lutheran (10%), Anglican (10%), Ukrainian Catholic (4%), Greek Orthodox (3.5%), Mennonite (3%), Presbyterian (3%), Baptist (2%), and a host of others.

The birth rate in Saskatchewan has, since 1950, been close to the national average, and like it has declined sharply: it was 27.5 per 1,000 population for the years 1951–5, and by 1970 was 19.0, ranking sixth among the provinces. The death rate during the same periods has remained stable, rising from 7.6 to 7.8. The whole population grows slowly, when it does, because of the high emigration rate, which exceeds immigration by over five to one: the net migration loss between the censuses of 1961 and 1966 was 45,528, and this is attributed to increases in the efficiency of Saskatchewan's basic industries, which can steadily produce more with less manpower. Internally, the province, although still one of the least urbanized, has one of the highest rates of urbanization in Canada, the growth coming chiefly from the movement of rural dwellers into urban areas. Rural and urban populations were of virtually equal size by the census of 1966.

THE PROVINCE'S ECONOMY

Saskatchewan has since its beginning been based economically on extractive industries: furs, agriculture, oil and gas, and potash, in almost all cases the products being consumed outside the province, and generally outside Canada, a fact that makes the province one of the most economically vulnerable areas in the world. The grain belt (predominantly wheat, but also including large acreages of barley, oats, rape, flax, and rye) lies between the southern border and the 54th parallel of latitude; over 540,000,000 bushels of wheat were harvested annually by the decade of the 1970s and the barley and oats crops were each nearly 100,000,000. Potash is found in a narrower band running diagonally across the province from west to east, its northernmost point being west of Saskatoon. Oil and gas lie in the southernmost quarter of the province, while there are rich uranium deposits in the far north. Other significant minerals include salt, sodium sulfite, and a variety of clays. In terms of employment, manufacturing has always played a relatively minor role in the provincial economy and is characterized by several hundred small establishments, few of which have over 100 employees. The trade union movement is correspondingly small, its total membership rarely exceeding 50,000. The gross farm value of the principal field crops, by 1970, was almost \$1,000,000,000; of mineral production, \$370,000,000, of which \$225,000,000 was fuel; of all manufacturing \$514,000,000. By the start of the 1970s, Saskatchewan generated nearly 4,000,000,000 kilowatt hours electrical energy, all of it consumed domestically.

The Saskatchewan economy, always dependent on external markets, has internally required a variety of governmental supports; and as a result the province has never had a truly free-enterprise system, while public enterprise, and mixed public and private ventures, have characterized the development of the economy from the beginning. The Canadian protective tariff, long criticized by prairie dwellers because it made them pay more for goods of all kinds, appears to be the mainstay of the secondary industries developing in the province. The first waves of settlers, attracted to Saskatchewan by federal government policies, were carried on railways built with federal assistance. Saskatchewan grain moves to federal terminal ele-

ment
support

vators at controlled freight rates. Within the province, political parties in power, regardless of ideology, have sponsored and maintained publicly owned utilities, a bus company, an insurance company, and public hospitalization and medical care. Although ostensibly a free-enterprise party, the Liberal Party, when elected in 1964, kept intact, for the remainder of the decade, many of the major policies of its allegedly Socialist predecessor.

TRANSPORTATION

Modern Saskatchewan was originally the creation of trans-continental railroads, which carried settlers and supplies in, and grain out. Though freight remains an important rail component, passenger carriage has declined to such an extent that the major railways have for years been seeking permission to curtail and even abandon services, so far with modest success. The province is now criss-crossed with highways, the main routes among which have been paved only since 1945. The system of land division in the rural areas makes provision for "road allowances," strips of territory a mile or two apart, and while most of these are simple dirt, they are, as long as they are dry, firm passable roads, widely used for local travel.

Except for recreation, water transportation is all but obsolete in Saskatchewan; small shallow-draft steamers formerly sailed the main rivers, but since the rivers are shallow with shifting sandbars, they have not been significant transportation routes since before World War I. Airlines, by contrast, have developed dramatically in Saskatchewan, where approximately half the province is accessible only by air. The small plane serves the north for both commercial and recreational purposes, and all major centres are on scheduled airlines.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Saskatchewan's constitution, based on custom and the Saskatchewan Act (of admission) of 1905, in essence provides for a British parliamentary system, in which the life of the executive depends on the support of a majority in the legislature. By law (1972) the legislature has 60 to 65 members. A general election must be held every five years; short of that period, the premier may advise the holding of an election at any time, and most assemblies last only four years. As in all the provinces, the lieutenant governor is appointed (for a term) and paid by the Dominion government and has become by custom and judicial decision the counterpart of a constitutional monarch, with powers whose exercise is almost wholly formal. At Ottawa, Saskatchewan is represented by six senators (all appointed by the Dominion government) and thirteen MPs in the House of Commons, scheduled to become 12 after the census of 1971. The administration of justice is under provincial jurisdiction, but all judges above the rank of magistrate are appointed by the Dominion government. Saskatchewan's larger centres have their own local police, but in the province as a whole the law is enforced by the Royal Canadian Mounted Police under a contract between federal and provincial authorities.

Unlike Canada's other prairie provinces, the Saskatchewan legislature has a long tradition of strong vocal opposition in the assembly, with the Liberals and the New Democratic Party (formerly the CCF) providing what is in effect a two-party system ideologically divided into free enterprise versus democratic socialism; there are other parties, but they have been of negligible significance for nearly 40 years. The Liberal Party draws its greatest strength from rural ridings; the New Democrats have a stronger urban base. Whichever party is in power is vigorously opposed by the other, with the Liberals generally espousing development of the province by business and corporate devices and the NDP as strongly urging the use of public and cooperative enterprise.

The great proportion of the province's annual budget, which by the 1970s exceeded \$450,000,000, goes to education, health and welfare, and highways, in that order. (Saskatchewan, averaging from three to five persons per square mile in its rural areas, has one of the highest per capita road mileages in the world.) The province is divided into a multiplicity of local administrations including

hospital districts and school districts, all constitutionally under provincial jurisdiction, but all having considerable local responsibility. Municipal government in Saskatchewan is based on the American model, with a mayor elected separately from the council, and a number of boards and commissions operating largely independently of either.

For most of its history the province has qualified for the kinds of federal aid available to those whose economy operates below the national average. The province's reliance on federal subsidies as a percentage of total revenues, though it varies with crop conditions, is generally above the national average. Saskatchewan's wage levels for both industry and agriculture are never among the lowest for the provinces, but are never among the highest, either. The province's "middle" position carries over into its internal affairs: it is socially and economically (except for its Indian and Métis peoples) one of the least stratified areas in Canada, having little of great individual or corporate wealth on the one hand, and little general destitution on the other.

CULTURAL LIFE AND INSTITUTIONS

Lacking great metropolitan centres, Saskatchewan has been unable as yet either to develop large permanent art collections, and theatre and opera companies, or to retain within the province its own leading professional artists. The province has, nonetheless, contributed a number of outstanding performers to the world at large, in both popular and classical fields of musical endeavour. The Saskatchewan writer most sensitively attuned to the prairie is Edward McCourt, who has written both fiction and descriptive works. The province has many competent painters who exhibit widely, and both Saskatoon and Regina have small but excellent galleries. Both cities have civic auditoriums capable of staging any known theatrical or operatic work, resident symphony orchestras, and Regina has a fine provincial museum of natural history and a professional theatrical company.

Saskatoon has a Western Development Museum whose chief exhibits consist of outmoded farm machinery and automobiles, many of which are annually refurbished in a celebration of pioneer days. The machinery museum serves to remind the observer that culture in Saskatchewan is not, for most citizens, associated with the values of an intellectual middle class. It centres, instead, around the curling and hockey rinks, the small radio and television stations serving their immediate localities, and the daily and weekly newspapers. The splendid services of the Canadian Broadcasting Corporation's radio network reach most of settled Saskatchewan, but it is the local stations that have the mass audiences. Apart from the CBC, the province supports 18 radio stations (two broadcasting in French) and 24 television outlets, four daily newspapers, and over 100 weeklies (six in French). None of these (again except for the CBC) attempts to qualify as a national institution. Each serves one local constituency, and many of them do it very well. A central focus is given to many of them part of each year when the province's only major league athletic team, the Saskatchewan Roughriders football club, which has won the Canadian championship, is playing. Though the province has produced many famous hockey players, it has no major team.

The province's oldest recognizable cultural institution is the University of Saskatchewan, established in 1907 and, with remarkable foresight, given a huge campus at Saskatoon, and later a second campus in Regina. It has a total student body of 16,000. The university has produced much fundamental research relevant to Saskatchewan and has also a tradition of extension services on and off campus. It has sent forth a steady stream of distinguished workers in a variety of fields, from acting to nuclear physics. As a result of the limited opportunities offered, not many of these have been able to remain in the province.

PROBLEMS AND PROSPECTS

Saskatchewan, since shortly after World War II, has been slowly progressing toward a state of modest affluence. A whole generation exists that has no recollection of the drought and depression of the 1930s, a fact that occasion-

The
constitu-
tion

Political
parties

ally gives rise to interesting confrontations with those who do remember. For several consecutive years in the 1950s and 1960s, almost every economic indicator showed continuing development, and in 1966 the province failed for the first time to qualify, as a "have-not" province, for important federal subsidies. Since then, thanks in part to crops so large that the world market has been unable to absorb them, the province has hovered on the brink of being a "have" province.

It is clear that Saskatchewan's future will continue to rest on external markets, for there is no way it can consume its own chief products. It is equally clear that Canadian population patterns will make the province an increasingly smaller fraction of the Dominion, with its representation in Parliament dwindling accordingly. Both these facts suggest that Saskatchewan will remain indefinitely an area acutely sensitive to influences beyond its borders. It has, on the other hand, one immense and almost untapped resource: fresh and relatively clean water. If water users can be induced to move to the province, Saskatchewan's history could undergo a dramatic change of direction; but if the established pattern is followed, the water will move to those who need it.

BIBLIOGRAPHY. The most comprehensive source book is J.H. RICHARDS and K.I. FUNG (eds.), *Atlas of Saskatchewan* (1969). Other invaluable aids are the two annuals: *Canada Year Book*, and J.T. SAYWELL (ed.), *Canadian Annual Review of Politics and Public Affairs*. A brilliant survey of the land and its peoples is E.A. MCCOURT, *Saskatchewan* (1968); the main political developments are in N. WARD and D. SPAFFORD (eds.), *Politics in Saskatchewan* (1968); and S.M. LIPSET, *Agrarian Socialism*, rev. ed. (1968). J.H. ARCHER and A.M. DERBY, *The Story of a Province* (1955), is a readable introduction to the history of Saskatchewan; an excellent economic history is V.C. FOWKE, *The National Policy and the Wheat Economy* (1957). (N.W.)

Satellite Communication

Satellite communication, the use of man-made satellites travelling in Earth orbits to provide communication links between various points on Earth, is the most important nonmilitary exploitation of space technology. Communication satellites permit the exchange of live television programs between nations and continents. International telephone and data services are provided through Earth stations located in more than 100 countries, and a number of other satellite systems provide regional and domestic service, as well as communication with ships. The technique basically involves transmitting signals from an Earth station to an orbiting satellite. The equipment aboard the satellite receives these signals, amplifies them, and transmits them to a region of the Earth. Any station within this region can pick up the signals, thus providing a communication link.

The International Telecommunications Satellite Organization, usually referred to as Intelsat, is responsible for all international nonmilitary satellite communication outside the Soviet bloc. Intelsat also provides domestic service in a number of countries. A government-regulated private corporation known as the Communications Satellite Corporation (Comsat) is the U.S. member of Intelsat. An organization called Intersputnik manages satellite communication within the Soviet bloc.

Satellites provide communication circuits between widely separated locations via microwaves. To transmit television and telephone signals between population centres requires high-capacity circuits. Over land such circuits can be provided in many ways, including pairs of wires, coaxial cables, waveguides, optical fibres, and microwave radio relay systems. Improved submarine cables can carry thousands of telephone signals across oceans, but satellites can provide even greater capacity, in many cases at less cost per channel. Moreover, a satellite system can be put into service quickly, for it does not require the laying of wires or cables from one point to another or, as does a ground microwave system, the construction of intermediate relay or repeater stations. Once a satellite has been launched, communication between two points can be established merely by constructing two Earth stations, and one satellite can serve many stations.

Microwaves are very short radio waves, of wavelengths ranging from 10 centimetres to one centimetre (four inches to $\frac{2}{5}$ inch). This corresponds to a frequency range of from three to 30 gigahertz ([GHz]; a gigahertz is 1,000,000,000 [10^9] hertz [Hz], or cycles per second). Microwaves are launched from and received by parabolic (bowl-shaped) antennas. The waves diverge along straight lines in narrow beams; microwave repeaters or amplifiers, therefore, must be located within line of sight of one another. On land this can be achieved by using towers and hilltop locations, but transoceanic microwave systems were impossible until the stationing of satellites in the sky.

The width of a beam of microwaves is proportional to the ratio of the wavelength of the microwaves to the diameter of the antenna. Thus, a small antenna on a satellite will receive from or transmit to the part of the Earth that is visible from the satellite, nearly a complete hemisphere, while a larger antenna will receive from and transmit to a more limited region of the Earth's surface. Similarly, a large antenna at an Earth station will transmit to and receive from only the satellite to which it is pointed and not from other nearby satellites.

HISTORY

Rockets were first seriously considered as a means for sending humans through space by the Russian scientist Konstantin E. Tsiolkovsky and the U.S. scientist Robert H. Goddard early in the 20th century. The use of unmanned space vehicles has been appreciated only since World War II, when German V-2 rockets were used in air assaults on London. Although early proposals envisioned manned satellites, the great success of satellite communication has been achieved by the use of highly reliable unmanned satellites.

The theoretical stage. The idea of radio transmission through space is at least as old as the space novel *Ralph 124C41+* (1911), by the U.S. science fiction pioneer Hugo Gernsback. Yet the idea of a radio repeater located in space was slow to develop. In October 1942 the U.S. science fiction writer George O. Smith published the story "QRM Interplanetary" in the magazine *Amazing Science-Fiction*. Smith's "Venus Equilateral" radio repeater, in a position equidistant from Venus and the Sun, was used to relay signals between Venus and the Earth.

In 1945 the British author-scientist Arthur C. Clarke proposed the use of an Earth satellite for radio communication between, and radio broadcast to, points widely removed on the surface of the Earth. Clarke assumed a manned space station with living quarters for a crew, built of materials flown up by rockets. The station would be positioned at an altitude of about 35,900 kilometres (22,300 miles) so that its period of revolution about the Earth would be the same as the period of the Earth's rotation. This synchronous satellite, which would always appear in the same place in the sky, would be provided with receiving and transmitting equipment and directional antennas to beam signals to all or parts of the visible portion of the Earth. Clarke suggested the use of solar power, either a steam engine operated by solar heat or photoelectric devices. Three such space stations would provide broadcast to or communication among all locations on Earth except for the most remote regions of the Arctic.

In a paper published in April 1955 the U.S. engineer-scientist J.R. Pierce analyzed various types of unmanned communication satellites. These included passive devices, such as metallized balloons and plane and corner reflectors, that would merely reflect back to Earth part of the energy directed to them. Active satellites, incorporating radio receivers and transmitters, were also considered. Pierce discussed satellites at synchronous altitudes, satellites at lower altitudes, and the use of the Earth's gravity to control the attitude or orientation of a satellite.

These two early papers by Clarke and Pierce showed that very modest powers would suffice for transoceanic communication.

Early satellites. The first satellite communication experiment was the U.S. government's Project SCORE (Signal Communication by Orbiting Relay Equipment), which

Early plan for a manned space station

Project SCORE

launched a satellite on December 18, 1958. This satellite circled the Earth in an elliptical orbit, with a 180-kilometre perigee, its closest point to Earth, and an apogee, its greatest distance from Earth, of 1,490 kilometres. The satellite operated in a real-time (immediate) and a delayed-repeater mode, in which messages were recorded on magnetic tape and retransmitted, SCORE functioned for 13 days, until its batteries ran down. It reentered the atmosphere and was destroyed on January 21, 1959.

The U.S. Army Signal Corps's Courier project was a further development of the SCORE approach. Courier 1B was designed primarily to handle teletypewriter data and secondarily to handle voice and facsimile (photographs and drawings) messages. It was launched on October 4, 1960, into an orbit with a 968-kilometre perigee and a 1,215-kilometre apogee. It operated for 17 days.

Echo 1

Echo 1, a balloon 30 metres (100 feet) in diameter, made of a plastic called Mylar and coated with a thin layer of aluminum, was launched on August 12, 1960. The satellite was placed in an almost exactly circular orbit at an altitude of 1,600 kilometres and an inclination of 47.3°. The satellite stemmed from two sources: the construction of such a balloon by the U.S. engineer William J. O'Sullivan as a means for measuring the atmospheric density in a 1,600-kilometre orbit and from Pierce's proposal for a passive satellite in his 1955 article.

Communications tests carried out by reflecting radio signals from Echo 1's surface were completely successful. The first transmissions were made between terminals built on the East and West coasts of the United States. Bell Telephone Laboratories built a terminal in New Jersey, the U.S. National Aeronautics and Space Administration (NASA) paying for its use. A terminal on the West Coast was built at Goldstone, California, by NASA's Jet Propulsion Laboratory. Echo 1 was used for experimental telephone, data, and facsimile transmission. Signals from Echo 1 were detected in Europe, but no messages were transmitted across the ocean. Echo 1 remained in orbit for almost eight years and was a conspicuous object in the night sky. Echo 2, launched in 1964, remained in orbit for five years.

Echo 1 stimulated a great deal of interest in the development of active satellite communication and led American Telephone and Telegraph Company (AT&T) to build Telstar, launched on July 10, 1962. Telstar was an active satellite with a microwave receiver and transmitter. It was the first satellite to transmit live television and telephone conversations across the Atlantic, which it did on an experimental basis. Telstar was turned off on February 21, 1963. A second Telstar satellite was launched on May 7, 1963 and operated for about two years.

Telstar

NASA's Relay 1 satellite, built by the Radio Corporation of America (RCA), was launched into an elliptical orbit on December 13, 1962. This active satellite was successfully employed in a number of communication experiments. In September 1963 it was used, with the Syncom 2 satellite, to make a brief transmission between the United States, Brazil, and Nigeria.

First synchronous satellite

Syncom 2, the first synchronous communication satellite, was launched on July 26, 1963. This simple but effective satellite was conceived by Harold A. Rosen of Hughes Aircraft Company. The satellite weighed only 39 kilograms (86 pounds); its light weight made insertion into a synchronous orbit possible with the small boosters available at the time. The satellite performed well.

Syncom 3, launched on August 19, 1964, relayed the first sustained transpacific television picture from the opening ceremonies of the Olympic Games in Tokyo. The first commercial communication satellite, Intelsat 1 (Early Bird), launched on April 6, 1965, was a modified version of Syncom.

Other early experiments. In the early days of satellite communication it was not clear what techniques would prove to be practical or useful, and many were proposed and tested. The very earliest communication by means of a satellite made use of signals reflected from the Moon. As early as 1954 the U.S. Naval Research Laboratory transmitted voice messages in this way, and a naval communications link was established between Washing-

ton, D.C., and Hawaii in 1960. The goal of the West Ford project, which originated in 1958, was communication by reflection from a cloud of wires that had been launched into orbit; 20 kilograms of wires were put into a 3,000-kilometre orbit in May 1963. Measurements were made of microwave signals reflected from them, but there was little further development of the project.

The success of Echo decided the issue in favour of man-made satellites, and the success of Telstar in favour of active satellites. The success of Syncom led to the universal use of active synchronous satellites for communication.

SATELLITE AS A RADIO REPEATER

A typical communication satellite has a number of transponders, or repeaters, each providing a channel of information. Each transponder consists of a receiver tuned to a channel, or range, of frequencies lying in the uplink (receive) band of frequencies; a frequency shifter to lower the received microwaves to a downlink (transmit) range of frequencies; and a power amplifier to produce an adequate microwave output power. The number of transponders, or channels, indicates the communication capacity of a satellite. Typically, one channel (a half-circuit) can carry a colour television signal or 1,200 telephone voice signals in one direction.

Satellite capability

Propagation. As shown in Figure 1, electromagnetic waves are attenuated (*i.e.*, lose power) in passing through

Figure 1: The attenuation of radio waves by the Earth's atmosphere as a function of frequency for an Earth-to-space signal. The chart assumes that the waves originate in clear weather at a high and dry location on the Earth and are directed upward toward space within 45° of vertical (see text).

the ionosphere and the lower atmosphere. In general, an atmospheric attenuation greater than three decibels (dB), corresponding to a loss of half of the transmitted power, is considered excessive. Deliberate attenuation, made by using high microwave frequencies for which atmospheric absorption is great, may be used in communication between military satellites in order to avoid interception of such signals on the ground. For satellite communication with Earth stations, however, only low microwave frequencies are suitable.

Rain also attenuates microwaves. In dealing with rain attenuation, it is useful to consider the attenuation in decibels that is exceeded 0.01 percent of the time, or 52.5 minutes a year. In a region that is neither very dry nor very rainy, the attenuation for this period of time exceeds 43 decibels at 28 gigahertz, 22 decibels at 19 gigahertz, nine decibels at 14 gigahertz, and only one decibel at four gigahertz. In regions where rain attenuation is a serious problem, two Earth stations can be used to communicate with one satellite (diversity), since it is less likely that rainfall will be heavy at both stations simultaneously. Diversity may be desirable at 12 gigahertz in some areas of the world. Except in very dry regions, diversity is necessary for reliable commercial service at 20 gigahertz.

Frequency allocations. Through international agreement, three major frequency bands have been assigned for nonmilitary satellite communication. Each band consists

Figure 2: Antennas.

(A) Cassegrain Earth station antenna. The parabolic dish directs received microwaves to the convex secondary reflector, which in turn reflects the microwaves in a beam through a hole in the centre of the dish, where they are collected and sent to the receiver. (B) Antennas of the Intelsat 4A satellite. The large reflectors are illuminated by complex arrays of small horns so that the microwave beam covers only a portion of the Earth's surface.

Major
frequency
bands

of an uplink (Earth station to satellite) and a downlink (satellite to Earth station) at a somewhat lower frequency. The lower frequency band is chosen for the more difficult downlink because rain and atmospheric attenuation are less at lower frequencies. Bands in service include the C band, which uses frequencies from 5.925 to 6.425 gigahertz for the uplink and frequencies from 3.7 to 4.2 for the downlink, and the K band, which uses frequencies from 14 to 14.5 gigahertz for the uplink and from 11.7 to 12.2 gigahertz for the downlink. There also is an assignment, with an uplink from 12.75 to 13.25 gigahertz and from 14 to 14.5 gigahertz and a downlink of from 10.7 to 11.7 gigahertz, that within the United States can be used only for international service. Another assignment has an uplink of 27.5–30 gigahertz and a downlink of 17.7–20.2 gigahertz. The 20-gigahertz downlink is vulnerable to rain and is no longer used commercially.

Characteristics of channels. The bandwidth of a transponder is commonly 36 megahertz (MHz). Such a channel will transmit about 1,200 telephone signals, each with a bandwidth of 4,000 hertz, or one television signal. The total bandwidth of 1,200 telephone signals is only 4.8 megahertz, and the 36-megahertz channel that is used to transmit these signals has seven and a half times this bandwidth. Either wide-deviation frequency modulation is used in satellite communication, or the telephone signals are transmitted as binary pulses by pulse-code modulation. In either case, the use of a broad band of radio frequencies reduces the transmitter power necessary to attain an adequate signal-to-noise ratio in the overall system.

Path loss and power requirements. The power necessary for satisfactory transmission between a satellite and the Earth depends on the total received power necessary at the input of the Earth-based receiver and on the fraction of the power transmitted from the satellite that is picked up by the Earth station antenna. This fraction is the ratio of the area of the receiving antenna on Earth to the area covered by the microwave beam on the Earth. A standard Earth station antenna, for example, has a diameter of about 30 metres. If the antenna beam from the satellite just covers the Earth, the 30-metre antenna receives about $4/1,000,000,000,000$ (4×10^{-12}) of the transmitted power, and the received signal is 114 decibels weaker than the transmitted signal. If the antenna beam of the satellite just covers the continental United States, the received power is about 103 decibels weaker than the transmitted power, or about 11 decibels (14 times) stronger than the power received from a satellite whose antenna beam covers the entire Earth. Because the path loss for transmitting between a pair of antennas is the same in either direction, it is also advantageous to use a narrow receive-

ing beam on a satellite. Thus, it can be advantageous to use a satellite with narrow transmitting and receiving beams, pointed only toward those regions with which communication is desired. Advanced satellites, such as Intelsat 5, have global coverage beams for communicating with nations that have small amounts of traffic, as well as hemispheric and spot beams for areas of heavy traffic.

In order to get a narrow antenna beam, the antenna on the satellite must have a considerable area. The minimum beam width, measured in radians, that can be attained with an antenna of a given diameter is roughly equal to the wavelength divided by the diameter of the antenna. Thus, for a given beam width the diameter of the antenna must be greater at lower frequencies (longer wavelengths) than at higher frequencies. In order for the antenna beam to cover a limited area on Earth, the antenna on the satellite must be quite large (about 2.5 metres in width in Intelsat 5), and the feed, which directs the transmitted power toward the antenna dish or collects the received power from it, must consist of an array of microwave sources such as feed horns. The relative phases and amplitudes of the signals going to the feed horns determine the area of the Earth covered by the antenna beam. This area can be shifted by changing the phases of the signals to the feed horns, either mechanically or electronically. If the phases are shifted electronically, the beam can be made to scan, or hop, from one point to another. By dividing signals among the feed horns it is possible to produce several simultaneous beams aimed at different spots on the Earth. Figure 2 indicates the general configuration of some microwave antennas used for Earth stations and satellites.

The power that must be received at an Earth station for satisfactory operation of a communication satellite channel is proportional to the required ratio of the carrier (received power) to the noise. In normal operation the carrier-to-noise ratio is about 13 to 20 decibels. Signals can be received with some degradation in quality with a carrier-to-noise ratio as low as six or seven decibels, so the design carrier-to-noise ratio provides some protection against rain attenuation or other loss of signal strength.

Some noise in the receiver can be Johnson, or thermal, noise from rain; thermal noise from space is negligible unless the antenna is pointed at the Sun. Part of the noise comes from the receiver itself. Because Johnson noise is proportional to temperature in kelvins (K; -273.15°C), the noisiness of a receiver is specified by a noise temperature T , such that Johnson noise for temperature T added at the input of the receiver doubles the observed output noise. Thus, in the absence of rain noise power is proportional to the receiver noise temperature T . It is also

proportional to the bandwidth, which for a satellite channel is about 36 megahertz (the noise power is $N = kTB$ watts, where B is the bandwidth in hertz and k is the Boltzmann constant [$k = 1.38062 \times 10^{-23}$ joule per degree]). The received power per channel is typically about 126 decibels less than a watt (2.5×10^{-13} watt).

The power received at an Earth station depends on the power transmitted by the satellite (usually from five to 10 watts per transponder), on the area of the Earth's surface covered by the satellite's transmitting beam, and on the area of the Earth station antenna. The gain G of an antenna is related to its area, being proportional to the area divided by the square of the wavelength. The "figure of merit" of an Earth station receiving system is defined as the ratio G/T , the ratio of antenna gain to receiver noise temperature. This ratio may be expressed in decibels. A typical Earth receiver noise temperature is 50 kelvins, and a typical antenna gain is 60 decibels, giving a figure of merit of 20,000, or 43 decibels.

The transmitter power on a satellite is limited by considerations of weight and life; it is important, therefore, that Earth stations have antennas with large areas and that they have low-noise receivers. It is of little use to provide the receiver on a satellite with low-noise receivers because noise at between 200 and 300 kelvins is received from the Earth. Large Earth station antennas can be used for transmitting to satellites as well as receiving from them, and high powers can be used in transmitting (about three kilowatts [kW] for all channels combined).

Limitations. The maximum amount of communication available from satellites is limited by the number and bandwidth of frequency assignments and by other considerations. For a given bandwidth the amount of communication can be increased several ways. Sending independent signals on two polarizations doubles the communication capacity. The first use of two polarizations was on the domestic satellites Satcom, launched on December 12, 1975, and Comstar, launched on May 13, 1976. In addition, using narrow beams from satellites to various regions of the Earth allows reuse of the same frequencies.

The more satellites that can be used simultaneously in synchronous orbit, the greater the total communication capacity. Larger, and hence more directive, Earth station antennas allow the simultaneous use of more satellites. Some Intelsat satellites are spaced as closely as 3° from other satellites. Satellites spaced as far as 14° apart can interfere, however, if small Earth station antennas and correspondingly high powers are used. The U.S. Federal Communications Commission (FCC) has proposed that domestic satellites be spaced 2° apart, even though this spacing is considered too close by some experts.

SATELLITE TECHNOLOGY

Communication satellites are put into orbit by means of rocket launch vehicles, or boosters. During insertion into orbit control is maintained partly by inertial guidance, using gyroscopes and accelerometers, and partly by microwave radar observations, by means of which the position and velocity of the vehicle is determined and commands are given for correcting the orbit.

Launch sequence. Satellites are put into synchronous orbits in the plane of the Equator from sites that do not lie on the Equator. This requires adjusting the plane of the orbit during or after the initial launch phase. The first, or boost, stage lifts the satellite out of the atmosphere and gives it considerable velocity. When this stage burns out, it is separated from the satellite and other stages, falls to Earth, and is destroyed as it passes through the atmosphere. The fairing, which protects the payload (the satellite and associated final stages) as it passes through the atmosphere, is jettisoned. The second stage is then fired, putting the satellite into an intermediate orbit. After the second stage is jettisoned, it remains in orbit for some time. The perigee stage is then fired and ejected; this puts the satellite in an inclined elliptical orbit, an orbit whose apogee is at synchronous altitude (35,900 kilometres above the surface of the Earth). While the satellite is in this transfer orbit, tests are performed, and the satellite is positioned for the firing of the apogee motor, which is commonly built into the body of the satellite. (The Titan IIIC transtage can eject into synchronous orbit, so that no apogee motor is needed.) At the apogee of the transfer orbit, the apogee motor is fired, which puts the satellite in a circular synchronous orbit. Satellite antennas and the solar panels can then be extended and the satellite put into its final physical configuration.

The orbit at this point will not be exactly right, nor will the satellite have the correct attitude (point in the right direction). Throughout the life of the satellite the attitude must be controlled and the station kept (the orbit adjusted), because irregularities in the gravitational fields of the Earth, Sun, and Moon—as well as the pressures of light from the Sun and of the solar wind—tend to change the attitude and station.

Launch vehicles. Advances in satellite communication have been made possible by the development of powerful boosters that can launch heavier satellites. In the early 1960s Syncom was launched by a Delta vehicle, which at that time was just able to insert the 39-kilogram satellite into a synchronous orbit. By the 1980s the Delta vehicle could launch a satellite such as the 550-kilogram SBS (Satellite Business System). Heavier satellites, such as Intelsat 5, which weighs almost 2,000 kilograms, can be launched with the Atlas-Centaur. Military satellites have been launched with these vehicles, and several at a time have been launched with the more powerful Titan IIIC.

Figure 3 shows the relative sizes of various launch vehicles. All of the launch vehicles used through the early 1980s—the Delta, Atlas-Centaur, and Titan—have been refinements and developments of military ballistic missiles—the Thor, Atlas, and Titan, respectively. The Japanese N launch, in some ways similar to the U.S. Delta, is a civilian vehicle. The French Ariane, which has made several successful flights, is a civilian vehicle with capabilities somewhat greater than the Delta or Atlas-Centaur; in its most powerful configuration it should be capable of launching two communication satellites, and a number of commitments have been made to use the Ariane to launch commercial satellites. The U.S. sts (Space Transportation System), or space shuttle, is a manned vehicle; the

Control

and
station

The
reusable
U.S.
space
shuttle

manned portion is recoverable through a gliding landing on an airfield, and the solid rocket shells through descent into the ocean by parachute. The space shuttle itself can put a payload consisting of several satellites into a low Earth orbit. Propulsion such as the Inertial Upper Stage (IUS), under development in the early 1980s, or propulsion incorporated in the satellite itself is necessary for insertion into synchronous orbit. The first use of the space shuttle for commercial satellite communication was scheduled for late 1982, with the launching of both an SBS and a Canadian Anik satellite.

The space shuttle is designed to put up to 30,000 kilograms into a low orbit. Manned space shuttle flights might make it possible to assemble or to repair large communication satellites in low Earth orbit. Assembly in orbit would be extremely expensive, however, and does not appear to be necessary. Space shuttle plans provide no means for sending astronauts into synchronous orbit, where they would have to go in order to repair communication satellites. In addition, communication satellites have proved to be very long-lived; they tend to become obsolete before they wear out. Repair costs may greatly exceed the cost of launching a new satellite. (See also SPACE EXPLORATION: Space programs.)

Attitude
control
by
pulsed
jets

Attitude control and station keeping. In the Syncom and Intelsat 1 satellites, the entire satellite, including the antenna, spun stably around the axis of maximum moment of inertia. Adjustments in axis of spin, or attitude, in rate of spin, and in orbit, or station keeping, were made by an ingenious scheme in which either of two jets were pulsed on briefly. One jet had an off-centre axial thrust and could be used to control both the axis of spin and the plane of the orbit. The other jet had a radial thrust and could be used to alter orbital speed and hence to adjust the period and the eccentricity of the orbit. This scheme of pulsed jet control, which was invented by Harold A. Rosen and Donald Williams, has been used in most later satellites in which the body of the satellite spins in order to attain a stable attitude. Two sets of pulsed jets are provided to guard against failure.

Intelsat 3, launched in 1968, and all subsequent spinning satellites have had motor-driven, despun platforms at one end, so that antennas can be pointed stably at some point on Earth. Pointing is usually achieved by means of an optical or infrared Earth sensor, which provides a reference for pointing at the Earth. In Intelsat 4, 4A, and 5 and in Comstar a Sun sensor and a clock are used as well. Pointing also can be done by ground command. Pointing is attained by attitude control and by regulating the rate of the motor that drives the despun platform.

Early spinning satellites had a serious disadvantage. A spinning body is stable only if it spins about its axis of maximum moment of inertia; a lossy damper (such as sloshing fluid) will then diminish any periodic nutation, or nodding, of the axis. If the spin is not about the axis of maximum moment of inertia, the damper will cause the nutation to increase rather than diminish, and the satellite will tumble. This arrangement suggested that spinning satellites had to be short along the axis of spin and that only a small satellite could be fitted into a fairing of practical diameter. Anthony Iorillo found theoretically that, if the damping were put in the despun platform rather than in the body of the satellite, the satellite could spin stably around an axis that was not the axis of maximum moment of inertia; his discovery made longer, narrower spinning satellites possible. This feature was first incorporated in a military satellite, Tacsat (tactical communication satellite), launched in 1969, and has been used in most subsequent spinning satellites.

Three-axis
stabilization

The alternative to attitude control by spinning the body of the satellite and despinning the antenna platform is to control the attitude of the body of the satellite with respect to the Earth (body stabilization). If all three axes of the body are stable with respect to the Earth, as is necessary in pointing an antenna at a particular point on Earth, the satellite must have three-axis stabilization. Three-axis stabilization has been used in many types of space vehicles. A satellite with such stabilization must use jets for station keeping and for gross corrections of attitude.

Routine maintenance and corrections of attitude are made by means of spinning inertia wheels. These have a stabilizing effect, and small changes in the rate of spin can cause the body of the satellite to rotate. All Soviet communication satellites, starting with the first Molniya satellite in 1965, have been body-stabilized. The first U.S. operational satellites to use three-axis stabilization were RCA's Satcom, launched in 1975; the LES (Lincoln Experimental Satellite) 8 and 9, launched in 1976; FLTSATCOM (Fleet Satellite Communications), a military satellite launched in 1978; and Intelsat 5, launched in 1980.

In spinning satellites the solar cells that provide electric power cover the outer cylindrical surface. As the satellite spins, half of the cells are shadowed from the Sun, and most do not face the Sun directly. In a three-axis stabilized satellite the solar cells are placed on panels that can be rotated so that they directly face the Sun. Erecting the solar panels and the antenna arrays on a three-axis stabilized satellite, however, are more complicated operations than deploying the antennas on a spinning satellite. By the early 1980s, of U.S.-made satellites, more spinning satellites were in operation and under construction than three-axis stabilized satellites. Further, Intelsat 6, unlike Intelsat 5, was designed to be a spinning satellite.

Electronic technology. Solar cells are the universal source of electric power in operational communication satellites, although some experimental satellites have used thermoelectric generators heated by radioisotopes. A synchronous satellite, which is eclipsed by the Earth during two 44-day seasons each year, for times as long as 70 minutes, carries secondary batteries to provide power during the eclipse. The power necessary for the operation of a communication satellite is considerable; the solar cells of Intelsat 4A, for example, provide 600 watts.

The most common source of microwave power for transmitting signals from communication satellites is the traveling-wave tube. Transistors have been used in some transmitters, but by the early 1980s they were not as efficient for microwave frequencies as were traveling-wave tubes. Linearity is another consideration when signals from Earth stations must be transmitted through the same transponder. As improvements are made, the transistor or some other solid-state amplifier may eventually replace the traveling-wave tube, the last vacuum tube used in communication satellites.

As was noted, it is important to have a low-noise receiver at an Earth station in order to reduce the signal power that must be transmitted from the satellite. In some early satellite experiments a very low-noise microwave amplifier, called a maser, was used. The maser is expensive, for it must operate at the temperature of liquid helium, only slightly above absolute zero. The signal received from a satellite is weakest during a rainstorm. Unfortunately, during a rainstorm a considerable amount of Johnson noise is received, corresponding to a temperature of more than 200 kelvins. For this reason there is little advantage in using a receiver with a noise temperature below the 50 kelvins that can be attained with a parametric amplifier. Thus, parametric amplifiers rather than masers are used even in large and costly Earth stations.

Almost all electronic functions in satellites are carried out by means of solid-state devices, especially transistors, which are used to generate and amplify signals and to operate various control functions. LSI and VLSI (large-scale integration and very large-scale integration) circuits, in which many complex on-off or digital functions are performed by a silicon chip about 0.4 square centimetre ($\frac{1}{16}$ square inch) in size, have come to play an increasingly important part in satellite communication.

An important advance has been the production, by Western Electric, of an LSI chip that can be used to cancel echoes. Telephone calls that are transmitted by satellite reach a home or an office over a single pair of wires that transmits the voice to and from the telephone. A speaker can often hear a faint echo of his own voice. If this is much delayed, talking becomes difficult. For this reason, in circuits longer than 2,400 kilometres, echo suppressors are used to prevent or reduce an incoming signal while a speaker is talking. In satellite communication it takes a

Echo
suppressors

signal almost 0.3 second to reach the satellite and return to Earth, and echoes of one's voice are heard about 0.6 second after speaking. When echo suppressors are used in a circuit with so great a time delay, they sometimes cause a speaker to miss remarks of the other party. Tests show that satellite circuits with echo suppressors are rated by users as considerably inferior to usual telephone circuits. The echo-cancelling chip can detect the presence of echoes by comparing the incoming signal with the outgoing signal and can add artificial echoes that cancel those present in the communication circuit. This arrangement makes satellite circuits comparable in quality to ordinary telephone circuits. The idea of cancelling echoes is an old one, but it became economically feasible only through LSI.

Although satellites use both wide-deviation frequency modulation (FM) and digital transmission of voice by pulse-code modulation in order to conserve power and reduce interference, the trend is toward digital transmission. In part this is a general trend in all voice communication, in switching as well as in transmission. Digital transmission also is more efficient than FM when more than one Earth station uses the same satellite repeater. If several FM signals are sent through one repeater, the transponder must operate at a reduced power level in order to reduce nonlinearities that cause one signal to interfere with the others. In digital transmissions Earth stations can be assigned different, short repetitive time intervals for their transmissions (time-division multiplex), and the repeater can operate at full power.

Time-division multiplex requires that Earth stations operate synchronously and send out bursts of data at specific times, so as not to interfere with one another. Besides being more efficient, time-division multiplex makes it easy to switch between channels groups of data that occur in particular time intervals. Time-division switching makes the use of satellite communication much more flexible, and it is becoming a standard feature of satellites. This function, of course, requires complex digital operations, for which LSI and VLSI are ideally suited.

LSI and VLSI also can be useful in controlling the antenna beam position in satellites. The beam direction can be changed by shifting the phases of the microwave signals sent to various feed horns that illuminate the antenna dish, or reflector. For use in satellites all solid-state devices, including LSI and VLSI, must be highly reliable, and they should not be harmed by the low-level but penetrating radiation that is found at synchronous altitudes.

SATELLITE SYSTEMS

Several satellites of the same or of different designs used in communicating among a group of Earth stations form a satellite communication system. A system may provide international communication, as does the Intelsat system, or both international and domestic communication; the Soviet Intersputnik organization provides communication within the Soviet Union and among countries of the Soviet bloc. Other satellite systems provide regional or domestic communication. Some systems, such as the Marisat and Marecs and a number of military satellites, provide mobile communication, primarily to ships. Other satellites serve military uses only. Several experimental satellites have been launched, and there are some satellites reserved for use by amateur radio operators.

Intelsat. The first use of communication satellites was to provide international communication. When the U.S. Congress passed the Communications Satellite Act in 1962, creating Comsat and giving it a U.S. monopoly on international satellite communication, no clear provision was made for supplying other forms of satellite service.

International satellite communication required the participation of other nations. Intelsat originated as a joint venture in August 1964, when 11 countries signed agreements to form a global communication system. It has become an international legal entity, which by 1980 had an owner's investment of about \$672,000,000, and in which more than 100 countries held investment shares. Comsat is the designated U.S. participant in Intelsat, which is responsible for the design, development, and maintenance of the space segment of the global telecommunication system.

Earth stations used for international communication are owned and operated by entities in the countries in which they are located.

Nations that are not members of Intelsat, including those that cannot join because they are not recognized by the United Nations, can obtain satellite communication through Comsat General, a domestic subsidiary of Comsat. An example is Taiwan, which has a large international telecommunications traffic.

By the 1980s the Intelsat system included about 400 Earth stations with some 500 antennas, located in about 150 countries. By 1980 Intelsat was providing about 20,000 two-way telephone circuits that were leased full time and a great deal of television and other transmission.

By 1981 Intelsat had successfully launched 24 satellites, of which eight were either primary (serving all countries) or major (serving a few countries with heavy traffic), or were providing leased transponders; three satellites were available for limited use or for contingencies. The advance in satellite communication has been outstanding. Intelsat 1, launched in 1965, has one transponder, which provides 240 two-way telephone circuits or one television channel. Intelsat 5, launched in 1980, provides 12,000 telephone circuits and two television channels. Intelsat 1 operates in the 6/4-gigahertz band only. In Intelsat 5 the 6/4-gigahertz frequencies are used four times, and the 14/11-gigahertz frequencies are used twice. Intelsat 5 also has six communication antennas: two global-coverage beams, two hemispheric beams, and two steerable spot beams. The specifications for additional Intelsat satellites provide for even greater capabilities.

The reduction in rates for satellite communication also has been remarkable. The annual charge for satellite use per telephone circuit dropped from \$64,000 in 1965 to \$9,360 in 1981.

Soviet satellites. There are two major types of Soviet satellites. The Molniya satellites, first launched in 1965, are placed in elliptical orbits with a 65° inclination. At this angle the perigee moves very slowly, and the apogee remains in the Northern Hemisphere. Under suitable conditions, the angular velocity near apogee roughly matches the angular velocity of the Earth, and the satellite appears almost stationary in the sky. The satellite is positioned over the Soviet Union every other revolution for about eight hours. Due to its inclination, the Molniya satellite is visible in the most northerly regions of the Soviet Union, where a synchronous satellite would be below the horizon. The second type of Soviet communication satellite is the Statsionar. It is a synchronous satellite and was first launched in 1975.

By the end of 1979, 75 Molniya satellites had been launched, of which 28 were known to be out of service. Only one of the 14 synchronous satellites launched was no longer operating. Technical details of Soviet satellites are known only in part. Their communication capacity appears to be less than that of Intelsat satellites.

Domestic systems. Some domestic satellite systems have been established because the communication they provide would be difficult to obtain in any other way. Canada's Telesat system provides communication to the sparsely populated regions of the Northwest Territories as well as to the nation's urban areas. Indonesia's Palapa system provides communication among many islands that would be hard to link otherwise.

Domestic satellite systems in the United States add communication capacity to a range of other communication channels. Such satellite service has several advantages. In the distribution of programs for cable television the same signal must be sent simultaneously to stations in many parts of the country. The transmission of plates from which newspapers and magazines can be printed simultaneously in many locations is a similar application. Satellites can provide many additional long-distance circuits more quickly than laying cables or building ground microwave systems. Once in place, a satellite system can be used to supplement other long-haul facilities when they become overloaded because of regional changes in traffic or because of disasters. The SBS, for example, provides large industries with private networks in which the Earth

station is on company premises, thus avoiding the use of cables or ground microwave systems to link the networks to communication facilities.

Canada. Canada's Telesat system uses satellites, called Anik, built by U.S. companies. Three Anik A satellites were in service by the early 1980s; the first was launched in 1972. They have antennas with beams that cover Canada and have 12 transponders. One Anik B satellite, launched in 1978, has 12 transponders in the 6/4-gigahertz band that cover all of Canada and six transponders in the 14/12-gigahertz band that serve a fourth of the nation. Advanced Anik satellites have been designed.

Indonesia. The first two satellites of Palapa A, Indonesia's satellite system, were launched in 1976 and 1977. They are of the Anik A type, and the antenna beams cover some 3,000 islands. The larger and more powerful Palapa B system is designed to use both polarizations and to have 24 transponders.

United States. The United States has the greatest number of domestic satellites. Western Union launched two Westar satellites in 1974 and one in 1979. These operate in the 6/4-gigahertz band and have 12 transponders. The antennas cover the conterminous United States and, with less power, Alaska and Hawaii. Plans have been made for a TDRSS, or Advanced Westar, satellite (TDRSS stands for Tracking and Data Relay Satellite to Satellite) to be used for domestic communication and for picking up signals from various spacecraft and relaying them to Earth. Launch of this satellite is possible only with the space shuttle.

RCA launched Satcom satellites in 1975, 1976, and 1981. These operate in the 6/4-gigahertz band, use both polarizations, and have 24 transponders. Half of the transponders are used in conjunction with separate antennas so that they cover Hawaii as well as the rest of the United States; the other transponders cannot be used for traffic with Hawaii.

Four Comstar satellites were in service by the early 1980s; the first was launched in 1976. They are Comsat General satellites, but their entire communication capacity is leased by AT&T. The satellites operate in the 6/4-gigahertz band and use both polarizations to provide 24 transponders. Communication is provided within all of the United States, including Alaska, Hawaii, and Puerto Rico. In 1981 AT&T ordered three advanced communication satellites, called Telstar 3, which can operate in a higher frequency and have an increased life expectancy of 10 years, instead of the average seven years.

SBS is a joint venture of Comsat General, Aetna Life and Casualty, and IBM (International Business Machines). It launched its first satellite in 1980 and its second in 1981. SBS satellites operate with small ground terminals that use antennas with diameters of 5.5 and 7.7 metres. They provide high-speed networks for large organizations that have multiple, dispersed locations, and they supply data, telephone, teleconferencing and other communication services. The organization using the service owns the Earth station and the rest of the ground-based communication equipment. Service to smaller enterprises is under way. The SBS satellites operate in the 14/12-gigahertz range. The antenna beams cover the United States and the lower part of Canada.

Maritime communication. In general, mobile satellite communication is difficult because of the problem of placing microwave antennas on vehicles. Some narrow-band communication can be provided by ultrahigh frequency (UHF) using essentially nondirectional antennas, but the amount is limited. In contrast to automobiles and airplanes, ships are suitable platforms for microwave antennas of moderate size; the first commercial mobile service was to ships.

The Marisat system, developed by Comsat General, began serving both the U.S. Navy and commercial shipping in 1976. Three satellites were launched, operating in three frequency ranges. The UHF capability, in the 300/250-megahertz band, was leased by the U.S. Navy for five years. Commercial maritime traffic is carried in the 1.6/1.5-gigahertz range. The 6/4-gigahertz range is used for commercial communication links between satellites and

Earth stations on both coasts of the United States. Each satellite provides 16 voice and 88 telex channels in the high-power mode (60 watts transmitter power), eight voice and 44 telex channels in the medium-power mode (27 watts), and one voice and 44 telex channels in the low-power mode (seven watts). By 1980 ships flying the flags of more than 35 nations were using Marisat, and more than 460 shipboard terminals had been commissioned for operation with the satellites.

Inmarisat (International Maritime Satellite Organization) was established in July 1979; Comsat was designated the U.S. participant. Marecs, the first Inmarisat satellite, was launched in 1981 from French Guiana, using an Ariane vehicle. Marecs are designed to communicate between shore and satellite in the 6/4-gigahertz band and between ship and satellite in the 1.6/1.5-gigahertz band. By 1982 Marecs had become the primary satellite for Atlantic communication and with Comsat's Marisat was used for the primary Indian and Pacific coverage; Inmarisat provided worldwide maritime service to about 1,200 ships.

Military satellites. In 1960 ARPA (Advanced Research Projects Agency of the U.S. Department of Defense) proposed an elaborate military communication satellite called Advent. The satellite proved far beyond the state of the art and was abandoned in 1962. In June 1965 the Department of Defense directed the U.S. Air Force to launch simple near-synchronous satellites in equatorial orbits. Some 26 of these IDCSF (Initial Defense Communication Satellite Program, later renamed Initial Defense Satellite Communication System [IDSCS]) satellites were launched from 1966 to 1968, usually eight at a time, using the Titan IIIC vehicle. Although these satellites provided useful communication, they were soon outdated.

Tacsat, a large and elaborate communication satellite, was launched for the U.S. Air Force early in 1969 but failed at the end of 1972.

By the early 1980s the major U.S. military communication satellites were the DSCS 2 and FLTSATCOM satellites. The DSCS 2 satellite, of which 10 had been successfully launched by 1981, is a spinning satellite with both global coverage and spot beam antennas. It has a capacity of 1,300 two-way voice circuits. The uplink frequency band ranges from 7.9 to 8.4 gigahertz; the downlink varies from 7.25 to 7.75 gigahertz. The FLTSATCOM satellite began operation in 1978, and by 1981 five had been launched. Each satellite provides high-frequency communication between military forces through more than 20 channels.

Eight LES satellites of various types were launched from 1965 through 1976. These were used to explore various frequencies and to conduct experiments with steerable antenna beams and in nulling against jamming.

The initial requirement of U.S. military satellites was that they provide adequate and reliable communication. The armed forces have become more and more dependent on satellite communication for both strategic and tactical use, but it had become increasingly apparent by the 1980s that existing military satellites would be vulnerable in a number of ways during a war: to jamming by high-power ground-based jammers; to destruction of ground facilities that are used in connection with satellite station keeping and internal operation; to high-altitude nuclear explosions, whose electromagnetic fields and radiation could destroy or cause errors in the operation of satellite electronic equipment; and, finally, to enemy antisatellite weapons. In the future military communication satellite systems will diverge increasingly from commercial systems in several respects.

New, more survivable military satellites will utilize broad bandwidths to transmit comparatively small amounts of teletypewriter and coded voice communication, which works against jamming and allows operation with relatively small Earth antennas. Multiple steerable satellite antenna transmitting and receiving beams also will be helpful in both respects. Electronic equipment aboard the satellites will be both shielded against electromagnetic radiation and made to withstand radiation. Satellites will be made more autonomous; that is, their operations will be made to depend less on control from Earth. Some

protection will be provided against direct attack. It is believed that such a military satellite system can provide vital communication to small land-, ship-, and aircraft-based terminals even during major hostilities.

JDSCP satellites were used to provide early communication for the North Atlantic Treaty Organization (NATO). Two NATO satellites were launched in 1971 and 1972, and three NATO 3 satellites were launched in 1976, 1977, and 1978. The NATO 2 satellites are spinning satellites, with an antenna coverage optimized for NATO use. The up-band is 7.976–8.005 gigahertz, and the down-band is 7.257–7.286 gigahertz. The NATO 3 satellite has one global beam antenna and one spot beam antenna for Europe; it operates in about the same frequency band as NATO 2. Skynet 1 and 2 are British satellites. They were launched in 1969 and 1974 and are similar to DSCS 2.

The United States has planned two chief military satellites: DSCS 3 and LEASAT. The communication capacity of DSCS 3 is with a 7.9–8.4-gigahertz uplink and a 7.25–7.75-gigahertz downlink. A channel with a 300–400-megahertz uplink and a 225–260-megahertz downlink is designed for communication with UHF equipment. LEASAT, to be built and operated by Hughes Aircraft Company and leased for military use, is designed for launch from the space shuttle to provide UHF communication.

Amateur satellites. From 1961 to 1978 the United States successfully launched eight OSCAR (Orbiting Satellite Carrying Amateur Radio) satellites for the use of amateur radio operators; by 1980 five remained, OSCAR 7 has two channels: a 145.85–145.95-megahertz uplink with a 29.40–29.50-megahertz downlink and a 432.125–432.175-megahertz uplink with a 145.925–145.975-megahertz downlink. In 1978 the Soviet Union launched two RS satellites for amateur use.

Experimental satellites. In addition to early experimental satellites such as Echo, Telstar, and Syncom, a large number of other experimental satellites have been launched. NASA launched a series of ATS's (Applications Technology Satellite) that were used mainly to explore various technological features and to gather data on microwave propagation. The last satellite in the series, ATS 6, was used in an experiment in India for direct broadcasting of educational programs to receiving equipment in numerous villages.

There were several joint ventures in the mid-1970s. Two French-German Symphonie satellites were launched in 1974 and 1975. These three-axis stabilized satellites have global and spot beams in the 6/4-gigahertz band and four transponders. The CTS (Communications Technology Satellite), or Hermis, a U.S.-Canadian experimental satellite launched in 1976, operates in the 14/11-gigahertz band. It has a high-power (200 watts) transmitter for use with small Earth stations, as well as a transmitter of moderate power. Among other options, it can transmit FM television with up to three simultaneous channels.

Other programs include the Italian Sirio, launched in 1977, with beams that cover Europe. The European Space Agency's OTS (Orbital Test Satellite), a three-axis satellite, was launched in 1978. It operates in the 14/12-gigahertz band, uses dual polarization, two European spot beams, and six repeaters of various bandwidth.

Japan had two major experimental programs by the late 1970s. The CS, or Sakura satellite, launched in 1977, has six repeaters in the 30/20-gigahertz band and two repeaters in the 20/18-gigahertz band. The BSE (Medium-Scale Broadcasting Satellite for Experimental Purposes), or Yuri satellite, was launched in 1978 and operates in the 14/12-gigahertz range. It can transmit two FM high-power (100 watts) colour television signals to Japan for experimental broadcasting to homes.

Disadvantages and prospects. Satellites cannot provide separate circuits to individual homes and offices, as can telephone wires, cables, and optical fibres. Although the SBS can link various corporate locations, wires, cables, or fibres must connect individual users to the Earth station. Thus cables compete successfully with satellites between Europe and the United States, and cables with optical fibres are expected to perform even more successfully. The amount of communication that satellites can provide

is limited further by the number of orbital positions and the frequencies available.

Although it was suggested early in the history of satellite communication, the advantages of direct broadcasting of television signals from satellites to individual users has been questioned. The U.S. experimental Intelsat 4 (1974) was used for a time by India to broadcast educational programs to villages. The joint U.S.-Canadian CTS satellite (1976) had a transmitter powerful enough to transmit television signals to small Earth stations. The Japanese Yuri satellite (1978) was capable of transmitting television signals to small rooftop antennas, but part of the motivation for doing this was a law that required television service to all parts of Japan, a country with regions where cable is uneconomical and reception from Earth-based transmitters impractical. In the United States, by the early 1980s, a number of people had erected antennas to pick up cable and network television programs relayed by satellite. One satellite alone relayed 24 channels, but tens of channels were available from other satellites.

The practicality of commercial direct-to-user satellite television service should be settled in the 1980s. Comsat has announced plans to initiate such service early in 1986. It would begin with a satellite providing three television channels to the most densely populated Eastern states. Ultimately, four satellites would cover the U.S. time zones. The satellites would operate in the 12/14-gigahertz band, and the transmitters would be powerful enough to allow reception with a small rooftop antenna.

Satire

"Satire" is a protean term. Together with its derivatives, it is one of the most heavily worked literary designations and one of the most imprecise. The great English lexicographer Samuel Johnson defined satire as "a poem in which wickedness or folly is censured," and more elaborate definitions are rarely more satisfactory. No strict definition can encompass the complexity of a word that signifies, on one hand, a kind of literature—as when one speaks of the satires of the Roman poet Horace or calls the American novelist Nathanael West's *A Cool Million* a satire—and, on the other, a mocking spirit or tone that manifests itself in many literary genres but can also enter into almost any kind of human communication. Wherever wit is employed to expose something foolish or vicious to criticism, there satire exists, whether it be in song or sermon, in painting or political debate, on television or in the movies. In this sense satire is everywhere. Although this article deals primarily with satire as a literary phenomenon, it records its manifestations in a number of other areas of human activity.

THE NATURE OF SATIRE

Historical definitions of satire. The terminological difficulty is pointed up by a phrase of the Roman rhetorician Quintilian: *satura tota nostra est* ("satire is wholly our own"). Quintilian seems to be claiming satire as a Roman phenomenon, although he had read the Greek dramatist Aristophanes and was familiar with a number of Greek forms that one would call satiric. But the Greeks had no specific word for satire; and by *satura* (which meant originally something like "medley" or "miscellany" and from which comes the English "satire") Quintilian intended to specify that kind of poem "invented" by Lucilius, written in hexameters on certain appropriate themes, and characterized by a Lucilian-Horatian tone. *Satura* referred, in short, to a particular poetic form, established and fixed by Roman practice. (Quintilian mentions also an even older kind of satire written in prose by Marcus Terentius Varro and, one might further add, by Menippus and his followers Lucian and Petronius.) After Quintilian's day the term *satura* began to be used metaphorically to

Direct
television
broadcasts

designate works that were "satirical" in tone but not in form. As soon as a noun enters the domain of metaphor, as one modern scholar has pointed out, it clamours for extension; and *satura* (which had had no verbal, adverbial, or adjectival forms) was immediately broadened by appropriation from the Greek word for "satyr" (*satyros*) and its derivatives. The odd result is that the English "satire" comes from the Latin *satura*; but "satirize," "satiric," etc., are of Greek origin. By about the 4th century AD the writer of satires came to be known as *satyricus*; St. Jerome, for example, was called by one of his enemies "a satirist in prose" ("satyricus scriptor in prosa"). Subsequent orthographic modifications obscured the Latin origin of the word satire: *satura* becomes *satyra*, and in England, by the 16th century, it was written "satyre."

Elizabethan writers, anxious to follow Classical models but misled by a false etymology, believed that "satyre" derived from the Greek *satyr* play: satyrs being notoriously rude, unmannerly creatures, it seemed to follow that "satyre" should be harsh, coarse, rough. The English author Joseph Hall wrote:

The Satyre should be like the Porcupine,
That shoots sharpe quills out in each angry line,
And wounds the blushing cheek, and fiery eye,
Of him that heares, and readeth guiltily.

(*Virgidemiarum*, V, 3, 1–4.)

The false etymology that derives satire from satyrs was finally exposed in the 17th century by the Classical scholar Isaac Casaubon; but the old tradition has aesthetic if not etymological appropriateness and has remained strong.

In the prologue to his book, Hall makes a claim that has caused confusion like that following from Quintilian's remark on Roman satire. Hall boasts:

I first adventure: follow me who list,
And be the second English Satyrist.

But Hall knew the satirical poems of Geoffrey Chaucer and John Skelton, among other predecessors, and probably meant that he was the first to imitate systematically the formal satirists of Rome.

Influence of the satires of Horace and Juvenal. By their practice, the great Roman poets Horace and Juvenal set indelibly the lineaments of the genre known as the formal verse satire and, in so doing, exerted pervasive, if often indirect, influence on all subsequent literary satire. They gave laws to the form they established, but it must be said that the laws were very loose indeed. Consider, for example, style. In three of his Satires (I, iv; I, x; II, i) Horace discusses the tone appropriate to the satirist who out of a moral concern attacks the vice and folly he sees around him. As opposed to the harshness of Lucilius, Horace opts for mild mockery and playful wit as the means most effective for his ends. Although I portray examples of folly, he says, I am not a prosecutor and I do not like to give pain; if I laugh at the nonsense I see about me, I am not motivated by malice. The satirist's verse, he implies, should reflect this attitude: it should be easy and unpretentious, sharp when necessary, but flexible enough to vary from grave to gay. In short, the character of the satirist as projected by Horace is that of an urbane man of the world, concerned about folly, which he sees everywhere, but moved to laughter rather than rage.

Juvenal, over a century later, conceives the satirist's role differently. His most characteristic posture is that of the upright man who looks with horror on the corruptions of his time, his heart consumed with anger and frustration. Why does he write satire? Because tragedy and epic are irrelevant to his age. Viciousness and corruption so dominate Roman life that for an honest man it is difficult not to write satire. He looks about him, and his heart burns dry with rage; never has vice been more triumphant. How can he be silent (Satires, I)? Juvenal's declamatory manner, the amplification and luxuriousness of his invective, are wholly out of keeping with the stylistic prescriptions set by Horace. At the end of the scabrous sixth satire, a long, perfervid invective against women, Juvenal flaunts his innovation: in this poem, he says, satire has gone beyond the limits established by his predecessors; it has taken to itself the lofty tone of tragedy.

The results of Juvenal's innovation have been highly confusing for literary history. What is satire if the two poets universally acknowledged to be supreme masters of the form differ so completely in their work as to be almost incommensurable? The formulation of the English poet John Dryden has been widely accepted. Roman satire has two kinds, he says: comical satire and tragical satire, each with its own kind of legitimacy. These denominations have come to mark the boundaries of the satiric spectrum, whether reference is to poetry or prose or to some form of satiric expression in another medium. At the Horatian end of the spectrum, satire merges imperceptibly into comedy, which has an abiding interest in the follies of men but has not satire's reforming intent. The distinction between the two modes, rarely clear, is marked by the intensity with which folly is pursued: fops and fools and pedants appear in both, but only satire tries to mend men through them. And, although the great engine of both comedy and satire is irony, in satire, as the 20th-century critic Northrop Frye has said, irony is militant.

Boileau, Dryden, and Alexander Pope, writing in the 17th and 18th centuries—the modern age of satire—catch beautifully, when they like, the deft Horatian tone; however, satire's wit can also be sombre, deeply probing, and prophetic, as it explores the ranges of the Juvenalian end of the satiric spectrum, where satire merges with tragedy, melodrama, and nightmare. Pope's *Dunciad* ends with these lines:

Lo! thy dread Empire, CHAOS! is restor'd;
Light dies before thy uncreating word:
Thy hand, great Anarch! lets the curtain fall;
And Universal Darkness buries All.

It is the same darkness that falls on Book IV of Jonathan Swift's *Gulliver's Travels*, on some of Mark Twain's satire—The Mysterious Stranger, *To The Person Sitting in Darkness*—and on George Orwell's *1984*.

Structure of verse satire. Roman satire is hardly more determinate in its structure than in its style; the poems are so haphazardly organized, so randomly individual, that there seems little justification for speaking of them as a literary kind at all. Beneath the surface complexity of the poems, however, there exists, as one modern scholar has pointed out, a structural principle common to the satires of the Roman poets and their French and English followers. These poems have a bipartite structure: a thesis part, in which some vice or folly is examined critically from many different angles and points of view, and an antithesis part, in which an opposing virtue is recommended. The two parts are disproportionate in length and in importance, for satirists have always been more disposed to castigate wickedness than to exhort virtue.

Most verse satires are enclosed by a "frame." Just as a novel by the early-20th-century writer Joseph Conrad may be framed by a situation in which his narrator sits on a veranda in the tropics, telling his tale, stimulated into elaboration by the queries of his listeners, so the satire will be framed by a conflict of sorts between the satirist (or, more reasonably, his persona, a fictive counterpart, the "I" of the poem) and an adversary. Usually the adversary has a minor role, serving only to prod the speaker into extended comment on the issue (vice or folly) at hand; he may be sketchily defined, or he may be as effectively projected as Horace's Trebatius (Satires, II, i) or his awful bore (I, vi) or his slave Davus, who turns the tables on his master (II, vii). Similarly, the background against which the two talk may be barely suggested, or it may form an integral part of the poem, as in Horace's "Journey to Brundisium" (I, v) or in Juvenal's description of the valley of Egeria, where Umbricius unforgettably pictures the turbulence and decadence of Rome (Satires, III). In any event, the frame is usually there, providing a semidramatic situation in which vice and folly may reasonably be dissected.

The satirist has at his disposal an immense variety of literary and rhetorical devices: he may use beast fables, dramatic incidents, fictional experiences, imaginary voyages, character sketches, anecdotes, proverbs, homilies;

the satirist

he may employ invective, sarcasm, burlesque, irony, mockery, raillery, parody, exaggeration, understatement—wit in any of its forms—anything to make the object of attack abhorrent or ridiculous. Amid all this confusing variety, however, there is pressure toward order—internally, from the arraignment of vice and appeal to virtue, and externally, from the often shadowy dramatic situation that frames the poem.

The satiric spirit. Thus, although the formal verse satire of Rome is quantitatively a small body of work, it contains most of the elements later literary satirists employ. When satire is spoken of today, however, there is usually no sense of formal specification whatever; one has in mind a work imbued with the satiric spirit—a spirit that appears (whether as mockery, raillery, ridicule, or formalized invective) in the literature or folklore of all peoples, early and late, preliterate and civilized. According to Aristotle (*Poetics*, IV, 1448b–1449a), Greek Old Comedy developed out of ritualistic ridicule and invective—out of satiric utterances, that is, improvised and hurled at individuals by the leaders of the phallic songs. The function of these “iambic” utterances, it has been shown, was magical; they were thought to drive away evil influences so that the positive fertility magic of the phallus might be operative. This early connection of primitive “satire” with magic has a remarkably widespread history.

In the 7th century BC, the poet Archilochus, said to be the “first” Greek literary satirist, composed verses of such potency against his prospective father-in-law, Lycambes, that he and his daughter hanged themselves. In the next century the sculptors Bupalus and Athenis “knit their necks in halters,” it is said, as a result of the “bitter rimes and biting libels” of the satirical poet Hipponax. Similar tales exist in other cultures. The chief function of the ancient Arabic poet was to compose satire (*hiǧāʾ*) against the tribal enemy. The satires were thought always to be fatal, and the poet led his people into battle, hurling his verses as he would hurl a spear. Old Irish literature is laced with accounts of the extraordinary power of the poets, whose satires brought disgrace and death to their victims:

. . . saith [King] Lugh to his poet, “what power can you wield in battle?”

“Not hard to say,” quoth Carpre. . . . “I will satirize them, so that through the spell of my art they will not resist warriors.”

(“The Second Battle of Maytura,” trans. by W. Stokes, *Revue Celtique*, XII [1891], 52–130.)

According to saga, when the Irish poet uttered a satire against his victim, three blisters would appear on the victim’s cheek, and he would die of shame. One story will serve as illustration: after Deirdriu of the Sorrows came to her unhappy end, King Conchobar fell in love again—this time with the lovely Luaine. They were to be married; but, when the great poet Aithirne the Importunate and his two sons (also poets) saw Luaine, they were overcome with desire for her. They went to Luaine and asked her to sleep with them. She refused. The poets threatened to satirize her. And the story says:

The damsel refused to lie with them. So then they made three satires on her, which left three blotches on her cheeks, to wit, Shame and Blemish and Disgrace. . . . Thereafter the damsel died of shame

(“The Wooing of Luaine,” trans. by W. Stokes, *Revue Celtique*, XXIV [1903], 273–85.)

An eminent 20th-century authority on these matters adduces linguistic, thematic, and other evidence to show a functional relation between primitive “satire,” such as that of Carpre and Aithirne, and the “real” satire of more sophisticated times. Today, among various preliterate peoples the power of personal satire and ridicule is appalling; among the Ashanti of West Africa, for example, ridicule is (or was recently) feared more than almost any other humanly inflicted punishment, and suicide is frequently resorted to as an escape from its terrors. Primitive satire such as that described above can hardly be spoken of in literary terms; its affiliations are rather with the magical incantation and the curse.

SATIRICAL MEDIA

Literature. When the satiric utterance breaks loose from its background in ritual and magic, as in ancient Greece (when it is free, that is, to develop in response to literary stimuli rather than the “practical” impulses of magic), it is found embodied in an indefinite number of literary forms that profess to convey moral instruction by means of laughter, ridicule, mockery; the satiric spirit proliferates everywhere, adapting itself to whatever mode (verse or prose) seems congenial. Its targets range from one of Pope’s dunces to the entire race of man, as in *Satyr against Mankind* (1675), by John Wilmot, the earl of Rochester, from Erasmus’ attack on corruptions in the church to Swift’s excoriation of all civilized institutions in *Gulliver’s Travels*. Its forms are as varied as its victims: from an anonymous medieval invective against social injustice to the superb wit of Chaucer and the laughter of Rabelais; from the burlesque of Luigi Pulci to the scurilities of Pietro Aretino and the “black humour” of Lenny Bruce; from the flailings of John Marston and the mordancies of Francisco Gómez de Quevedo y Villegas to the bite of Jean de La Fontaine and the great dramatic structures of Ben Jonson and Molière; from an epigram of Martial to the fictions of Nikolay Gogol and of Günter Grass and the satirical utopias of Yevgeny Zamyatin, Aldous Huxley, and Orwell.

It is easy to see how the satiric spirit would combine readily with those forms of prose fiction that deal with the ugly realities of the world but that satire should find congenial a genre such as the fictional utopia seems odd. From the publication of Thomas More’s eponymous *Utopia* (1516), however, satire has been an important ingredient of utopian fiction. More drew heavily on the satire of Horace, Juvenal, and Lucian in composing his great work. For example, like a poem by Horace, *Utopia* is framed by a dialogue between “Thomas More” (the historical man a character in his own fiction) and a seafaring philosopher named Raphael Hythloday. The two talk throughout a long and memorable day in a garden in Antwerp. “More’s” function is to draw Hythloday out and to oppose him on certain issues, notably his defense of the communism he found in the land of Utopia. “More” is the adversary. Hythloday’s role is to expound on the institutions of Utopia but also to expose the corruption of contemporary society. Thus he functions as a satirist. Here Hythloday explains why Englishmen, forced off their land to make way for sheep, become thieves:

Forsooth . . . your sheep that were wont to be so meek and tame and so small eaters, now as I hear say, be become so great devourers and so wild, that they eat up and swallow down the very men themselves. They consume, destroy, and devour whole fields, houses, and cities. For look in what parts of the realm doth grow the finest and therefore dearest wool, there noblemen and gentlemen, yea and certain abbots, holy men no doubt, not contenting themselves with the yearly revenues and profits that were wont to grow to their forefathers and predecessors of their lands, nor being content that they live in rest and pleasure nothing profiting, yea, much annoying the weal-public, leave no ground for tillage. They enclose all into pastures; they throw down houses; they pluck down towns and leave nothing standing but only the church to be made a sheep-house.

(More’s *Utopia*, Everyman edition, 1951.)

Here are characteristic devices of the satirist, dazzlingly exploited: the beast fable compressed into the grotesque metaphor of the voracious sheep; the reality-destroying language that metamorphoses gentlemen and abbots into earthquakes and a church into a sheep barn; the irony coldly encompassing the passion of the scene. Few satirists of any time could improve on this.

Just as satire is a necessary element of the work that gave the literary form utopia its name, so the utopias of Lilliput, Brobdingnag, and Houyhnhnmland are essential to the satire of More’s great follower Jonathan Swift. He sent Gulliver to different lands from those Hythloday discovered, but Gulliver found the same follies and the same vices, and he employed a good many of the same rhetorical techniques his predecessor had used to expose them. *Gulliver’s Travels*, as one scholar points out, is a salute across the centuries to Thomas More. With this

Power of
ancient
satire

Use of
satire in
fictional
utopias

kind of precedent, it is not surprising that in the 20th century, when utopia turns against itself, as in Aldous Huxley's *Brave New World* (1932), the result is satire unrelieved.

Drama. The drama has provided a favourable environment for satire ever since it was cultivated by Aristophanes, working under the extraordinarily open political conditions of 5th-century Athens. In a whole series of plays—*The Clouds*, *The Frogs*, *Lysistrata*, and many others—Aristophanes lampoons the demagogue Cleon by name, violently attacks Athenian war policy, derides the audience of his plays for their gullible complacency, pokes fun at Socrates as representative of the new philosophical teaching, stages a brilliantly parodic poetic competition between the dramatists Aeschylus and Euripides in Hades, and in general lashes out at contemporary evils with an uninhibited and unrivalled inventiveness. But the theatre has rarely enjoyed the political freedom Aristophanes had—one reason, perhaps, that satire more often appears in drama episodically or in small doses than in the full-blown Aristophanic manner. In Elizabethan England, Ben Jonson wrote plays that he called "comical satyres"—*Every Man Out of His Humour*, *Poetaster*—and there are substantial elements of satire in Shakespeare's plays—some in the comedies, but more impressively a dark and bitter satire in *Timon of Athens*, *Troilus and Cressida*, *Hamlet*, and *King Lear*. The 17th-century comedy of Molière sometimes deepens into satire, as with the exposure of religious hypocrisy in *Tartuffe* or the railing against social hypocrisy by Alceste in *The Misanthrope*. George Bernard Shaw considered himself a satirist. He once compared his country's morals to decayed teeth and himself to a dentist, obliged by his profession to give pain in the interests of better health. Yet, as inventive and witty as Shaw is, compared to the 20th-century German playwright Bertolt Brecht, whose anatomizing of social injustice cuts deep, Shaw is a gentle practitioner indeed.

Motion pictures and television. The movies have sometimes done better by satire than the theatre, and it is in the movies that an ancient doctrine having to do with principles of decorum in the use of satire and ridicule has been exploded. The English novelist Henry Fielding was reflecting centuries of tradition when, in the preface to *Joseph Andrews* (1742), he spoke of the inappropriateness of ridicule applied to black villainy or dire calamity. "What could exceed the absurdity of an Author, who should write the *Comedy of Nero*, with the merry Incident of ripping up his Mother's Belly?" Given this point of view, Hitler seems an unlikely target for satire; yet in *The Great Dictator* (1940) Charlie Chaplin managed a successful, if risky, burlesque. Chaplin has written, however, that, determined as he was to ridicule the Nazi notions of a superrace, if he had known of the horrors of the concentration camps, he could not have made the film. Stanley Kubrick's *Dr. Strangelove; or, How I Learned to Stop Worrying and Love the Bomb* (1964) denies all limitation; through some alchemy Kubrick created an immensely funny, savagely satirical film about the annihilation of the world. A combination of farce and nightmare, *Dr. Strangelove* satirizes military men, scientists, statesmen—the whole ethos of the technological age—in the most mordant terms; it shows the doomsday blast, yet leaves audiences laughing. "You can't fight in here," says the president of the United States as doom nears, "this is the War Room." The film's tone is less didactic than in most powerful satire—the mushroom cloud carries its own moral—yet satire's full force is there.

Television has not proved a notably receptive medium. *That Was the Week That Was*, a weekly satirical review started in England in 1962, had remarkable success for a time but succumbed to a variety of pressures, some of them political; when a version of the program was attempted in the United States, it was emasculated by restrictions imposed by sponsors fearful of offending customers and by program lawyers wary of libel suits. Jonathan Swift said that he wrote to vex the world rather than divert it; it is not an attitude calculated to sell soap.

Festivals. Yet satire does much more than vex, and even in Swift's work there is a kind of gaiety that is found

in many nonliterary manifestations of the satirical spirit. Satire always accompanies certain festivals, for example, particularly saturnalian festivals. Many different cultures set aside a holiday period in which customary social restraints are abandoned, distinctions of rank and status are turned upside down, and institutions normally sacrosanct are subjected to ridicule, mockery, burlesque. The Romans had their Saturnalia, the Middle Ages its Feast of Fools; and in the 20th century many countries still have annual carnivals (Fasching in Austria, the Schnitzelbank in Basel, Switzerland, for example) at which, amid other kinds of abandon, an extraordinary freedom of satirical utterance is permitted. Even in Africa among the Ashanti, for whom ridicule has such terrors, there is a festival during which the sacred chief himself is satirized. "Wait until Friday," said the chief to the enquiring anthropologist, "when the people really begin to abuse me, and if you will come and do so too it will please me." Festivals such as these provide sanctioned release from social inhibition and repression, and, in these circumstances, satire directed at men in power or at taboo institutions acts as a safety valve for pent-up frustrations.

Satire may often function this way. A story is told that the 16th-century pope Adrian VI was highly offended at satirical verses written against him and affixed to Pasquino's statue (a famous repository for lampoons in Rome), but he became a willing target once he realized that his enemies vented otherwise dangerous hostility in this relatively harmless manner. Similar mechanisms operate today when, at a nightclub or theatre, audiences listen to satirical attacks on political figures or on issues such as racial discrimination, identify with the satirist, laugh at his wit, and thereby discharge their own aggressive feelings. Satire of this order is a far cry, of course, from that written by a Swift or Voltaire, whose work can be said to have a revolutionary effect.

Visual arts. The critique of satire may be conveyed even more potently in the visual arts than by way of the spoken or written word. In caricature and in what came to be known as the cartoon, artists since the Renaissance have left a wealth of startlingly vivid commentary on the men and events of their time. The names alone evoke their achievement: in England, William Hogarth, Thomas Rowlandson, Sir John Tenniel, Max Beerbohm; in France, Charles Philipon (whose slow-motion metamorphosis of King Louis-Philippe into a poire—that is, "fat-head," or "fool"—is classic) and Honoré Daumier; in Spain, Francisco Goya—out of Spain, Pablo Picasso; among recent political cartoonists, Sir David Low, Vicky (Victor Welsz), Herblock (Herbert Block), Conrad. The favourite medium of these men is the black-and-white print in which the satirical attack is pointed up by a brief verbal caption. The social impact of their art is incalculable. Dictators know this, and in times of social tension political cartoonists are among the first victims of the censor.

THE SATIRIST, THE LAW, AND SOCIETY

Indeed, the relations of satirists to the law have always been delicate and complex. Both Horace and Juvenal took extraordinary pains to avoid entanglements with authority—Juvenal ends his first satire with the self-protective announcement that he will write only of the dead. In England in 1599 the Archbishop of Canterbury and the Bishop of London issued an order prohibiting the printing of any satires whatever and requiring that the published satires of Hall, John Marston, Thomas Nashe, and others be burned. Today, the satirist attacks individuals only at the risk of severe financial loss to himself and his publisher. In totalitarian countries he risks imprisonment or death. Under extreme conditions satire against the reigning order is out of the question: so canonical is this rule that political analysts use the amount and character of satire permitted in the U.S.S.R. as a gauge of political pressure at any given time. Whereas the poet Osip Mandelstam was sent to a concentration camp and his death for composing a satirical poem on Stalin, today Isaac Deutscher can interpret as a favourable sign the increasing amount of Soviet satire against internal abuses.

The gaiety of satire

Caricature and cartoon

Repressions of satire

Aristophanes' use of satire

One creative response the satirist makes to social and legal pressures is to try by rhetorical means to approach his target indirectly; that is, a prohibition of direct attack fosters the manoeuvres of indirection that will make the attack palatable: irony, innuendo, burlesque, parody, allegory, etc. It is a nice complication that the devices that render satire acceptable to society at the same time sharpen its point. "Abuse is not so dangerous," said Dr. Johnson, "when there is no vehicle of wit or delicacy, no subtle conveyance." The conveyances are born out of prohibition.

Anthony Cooper, 3rd earl of Shaftesbury, writing in the 18th century, recognized the "creative" significance of legal and other repressions on the writing of satire. "The greater the weight [of constraint] is, the bitterer will be the satire. The higher the slavery, the more exquisite the buffoonery." Shaftesbury's insight requires the qualification made above. Under a massively efficient tyranny, satire of the forms, institutions, or personalities of that tyranny is impossible. But, under the more relaxed authoritarianism of an easier going day, remarkable things could be done. Max Radin, a Polish-born American author, writes of how satirical journals in Germany before World War I, even in the face of a severe law, vied with each other to see how close they could come to caricatures of the Kaiser without actually producing them. "Satire which the censor understands," said the Austrian satirist Karl Kraus, "deserves to be banned." The 20th-century U.S. critic Kenneth Burke sums up this paradoxical aspect of satire's relation with the law by suggesting that the most inventive satire is produced when the satirist knowingly takes serious risks and is not sure whether he will be acclaimed or punished. The whole career of Voltaire is an excellent case in point. Bigots and tyrants may have turned pale at his name, as a famous hyperbole has it; but Voltaire's satire was sharpened and his life rendered painfully complicated as he sought to avoid the penalties of the law and the wrath of those he had angered. Men such as Voltaire and Kraus and the Russian Ye.I. Zamyatin attack evil in high places, pitting their wit and moral authority against cruder forms of power. In this engagement there is often something of the heroic.

Readers have an excellent opportunity to examine the satirist's claim to social approval by reason of the literary convention that decrees that he must justify his problematic art. Nearly all satirists write apologies, and nearly all the apologies project an image of the satirist as a plain, honest man, wishing harm to no worthy person but appalled at the evil he sees around him and forced by his conscience to write satire. Pope's claim is the most extravagant:

Yes, I am proud: I must be proud to see
Men not afraid of God, afraid of me:
Safe from the Bar, the Pulpit, and the Throne,
Yet touch'd and sham'd by *Ridicule* alone.
O sacred Weapon! left for Truth's defence,
Sole Dread of Folly, Vice, and Insolence!
(*Epilogue to the Satires*, II, 208-13.)

After the great age of satire, which Pope brought to a close, such pretensions would have been wholly anachronistic. Ridicule depends on shared assumptions against which the deviant stands in naked relief. The satirist must have an audience that shares with him commitment to certain intellectual and moral standards that validate his attacks on aberration. The greatest satire has been written in periods when ethical and rational norms were sufficiently powerful to attract widespread assent yet not so powerful as to compel absolute conformity—those periods when the satirist could be of his society and yet apart, could exercise a double vision. Neoclassic writers had available to them as an implicit metaphor the towering standard of the classical past; for the 19th and 20th centuries no such metaphors have been available. It is odd, however, that, whereas the 19th century in general disliked and distrusted satire (there are obvious exceptions), our own age, bereft of unifying symbols, scorning traditional rituals, searching for beliefs, still finds satire a congenial mode in almost any medium. Although much of today's satire is self-serving and trivial, there are notable achievements.

Relationship between the satirist and his audience

Joseph Heller's novel *Catch-22* (1961) once again employs farce as the agent of the most probing criticism: Who is sane, the book asks, in a world whose major energies are devoted to blowing itself up? Beneath a surface of hilariously grotesque fantasy, in which comic characters carry out lethal assignments, there is exposed a dehumanized world of hypocrisy, greed, and cant. Heller is a satirist in the great tradition. If he can no longer, like Pope, tell men with confidence what they should be for, he is splendid at showing them what they must be against. The reader laughs at the mad logic of *Catch-22*, and as he laughs he learns. This is the way satire has worked from the beginning.

Saturn

Saturn, symbol in astronomy ♄, is the outermost of the planets known in ancient times. The earliest known observations of it, by the Babylonians, can be reliably dated to the mid-7th century BC, but it was probably noticed much earlier, as it is brighter than most stars. To the naked eye it appears yellowish; it moves slowly against the background of stars. The Greeks named it after Cronus, the original ruler of Olympus, whose Roman equivalent is the god Saturn.

The sixth planet in order of distance from the Sun, Saturn cannot approach the Earth closer than about 1,190,000,000 kilometres (739,450,000 miles). Its brightness is due to its large size, inferior only to that of Jupiter. Saturn's equatorial diameter is 120,660 kilometres, but its globe is appreciably flattened, and the polar diameter is only 108,000 kilometres. The mass of Saturn is 95.17 times that of the Earth, or 1/3,500 of that of the Sun, and the escape velocity—the velocity which, once attained, will enable an object to "coast" away from the planet—is 32.26 kilometres per second, more than three times that of Earth. The density of Saturn is surprisingly low—only 0.7 that of water—and its surface gravity is 1.16 times that of the Earth. Saturn's outer layers are made up of gas, and it is a world quite unlike our own.

Saturn's ring system is in a class of its own. While Jupiter and Uranus also have rings, those of Saturn are striking, and a telescope of moderate power will show them excellently. There can be no doubt that Saturn is one of the most beautiful objects in the entire sky. Data for Saturn are given in Table 1.

Early telescopic observations. The first telescopic observations of Saturn are thought to have been made by

Physical properties

Table 1: Planetary Data for Saturn

Distance from the Sun	mean 9.54 a.u. (1,472,000,000 km) maximum 10.07 a.u. (1,507,000,000 km) minimum 9.01 a.u. (1,347,000,000 km)
Sidereal period of revolution	10,759.20 days, or 29.46 years
Mean synodic period	378.1 days
Rotation period (mean)	10 hours 39 minutes 24 seconds
Mean orbital velocity	9.6 km/sec.
Axial inclination	26-44'
Orbital inclination to the ecliptic	2°29'22"
Orbital eccentricity	0.056
Diameter (equatorial)	120,660 km
(polar)	108,000 km
Apparent diameter seen from Earth	maximum 21" minimum 15"
Mass (Earth= 1)	95.17
Volume (Earth= 1)	744
Density (water= 1)	0.7
Albedo	0.61
Satellites	15

Galileo in July 1610. He saw the disk of the planet clearly, but his telescope gave a magnification of only 32 diameters and was not good enough to show the ring system in recognizable form; moreover, conditions were unfavourable because the rings were placed almost edge-wise. Galileo thought that Saturn must be a triple planet and wrote that "Saturn is not one alone, but is composed of three, which almost touch one another." Two years later, he found to his surprise that the "companions" had vanished, so that Saturn appeared as a single object. The ring system was then edge-on to the Earth, so that it could not be seen at all in Galileo's telescope. The original aspect was again seen in the years following 1613, but Galileo was never able to interpret it correctly. Subsequently, various strange theories were proposed to explain the planet's unusual form; Hevelius of Danzig, for instance, believed Saturn to be elliptical in shape, with two appendages attached to the surface.

The problem was solved by the Dutch astronomer Christiaan Huygens, who began his observations in 1655. The telescopes that he used were much more powerful than Galileo's, and gave sharper definition, so that in a short time he was satisfied that "Saturn is surrounded by a thin, flat ring which nowhere touches the body" of the planet. His theory, published originally in anagram form, met with a surprising amount of opposition, but by 1665 it had been universally accepted, even though the nature of the ring system was not established until much later.

The orbit of Saturn. Among planetary orbits, that of Saturn is of fairly low eccentricity (0.056), though the difference in distance between perihelion (closest approach to the Sun) and aphelion (farthest retreat from the Sun) amounts to 160,000,000 kilometres. Because Saturn is so far from the Sun and the Earth, phase effects for its disk are negligible; that is, Saturn always appears to be full, or nearly so, in the sense of the full moon.

Synodic
period

The mean synodic period, the interval between successive oppositions, when the Earth passes approximately between Saturn and the Sun, is 378.1 days, so that Saturn is well placed for observation during several months in each year. Opposition dates up to 1990 are April 8, 1982; April 21, 1983; May 3, 1984; May 15, 1985; May 27, 1986; June 9, 1987; June 20, 1988; July 2, 1989; and July 14, 1990.

Like all the superior planets, that is, those outward from the Earth, Saturn moves for the greater part of each year eastward against the starry background; its average rate is about 1° in eight days. As it approaches opposition, however, its motion seems to slow down and to stop altogether about 70 days before the opposition date. For a period that may be as little as 133 days or as great as 141 days, it then seems to move in a retrograde, or westward, direction before reaching another stationary point and resuming its eastward movement. This behaviour does not, of course, indicate any real alteration in motion. The apparent regression is due to the fact that the Earth, moving in a much smaller orbit at a greater velocity (average 29.8 kilometres per second as against only 9.6 kilometres per second for Saturn), is catching up with Saturn and passing it.

When at conjunction, on the far side of the Sun, Saturn cannot be observed, as it passes too close to the Sun in the sky. The inclination of the orbit to the ecliptic is $2^\circ 29' 22''$. During its synodic period of 378 days, Saturn advances for nearly eight months and retrogrades slowly for about 4% months, so that on balance it progresses along its path by about $12''$ per year.

Saturn through the telescope. Saturn's colour is yellowish; darker belts, parallel with its equator, are always seen. These belts are not nearly so conspicuous as those on Jupiter, nor do they show so much detail. Saturn's greater distance and smaller size make it less easy to study than Jupiter; moreover, the beauty of Saturn's ring system tends to divert attention from its disk, particularly when the rings are wide open, thereby hiding a considerable part of the globe.

Saturn's albedo (the proportion of incident sunlight it reflects) is 0.61. The planet's apparent magnitude (its brightness as it appears from Earth), however, depends

largely upon the angle at which the ring system is displayed, largely because the rings are more reflective than the disk. When the rings are wide open, the magnitude attains -0.3 , so that, of the stars, only Sirius and Canopus appear brighter than Saturn. At oppositions when the rings are edge-on, as in 1980, the magnitude is as low as $+0.8$, though even at these times Saturn is still prominent.

The equatorial zone appears creamy, sometimes almost white, in colour. The polar regions are always less brilliant; the belts, unlike those of Jupiter, do not show obvious colours. As with Jupiter, the two most prominent belts flank the equatorial zone; the other belts are much less conspicuous. Unless the rings are at a narrow angle, one or other of the equatorial belts will be covered.

Polar and
equatorial
zones

Well-defined spots on Saturn are rare. The most prominent example sighted during the present century was that discovered on August 3, 1933, by the English amateur W.T. Hay, using a six-inch (15-centimetre) refractor. The spot took the form of a large white oval patch in the equatorial zone, about one-fifth of the planet's diameter in length, and with both ends well defined. During the next few weeks it lengthened rapidly, until by mid-September it had spread out so much that it could no longer be called a spot.

Space probes to Saturn. Pioneer 11 was the first unmanned space probe to rendezvous with Saturn in September 1979. It had already passed by Jupiter, which had been its main objective, but valuable information about Saturn was obtained. The second probe was Voyager 1, which made its closest approach on November 12, 1980, when it passed only 124,200 kilometres above Saturn's clouds; its twin, Voyager 2, was scheduled to make its rendezvous with Saturn in August 1981.

Detailed views and a great amount of new information

By courtesy of the Jet Propulsion Laboratory/
National Aeronautics and Space Administration

Voyager 1 photograph of Saturn taken October 18, 1980, and colour-enhanced to increase the visibility of features in Saturn's North Temperate Belt

were obtained by Voyager 1. Though Saturn's disk is blander than that of Jupiter because of a greater amount of overlying "haze," much detail was shown. A red spot was detected in the southern hemisphere, with brownish ovals in the northern hemisphere. Measurements of the locations of individual features at different times yielded data concerning the speed of the winds, and it seems that Saturn's circulation is different from that of Jupiter. The maximum westward velocities of Saturn occur near the centres of the darker regions, while on Jupiter they occur at the poleward interfaces between the belts and bright zones. In the polar latitudes, the large-scale light and dark bands break down into small-scale features, giving the impression of waves and eddies. The wind velocity at the cloud tops seems to be about 1,400 kilometres per hour, or twice that of Jupiter.

Composition. According to a recent theory, Saturn has an iron and rock core that extends out 13,000 to 14,000 kilometres from its centre and is so compressed that it contains 15 to 20 times the mass of the Earth. Surrounding the core is a layer of electrically conductive metallic hydrogen in liquid form, outside of which is an envelope of hydrogen and helium. There is a magnetic field 1,000 times stronger than that of the Earth, though far weaker than that of Jupiter; the magnetic axis is almost coincident with the axis of rotation, and the magnetosphere extends out beyond the orbit of the largest satellite, Titan. There are fairly strong radiation belts, but these, again, are much weaker than those of Jupiter.

The temperature at the cloud tops of Saturn is approximately -180°C (-292°F). A theory that the planet might be self-luminous has been disproved. Saturn, like Jupiter, however, releases about twice the amount of energy it receives from the Sun, indicating the existence of an internal source of heat. While Jupiter emits energy from the gravitational contraction that occurred when the planet was formed about 4,600,000,000 years ago, it is unlikely that the heat source of Saturn is similar. Saturn is smaller and less massive and has a lower overall density (less than that of water); therefore, any heat remaining from the gravitational contraction of Saturn would have been dissipated long ago. Instead, the heat source of Saturn may result from the separation of hydrogen and helium in the planet's outer layers, with the heavier helium sinking through the liquid hydrogen middle layer.

The rings. The rings of Saturn are much more prominent than those of Jupiter or Uranus, and they are different in nature. Saturn's rings are made up of icy or ice-covered particles, each ring moving around Saturn in its own independent orbit. The ring plane remains in an almost fixed position with reference to the stars, but as seen from the Earth and the Sun the tilt of the rings is continually changing. Twice in each Saturnian revolution—at alternate intervals of 13 years nine months and 15 years nine months—the plane of the rings passes through the Sun. A few months before and after each such occasion, the ring plane passes through the Earth, which is near the Sun as viewed from Saturn. During the shorter interval, when Saturn passes through perihelion, the south pole of Saturn is tilted toward the Sun, so that the southern aspect of the rings is illuminated and the northern hemisphere of the planet is partly obscured. When the northern face is displayed, and the southern hemisphere of the globe is partly obscured, Saturn passes through aphelion; it is then moving slowly in its orbit, resulting in the inequality of the two intervals between successive edge-on presentations. The ring system is thin, so that at times of edge-on presentation the rings almost disappear as seen from the Earth.

Two of the three main rings—termed A (outer) and B—are bright. In 1675 G.D. Cassini, at the Paris Observatory, discovered the gap between them, known as Cassini's Division. The "ring" seen by Huygens was a combination of the two, and his telescope was not good enough to show the division. Ring B is much the brighter of the two. In 1837 J.F. Encke, at Berlin, discovered a less prominent division in Ring A, known as Encke's Division. In 1850 a dusky inner ring, Ring C, was discovered by W.C. Bond and G.P. Bond at Harvard, and

independently by W.R. Dawes in England; this is generally known as the Crêpe Ring.

The outer diameter of Ring A is 272,300 kilometres, the inner diameter 239,600 kilometres; for Ring B, the outer and inner diameters are 234,200 kilometres and 181,100 kilometres, respectively. The inner diameter of Ring C is 149,300 kilometres, so that it extends to 17,000 kilometres above the cloud tops.

New rings have since been discovered. A dusky ring, closer in than Ring C, was reported by telescopic observers; Voyager 1 results indicate that a ring, designated Ring D, does exist there, but whether it is genuinely observable from Earth is dubious. Outside Ring A is the clumpy and braided Ring F; Rings E and G were also shown on the Voyager 1 images.

By courtesy of the Jet Propulsion Laboratory/
National Aeronautics and Space Administration

Voyager 1 photograph of Saturn's rings taken November 6, 1980. Saturn's 14th satellite, discovered by Voyager 1, can be seen (upper left) just inside Ring F.

Voyager 1 showed that the rings are much more complex than had been thought. Each contains hundreds of components, and there are several distinct narrow rings inside the Cassini Division. It was once thought that the main divisions in the ring system were due to the cumulative perturbation effects of Saturn's satellites, but this explanation is clearly inadequate, and other forces must be involved.

The satellites. Saturn has 15 known satellites, details of which are given in Table 2. An additional satellite, named Themis, was reported by W.H. Pickering in the early 20th century, but it has not been recovered and probably does not exist. In 1966 A. Dollfus announced the discovery of an inner satellite, named Janus, moving at 169,000 kilometres from Saturn in a period of 0.815 day; the Voyager probe showed that there is no satellite moving in this orbit, however, and the name Janus has been dropped. It is probable that Dollfus' observations actually related to some of the small inner satellites discovered by the Pioneer 11 and Voyager probes.

Table 2: Satellites of Saturn

satellite	distance from centre of Saturn (kilometres)	period (days)	orbital eccentricity	orbital inclination (degrees)	diameter (kilometres)*
S.15	138,200	0.60	?	?	80
S.14	138,600	0.613	?	?	500
S.13	141,000	0.629	0.007	?	600
S.10	149,400	0.695	0.013	?	700
S.11	149,400	0.695	0.013	?	135×70
Mimas	185,400	0.942	0.020	1.5	350
Enceladus	238,200	1.370	0.004	0.0	520
Tethys	294,600	1.888	0.000	1.1	1,020
Dione	377,400	2.737	0.002	0.0	1,120
S.12	377,400	2.737	0.0?	0.5?	80
Rhea	526,800	4.518	0.001	0.4	1,530
Titan	1,200,000	15.95	0.029	0.3	5,100
Hyperion	1,482,000	21.28	0.104	0.4	440
Iapetus	3,558,000	79.33	0.028	14.7	1,440
Phoebet	12,960,000	550.4	0.163	150	80

*The diameters of some of the smaller satellites remain somewhat uncertain. †Phoebe moves around Saturn in a retro-grade direction.

The unnamed satellites S.14 and S.13 move in orbits close to the inner and outer edges of Ring F and presumably keep this ring stable. S.10 and S.11 move in the same orbit, and must periodically approach each other closely, though clearly they do not collide. S.12 moves in the same orbit as Dione.

Phoebe, the outermost satellite, was not within range of the Voyager 1 probe, and little is known about it; it may be a captured asteroid. Iapetus is unique in having one hemisphere of high albedo and the other of low albedo; this explains why, as seen from Earth, it appears much brighter when west of Saturn than when east of the planet. As with all the other satellites, Iapetus has a captured, or synchronous, rotation; that is, its axial rotation period is equal to the time taken to complete one orbit, as is true of our Moon with respect to the Earth. Rhea, Dione, Tethys, and Mimas have icy, cratered surfaces; one huge crater on Mimas has more than one-third the diameter of the satellite itself, so that, if the crater were formed by impact, it seems that Mimas would have been in danger of breaking up. Enceladus was not well shown from Voyager 1, but it may be comparatively smooth.

Titan, by far the largest of Saturn's satellites, is in a class of its own because of its dense atmosphere. Data obtained from Voyager 1 indicate that the atmospheric pressure at Titan's surface is 1.5 to two times that of the Earth at sea level. The actual surface of the satellite is obscured by the top of an orange-coloured layer of what may be called "photochemical smog." Titan's atmosphere is made up almost entirely of nitrogen with trace amounts of methane and cyanide; it is possible that the intensely cold surface is covered, at least in part, by oceans of liquid nitrogen.

(P.Mo.)

Saudi Arabia

Saudi Arabia is a kingdom in southwestern Asia, with an estimated area of 865,000 square miles (2,240,000 square kilometres), occupying about four-fifths of the Arabian Peninsula. The capital is Riyadh. The population, about one-fourth of which is nomadic, was estimated by the Saudi Central Department of Statistics to have been 7,012,642 in September 1974, the date of the first population and household census. In 1980, the population was estimated to be 8,367,000.

Saudi Arabia is a Muslim and an Arab state, two attributes that have had a fundamental influence upon the country's foreign relations. It is a member of the Arab League and has made attempts to form an Islamic congress that would transcend the limits of the Arab world.

Nevertheless, the kingdom continues to exhibit a certain aloofness. A foreigner can secure a visa to visit it only if invited by an individual or an organization within the country. Once inside, a visitor encounters a pervading sense of independence and pride.

Yet change has not bypassed Saudi Arabia. The possession of Mecca and Medina, the two holiest cities of Islam, has always provided the country with outside contacts, and such contacts have been expanded by innovations in transportation technology and organization. More recently, petroleum has wrought irreversible domestic changes—educational and social as well as economic. Modern industrial skills, technology, and methods of organization have been superimposed on the traditional society by the introduction of tens of thousands of foreign skilled workers and the employment of hundreds of thousands of Saudis in nontraditional jobs. The transistor radio became, and television is increasingly becoming, a medium of education and entertainment and a force for social change. Highways and airways are replacing traditional means of transportation, notably the camel caravan. Thus, whereas to the outside world Saudi Arabia may still appear secluded behind a wall of traditionalism, from within the country there is now access to windows that offer an outside perspective.

This article is concerned with modern Saudi Arabia. Articles on associated subjects include MECCA and ARABIAN DESERT; historical aspects are treated in ARABIA, HISTORY OF.

THE LANDSCAPE

Physiography. Relief. The Arabian Peninsula is dominated by a plateau that rises abruptly from the Red Sea and dips gently toward the Persian Gulf. In the north, the western highlands are upward of 5,000 feet (1,500 metres) above sea level, decreasing slightly to 4,000 feet (1,200 metres) in the vicinity of Medina and increasing southeastward to more than 10,000 feet. The watershed of the peninsula is only 25 miles (40 kilometres) from the Red Sea in the north, receding to 80 miles near the Yemen (Ṣan'ā') border. The coastal plain, known as Tihāmah, is virtually nonexistent in the north, except for occasional wadi deltas, and widens slightly toward the south. Watercourses flowing to the Red Sea are short and steep, though there is one unusually long inland extension made by Wādī al-Hamd, which rises near Medina. The imposing scarp that runs parallel to the Red Sea is somewhat interrupted by a gap northwest of Mecca but becomes more clearly continuous southward.

Toward the interior, the surface gradually descends into a broad plateau covered with lava flows and volcanic debris as well as with occasional sand accumulations; its average elevation is about 4,000 feet. There the drainage is more clearly dendritic (*i.e.*, branching in tree-like fashion) and is much more extensive than that flowing toward the Red Sea. To the east, this region is bounded by a series of long, low ridges, with steep slopes on the west and gentle slopes on the east; the area is 750 miles

The
Tihāmah

(1,200 kilometres) long and curves eastward from north to south. The most prominent of the ridges is Jabal Ṭuwayq, which rises from the plateau at an elevation of some 2,800 feet (850 metres) above sea level and reaches a height of more than 3,500 feet southwest of Riyadh, overlooking the surface to the west by 800 feet and more.

The interior of the Arabian Peninsula contains extensive sand surfaces. Among them is the world's largest continuous sand area, the Rub' al-Khali (the Empty Quarter), which dominates the southern part of the kingdom and covers about 250,000 square miles (647,500 square kilometres). It slopes from above 3,400 feet near the border with Yemen (San'ī) northeastward down almost to sea level near the Persian (Arabian) Gulf; individual sand mountains rise to 800 feet. A smaller sand area of about 22,000 square miles (57,000 square kilometres), called an-Nafūd (*naḥūd* designating a sandy area or desert), is in the north central part of the country. A great arc of sand, ad-Dahnfi', almost 900 miles long and in places only 30 miles wide, joins an-NaWd with the Rub' al-Khali. Eastward, as the plateau surface slopes very gradually down to the Gulf, there are numerous salt flats (*sabkha*s) and marshes. The Gulf coastline is irregular, and the coastal waters are very shallow.

Geology. Geologically, Saudi Arabia may be divided into two regions, one composed of rocks that are crystalline and metamorphic and the other of sedimentary rocks. The crystalline-metamorphic series, of Precambrian age (from 4,600,000,000 to 570,000,000 years ago), occupies the western third of the country. Volcanic flows and cinder cones that are probably about 2,500,000 years old or less are present here and occasionally intrude upon and overlie the Tertiary sediments (laid down from 65,000,000 to 7,000,000 years ago) in the north. The sedimentary rocks surrounding the Precambrian rocks on the northwest, east, and southwest range in age from Cambrian and Ordovician (from 570,000,000 to 430,000,000 years ago) to Tertiary. They dip gently toward the Gulf, where they exceed 20,000 feet in thickness. Saudi Arabia's vast petroleum reserves occur in rocks of Cretaceous and Jurassic age (*i.e.*, dating from 190,000,000 to 65,000,000 years ago).

Drainage. There are no permanent surface streams in the country, but wadis are numerous. Those leading to the Red Sea are short and deep, but those draining eastward are longer and more developed except in an-Nafūd and the Rub' al-Khali. Soils are poorly developed and reflect in composition the rocks from which they were formed, such as the volcanic rocks in the west. Large areas are covered with pebbles of different sizes. Alluvial deposits are found in wadis, basins, and oases. Salt flats are especially common in the east.

Climate. Climatically, the kingdom is almost entirely a desert. In winter, cyclonic weather systems skirt the Arabian Peninsula, moving from the eastern Mediterranean region to the area of the Tigris and Euphrates rivers. Some weather systems move southward along the Red Sea trough and provide winter precipitation as far south as Mecca and sometimes as far as Yemen (San'ī). In March and April some rain, normally torrential, falls. In summer the highlands of Asir, southeast of Mecca, receive enough rain from the monsoonal winds from the west and southwest to support a strip of steppe conditions.

Winters, from December to February, are cool, and frost and snow may occur in the southern highlands. Average temperatures for the coolest months, December through February, are 74° F (23° C) at Jidda, 58° F (14° C) at Riyadh, and 63° F (17° C) at ad-Dammim. Summers, from June to August, are hot, with daytime shade temperatures exceeding 100° F (38° C) in almost all of the country and frequently reaching 120° F (49° C). Humidity is low, except along the coasts, where it can be high and very oppressive. Precipitation is low throughout the country, amounting to about 2½ inches (64 millimetres) at Jidda, a little more than three inches at Riyadh, and three inches at ad-Dammim. These figures, however, represent mean precipitation, and large variations are normal. In the highlands of Asir more than 15 inches (380 millimetres) a year may be received, falling during

the summer when the monsoon winds prevail. In the Rub' al-Khali, a decade may pass with no rain at all.

There are three climatic zones: (1) desert almost everywhere; (2) steppe along the western highlands, forming a strip less than 100 miles (160 kilometres) wide in the north but becoming almost 300 miles wide at the latitude of Mecca; and (3) a very small area of humid and mild temperature conditions, with long summers, in the highlands just north of Yemen (San'ā).

Vegetation and animal life. Saudi Arabia's vegetation belongs to the North African and Indian desert region and is characterized by poverty; there are only about 370 plant species in the country, all xerophytic and mostly small herbs and shrubs that are useful as forage. Animal life includes wolf, hyena, fox, honey badger, mongoose, porcupine, hedgehog, hare, sand rat, and jerboa. Such larger animals as gazelle, oryx, leopard, ostrich, and mountain sheep were relatively numerous until quite recently. Birds include eagles, hawks, falcons, vultures, owls, ravens, flamingos, egrets, pelicans, doves, and quail, as well as sandgrouse and bulbuls. Five species of harmless snakes have been identified. Domesticated animals include camels, fat-tailed sheep, long-eared goats, Salukis, donkeys, and chickens. The Arabian horse, the earliest improved breed, developed in the peninsula probably before the 7th century AD, is now bred by a few rich persons and by the Ministry of Agriculture and exhibited on special occasions such as shows and parades.

The landscape under human settlement. Traditional regions. Four traditional regions stand out—the Hejaz, Asir, Najd, and al-Hasa (transliterated more precisely as al-Ḥijāz, 'Asir, Najd, and al-Ḥasā). The Hejaz, in the north, contains the two holiest cities of Islām, Mecca and Medina, as well as the kingdom's primary port and diplomatic centre, Jidda. Asir is the highland region south of the Hejaz; its capital, Abhā, lies at an elevation of about 8,000 feet. Subregions in Asir are formed by the oasis cluster of Najrān—a highland area east of Yemen (San'ā)—and by the coastal plain, the Tihāmah. Najd occupies a large part of the interior and includes the capital, Riyadh. Al-Hasa (Eastern province, or al-Minṭaqah ash-Sharqiyah) is in the east along the Persian Gulf; it includes the principal petroleum-producing areas as well as parts of the Rub' al-Khali.

The cultural landscape. In Saudi Arabia land use is a noncontinuous phenomenon: a person travels long distances between visible evidences of human activity. Nomadism, the form of land use with which the kingdom is traditionally associated, is practiced by only a fourth or less of the population. About half of the nomads, or some 10 percent of the national population, are camel herders. The rest are semi-nomads who raise sheep and goats for meat and wool. Semi-nomadism is more clearly associated with the better watered pastures such as occur in southern Hejaz and in Asir. In September 1974 the migratory population was estimated at 1,884,000, of whom about two-thirds lived in northern and central Saudi Arabia. The nonsettled population is estimated to be decreasing by 2 percent a year as a result of migration to expanding urban areas and of active inducements by government agricultural settlement projects. This rate of decline is expected to increase.

There are scores of thousands of square miles that are rarely utilized even by the nomadic or semi-nomadic segment of the population. The virtually empty sand expanses of the Rub' al-Khali and an-Nafūd alone occupy nearly a third of the national territory.

Only about 0.2 to 0.3 percent of the total land area is cropped land, and of this area about one-fourth is irrigated, the rest being watered by rain. Ninety-five percent of the unirrigated cropped land is in Asir, for it is there that rainfall is most plentiful and reliable. Almost half of the irrigated area is in Najd, mostly around Riyadh, and underground water is utilized. One-fifth of the irrigated area is around Mecca. Cropped land could be more than doubled if more water were available. The 1,300,000 acres (525,000 hectares) under cultivation are shared among 181,000 holdings, for an average of less than 20 acres (8 hectares) per holding. The agricultural

Three
climate
zones

Irrigation

labour force was 28 percent of the national labour force in 1975, a decrease from 40 percent in 1970. The decline is occurring at an annual rate of about 1 percent, and it is reflected in abandoned farmland and partly depopulated villages, especially in Asir.

The largest towns are cosmopolitan in character, and some are associated with dominant functions: Mecca and Medina are religious; Riyadh is political and administrative; and Jidda is commercial. Dhahran (*aḏ-Ḍaḥrān*) is the administrative centre of the Arabian American Oil Company (Aramco), and nearby al-Khubar and *ad-Dammām* are commercial coastal towns.

PEOPLE AND POPULATION

Language. Arabic is a Semitic language, and its home is Saudi Arabia, where the language is presumed to be the "purest." Classical written Arabic is standard throughout the Arab world, while spoken Arabic varies considerably. Such colloquial variations are evident even within Saudi Arabia—in part because of the strength of traditional group allegiances that have limited intermixture, and in part because of different external influences prevalent in different parts of the kingdom. These differences, however, should not be overemphasized. English is gradually becoming understood, especially in the Eastern province, where the oil industry is centred, as well as in the commercial and diplomatic centre of Jidda.

Ethnic groups. Considerable ethnic homogeneity is also evident. Saudi nomads are "pure" Arabs, or at least descendants thereof. As in the case of language, variations have developed because of a long history of regionalism and tribal autonomy and because some localities have been subjected to important outside influences. Thus, the influence of black Africa is evident along the Red Sea littoral, and influences from Iran, Pakistan, and India can be noticed in the east. Blacks from Africa, intermixed with Semitic stock, live along the Red Sea.

An increasing number of outsiders—annually exceeding half a million—enter and leave Saudi Arabia. Of these, about 70 percent travel from and to Arab countries (and of these about half from and to the Gulf area, Oman, and the two Yemens), and 10 percent each from and to Europe and the United States. About 350,000 foreigners have been issued "permanent" residence permits, and half of these reside in or near Riyadh, Jidda, and *ad-Dammām*. The annual influx of persons making the pilgrimage (*hajj*) to Mecca, numbering a million or more outsiders a year (plus half a million from within Saudi Arabia), must also be noted. The pilgrimage has been a two-way vehicle for the diffusion of ideas since the beginning of the Muslim era in the 7th century AD.

Religion. Saudi Arabia is the home of Islām, and its population is almost entirely Sunni Muslim (*i.e.*, adhering to the chief branch of Islām, called traditionalist or orthodox). The Sunni Muslims recognize four schools of classical law—the Hanbali (the most rigid), the Ḥanafī (the most liberal), the Shāfiʿī, and the Mālikī. The puritan Wahhābī sect, which was founded in the 18th century in Najd and represents the Hanbali school of thought, is dominant, particularly in the Eastern province (al-Ḥasa), the Hejaz, and Asir. The Hanafi school is represented in the areas that reflect Turkish influence—the Eastern province and the Hejaz. Also in the Eastern province are Mālikīs, while Shāfiʿīs live in the Hejaz and Asir. In Asir the strict Idrisi order is also found. There are some 100,000 Shiʿites (adherents of the second major branch of Islām, the Shiʿah), particularly Jaʿfarīs, in al-Ḥasa and al-Qaṭīf oases in the east. Other Shiʿite groups are the Makramīs, once established in Najrān in southern Asir, and the Zaydis, represented near Mecca. Only noncitizens, such as oil industry employees and businessmen, are Christian.

Demography. A population and household census that was conducted in September 1974 showed an estimated population of 7,012,642. Of this total, 5,128,655 (73.1 percent) were settled and 1,883,987 (26.9 percent) were nomadic or semi-nomadic. Major population regions, with the respective percentages of the total population,

were: Mecca area, 25; Riyadh area, 18; eastern area, 11; Asir, 9.7; Medina area, 7; and Qizān area, 5.7. The 16 largest cities were Riyadh, 666,840 persons; Jidda, 561,104; Mecca, 366,701; at-Ṭāʿif, 204,757; Medina, 198,186; *ad-Dammām*, 127,844; al-Hufūf, 101,271; Tabiik, 74,825; Buraydah, 69,940; al-Mubarrāz, 54,325; Khamīs Mushayṭ, 40,581; al-Khubar, 48,817; Najrān, 47,501; Ḥāʾil, 40,502; Qizān, 32,812; Abhā, 30,150. These 16 cities contain 38 percent of the total national population, and this proportion is expected to continue to rise. The number of settlements accorded municipality status was 85 in 1975.

In mid-1976, according to estimates by the Population Reference Bureau (Washington, D.C.), the birth rate was 49 and the death rate 20 per 1,000, giving an annual growth rate of 2.9 percent. If this rate is maintained, the population will have doubled by the year 2000. The infant mortality rate is estimated at 152 per 1,000 live births per year. About 45 percent of the population is less than 15 years old, and the median age is a very young 17.6 years.

THE NATIONAL ECONOMY

Resources. The economy of Saudi Arabia is dominated by petroleum and its associated industries. In 1970 it was estimated that the known reserves would be exhausted in 107 years if production continued at that year's rate. However, the amount of reserves is likely to continue to be revised upward for some years, and production will generally increase. In 1975 production was 3.2 times that of 1965 and 1.9 times that of 1970. In terms of known world reserves, Saudi Arabia ranks first, with about one-fifth of the world total of proved reserves. In terms of production, it was third in 1975, after the Soviet Union and the United States.

Oil deposits are located in the east, southward from Iraq and Kuwait into the Rub' al-Khali and under the waters of the Persian Gulf. Numerous other mineral resources are known to exist, and the government is actively pursuing a policy of exploration and production in order to diversify the economic base. Geologic reconnaissance mapping of the Precambrian shield in the west is well under way. Nine belts have been identified: gold, silver, copper, zinc, lead-zinc, iron, titanium-iron, sulfur-iron (pyrite), and magnesite. Also basic and ultrabasic rock masses have been defined.

Exploration licenses are normally granted to a foreign mining company only after the company has concluded a partnership agreement with the state organization, *Petromin*, providing for joint investment in mining if exploration proves successful; the degree of participation has been 50 percent. Exploration beyond the Precambrian shield and a program to inventory nonmetallic mineral resources are under way, and commercial production of metallic minerals is expected to start by the mid-1980s.

Coal is not known to exist in usable quantities. Vegetation and animal resources are very limited.

Sources of national income. Revenues are derived mostly from petroleum, either as direct royalties or as taxes on income. In the later 1970s around 70 percent of expenditures were devoted to development projects and around 30 percent to defense. Oil revenue in 1975 was six times that in 1973, 21 times that in 1970, and 39 times that in 1965. In 1975 the Arabian American Oil Company (Aramco) accounted for more than 96 percent of total oil production and of oil revenue; these proportions are representative of most years. The primary customer has been Japan, followed by western Europe, four-fifths of whose purchases were accounted for by members of the European Economic Community (EEC).

Development plan. In May 1975 Saudi Arabia announced a \$142,000,000,000 Five-Year Plan of development (1975–80), the equivalent of \$20,000 per Saudi citizen. An overall objective was to diversify the economy and to increase national integration. Industrial development was to be based on two growth poles, al-Jubayl on the Gulf and Yanbu' on the Red Sea, which were to be connected by one oil and one gas pipeline. Industries to be established were: (1) at al-Jubayl, a gas-gathering

resources

plant, a steel and iron plant, an aluminum plant, two oil-exporting refineries, three petrochemical complexes, and grain silos; (2) at ad-Dammim, two ammonia and urea fertilizer plants and a cement factory; (3) at Yanbu', an oil-exporting refinery, a petrochemical complex, a cement factory, and a refinery for oil lubricants; (4) at Jidda, a cement factory and enlargement of the existing refinery; (5) at Buraydah, a soap mill, an auto-tire plant, a car assembly complex, a cement factory, an oil-products distribution centre, grain silos, and flour mills; (6) at Riyadh, expansion of the existing refinery, plants manufacturing dry cells, ceramics, clothing, glass, and household utensils, brick-making factories, grain silos, and flour mills; (7) at Qizān, a cement factory and an oil-products distribution centre; (8) at Tabiik, a cement plant, a cardboard mill, a hides-drying mill, and a carbonated water bottling plant. A vast desalination program was also under way, and the planned increases should more than keep up with the projected 158 percent increase in water demand between 1975 and 1980.

Grain production

The development plan also attends to other sectors. In agriculture, the expectation was that wheat production would increase from 15 to 50 percent of national need, barley from 15 to 38 percent, millet from 99 to 100 percent, and dates from 100 to 154 percent (for export). Attention was also given to other crops and to poultry. Investment in vocational training centres should increase the domestic labour supply. University enrollment was expected to go from 15,600 to 53,300, the number of hospital beds to increase from 8,800 to 20,300, and the number of doctors from 2,900 to 4,200. Television would become available to 90 percent of the inhabitants. Seaport capacity would be expanded at Jidda, Yanbu', and Qizān on the Red Sea and at ad-Dammim and al-Jubayl on the Gulf, with new ports at Yanbu' and al-Jubayl. Two permanent satellite ground stations were being established in Riyadh and Jidda, while two existing mobile stations would be moved to Abhā and Tabiik. Airport expansion was planned to take place at Jidda, Riyadh, Dhahran, Medina, at-Ṭā'if, Qizān, Najrān, and Ḥā'il, and new airports would be completed at Abhā and Badanah. All of these may, but do not regularly, handle international traffic. Five domestic airports were to be improved and five new ones to be constructed. Pilgrimage facilities are being improved throughout the kingdom.

The capacity to generate electricity was expected to increase by 261 percent, from 1,256 megawatts in 1974 to 4,538 megawatts in 1980. Priority was given to the growth poles (al-Jubayl and Yanbu') and the connecting axis, and also to the Eastern province where the oil industry is concentrated. In terms of the proportion of people served, 100 percent of those in the Eastern province were being served by 1974, in contrast to 5.9 percent in the southwest. In the southwest the proportion would rise to 53 percent by 1980.

Imports by sea in the 1970s were chiefly livestock and foodstuffs, construction material, and consumer products. Exports (other than oil products) were meagre, consisting mostly of fertilizers.

TRANSPORTATION

Saudi Arabia is a large country with a sparse, widely dispersed population. Nowhere in the kingdom is there anything approaching a transportation network. Modern means of transport reached the country only very recently and are receiving considerable attention. In 1970 there were 5,243 miles (8,438 kilometres) of paved roads; by 1975, 2,001 miles (3,221 kilometres) of new roads had been completed and 564 miles (908 kilometres) of existing roads reconstructed, and 2,696 miles (4,338 kilometres) of rural roads had been opened. By 1980, 8,119 miles (13,066 kilometres) of main, secondary, and paved feeder roads were expected to be completed, as well as 6,369 miles (10,250 kilometres) of earth-surface rural roads. Also by 1980, studies and designs were to have been completed for an additional 3,544 miles (5,704 kilometres) of main roads, 4,350 miles (7,000 kilometres) of secondary and tertiary bitumen-surface roads, and 6,200 miles (10,000 kilometres) of tertiary earth-surface roads.

By comparison, in 1951 there were hardly 34 miles (55 kilometres) of paved roads. The first coast-to-coast connection, from ad-Dammām on the Gulf to Jidda on the Red Sea, by way of Riyadh, was opened in 1967; it includes a spectacular descent of the western escarpment from at-Ṭā'if to Mecca. Another transpeninsular connection is from ad-Dammām to Jordan, with the road running along Tapline (the trans-Arabian oil pipeline). Other important connections are (1) from Riyadh northwestward into Najd, (2) between central Najd and Medina, (3) from Medina northwestward through the Hejaz to Jordan and southwestward to the Red Sea, (4) from at-Ṭā'if southeastward along the plateau edge through Asir, and (5) from Riyadh to Najrān in southern Asir.

The country's only railroad, from ad-Dammim port to Riyadh, was completed in 1951. It is 360 miles (579 kilometres) long and passes through al-Hufūf, Harad, and al-Kharj. No extension is contemplated.

The railroad

The country's two main ports are Jidda and ad-Dammām, which account for around 80 percent of the country's imports, excluding oil and refined products. The third port is Yanbu', followed by Qizān. A feasibility study was completed for the Red Sea ports of Ḍibā, al-Wajh, Umm Lajj, al-Lith, and al-Qunfudhah, and some minor construction has been done at al-Jubayl on the Gulf. In addition to expanding and improving harbour

Roads

facilities, specialized industrial ports were to be constructed at al-Jubayl and Yanbu', the two poles of the development axis.

Air
transport

Aviation has rapidly become an important component of Saudi Arabia's transport network. Twenty airports are served regularly, and in the mid- and late 1970s passenger traffic was increasing at about 20 percent every year. The Saudi Arabian airline is Saudia, which in 1975 had scheduled service to 28 foreign airports in addition to the kingdom's own airports. Rapid increases were expected in both domestic and international service.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. Saudi Arabia's constitutional basis is the law of Islām, the Shari'ah, based on Muhammad's pronouncements and on the traditions of Islam's first adherents (see ISLAMIC LAW). Muslim law prescribes civil as well as religious rights, duties, obligations, and responsibilities, insofar as these apply to both ruler and ruled. Law is revealed and not created, and it is interpreted by the 'ulamā', or learned religious men. A reserve of power resides in the monarch, acting through his Council of Ministers.

The
monarchy

The person of the king combines legislative, executive, and judicial functions. The Council of Ministers is a legislative body, although it is also responsible for such executive and administrative matters as foreign and domestic policy, defense, finance, health, and education. Appointment to and dismissal from the council are prerogatives of the king; prospective members must swear allegiance to him. The king has veto power over council decisions unless he fails to act within 30 days.

Succession to the throne is not hereditary; the crown prince is designated by the royal family with the support of the 'ulamā' and the Council of Ministers. These three groups form the Consultative Council. The Council of Ministers has considerable authority for the supervision of regional and local government. The kingdom is divided into 17 administrative districts, or *manātiq idāriyah*, and local officials of the central government report directly to the ministries in Riyadh. Provincial governors are responsible for such functions as finance, health, education, agriculture, and municipalities. The consultative principle operates at all levels of government, including the government of villages and tribes.

Justice. The Shari'ah law is the basis of justice. Judgment is according to the Hanbali tradition of Islām; the law thus tends to be conservative and punishments severe. Rapid changes since the mid-century have produced circumstances — such as traffic violations and industrial accidents — not encompassed by the traditional law, and these have been handled by the issuance of royal decrees, which, in turn, have evolved into a body of administrative law. Avenues of appeal are available, and the monarch is both the final court of appeal and the dispenser of pardon.

The armed forces. Military service is voluntary. In 1975 there were 36,000 in the army, 1,500 in the navy, and 5,500 in the air force. A paramilitary force numbered 26,000.

Education. Education is free at all levels and is receiving increasing emphasis and attention. In elementary schools (grades 1 through 6) the enrollment of boys is expected to increase from 401,300 to 677,500 between 1975 and 1980 and the enrollment of girls from 214,600 to 353,400. The number of boys' schools is expected to increase from 2,063 to 2,908 and that of girls' schools from 827 to 1,534. At the intermediate level (grades 7 through 9) the number of boys enrolled should increase from 70,300 to 127,100 and that of girls from 34,000 to 70,200. In addition to improving existing facilities, 224 new intermediate boys' schools and 140 girls' schools were to be constructed by 1980. At the secondary level (grades 10 through 12), the equivalent increases would be from 19,900 to 39,800 boys and from 7,600 to 17,600 girls, with 37 new boys' and 32 new girls' schools.

Expansion
in higher
education

A phenomenal expansion is occurring in higher education, with a planned increase of combined enrollment from 15,598 in 1975 to 53,290 in 1980. Institutions of higher education are the University of Riyadh (founded

in 1957), the Islāmic University (founded in 1961) at Medina, and the King 'Abd al-'Aziz University (founded in 1967) in Jidda. Other institutes include the Higher Institute of Technology, the Higher Juridical Institute, the King 'Abd al-'Aziz Military Academy, the College for the Arabic Language, the Technical Institute, and the College of Islāmic Jurisprudence, all at Riyadh; the University of Petroleum and Minerals (Petromin) at Dhahran; the School of Hadith (narrative traditions), the Shari'ah College of Islāmic Jurisprudence, and the Saudi Arabian Institute for Higher Education, all at Mecca; the School of Applied Arts and the Teacher Training Centre, both at Medina; and schools of industrial education at Riyadh, Jidda, Medina, and ad-Dammām. Institutes for religious teaching are located in at least 20 towns.

Under the development plan for 1975–80, in addition to extensive expansion of existing institutions, a new campus of the University of Riyadh is expected to be completed at ad-Dir'yah, a new campus for King 'Abd al-'Aziz University to be built in Mecca, and a college of medicine to be started in Jidda.

Health. In 1973 there were 84 hospitals with 8,800 beds and 2,900 doctors. Local staffing has been inadequate; between 1970 and 1974, for example, only 152 female nurses and 357 technical assistants graduated from nursing schools and health institutes. The development plan for 1975–80 aims to provide all regions of the kingdom with preventive and curative health services. The number of hospital beds is to be increased to a ratio of 2.5 beds per 1,000 persons, and the targeted ratio of doctors is 1 per 2,000 persons. Mother and child care clinics are being established with the aim of reducing infant mortality to no more than 110 per 1,000 births. A network of 427 dispensaries is expected to serve communities of 10,000 or more persons, and mobile health services should cover small communities and the nomadic population. The number of health training institutes is to be increased from seven to 15.

Social and economic divisions. Socially and economically, Saudi Arabia has traditionally been composed of nomads, villagers, and townsmen. Pervading this trinity, however, is the patrilineal kinship principle, and superimposed on all is the administrative organization. The kinship principle is most pronounced among the nomads, who are organized along tribal and subtribal lines. Villages constitute local service centres and usually contain representatives from more than one tribe, though one family will be dominant. Towns are not tribally organized, though local affairs still tend to be dominated and administered by a few families. Social stratification is much more clearly developed in the towns than elsewhere. Before the effects of oil were felt on the economy, status was a matter of lineage and occupation rather than of wealth; with the development of the oil industry, however, wealth and material position have acquired social value. The new technology and industry have produced a growing middle income economic group that is increasingly aware of the widening gap between the ruling elite and the rest of the population. Thus, the traditional links between the upper and lower levels of Saudi society are being disrupted, and substitutes have not yet evolved.

The urbanization resulting from oil-related activity has already pushed much of Arabia's traditionalism back from a present reality to a receding memory. The now omnipresent automobile has brought about a reduction in effective physical distances within the kingdom. Similar has been the effect of the airplane and satellite communication. This is not to say, however, that Saudi society has become homogenized, for social distances have not been similarly reduced.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. The cultural setting is Arab and Muslim. For a thousand years artistic expression usually perpetuated ancient forms. From the 18th century onward the strict Wahhābī religious outlook discouraged intellectual deviation from accepted purist positions, and the nomadic life greatly limited the development of non-portable art forms. The theatre and public cinema do

Nomads,
villagers,
and
townsmen

Tradi-
tional arts

not exist. With the petroleum industry came exposure to outside influences, such as housing styles, furnishings, and clothes, and at the same time local craftsmen found themselves in competition with imported goods.

Intellectual activity is dominated by religious studies, though influences from other Arab countries are filtering in, and Saudi students who study abroad are exposed to radically different milieus. Poetry and formal prose, including speech, have been among the highest of arts since pre-Islāmic days, and poets and peripatetic storytellers abound. Literary works now appear in newspapers and periodicals, though the nomad and the illiterate villager still have their own body of folk literature. Music and dance have always been part of Saudi everyday life, though the strict Wahhābī code forbids their public expression. Visual arts are limited to geometric, floral, and abstract designs and to calligraphy. Architecture has been simple, with designs on doors and windows and with a tendency to build crenellated walls. Mud bricks, limestone, coral rock, and reinforced concrete are used in construction. The recent wave of change has influenced architectural styles, so that "modern" stark, linear motifs are becoming common in office and residential buildings as well as at airports and hotels. Crafts are limited to such products as textiles, brass and copper ware, jewelry, wooden articles, pottery, baskets, mats, and leatherwork.

Press and broadcasting. In 1976 there were seven daily Arabic newspapers (four in Jidda, two in Riyadh, and one in Mecca) with a combined circulation of about 115,000. There were 7 weeklies in Arabic (three in Riyadh, two in ad-Dammām, and one each in al-Khubar and Mecca). Two English-language dailies were published in Jidda; two English weeklies were published in Dhahran and Jidda, and one each in Mecca and Riyadh.

There are two radio and two television services, one of each operated by the Ministry of Information and by Aramco. Programs are commonly religious and literary.

PROSPECTS FOR THE FUTURE

Since the 1950s, Saudi Arabia has experienced enormously greater and more rapid changes than it had in the several preceding centuries. Exposure to alien cultures and technologies is having irreversible effects on both culture and mental perspectives. The Eastern province, where the oil industry is centred, has been most affected, and the changes that have been wrought there are phenomenal. Dhahran is a pleasant suburban community in the American style, with even a golf course, though the "greens" are black, consisting of hardened crude oil spread over a smoothed desert surface. Bedouins come to the towns, perhaps first as individuals, but soon as families; almost invariably the movement is one way. Tribal ties tend to loosen. The Bedouins witness the evolving social and economic rifts between their earlier world and the new, finding it difficult to blend into the new milieu. Their lot is not so different from that of other migrants: they become rootless, often frustrated. Today a pure Bedouin is as representative of Saudi Arabia as a Navajo is of the United States.

Saudi Arabia's historic isolation is at an end. Change is clearly the norm. The powerful traditional religious mores and convictions remain, and are all-pervading. But the pull of new ideas and new material values is also strong and is increasing. A shot fired in Palestine reverberates to the fringes of the Rub' al-Khali. A speech given in Cairo causes a stir in the heart of Najd. Saudis are caught in the political crosscurrents, both as individuals and as groups. Dislocations and disruptions will continue—social, economic, ideological, and moral. What remains problematical is the way Saudi Arabia will be affected by the strain.

(B.K.N.)

Saul

The first king of Israel (c. 1020-1000 BC), Saul instituted the Israelites' experiment with monarchy that culminated in the illustrious kingdom of David.

The account of Saul's life comes from the Old Testament book of I Samuel. The son of Kish, a well-to-do member of the tribe of Benjamin, he was made king by the league of 12 Israelite tribes in a desperate effort to strengthen Hebrew resistance to the growing Philistine threat. For roughly two centuries, Israel had existed as a loose confederation of tribes, dependent for their unity upon bonds of religious faith and covenant that were renewed periodically in cultic ceremonies at the central shrine at Shiloh. The Book of Judges attests to the effectiveness of these religious ties in uniting the tribes behind their judges in time of enemy attack. By Saul's day, however, the tribal rallies were no match for the superior iron weapons and chariots of the Philistines, who were pressing ever deeper into the central highlands.

Two literary strands are discernible in the accounts in I Samuel involving Saul. One of these (9:1-10:16), reflecting a favourable attitude toward the monarchy, relates how the tall, handsome son of Kish was initially selected by Samuel the seer in a private encounter between the two men. From this same circle of tradition (ch. 11) comes the account of Saul's heroic deliverance of the town of Jabesh-Gilead from oppression by the Ammonites, which brought him to the attention of all Israel and resulted in his acclamation as king in a public ceremony at Gilgal. A second body of tradition (I Sam. 8, 10:17-27, 12) is at pains to record Samuel's misgivings about the kingship. Although in this account he anoints Saul as a concession to popular pressure, Samuel warns of the loss of personal and tribal freedom that will follow and interprets the action as tantamount to a rejection of God. This latter tradition may reflect Israel's subsequent disappointments with the monarchy, but it doubtless preserves an authentic memory of the suspicion with which some Israelites viewed monarchical rule from the beginning.

In many respects, Saul's reign bears a closer resemblance to the judges who preceded him than to the succession of kings that followed. His chief service to Israel, like that of the judges, lay in the sphere of military defense. Together with his stalwart son Jonathan and an army constituted largely of volunteers, he won significant victories over the Philistines and succeeded in driving them out of the central hills. A successful campaign against the Amalekites in the south is also recorded (I Sam. 15). There is no evidence, however, that Saul made any appreciable changes in the nation's internal structures. There appears to have been no reordering of the old tribal territories into governmental districts and, accordingly, no formal programs of taxation or military

Assump-
tion
of
kingship

conscripted. The only royal official named in the accounts is the military commander Abner, Saul's cousin. In effect, Saul's reign was marked by few of the trappings of the typical eastern monarchies, with no court bureaucracy, splendid palace, or harem. His capital at Gibeah is revealed by archaeology as a simple, rustic fortress.

The two men who significantly influenced Saul's career were Samuel and David. Even as Samuel's endorsement proved crucial in assuring Saul the kingship, probably nothing contributed so much to the King's subsequent disintegration as his break with the powerful and respected Samuel. Separate accounts attributed this to Saul's failure in religious duties: presumption in offering unauthorized sacrifice before battle and a reluctance to devote Amalek to destruction according to the principle of holy war. Samuel's rejection of Saul, which was complete and irrevocable, withdrew from the King the religious sanctions essential for popular support and Saul's own mental well-being.

David, who came into Saul's court because of either his military prowess or his skill as a harpist, according to varying accounts in I Samuel, is named both as the one who soothed the King with his sweet music and as the object of a fierce jealousy resulting from the young warrior's successes in battle. When secret attempts to take David's life proved no more successful than the King's efforts to turn the hearts of his daughter Michal (David's wife) and his son Jonathan away from their winsome husband and friend, Saul declared openly his intention to slay David. Only David's flight to Philistia, which was beyond Saul's reach, saved him from the King's unprovoked and manic attacks. These accounts, though written from a perspective favourable to David, portray dramatically and convincingly the mental deterioration of Saul. Nothing is more revealing of the extent of the King's derangement than the story of his senseless slaughter of the 85 priests at Nob in I Sam. 22.

Adding to the problems of Saul's final days, the Philistines mounted new attacks on the Israelite heartland. At no time strong enough to deliver a final knockout blow to the persistent enemy, Saul gathered his forces at Mount Gilboa in an effort to cut off their drive into the Valley of Jezreel. A vivid story in I Sam. 28 relates how, on the eve of the fateful battle, Saul sought, through a necromancer at Endor, some word of encouragement from the dead Samuel. The oracle of Samuel's ghost, however, could only foretell the doom awaiting on the following day: the defeat of the Israelite forces and the death of Saul and his sons. The Israelites, once again confronted by the desperate conditions prevailing at Saul's accession to the throne, had to look to a new deliverer. The man best fitted for the job was David.

Any fair evaluation of Saul's stormy career must look beyond the antimonarchal tendencies of his biographers and the implicit comparisons with the more successful David. Best described as a tragic hero, Saul displayed a strength in battle and an ability to inspire his followers that place him high in the ranks of the military great. If unable finally to solve the Philistine problem, he nevertheless prevented their complete subjugation of the land. So enduring was the devotion of the men of Jabesh-gilead that they risked their lives to remove Saul's exposed body from the Philistine fortress at Beth-shan and give it proper burial (I Sam. 31:11–13). The finest tribute paid the fallen leader is found in the immortal words of David's magnificent elegy in II Sam. 1, which begins, "Thy glory, O Israel, is slain upon thy high places! How are the mighty fallen!"

MARTIN NOTH, *Geschichte Israels* (1950; Eng. trans., *The History of Israel*, 2nd ed., pp. 164–178, 1960); and JOHN BRIGHT, *A History of Israel*, pp. 163–174 (1959), provide the best historical assessments of Saul's reign. A somewhat romanticized but provocative personality study is in FLEMING JAMES, *Personalities of the Old Testament*, pp. 96–116 (1939).

(J.K.W.)

Sauria

Lizards (suborder Sauria) are familiar scaly-skinned reptiles, closely allied to snakes but usually distinguished by

the possession of legs, movable eyelids, and external ear openings. Most of the 3,000 species of lizards inhabit warm regions, but some species of lizards are found nearly to the Arctic Circle in Eurasia and others to the southern tip of South America. The lizards are usually considered part of the reptilian order Squamata. The "worm lizards," or amphisbaenians, included in this article for convenience of comparison with lizards, are placed in their own suborder, Amphisbaenia, by many modern taxonomists. For a further discussion of this problem, see the article REPTILIA.

GENERAL FEATURES

Lizards are by far the most diverse group of modern reptiles in body shape and size. They range in total length from geckos of 3 cm to monitor lizards of 3 m, and in adult weight from less than a gram to more than 150 kg. The popular conception of a lizard as a scampering reptile with head and body about 15 cm long and a slender tail of about equal length may be applied accurately to only a small number of species. Representatives of several families are limbless, resembling snakes; others have elongate hind legs and can run bipedally. A variety of ornaments is found, including extensible throat fans, tail crests, horns or casques on the head, and spines and frills around the throat.

Lizards occupy diverse habitats: underground, on the surface, and in elevated vegetation. Some are slow-moving, relying on cryptic coloration for protection; others can run swiftly across desert sands. The mosasaurs, an extinct family, were strictly marine. Some were giants, attaining lengths of 10 m (30 ft), with an elongate head, short neck, and long thin body and tail. One living lizard, the marine iguana of the Galapagos Islands, feeds on algae in the sea. No other extant species is marine, but several are partially aquatic, feeding on freshwater organisms.

Modern lizards do not play a major role in human ecology. Some large species (iguanas) are eaten, and others are used for leather goods. Predators, such as the tegu, can be pests around chicken farms, but the vast majority are primarily insectivorous or consume undesirable rodents. Small species such as geckos, which tend to live around houses, are often welcomed because of their efficiency in destroying insects; they may transmit *Salmonella* bacteria, however. In general though, lizards are not disease vectors.

Only two species, the Gila monster of the southwestern United States (*Heloderma*) and a close relative in Mexico, are venomous. They bite man only when provoked and fatalities are very rare. Unfortunately, diabolical powers attributed to lizards have made them objects of fear in many countries. Lizards are valued as subjects for biological research: the varied modes of reproduction and ability to regulate body temperatures are only two of many areas studied by comparative physiologists; the great abundance and easy observability of numerous species make them ideal subjects for ecologists and ethologists; the ability of some species to regenerate broken tails has led to their use by developmental biologists. In addition, because they are clean and easy to keep, lizards are quite popular as house pets.

NATURAL HISTORY

Life cycle. Most lizards reproduce by laying eggs. In some small species the number of eggs is rather uniform for each laying or clutch. For example, all anoles lay but a single egg at a time; many geckos lay one or two eggs (depending upon the species), and some skinks have fixed clutches of two eggs. A more general rule is that clutch size varies with size, age, and condition of the mother. A clutch of four to eight eggs may be considered typical, but large species such as iguanas may lay 50 or more eggs at one time. Lizard eggs are usually leathery shelled and porous and can expand by absorption of moisture as the embryos grow. An exception occurs in the majority of egg-laying geckos, whose eggs have shells that harden soon after deposition and then show no further change in size or shape.

(G) Glass snake (*Ophisaurus*). (H) Worm lizard (*Amphisbaena*). (I) Gila monster (*Heloderma*). (J) Cylindrical skink (*Chalcides*).

Some lizards bear live young. In the family Scincidae this is true for about one-third of the species, many of which are tropical. In most other families that have live-bearing representatives, the species that are exposed to cold—either at high altitude or at extreme latitude—generally are the live bearers. For example, all New Zealand geckos have live young, yet all other geckos lay eggs. Live bearers are divided into two categories. Ovoviviparous forms essentially retain eggs in the oviduct with no definite shell laid down, whereas truly viviparous forms have a chorio-allantoic placenta. Whether there is an actual exchange of nutrients across this placenta, as in mammals, is currently under study.

Sex in lizards is genetically and rigidly determined; a hatchling normally has either only male or female reproductive structures. In representatives of at least three diverse families (Iguanidae, Teiidae, Pygopodidae), the males have dissimilar sex chromosomes. This is similar to the sex-chromosome system of most mammals but differs from snakes, in which sex-chromosome differences, when present, are found in the female.

Most lizard populations are evenly divided between females and males. Deviations from this pattern are found

in parthenogenetic (all female) species, in which the young are produced from unfertilized eggs. In the Caucasus all-female races of *Lacerta* and in the southwestern United States and parts of Mexico all-female species of whiptailed lizards (*Cnemidophorus*) have interesting parallels. They appear to live in areas ecologically marginal for representatives of their genera. In the case of *Cnemidophorus*, there is convincing evidence that parthenogenetic forms arose through hybridization between two bisexual species.

Parental care among lizards tends to be minimal following egg deposition. Many species dig holes in which the eggs are placed; others bury them under leaf litter or utilize a cranny in a tree or cave. Some species, however, notably the five-lined skink (*Eumeces fasciatus*) of the United States, remain with their eggs throughout incubation time (about six weeks), leaving only infrequently to feed. These skinks turn the eggs regularly and, if the eggs are experimentally scattered, will return them to the nest cavity. As soon as the young disperse, family ties are severed.

Certain lizards, particularly some geckos, are known to be communal egg-layers, many females depositing their

Parthenogenesis

eggs at the same site. Whether this is due to social interaction or simply to ideal site conditions has not been determined.

Juvenile lizards are essentially miniature adults; they do not go through any larval phase nor any stage of depen-

Figure 2: Comparison of heads of a typical lizard and a typical snake.. (Top) Legless lizard (*Ophisaurus*). (Bottom) Green rat snake (*Elaphe triaspis*).

dence upon adults. They often differ from the adult in colour or pattern and in certain body proportions. For example, heads of hatchling lizards of some species tend to be proportionally larger than those of adults. Certain ornamental structures, such as the throat fan of the male American chameleon (*Anolis*) or the horns of some true chameleons, develop as the lizards become sexually mature.

Some of the smaller lizards mature very quickly, and population turnover is essentially an annual event. The small, side-blotched lizards of the iguanid genus *Uta* of western North America have this type of population dynamics. The young hatch in July and reach sexual maturity that autumn. At this time males undergo spermatogenesis and mating takes place. Females accumulate large quantities of fat, which appears to be utilized in the production of eggs the following spring. Losses of 90 percent or more adults per year may come from predation, inclement weather, or other environmental variables. A single species living under a variety of environmental conditions may have very different population dynamics in different regions. For example, in areas with long winters there are periods of hibernation, coupled with greater longevity and slower population turnover.

Large lizards may take several years to reach sexual maturity. Unfortunately, there is little information on the dynamics of natural populations of most lizard species. In captivity many species are long-lived. There is a report of a male slowworm (*Anguis fragilis*) 46 years old mating with a female 20 years old. Gila monsters (*Heloderma*) have been kept in captivity for more than 25 years, and even some small geckos have been kept for as long as 20 years.

Ecology. The most important environmental variable to a lizard is almost certainly temperature. Like fish and amphibians, lizards are ectothermic ("cold-blooded"); they tend to assume the temperature of their surroundings. Yet all temperatures are not equally acceptable to lizards. Most species seek out relatively specific body temperatures, called "preferred temperatures," mostly ranging from 28° to 38° C. Although metabolic energy is not utilized to control body temperature, considerable thermoregulation can be accomplished largely through behavioral means, if the lizard has a choice. Typically, a diurnal lizard will emerge early in the morning and will sun itself, orienting the body to maximize exposure to the sun, until the preferred temperature is approached. The ability to absorb heat from solar radiation may permit the lizard to warm itself well above air temperatures. For example, *Liolaemus multiformis*, a small iguanid that lives high in the Andes, has the ability to raise its body

temperature to 35° C, while air temperatures are at 10° C or lower.

The preferred body temperature plays a critical physiological role in the life of a lizard. It has been demonstrated in the laboratory that animals kept without the opportunity to achieve the preferred temperature may be unable to attain the normal reproductive condition or may become sterilized. There is also evidence that enzymes catalyze reactions most efficiently at or near the preferred body temperature.

A lizard living in the tropics often will find the immediate environmental temperatures within its preferred range. To be successful in other habitats, a species must be able either to function at less than optimal temperature or, at least, to have less time at the optimal temperature and spend more time attaining this temperature. Thus it is not surprising that diversity of lizard species decreases with increasing latitude or with high altitude within the tropics.

Water is less of a problem to lizards than is temperature. All reptiles excrete uric acid and hence do not need great amounts of liquid to get rid of nitrogenous wastes. Many lizards have salt glands for active excretion of mineral salts. Deserts, therefore, do not pose severe problems to lizards and actually serve as a major habitat for the group. Lizards form a conspicuous portion of the fauna of oceanic islands, where amphibian and mammalian species' diversity is generally low. The ability of lizards to withstand desiccation may well account for their success at colonizing oceanic islands. They are believed to arrive on mats of floating vegetation washed up on the island shore. Hard-shelled gecko eggs seem to be particularly equipped for such journeys.

Other variables that affect lizards are day length (photoperiod) and rainfall. Lizards living far from the equator experience marked variation in photoperiod, with short winter days and long summer days. Certain species are adapted to respond to such cues. *Anolis carolinensis* of the southeastern United States ceases reproduction in the late summer and fattens up for winter hibernation. This change occurs while the days are still warm and appears to be triggered by decreasing day length. It is adaptive for the species because eggs laid in September would essentially be wasted, the young hatching in November when food is not readily available and temperatures are too low to permit efficient, rapid growth. Some tropical species respond to alternations between rainy and dry seasons, and egg-laying may cease during the driest months of the year. This may be adaptive for a variety of interrelated reasons. When food abundance is low, it is of direct advantage to the parent not to channel energy into production of eggs. Additionally, eggs might be less viable because of desiccation.

Lizards provide valuable models for the study of competition between species. On some Caribbean islands as many as ten species of *Anolis* may live in a single restricted area. For so many species to be accommodated, each must be specialized for a rather precise niche. The species come in a variety of sizes, feed on different sizes of prey, and have different preferences for structural and climatic niches. Some live in tree crowns others on trunks, others in grass; some live in open sun, others in "filtered" sun, and still others in deep shade. Thus, with ten anoles in a single area, each species has its own characteristic microhabitat.

Behaviour. Most lizards are active during daylight hours, when acute binocular vision is necessary for most nonburrowing species. The family Gekkonidae, however, is comprised predominantly of species that are most active from dusk to dawn. In conjunction with night activity, geckos are highly vocal and communicate by sound, whereas most other lizards are essentially mute.

Lizards spend considerable time obtaining food, usually insects. Iguanids and agamids tend to perch motionless at familiar sites and wait for prey. They are attracted by motion and dart suddenly for the capture. The true chameleons move slowly, carefully observant, each eye moving independently, and capture their prey by shooting out the sticky tongue. Lizards of other groups actively search

Popula-
tion
turnover

Hiberna-
tion

Tempera-
ture
regulation

for prey by probing and digging, using scent as well as visual cues. Plants are eaten by many of the largest lizards, such as the iguanas and the spiny-tailed agamid (*Uromastix*).

Defense

Lizards themselves are food for many birds, mammals, and reptiles, and they have many defensive mechanisms. The chuckwallas (*Sauromalus*) remain close to rock piles. When danger threatens, they move into crevices and puff themselves up so that extrication is most difficult. A number of spiny-tailed forms also move into crevices and expose only the formidable tail. Perhaps the highest development of this sort of defense is found in the African armadillo lizard (*Cordylus*), which holds its tail in its mouth with the forefeet and presents a totally spiny appearance to an attacker. To intimidate intruders on its territory, the frilled lizard of Australia (*Chlamydosaurus*) extends a throat frill almost as wide as the lizard is long. The tails of many lizards break off (autotomize) easily. The broken-off section wriggles rapidly, distracting the predator as the tailless lizard scurries for cover.

Social interactions among lizards are best understood for the species that respond to visual stimuli. Many lizards defend certain areas against intruders of the same or closely related species. Territorial defense does not al-

ways involve actual combat. Elaborate, ritualized displays have evolved, presumably to avoid physical harm. The displays often involve erection of crests along the back and neck, increasing apparent size; showing bright colours, either by extending a throat fan or exposing a coloured patch of skin; and stereotyped movements such as push-ups, head bobbing, and tail waving. Impressive ornamentation is often restricted to males, but females of many species defend territories by stereotyped movements similar to those of males. Energy is expended in territorial defense, and a displaying male is very conspicuous and vulnerable to predation; but territoriality is evidently advantageous and has evolved through natural selection. Successful defense of a territory increases the chances of obtaining the necessary amount of food and at the same time increases the probability of a successful mating with any females living within the defended area. Thus a successful territorial male has a higher probability of reproductive success than one living in a marginal area. The displays used by males in establishing territories also may function to "advertise" their presence to females; in species that breed seasonally, territoriality diminishes during the nonbreeding season. In iguanids, actual courtship displays differ from territorial displays in that males approach females with pulsating, jerky movements. In addition to visual cues used for bringing the sexes together, there are undoubtedly chemical stimuli, but these have not been well studied. Numerous lizard species have femoral pores, small blind tubes along the inner surface of the thighs, whose function may be to secrete chemical attractants and territorial markers.

Courtship

Copulation follows a common pattern. The male grasps the female by the skin, often of the neck or side of the head, places the fore and rear legs on the near side over the female, pushes his tail beneath hers, and twists his body to bring the cloacae together. One hemipenis is then everted and inserted into the cloaca of the female. Depending upon the species, copulation may last from seconds to 15 minutes or more.

FORM AND FUNCTION

Rather than present a detailed anatomical report of a lizard, this section discusses certain structures either characteristic of lizards in general or specializations of certain groups.

Skull and jaws. The skull is derived from the primitive diapsid condition; but the lower bar leading back to the quadrate bone is absent, giving greater flexibility to the jaw. In some burrowers, for example *Anniella* and the amphisbaenians, as well as some surface-living forms including the geckos, the upper as well as lower temporal bar has been lost. The small burrowers have thick, tightly bound skulls, with braincases well protected by bony walls. In most lizards the front of the braincase is made up of thin cartilage and membrane. The eyes are separated by a thin vertical interorbital septum. In burrowing forms with degenerate eyes, the septum is reduced, adding to the compactness of the skull. Most lizard skulls are kinetic; i.e., the upper jaw can move in relation to the rest of the cranium. Since the anterior part of the braincase is cartilaginous and elastic, the entire front end of the skull can move as a single segment on the back part, which is solidly ossified. This increases the gape of the jaws and probably assists in pulling struggling prey into the mouth.

Teeth. Most lizards are insectivores (insect eaters), with sharp, tricuspid teeth adapted for grabbing and holding. Some herbivorous (plant-eating) species, for example iguanas, have tooth crowns expanded to a leaf shape with serrated cutting edges. The teeth of some large predators are conical and slightly recurved. Mollusk and crustacean feeders, such as the caiman lizard (*Dracaena*), may have blunt, rounded teeth in the back of the jaw designed for crushing. The venomous lizards (*Heloderma*) have a longitudinal groove or fold on the inner side of each mandibular tooth. These grooves conduct the venom. In most lizards, teeth are present along the jaw margin (on the maxilla, premaxilla, and dentary bones) and, in some forms, on the palate. In the embryo, an egg-tooth develops on the premaxilla and projects forward from the

The egg-tooth

snout. It aids in piercing the shell and is lost soon after hatching. This is a true tooth, unlike the horny epidermal point in turtles and crocodilians.

The common mode of tooth implantation is **pleurodonty**, in which the teeth are fused to the inner side of the labial wall. In the other mode, **acrodonty**, teeth are fused to the tooth-bearing bone, often to the crest of the bone. Acrodont teeth are rarely replaced, once a certain growth stage is reached. The dentition of the Agamidae is usually described as acrodont, but most species have several **pleurodont** teeth at the front of the upper and lower jaws.

Locomotion and limb adaptations. The majority of lizards are quadrupedal, with powerful limb musculature. They are capable of rapid acceleration and possess great ability to change direction of motion rapidly. The **race-runners** (*Cnemidophorus*) can attain speeds of 15 mph, which, in terms of their own body length, puts them in a class with fast terrestrial mammals. A tendency toward elongation of the body is found in some families, often accompanied by reduction of limb length and, not infrequently, complete loss of limbs. Such lizards propel themselves entirely by lateral undulations emanating from highly complicated ventral abdominal musculature. Limbless lizards that move quickly on the surface or through sand tend to have elongate tails (*Ophisaurus*, the glass "snake"), whereas the burrowers have extremely reduced tails (*Amphisbaenians*). The burrowers (**amphisbaenians** in particular) dig by ramming the head into the substrate, then rotating the head around the head joint, compacting the substrate.

Many modifications of the toes are to be seen in lizards. Some desert geckos, the **iguanid** *Uma*, and the lacertid *Acanthodactylus* have fringes on the toes that provide increased surface area and prevent sinking into loose desert sand. Arboreal geckos and anoles have **lamellae** (fine plates) on the undersides of the toes. Each lamella is made up of brushlike setae, each double; and the tips divide several times, the final strand less than $.25 \mu\text{m}$ ($1/100,000$ in) in diameter. These fine hairlike processes greatly enhance the clinging ability of the lizards, as they are able to find purchase in the smallest irregularities of the substrate. Geckos and anoles can easily climb vertical panes of glass.

The true chameleons (*Chamaeleontidae*), a predominantly arboreal family, have a different type of highly specialized limb. The digits on each foot are divided into two groups by webs of skin. On the hind limb, three of the

White rectangle indicates the area covered by the photograph at the next larger magnification. (Top right) More detailed view of six of the lamellae (magnified $25\times$). (Bottom left) Part of lamella revealing its surface, covered by setae (magnified $220\times$). (Bottom right) Seta with attached suction cups visible at fringe terminals (magnified $2,550\times$).

toes are on the outside, two on the inside (a form of **zygodactyl**); on the forelimb the pattern is reversed. Each foot is thus divided into an outer and an inner portion, which can be opposed as the branch is gripped. In addition, these and some other lizards have prehensile tails, which aid in grasping branches.

Several terrestrial iguanids and agamids are able to run bipedally. Basilisks are actually able to run across water for short distances. During bipedal locomotion the tail is held out backward and upward and acts as a counterweight.

Some lizards are able to parachute or glide through the air and make soft landings. The most highly adapted of these are the agamid lizards called flying lizards (*Draco*), which have extensible lateral expansions of the skin, supported by elongate ribs.

Skin and colour change. Except for openings of nostrils, mouth, eyes, and cloaca, most lizards are completely covered in scales, which vary among species and on different parts of the body of the individual. Scales may be smooth and overlapping, form a mosaic of flat plates, or have keels or tubercles. Osteoderms, bony plates that de-

Bipedal locomotion

velop in the dermis, underlie head and body scales of some lizards. The outer parts of the scales are composed of dead horny tissue made up largely of the protein keratin. The dead layer is shed at intervals and is replaced by proliferating cells in the deep part of the epidermis. Certain lizards have scale organs, with a stiff projecting seta emerging from the serrated edge of the scale and presumably responsive to tactile stimuli.

Many lizards can show some colour change. Two groups, the chameleons and the anoles, are particularly noteworthy in this ability. They can change from bright green to deep, chocolate brown, and patterns such as lines and bars may appear and disappear. The pigment cells that permit colour change are melanophores. Within these cells, pigment granules are able to migrate. In general, the animal is light when pigment is concentrated and dark when it is dispersed throughout the cells. The actual colour state, complexly controlled, is not simply matching of background but seems to be controlled by an interaction of hormones, temperature, and the nervous system.

PALEONTOLOGY

Lizards belong to the diapsid reptiles, a group characterized by the presence of an opening in the temporal bone of the skull, both above and below a bar formed by the postorbital and squamosal bones. The diapsids comprise two subclasses of reptiles: the Archosauria (crocodiles, pterosaurs, dinosaurs) and the more primitive Lepidosauria (lizards, snakes, eosuchians, and rhynchocephalians). The earliest known Lepidosaurian order (Eosuchia) appeared in the Late Permian (about 230,000,000 years ago) and almost undoubtedly was ancestral to lizards. Modern lizards differ from their ancestors in several skeletal features, the most diagnostic differences being in the construction of the upper temporal and quadrate regions of the skull. A.S. Romer divides true lizards from their ancestors on the basis of the quadrate region. Among true lizards the quadrate articulates flexibly with the squamosal above it. This occurred through loss of the lower temporal arch and reduction of squamosal development. The oldest fossil true lizards appeared in the Late Triassic (200,000,000 years ago). These were not primitive but highly specialized, having ribs that could be projected outward to provide a gliding ability. Thus it is possible that even older lizards will be found. Representatives of many modern lizard families have been found in Cretaceous deposits (from 136,000,000 to 65,000,000 years ago); and representatives of modern genera, virtually indistinguishable from living forms, were common from the Oligocene (38,000,000 to 26,000,000 years ago) on.

CLASSIFICATION

Distinguishing taxonomic features. Lizards differ from other reptilian groups in several anatomical characters, including the possession of not more than a single bony arch across the temple and paired reversible copulatory organs, the hemipenes.

G. Underwood (1967) summarized the differences between snakes and lizards. Lizards have the eyes separated by a thin vertical interorbital septum, whereas in snakes this septum is absent and the entire width of the bony braincase separates the orbits. Other features that distinguish lizards from snakes include: (1) the pectoral (shoulder) girdle, absent even as a trace in all snakes, present in all lizards; (2) the histological structure of the adrenal glands; (3) the placement of the thymus bodies. M.R. Miller (1968) found that the internal ear of snakes is considerably different from and more primitive than that of any lizard. The families of lizards are defined primarily by osteology and dentition, as well as presence or absence of the rectus superficialis muscle. When this muscle is absent in a group, there is not the slightest tendency for limb reduction and serpentine locomotion. The limits of the families seem to be agreed upon by most systematists; although relationships among the families are not always so clear.

Annotated classification. The classification presented here is adapted from Underwood (1957), which is an updating of C.L. Camp (1923). Definitions of taxa follow

Camp where feasible. The classification of the Gekkoniidae follows A.G. Kluge (1967). The dates of earliest fossils are from R. Hoffstetter (1962).

SUBORDER SAURIA

Reptiles with a single temporal opening lying above the bar formed by postorbital and squamosal bones. Pectoral girdle and interorbital septum always present. About 3,000 species.

Infraorder Ascalabota

Rectus superficialis rarely present; usually more than four transverse rows of ventral scales over each body segment; body covered by scales that overlap by wide margin ("deciduous").

Superfamily Gekkonoidea

Family Gekkonidae (geckos). No supratemporal arch; well defined limbs. Jurassic to present. Eighty-two genera, 650 species. Virtually worldwide in subtropical and tropical regions. Adult total length from slightly under 4 cm to 35 cm. Most with soft, granular skin, easily autotomized tails, no movable eyelids, and toes with fine setae.

Family Pygopodidae (flap-footed lizards). Australia and New Guinea. Some burrowers, others surface dwelling; hind limbs represented by scaly flaps. Eight genera, 15 species.

Family Dibamidae. Philippines and Viet Nam, to New Guinea. Burrowers; females limbless, males with flaplike hind limbs. One genus, 3 species.

Family Anelytropsidae. Eastern Mexico. Limbless; one species.

Superfamily Iguanioidea

Family Iguanidae. Dentition pleurodont. Teeth replaced when lost. Well-developed limbs-Movable eyelids. Oligocene, possibly late Eocene to present. Dominant family of North, Central, and South America, West Indies, and Galapagos Islands. One genus on Fiji and Tonga, two genera on Madagascar, no others in Eastern Hemisphere. Adult lengths from 10 cm (*Uta*) to 2 m (Iguana). A family of diverse forms including short, spiny desert dwellers (*Phrynosoma*), slender arboreal species (*Anolis*), and sea-going iguanas (*Amblyrhynchus*). Fifty genera, 600 species (200 in one genus, *Anolis*).

Family Agamidae. Most teeth acrodont. Many examples of convergent evolution with iguanids, but tooth difference absolute. Late Cretaceous to present. Old World tropics and subtropics, except Madagascar. Thirty-three genera, 300 species (60 in genus *Agama*).

Superfamily Rhytroglossa

Family Chamaeleontidae (Old World chameleons). Feet zygodactylous, grasping. Dentition acrodont. Tongue long, slender, extensible. Two genera, Brookesia 16 species, *Chamaeleo* 68 species. About half restricted to Madagascar, remainder primarily African, two species in western Asia, one in India, one reaching Mediterranean region. Most are insectivores 17–25 cm (7–10 in); the largest, reaching 60 cm, will eat birds.

Infraorder Autarchoglossa

Superfamily Scincomorphoidea

Family Scincidae (skinks). Skull arches present, osteoderms (dermal bone) present. Late Cretaceous to present. Worldwide (except in polar and subpolar regions), greatest diversity in Old World tropics. Typically with conical heads, cylindrical bodies, tapering tails. Less variable than the other large families. Primarily ground dwelling or burrowing, some arboreal with prehensile tails. Limb reduction common. Majority below 12 cm, largest reaches 60 cm. About 50 genera, 800 species.

Family Cordylidae (girdle-tailed lizards). Femoral pores and osteoderms present. Supratemporal fossa roofed over. Late Jurassic to present. Southern Africa and Madagascar. 20–60 cm (8–24 in). About ten genera, 50 species.

Family Lacertidae. Osteoderms absent, supratemporal fossa roofed over. Eocene (possibly Cretaceous) to present, Europe, Asia, and Africa. Morphologically uniform, conical heads, scaly bodies, movable eyelids, well developed limbs and tail. Length 15–60 cm. Approximately 20 genera, 150 species.

Family Teiidae. Osteoderms absent, supratemporal fossa open. Late Cretaceous to present. New World only, primarily in tropics and subtropics. Great variation in the family, including large terrestrial predators (*Tupinambis*), large semi-aquatic snail eaters (*Dracaena*), lacertid-like "racerunners" (*Cnemidophorus*), and small burrowers. Size range 7–120 cm. Forty genera, 200 species.

Superfamily Anguinomorphoidea

Family Anguinae. Skull h osteoderms present. Six mandibular bones. Late Cretaceous to present. Most in Americas, a few Eurasian, Glass lizards (*Ophisaurus*) are limbless "grass

swimmers" reaching 120 cm. Alligator lizards (*Gherrhonotus*) and galliwasp (*Diploglossus*) have four limbs, somewhat elongate bodies, and reach 37 cm. Seven genera, 67 species.

Family Anniellidae (California legless lizards). Limbless burrowers. No skull arches. Length 11–25 cm. California and Baja California. One genus, two species.

Family Xenosauridae. Shape of interclavicle bone and presence of tubercles in the osteoderms distinguishes the family. Late Cretaceous from North America. Presently, two genera, one in Mexico, one in China; four species.

Family Helodermatidae (gila monster and beaded lizard). Venomous; grooved hollow fangs in lower jaw; heavy-bodied. Skin texture "beaded." Oligocene to present; southwest United States and Mexico. Adult length to 50 cm in Gila monster, 80 cm in beaded lizard. One genus, two species.

Family Varanidae (monitor lizards). Osteoderms reduced, seven cervical vertebrae, postorbital arch incomplete. Restricted to Old World tropics and subtropics. Fossils from Cretaceous of North America. Smallest species is adult at 20 cm, largest exceeds 3 m. General uniformity of appearance with elongate head and neck, relatively heavy body, long tail, well developed limbs. One genus, 30 species.

Family Lanthanotidae (earless monitor lizard). Fossils from Recent only. No external ear. Restricted to Borneo; rare and little known. Length to 40 cm. One genus and species.

Family Xantusiidae (night lizards). Vertebrae procoelous, supratemporal arch present. No movable eyelid. Relationships to other lizards unclear, even as to assignment within suborder. Share some features with gekkonids, others with skinks. Four genera, 12 species, California through Central America, and Cuba. *All* moderately small; bodies covered with small scales; ventral surfaces and head with larger platelike scales.

SUBORDER AMPMSBAENIA

Family Amphisbaenidae (amphisbaenians or worm lizards). Long cylindrical bodies with shallow grooves. No external ears, no readily visible eyes. Burrowers. Eocene to present. Primarily tropical, one species reaches Florida, and one reaches Spain. All genera lack hind limbs, and all but three lack forelimbs. Fifteen genera, about 100 species.

Critical appraisal. The boundaries of most lizard families have been stable for the past half-century, with several exceptions. The most important involves Gekkonidae, which Underwood (1954) divided into three families but which Kluge (1967) reunited into a single family with four subfamilies. C. Gans (1960) considers the Amphisbaenia so distinct that he raised them to ordinal status, equivalent in rank to lizards and snakes, and raised the two amphisbaenid subfamilies to family status. Studies by M.R. Miller (1966, 1968) on the internal ear, and A.E. Greer (1970) on cranial osteology clarify the relationships of some of the obscure burrowers and demonstrate that members of the so-called family Feylinidae are merely specialized skinks and are not closely related to the superficially similar Anelytropidae. Perhaps of greatest significance is the finding that the cochlear duct of all snakes is more primitive than that of any lizard. This throws doubt on the theory that snakes are derived from highly advanced lizards (varanid relatives).

BIBLIOGRAPHY. General surveys of the species of lizards and their life histories, with many photographs, are found in K.P. SCHMIDT and R.F. INGER, *Living Reptiles of the World* (1957); A.F. CARR, *The Reptiles* (1963); and R. MERIENS, *La vie des amphibiens et reptiles* (1959; Eng. trans., *The World of Amphibians and Reptiles*, (1960).

Anatomy, paleontology and biology: A. BELLAIRS, *Reptiles*, 2nd ed. (1968), is a concise and well written introduction to all aspects of reptilian biology, with references to original scientific papers. V.A. HARRIS, *The Anatomy of the Rainbow Lizard* (1963), provides a dissection manual for students, moderately technical but very readable. Of a more technical nature are two works by A.S. ROMER: *Osteology of the Reptiles* (1956) and *Vertebrate Paleontology*, 3rd ed. (1966).

Behaviour and ecology: V.A. HARRIS, *The Life of the Rainbow Lizard* (1964); W.W. MILSTEAD (ed.), *Lizard Ecology; A Symposium* (1967), contains summaries of current research in population ecology, physiological ecology, and social behaviour, with panel discussions of the reports; an excellent source for understanding trends in current research.

Important taxonomic books and papers, not easily read by the layman, but fundamental to an understanding of the classification are: C.L. CAMP, "Classification of the Lizards,"

(G.C.G.)

Savigny, Friedrich Karl von

Friedrich Karl von Savigny was the most influential figure in 19th-century German jurisprudence. He was the founder of a modern system of German civil law and of a general theory of private law. He became internationally known for his system of private international law.

Deutsche Fotothek Dresden

Savigny, lithograph by E. Winterhalder (b. 1879) after a chalk drawing by Louise Claude Henry (1798–1839).

Savigny was born on February 21, 1779, in Frankfurt am Main, a descendant of landed nobility who had emigrated to Germany from Lorraine. He studied at the universities of Göttingen and Marburg, where he received his degree in 1800 and at once took up his teaching career. His wealth and social position enabled him to devote all of his considerable talents to scholarly work. In 1803 he established his reputation with *Das Recht des Besitzes* (Eng. trans., *Treatise on Possession*; or, the *Jus Possessionis of the Civil Law*, 6th ed., 1848), a book that was the beginning of the 19th-century scholarly monograph in jurisprudence.

In 1804 he married Kunigunde Brentano of the famous and artistic Frankfurt family. Through his wife's brother and sister (Clemens Brentano the poet, and Bettina Brentano, the writer, who married the poet Achim von Arnim) he came in close contact with the Heidelberg group of Romantic writers.

In 1808 Savigny went to the University of Landshut in Bavaria as a professor of Roman law, and in 1810 he was invited to the new University of Berlin, where he soon became one of the most famous and influential members of the faculty. He taught there for the rest of his career.

The German Romanticism of the early 19th century had a strong influence on Savigny's philosophy of law. In 1814 the wave of nationalism inspired by the war of liberation against Napoleon led the law professor A.F.J.

Education
and early
career

Legal
philosophy

Thibaut to demand a unified civil code for all the German states. Savigny replied in a famous pamphlet, "Vom Beruf unserer Zeit für Gesetzgebung und Rechtswissenschaft" (Eng. trans. "Of the Vocation of Our Age for Legislation and Jurisprudence," 1831), that started juristic thought along a new path. To him, the lesson of history was the futility of hasty codification. The essential prerequisite was a deep and far-reaching appreciation of the genius of the particular community. The prescriptive content of the law must accord with the spirit of the people, the *Volksgeist*. A law that was not in conformity with this was doomed. Custom becomes the chief manifestation of law, although as law grows more technical a specialist body of experts, known as lawyers, emerges, whose function is to reflect the *Volksgeist* in technical matters. In the current age, Savigny argued, few had the requisite skill or vocation to codify German law. In his classic words, law

is first developed by custom and popular faith, next by judicial decisions-everywhere, therefore, by internal silently operating powers, not by the arbitrary will of a law-giver.

He was not, it should be emphasized, opposed to legal reform and codification; he sought rather to uncover the content of existing law through historical research.

In 1815, shortly after the appearance of this epochal pamphlet, he founded, together with K.F. Eichorn and J.F.L. Goschen, the *Zeitschrift für geschichtliche Rechtswissenschaft*, which became the organ of the new historical school of jurisprudence. In the same year he began publishing his seven-volume work on the history of the Roman law in the Middle Ages, *Geschichte des römischen Rechts im Mittelalter* (1815–31). This was the foundation of the modern study of medieval law.

Savigny strove to establish a German science of civil law. His approach to legal methodology was first put forward in a lecture at Marburg in the academic year 1802–03 (published in 1951 as *Juristische Methodenlehre, nach der Ausarbeitung des Jakob Grimm*). He held that legal science should be both historical and systematic, meaning that it should endeavour to show the inner coherence of the material handed down in the historical sources of Roman law. For all his emphasis on history, Savigny was by no means an exponent of natural law theory. Instead he accepted the view of the philosopher Immanuel Kant, who held that law and morality were not identical; law, according to Kant, is the complex totality of conditions under which maximum freedom is provided for all. One might characterize Savigny's system of private law based on the Kantian approach as a system of the rights of private freedom of individuals who organize their legal relations mainly by independent contracts. This conception obviously harmonized well with the rising capitalism of the second half of the 19th century.

Savigny gave embodiment to his systematic approach in his eight-volume treatise on modern Roman law, *System des heutigen römischen Rechts* (1840–49). The eighth volume, which contained his system of international private law, showed the influence of the U.S. lawyer and Supreme Court justice Joseph Story.

In 1817 Savigny was made a member of the Prussian Privy Council. In 1819 he was appointed to the Berlin Court of Appeal and Cassation for the Rhine Provinces. In 1826 he became a member of the commission for revising the Prussian code, and in 1842 he gave up his teaching position to accept a ministerial post as head of the newly founded department for revision of statutes. The revolution of 1848 ended his governmental career.

In 1850 he published a collection of his monographs, *Vermischte Schriften*, and in 1851–53 a two-volume work on the law of contracts, *Das Obligationenrecht*, a supplement to his work on modern Roman law. He died in Berlin on October 25, 1861.

Judgments of Savigny have varied. His famous essay of 1814 caused him to be regarded for a long time as a leader of the romantic branch of the historical school of law. Only recently has he been seen more accurately as a thinker in the line of the rationalist jurisprudence of the 18th century, basing his system on Kant's critical philosophy.

BIBLIOGRAPHY. There is no definitive biography of Savigny. Much material about his life, with many letters, is contained in ADOLF STOLL, *Friedrich Karl v. Savigny*, 3 vol. (1927–39). A well-balanced description of his life and work is in ERIK WOLF, *Grosse Rechtsdenker der deutschen Geistesgeschichte*, 4th ed., pp. 467–542 (1963). Fundamental background is contained in FRANZ WIEACKER, *Privatrechtsgeschichte der Neuzeit*, 2nd ed., pp. 348–399 (1967). See also JULIUS STONE, *The Province and Function of Law*, pp. 421–448 (1946).

(H.Kie.)

Savonarola, Girolamo

The famous 15th-century Italian preacher, reformer, and martyr Girolamo Savonarola was born at Ferrara on Sept. 21, 1452, the son of Niccolò Savonarola and of Elena Bonaccorsi. He was educated by his paternal grandfather, Michele, a celebrated doctor and a man of rigid moral and religious principles. From this elderly scholar, whose own education was of the 14th century, Savonarola may have received certain medieval influences. In his early poetry and other adolescent writings the main characteristics of the future reformer are seen. Even at that early date, as he wrote in a letter to his father, he could not suffer "the blind wickedness of the peoples of Italy." He found unbearable the humanistic paganism that corrupted manners, art, poetry, and religion itself. He saw as the cause of this spreading corruption a clergy vicious even in the highest levels of the church hierarchy.

Alinari—Art Reference Bureau

Savonarola, painting by Fra Bartolomeo. In the Museo di S. Marco, Florence.

On April 24, 1475, he left his father's house and his medical studies, on which he had embarked after taking a degree in the liberal arts, to enter the Dominican Order at Bologna. Returning to Ferrara four years later he taught Scripture in the Convento degli Angeli. Scripture, together with the works of Thomas Aquinas, had always been his great passion.

Career in Florence. In 1482 Savonarola was sent to Florence to take up the post of lecturer in the convent of San Marco, where he gained a great reputation for his learning and asceticism. As a preacher he was unsuccessful until a sudden revelation inspired him to begin his prophetic sermons. At San Gimignano in Lent 1485 and 1486, he put forward his famous propositions: the church needed reforming; it would be scourged and then renewed.

The following year (1487) he left Florence to become master of studies in the school of general studies at Bologna. After the year of his appointment was over, he was sent to preach in various cities until Lorenzo de' Medici used his influence to have Savonarola sent back to Florence, thus opening the doors there to the bitterest enemy of Medici rule. Having returned to the city of his destiny (1490), Savonarola preached boldly against the tyrannical abuses of the government. Too late Lorenzo tried to dam the dangerous eloquence with threats and flattery, but his own life was drawing to a close, while popular enthusiasm

Attack on
Medici rule

Later
works

for Savonarola's preaching constantly increased. Soon afterward Savonarola gave his blessing to the dying Lorenzo. The legend that he refused Lorenzo's absolution is disproved by documentary evidence.

Medici rule did not long survive Lorenzo and was overthrown by the invasion of Charles VIII (1494). Two years before, Savonarola had predicted his coming and his easy victory. These authenticated prophecies, the part he had played in negotiations with the King and in moderating the hatred of the factions after the change of government, enormously increased his authority. Once the Medici had been driven out, Florence had no other master than Savonarola's terrible voice. He introduced a democratic government, the best the city ever had. He has been accused, but unjustly, of interfering in politics. He was not ambitious or an intriguer. He wanted to found his city of God in Florence, heart of Italy, as a well-organized Christian republic that might initiate the reform of Italy and of the church. This was the object of all his actions. The results he obtained were amazing: the splendid but corrupt Renaissance capital, thus miraculously transformed, seemed to a contemporary to be a foretaste of paradise.

Savonarola's
enemies

Savonarola's triumph was too great and too sudden not to give rise to jealousy and suspicion. A Florentine party was formed in opposition to him called the Arrabbiati. These internal enemies formed an alliance with powerful foreign forces, foremost of which were the Duke of Milan and the Pope, who had joined in the Holy League against the King of France and saw in Savonarola the main obstacle to Florence's joining them. It was then, after a firm rejection of the league by Florence, that the Pope sent to Savonarola the brief of July 21, 1495, in which he praised the miraculous fruits of Savonarola's work and called him to Rome to pronounce his prophecies from his own lips. As that pope was the corrupt Alexander VI, the trap was too obvious. Savonarola asked to be allowed to put off his journey, offering illness as his excuse.

The Pope appeared to be satisfied, but on September 8, under pressure from his political friends and Savonarola's enemies, he sent him a second brief in which praises turned into vituperation. He ordered him to go to Bologna under pain of excommunication. Savonarola replied to this strange document with respectful firmness, pointing out no fewer than 18 mistakes in it. The brief was replaced by another of October 16, in which he was forbidden to preach. As the Pope himself frankly confessed, it was the Holy League that insisted. After a few months, as Lent 1496 drew near, Alexander VI, while refusing the Florentine ambassadors a formal revocation of the ban, conceded this verbally. Thus Savonarola was able to give his sermons on Amos, which are among his finest and most forceful, and in which he attacked the Roman Court with renewed vigour. He also appeared to refer to the Pope's scandalous private life, and the latter took offense at this. A college of theologians found nothing to criticize in what the friar had said, so that after Lent he was able to begin without further remonstrances from Rome, the sermons on Ruth and Micah.

At that time, as Savonarola's authority grew, the Pope tried to win him over by offering him a cardinal's hat. He replied: "A red hat? I want a hat of blood." Then Alexander VI, pressed by the League and Arrabbiati, mounted a fresh attack. In a brief of Nov. 7, 1496, he incorporated the Congregation of San Marco, of which Savonarola was vicar, with another in which he would have lost all his authority. If he obeyed, his reforms would be lost. If he disobeyed, he would be excommunicated. Savonarola, however, while protesting vigorously, did not disobey, because no one came forward to put the brief into force. He therefore went on unperturbed in Advent 1496 and Lent 1497 with his series of sermons on Ezekiel. During the carnival season that year his authority received a symbolic tribute in the "burning of the vanities," when personal ornaments, lewd pictures, cards, and gaming tables were burned. Destruction of books and works of art was negligible. Events in Italy now turned against Savonarola, however, and even in Florence his power was lessened by unfavourable political and economic developments. A government of Arrabbiati forced him to stop preaching

and incited sacrilegious riots against him on Ascension Day. The Arrabbiati obtained from the Roman Court, for a financial consideration, the desired bull of excommunication against their enemy. In effect the excommunication, besides being surreptitious, was full of such obvious errors of form and substance as to render it null and void, and the pope himself had to disown it. The Florentine government, however, sought in vain to obtain its formal withdrawal; wider political issues were involved. Absorbed in study and prayer, Savonarola was silent. Only when Rome proposed an unworthy arrangement, which made withdrawal of the censure dependent on Florence's entry into the league, did he again go into the pulpit (Lent 1498) to give those sermons on Exodus that marked his own departure from the pulpit and from life. He was soon silenced by the interdict with which the city was threatened. He had no other way out but an appeal to a church council, and he began a move in this direction but then burned the letters to the princes that he had already written, in order not to cause dissension within the church. Once this road was closed the only remaining one led to martyrdom.

Martyrdom. The imprudence of the most impassioned of his followers, Fra Domenico da Pescia, brought events to a head. Fra Domenico took at his word a Franciscan who had challenged to ordeal by fire anyone who maintained the invalidity of Savonarola's excommunication. The Signoria and the whole population of the most civilized city in Italy greedily encouraged that barbarous experiment, as it alone seemed to promise a solution of an insuperable problem. Only Savonarola was dissatisfied. The decree, which assigned to the ordeal Fra Domenico himself and a Franciscan, declared the loser whichever might withdraw or even vacillate. In fact the Franciscan failed to appear and so the ordeal did not take place. Savonarola, victorious by the terms of the decree, was blamed for not having achieved a miracle. The following day the rabble led by the Arrabbiati rioted, marched to San Marco, and overcame the defenders. Savonarola was taken like a common criminal together with Fra Domenico and another follower. After examination by a commission of his worst enemies and after savage torture, it was yet necessary to falsify the record of the inquiry if he were to be charged with any crimes. But his fate was settled. The papal commissioners came from Rome "with the verdict in their bosom," as one of them said. After the ecclesiastical trial, which was even more perfunctory, he was handed over to the secular arm, with his two companions, to be hanged and burned. The sentence was carried out on May 23, 1498, and the account of his last hours is like a page from the lives of the Church Fathers. Before mounting the scaffold he piously received the Pope's absolution and plenary indulgence.

Trial and
execution

Assessment. In fact Savonarola's quarrel was with the corruption of the clergy of whom Alexander VI was merely the most scandalous example, not with the Roman pontiff, for whom he always professed obedience and respect. He was a reformer, but Catholic and Thomist to the marrow; his faith is borne out in his many works, the greatest of which is the *Triumphus crucis*, a clear exposition of Christian apologetics. His *Compendium revelationum*, an account of visions and prophecies that came true, went through many editions in several countries. Of his sermons, some exist in a version taken down verbatim.

After Savonarola's death a cult was dedicated to him, which had a long history. Saints canonized by the church, such as Philip Neri and Catherine de' Ricci, venerated him as a saint; an office was said for him, and miracles he had performed were recorded. He was portrayed in paintings and medals with the title of *beatus*. In the *Acta sanctorum* he was included among the *praetermissi*. When the 500th anniversary of his birth came around in 1952, there was again talk of his canonization.

BIBLIOGRAPHY. The most modern and up-to-date biography is that of ROBERTO RIDOLFI, *Vita di Girolamo Savonarola*, 2 vol. (1952; Eng. trans., 1959). JOSEPH SCHNITZER, *Savonarola*, 2 vol. (1924; Eng. trans., 1931), is a fundamental and irreplaceable work because of the enormous quantity of systematic notes. PASQUALE VILLARI, *La storia di Fra Girolamo*

Savonarola e de'suoi tempi (1859-61), 2 vol. (1887; new ed., 1927; Eng. trans., *The Life and Times of Girolamo Savonarola*, 2nd ed., 1889, reprinted 1969), is an old book but a classic. Fourteen volumes of the Italian national edition of Savonarola's works (1953-) have been published to date. *Le Lettere*, ed. by ROBERTO RIDOLFI (1933), is the only critical edition of his letters. PASQUALE VILLARI, *Scelta di prediche e scritti* (1898), is the best anthology of the writings of Savonarola. For a bibliography of the ancient editions of his works, see LUCIA GIOVANNOLZI, *Contributo alla bibliografia delle opere del Savonarola* (1953); MARIO FERRARA, *Bibliografia savonaroliana* (1958), is a complete bibliography of the published writings about Savonarola from 1801 to 1956.

(Ro.Ri.)

Saxifragales

Saxifragales is a large and diverse order of flowering plants containing 28 families and over 3,000 species. They may be large forest trees, shrubs, stout woody vines, or delicate herbs. Plants belonging to this order are distributed throughout the world; they grow on all continents and on many islands in the Pacific Ocean. Their distribution ranges from cold temperate regions to the tropics and from sea level to the high mountains, and they grow in habitats as diverse as deserts and tropical rain forests. Some species produce medicinal products; a few produce edible fruits; and one genus is an alternate host for a serious disease-causing organism that attacks pines. Certain groups of the order Saxifragales are reputed to capture and utilize the bodies of insects as a source of nitrogen. Flowers and fruits are borne directly on the leaf blades in one small group of trees and shrubs. Exceedingly fleshy, thick, and succulent leaves characterize hundreds of species in one section of the order.

ECONOMIC IMPORTANCE

Ornamental plants. Brexias (family Brexiaceae) are trees from Madagascar that are sometimes grown as specimen plants in greenhouses or outdoors in the subtropics or tropics. Indoors, brexias seldom become trees but grow to the size of tall shrubs. Both greenhouse specimens and those grown outdoors produce characteristic greenish or white, waxy-petalled flowers.

Species of several genera of the family Bruniaceae are widely grown as horticultural plants. Among them are *Berzelia*, *Brunia*, *Raspalia*, *Staavia*, and *Thamnea*. These plants are all natives of southern Africa and reflect the characteristic bushy, evergreen, heathlike nature of all members of the family Bruniaceae. In cooler temperate climates they must be grown under glass.

Among the most important and familiar perennial garden plants of temperate, subtropical, and tropical regions are members of the family Crassulaceae (stonecrop or orpine family). Many are grown as pot plants, especially in cooler climates, and a few are favoured for rock gardens and open border plantings in climatically suitable regions. The family Crassulaceae is native in many parts of the world, but the plants are often characteristic of arid and semi-arid regions and rocky places, particularly in southern Africa. They are typically fleshy-leaved plants, often with handsome, prevailingly red or yellow flowers. The genera *Rochea*, *Crassula*, *Cotyledon*, *Bryophyllum*, *Kalanchoë*, *Pachyphytum*, *Urbinia*, and *Echeveria* are frequently grown under glass or in the home in temperate or cold climates. *Sedum* (stonecrop), however, is used as an outdoor plant for rock gardens in temperate lands. Generally, flowers of plants in the family Crassulaceae are small, but the clusters are particularly showy, especially in *Sempervivum* (houseleek), *Gormania*, *Graptopetalum*, and *Oliveranthus elegans*. Other garden genera are *Monanthes*, from Morocco and the Canary Islands, and *Bynesia weinbergii*, which is Mexican.

The Crassulaceae, although easily propagated from seeds, also root readily from stem and leaf cuttings. Some species regularly produce offsets from the bases of parent rosettes. In *Kalanchoë* and *Bryophyllum* young plants appear in notches around the margins of leaves still attached to the parent plant; these plantlets either drop off naturally and become established below the main plant, or they can be removed from the parent leaf and planted.

Geissois racenzosa (of the family Cunoniaceae) of New Caledonia is a handsome tree with leathery leaves and showy, crimson flowers borne in elongated clusters. Strictly tropical, it is grown only in greenhouses in temperate climates. *Cunonia capensis* of southern Africa is a small tree or large shrub with leathery leaves and dense clusters of small, white flowers. It is occasionally grown as a greenhouse plant.

Davidsonia pruriens (of the family Davidsoniaceae), the Queensland itch tree, is sometimes grown in greenhouses for its two-foot- (60-centimetre-) long leaves, which are covered with bright-red, pungent hairs when young and for its long-stalked clusters of flowers. It is native in northeastern Australia.

Although several genera of the family Escalloniaceae have been introduced into ornamental horticulture—e.g., *Abrophyllum ornans* of New South Wales, Australia; *Anopterus glandulosus* of Tasmania; *Carpodetus serratus*, the putaputawheta of New Zealand; *Corokia coto-naster* of New Zealand; the New Zealand species *Quintinia acutifolia* and *Q. serrata*, tawhewheo; and *Valdivia gayana* of Chile—none has achieved the importance or interest of the various species and cultivated varieties of *Escallonia*. Escallonias are mainly shiny-leaved, evergreen shrubs or small trees native only to South America, where they are found mostly in the Andes mountains and eastern Brazil. White, pink, or red flowers are frequently present in large clusters; sometimes they are pleasantly aromatic. In the United States these handsome shrubs are very popular in California, where their late-autumn or winter bloom is most welcome.

Eucryphia (of the family Eucryphiaceae) is a small genus of glossy-leaved, evergreen trees and shrubs native in the Southern Hemisphere. *Eucryphia pinnatifolia*, a small tree of Chile, is grown outdoors in parts of England and Scotland—e.g., the Royal Botanic Garden, Edinburgh. The flowers, which are produced in late summer and early fall, are large and white-petalled, with a central cluster of conspicuous yellow stamens giving the whole the appearance of camellia flowers.

Francoa (of the family Francoaceae) is a genus, native in Chile, of several perennial herbs with horizontal underground stems (rhizomes). The plants bear deeply cut, hairy leaves and long-stalked clusters of pure-white, pink, or deep-rose-coloured flowers.

Although the gooseberries and currants (genus *Ribes*, of the family Grossulariaceae) are known chiefly for the edible fruits produced by some species, a number of strikingly handsome, sometimes thorny shrubs are available for the ornamental garden. Species of *Ribes* abound, particularly in western North America and in temperate Eurasia and South America. Among those most attractive as flowering plants are *R. odoratum* and *R. aureum*, both of which have fragrant, yellow flowers; *R. sanguineum* with white or reddish flowers; *R. viscosissimum* with sticky, greenish-white or pinkish, aromatic flowers; and *R. lobbbii* with velvety, purple-red flowers. Often the fruits are attractive, some species having translucent scarlet or deep-red fruits and others bearing powder-blue fruits. *Ribes roezlii*, of central and Southern California, has both handsome flowers, which are purple and white, and attractive leddish-purple fruits, which are clothed with reddish, bristly spines.

Probably the most important family of woody ornamental plants in the Saxifragales is Hydrangeaceae. The family is widely distributed in nature, and representatives occur in all parts of the world except Africa, Australia, New Zealand, and the coldest parts of both the Northern and Southern Hemispheres. Species of the family Hydrangeaceae are trees, shrubs, or woody vines, and at least one genus is composed of rhizomatous herbs (i.e., nonwoody plants with underground stems, or rhizomes). Among the plants that have been introduced into ornamental horticulture in greenhouses, gardens, and homes, are the following: *Cardiandra* from China and Japan; *Carpenteria californica*, a native shrub from California; *Decurnaria*, a woody climber with two species, one of which occurs in southeastern United States and the other in central China; *Deutzia*, a genus of mostly Asiatic shrubs; *Di-*

chroa febrifuga of the Himalayas, Malaysia, and China; *Fendlera*, a genus of western American shrubs; *Hydrangea*, a genus of trees, shrubs and woody vines of North and South America, the Himalayas, and central and eastern Asia; *Jamesia americana* (waxflower, wild mock orange), a shrub of semi-arid and mountainous parts of west central United States; *Kirengeshoma palmata*, a perennial herb of Japan; *Philadelphus*, a genus of shrubs of northern Asia and Japan, western America, the southern Atlantic Coast of the United States, and Mexico; *Pileostegia*, a genus of climbing or prostrate evergreen shrubs of the Himalayas and eastern Asia; *Platycrater arguta*, a prostrate shrub of Japan; *Schizophragma*, a genus of climbing shrubs of Japan and China; and *Wlzipplea*, a genus of low, barely shrubby plants endemic (native) in Oregon, California, Utah, and Colorado. Of the horticulturally important members of the family Hydrangeaceae, the most widely planted and best known to gardeners are species of *Philadelphus*, *Hydmngea*, and *Deutzia*.

Philadelphus (mock orange, sweet syringa) species are shrubs with solid, white pith and often flaky bark. The flowers are showy and usually white-petalled, with clumps of bright-yellow stamens. These shrubs and their many cultivated varieties, which are widely planted in shrubbery borders, bloom late in spring.

Hydrangeas are known to most gardeners as shrubs, although some are woody vines—e.g., *Hydrangea petiolaris*, climbing hydrangea—and others are small trees, such as *H. arborescens* (mountain hydrangea, seven-bark). *Hydrangea macrophylla* (hortensia), the common hydrangea of florists, is sold as a pot plant for household adornment in many northern cities in the early spring. *Hydrangea paniculata* and its varieties, particularly *grandiflora*, comprise the most commonly grown group. Variety *grandiflora*, a treelike shrub, is probably the best all-around hardy (cold-resistant) hydrangea now in cultivation. Many garden hydrangeas are not entirely hardy in the north, and the aerial stems may die partially or completely to the ground each winter, new flowering stems being produced at the beginning of the next growing season. Hydrangea flowers, white, blue, or pink in colour, are produced in large, showy clusters. Flower clusters of *H. paniculata* often remain on plants for long periods of time, providing colour during midsummer in temperate regions when other garden plants are not flowering. In some species of *Hydrangea*, flower colour seems to be related to soil acidity. The pink-flowered hortensias, for example, show a tendency to turn blue when iron filings or alum are added to the soil to increase acidity. Flowers of *H. paniculata* are white when young, later changing to pink and purple.

Deutzias are shrubs that bear white flowers mostly in terminal clusters. Blooms in some horticultural forms are "double flowered"; that is, they have more than the usual

single whorl of petals. Like the mock oranges, deutzias often have shreddy bark, but the stem is hollow and does not have the white pith of the mock oranges. Deutzias are very easy to cultivate and provide a fine floral display, mostly in the spring, even on small shrubs 12 inches (30 centimetres) tall. The best known, *Deutzia gracilis*, is a rather bushy shrub that produces numerous white flowers in loose clusters.

Virginian willow (*Itea virginica*) is one of several species of the genus *Itea*. Most species occur in tropical and subtropical Asia. *I. virginica*, the only American species, occurs southward from Pennsylvania and New Jersey to Florida and Louisiana. It is a slender-leaved, deciduous (i.e., the leaves fall in winter), low shrub, two to three feet tall. The white, fragrant flowers, which individually are tiny and not particularly showy, occur in terminal clusters. In autumn, the foliage becomes brilliant red. *Itea yunnanensis* is a large, stout shrub, nine or ten feet (about three metres) tall.

The family Parnassiaceae contains two genera, only one of which, *Parnassia* (grass-of-Pamassus), has any horticultural interest. The low-growing plants are moisture-loving, hardy, perennial herbs of tufted growth habit. The flowers, usually white, greenish white, or yellow, appear between June and September. Species of *Parnassia* occur throughout the Northern Hemisphere, but *P. palustris* is the only one common in Europe.

Penthorum sedoides, the Virginian stonecrop (Penthoraceae), is one member of a small family of plants native in North America and eastern Asia. The leaves of the Virginian stonecrop, which is a branched perennial herb that attains heights of two feet (60 centimetres), are pale green, becoming bright orange with age. These hardy plants, which are used for waterside or shallow-water planting, have flowers that are pale greenish yellow.

Species of several genera of the family Pittosporaceae have achieved horticultural importance; namely, *Billardiera*, *Marianthus*, *Sollya*, and *Pittosporum*. The first three genera consist of low sub-shrubs (shrubby forms that are woody only at the base or also very small shrubs) with rather slender, twining or climbing branches. *Pittosporum* is a genus of stout, evergreen shrubs and small trees. All species of the Pittosporaceae are natives of the Old World: *Billardiera* and *Sollya* occur in Australia; *Marianthus* in Australia and Tasmania; and *Pittosporum* chiefly in Australia but also in tropical and subtropical Africa, Asia, New Zealand, and the Pacific Ocean islands. A number of endemic species occur on the Hawaiian Islands. Greatest horticultural interest is centred in *Pittosporum*, certain species of which are hardy or half-hardy plants frequently grown outdoors in California and Florida. Several species, including *P. tobira* (tobira) of China and Japan, are excellent hedge plants. Tobira is also used to decorate the lobbies of hotels and office

Hydrangea
flowers

buildings. Most species of *Pittosporum* have fragrant flowers that may be white, red, yellow, purple, or greenish. *Pittosporum crassifolium* (karo) of New Zealand is a tall shrub or small tree sometimes reaching heights of 30 feet (ten metres). Planted in rows, it is suitable as a windbreak or shelter near the sea because it is resistant to strong winds and salt spray.

Among the herbaceous families of the Saxifragales, Saxifragaceae, perhaps with the exception of Crassulaceae, is the most important horticulturally. The genus *Saxifraga* (saxifrage, or rockfoil) has the largest number of species in cultivation. They occur in temperate (principally alpine) and boreal regions. They are rare in Asia, few in South America, and totally absent in southern Africa and the islands of the Pacific Ocean. Other genera with species of more or less horticultural importance include *Astilbe*, *Bergenia*, *Bolandra*, *Boykinia*, *Heuchera* (alum-root), *Leptarrhena*, *Lithophragma*, *Mitella* (bishop's-cap, mitrewort), *Oreotrophe*, *rupifraga*, *Peltiphyllum peltatum* (umbrella plant), *Rodgersia*, *Suksdorfia violacea*, *Sullivantia*, *Tanakaea mdicans*, *Tellima*, *Tiarella* (false mitrewort), *Tolmiea menziesii* (pickaback plant), and *Zahlbruckneria paradoxa*.

Practically all Saxifragaceae species are perennial except for a few species in the genus *Saxifraga*. Saxifrageous plants of ornamental value have a variety of uses in the garden. *Heuchera*, *Astilbe*, and *Rodgersia*, for example, are best suited to the open garden. Wild garden genera include *Boykinia*, *Heuchera*, *Mitella*, *Tellima*, and *Tiarella*. *Saxifraga*, *Tolmiea*, and *Lithophragma* do well in rock gardens. Species of *Bergenia* are often utilized in garden borders because of their ornamental foliage and very early blooming pink or white flowers.

Flowers in the Saxifragaceae range from greenish to white and yellow and from pink and red to purple. Leaves are often thick, almost leathery, shining, and evergreen.

Medicinal and folk uses. A number of saxifragean plants are used in native medicine and ceremony in different parts of the world. Although several remedies have been ascribed to these plants, it is doubtful that more than a few are of therapeutic value.

Kalanchoe laciniata is used as an external medicine in India. *K. paniculata* is said to have occult uses in Africa. *K. laciniata* is used by the Malays to attract good spirits; twigs of the plant are placed in houses to summon the return of good spirits after a death. The same process is used to drive away evil spirits and to ward them off during serious illnesses such as cholera and smallpox. Children are bathed in water containing leaves of the plant. Leaves are also used to make a poultice for application to the chest of persons with coughs or colds. A compound lotion made of the leaves of *K. laciniata*, *Cosmos speciosus*, *Stachyphrynium* species, *Drymoglossum heterophyllum*, and *Psophocarpus tetragonolobus* is used to treat smallpox. Pulped leaves of *K. laciniata* are used in the Philippines to treat chronic ulcers, sores, and headaches.

Bryophyllum pinnatum is widely used in Malaya; life-giving properties are attributed to it because of the production of plantlets by the leaves. It is used medicinally by the natives of India, Malaysia, and the Pacific islands. Poultices are prepared from the crushed leaves to relieve headache, coughs, and chest pains. Poultices are used to treat sore eyes in Java, and in Singapore the leaves are sometimes pounded in water, the resulting infusion being drunk to reduce fevers. As a ceremonial plant *B. pinnatum* is employed in connection with fishing—its twigs make up the besom (a brush made of bundled twigs) that is used to sprinkle yellow gruel during incantations designed to improve fishing. Leaves of this species are also used in Malaya during the ceremonial washing of newborn infants.

It has been reported in South Africa that the fresh juice of *Cotyledon orbiculata* is occasionally used beneficially to treat epilepsy even though the plant is considered toxic. Various species of *Sedum* are also employed medicinally; *S. acre* is sometimes used as a laxative; the juice of *S. dendroideum* is employed in Mexico as an astringent to harden the gums and to relieve hemorrhoidal discomfort.

Leaves of *Sernpervivum tectorum* are chewed in parts of Europe as a home remedy for toothache and to relieve the pain of bee stings. A decoction (extract produced by boiling) of the leaves is employed to cure intestinal worms.

The bark of *Weinmannia pinnata* is considered astringent; the same plant secretes a gum that is used in some parts of Cuba as an adulterant of quinine. Similarly, the bark of *W. selloi* is a strong astringent and is used in parts of Brazil to treat wounds. The bitter bark of *Belangera tomentosa* is used as a tonic in some parts of Brazil.

Wood of the Javanese *Polyosma longipes* is said to be useful in treating epidermal scaling (scurf), and the steam produced by boiling the leaves of this species is employed to relieve sore eyes. An extract from the leaves of *Corokia buddleioides* is used in some parts of New Zealand to treat stomachache.

A decoction of the shoots and bark of *Dichroa febrifuga* is taken in the Himalayas as an antipyretic (fever-controlling agent). In Indochina, a decoction of the leaves is used for the same purpose. In Java, the leaves are pounded finely and taken without cooking, together with certain other substances, for fever. In one prescription, the powdered leaves are taken with wormwood (*Artemisia absinthium* and other species of *Artemisia*) as an anthelmintic (intestinal-worm treatment). In another prescription, the powdered leaves are used externally, apparently for intestinal difficulties following childbirth. Fresh leaf and root juices cause vomiting; after the leaves and roots have been soaked in wine and boiled, however, the juice no longer causes vomiting but becomes a gentle purgative.

The dried rhizomes (horizontal underground stems) and roots of *Hydrangea arborescens* of northeastern United States are used medicinally as a diaphoretic (a substance that promotes perspiring) and diuretic. The active principle, hydrangin, is an organic compound known as a cyanogenic glucoside; apparently hydrangin is present in all species of *Hydrangea*. Hydrangin occurs in rhizomes, roots, leaves, and buds. Accidental ingestion of any plant part, under certain conditions, may cause nausea, vomiting, and diarrhea. Treatment consists of washing out the stomach or inducing vomiting.

Penthorum sedoides is employed medicinally in a variety of ways, some of which are quite contradictory—e.g., as a demulcent (a medicine used to soothe irritated mucous membranes) and astringent (a substance that contracts tissues); as a laxative and to treat diarrhea. It reportedly has been used to treat hemorrhoids and gastric ailments.

Phyllonoma laticuspidis is known as *hierba de la viruela* (smallpox weed) in parts of Oaxaca, Mexico. It is administered with sugar as a syrup prepared from the green leaves.

An aromatic decoction brewed from the leaves of *Pittosporum pentandrum* in the Philippines is used by women in their baths following childbirth. The powdered bark is employed in small doses to reduce fever. If taken in larger dosages, it is considered a general antidote. It is also effective in relieving bronchitis. The Malays use poultices of both leaves and roots of *P. ferrugineum* to treat malaria. The leaves and fruit are used as a fish poison in Malaysia; the toxic action is probably related to the presence of such complex compounds as saponins, tannins, and alkaloids.

Leaves of *Astilbe philippinensis* are used in northern Luzon, Philippines, for smoking. Sometimes a little tobacco is mixed with the leaves. The rhizome of *Bergenia purpurascens* is used in Chinese medicine to stop bleeding and as a tonic. *Tiarella cordifolia* of North America is considered useful as a diuretic and tonic; in particular, it is said to be beneficial in relieving cases of urinary-bladder stones and other urinary complaints. *Saxifraga sarmientosa*, a native of China and Japan, is used in Java to treat earache. In Tonkin (North Vietnam) and in various parts of China it is also used for complaints of the ear. It is also employed in China for attacks of cholera and to treat hemorrhoids. To treat the former, administration is internal; to treat the latter, application is by steaming.

Timber and other forest products. Timber from trees of *Brunellia* is only of limited importance in tropical

*Bryophyl-
lum*

America. The light wood is rather soft, finely textured, easy to work, and perishable when in contact with the ground. The hard, durable wood of *Crypteronia paniculata* trees is used extensively for house building in Malaysia and the Philippines. It is also used for fuel. The sapwood is white, the heartwood reddish brown.

Several trees of the family Cunoniaceae produce timber and other forest products. The bark of *Belangeria* of southern Brazil, Paraguay, and Argentina, is used in tanning. The light-pinkish-brown wood is easily worked. The principal use of *Caldcluvia paniculata*, a small tree of southern Chile, is as fuel.

Trees of several species of *Weinmannia* occur in both Old and New World tropics. The bark is rich in tannins, and the timber is suitable for furniture and for interior construction. Timber of *W. blumei* from Malaysia is fairly hard but easy to work; red and lustrous, it is moderately resistant to decay. *W. benthami*, the brush mahogany of Australia, produces a timber that is useful in construction and is occasionally used for cabinet work, handles of small utensils, brush backs, and veneer and plywood. *W. lachnocarpa* (rose marara of Australia) is noted for its straight-grained, hard timber, which is employed for turnery, machinery bearings, chisel handles, mallets, and printer's blocks. Timber of *W. racemosa* finds limited use in New Zealand for cabinet work, interior trim, fencing and mine timbers. Wood of *W. descendens* (encinillo) is imported into the United States from northern South America. The timber, light brown to pinkish and reddish brown, is of medium luster, moderately heavy, and fine textured; it is employed for general construction, furniture, cabinets, joinery, turnery (such as brushes, broom handles, dowels, shoe heels, bobbins), and sporting goods.

Tanning substances are extracted from the bark of *W. racemosa* of New Zealand, *W. luzoniensis* of the Philippines, and *W. tinctoria* of Mauritius. Bark of the last named imparts to animal skins a red hue, hence *tinctoria*, which means "used in dyeing."

Ceratopetalum apetalum, the coachwood, or rose mahogany, of Australia, is sometimes imported into the United States, where it is used for the same purposes as *Weinmannia descendens*. Red elms, or red alder, *Cunonia capensis* of southern Africa, produces a light, soft timber that is durable underwater. It is suitable for furniture, wagon building, and for construction. Species of *Pancheria* of New Caledonia produce wood that is locally important for cabinetwork and turnery. The wood of *Spiraeanthemum samoense* has been used by natives of the Samoa Islands for canoe construction and war clubs.

The timber of *Escallonia* apparently has no commercial possibilities, owing mostly to the small size of the trees. Locally, however, where trees of sufficient size occur, the wood is utilized for building purposes. The moderately hard and heavy wood is easy to cut, tough to split, and appears to be fairly resistant to decay. Fresh wood of *Escallonia floribunda* has a peculiar odour, and, in certain localities in the Venezuelan Andes, it is called *cochinito* or *puerquito*, both of which mean "little pig."

Eucryphia lucida, Tasmanian leatherwood, produces a fine-textured, tough, durable, brownish wood that is not in general use but is suitable for tool handles, furniture, and heavy construction. *E. moorei* of Australia is sometimes called coachwood because it has been used for frames and bodies of wooden vehicles. Ulmo trees, *Eucryphia cordifolia* of Chile, produce fine-textured timber with good working qualities but not very resistant to decay. The lustrous heartwood is brown and variable. In Chile, ulmo wood makes excellent flooring, and, in the nitrate-mining areas, it is used for railway cross-ties and for poles that support power lines. Other uses of ulmo are for furniture manufacture, vehicle parts, oars, and pilings. An extract of the bark, which contains about 15 percent tannins, is used in commercial tanning.

The fine-textured, whitish wood of *Deutzia scabra* is used in Japan for marquetry (delicate inlaywork) and for wooden nails. *Hydrangea paniculata* produces a hard, fine-textured wood prized in Japan for walking sticks, umbrella handles, tobacco pipes, and wooden nails; the

bark is used to manufacture paper. The wood of *Ztea nutans* is attractive and is used in Malaysia for small articles of turnery.

Pittosporum crassifolium of New Zealand furnishes a very tough, whitish wood favoured for marquetry. In the Philippines, fruits of *P. resiniferum* are known as "petroleum nuts" because of the fancied resemblance of the odour of the oil to that of petroleum and because even the green, fresh fruits bum brilliantly. The oil contains two organic compounds, a dihydroterpene and considerable quantities of heptane. The white, fine-textured wood of *P. resiniferum* is not durable; it is sometimes used in Malaysia for house rafters and for firewood.

Fruits, seasonings, and other edible products. *Sedum album* is sometimes used as an herb in salads; leaves of *S. reflexum* are occasionally consumed in salads or soups; and the leaves of *S. roseum* are eaten fresh, soured, or in oil by Eskimos in Alaska. Young shoots of *Crypteronia paniculata* are eaten as flavouring with rice in Indonesia. Flowers of *Eucryphia cordifolia* of Chile are rich in nectar and are prized as a source of honey.

Many species of *Ribes* bear edible fruits of considerable commercial importance. Among the important fruit-producing species is the European gooseberry (*R. grossularia*), which is used in desserts, in pies, and in jams and wines. The European black currant (*R. nigrum*) is eaten fresh or in jams or puddings. *R. rubrum* produces both red and white currants that are used for desserts, pastries, and wine. *R. vulgare*, an American currant, is eaten fresh or in desserts and pies. Other species of less importance for their edible fruits include the buffalo, or Missouri, currant (*R. odoratum*) and some American gooseberries, such as *R. hirtellum*, *R. cynosbati*, *R. oxyacanthoides*, *R. setosum*, and *R. inerme*. The most important fruit-bearing species of *Ribes* are available in many improved and selected varieties.

Young leaves of *Hydrangea thunbergii* from Japan are gathered, steamed, rolled between the hands, dried, and used as a substitute for tea; the preparation is called amacha, or ama-tsja (tea-of-heaven).

Plants of *Saxifraga erosa*, mountain lettuce, or deer-tongue, are used in salads by mountain people in southern Pennsylvania. The thick, fleshy leafstalks of *S. peltata* (Indian rhubarb) were peeled and eaten raw or boiled by Indians of the west coast of North America. Succulent leaves of *S. punctata* (dotted saxifrage) are consumed by Eskimos either raw or after being kept in oil. *Chrysosplenium alternifolium* (golden saxifrage), a perennial herb of Eurasia and North America, is occasionally used in salad and as an emergency food in the Vosges mountains (France). The leaves of *Bergenia crassifolia* (baldan) are used by the Mongols as a substitute for tea called tschager tea.

Role in white-pine blister rust disease. Among the most serious and widespread diseases of forest trees is the white-pine blister rust. This disease is caused by a parasitic fungus, *Cronartium ribicola*, which spends part of its life cycle as a parasite of a susceptible five-needled pine and the other part on certain species of *Ribes* (currants and gooseberries of the family Grossulariaceae). *Ribes nigrum* is the most susceptible species.

The fungus overwinters as a mycelium (filamentous vegetative body) in the stems of *Ribes*; spores (reproductive bodies) are produced by the first week in April, depending upon climatic conditions. The wind-borne spores may be carried several miles. They germinate on moist leaves of *Ribes* plants, and the fungal germination tube enters the leaves through stomates (pores) on the lower surface. Following growth of the fungus in the tissues of the leaves, pustules form on the leaves; from them, other wind-borne spores are released that carry the disease to the pines. The spores germinate on the pine needles, entering through stomates. Eventually, the rapidly growing fungus enters the water and food conducting system of the pine and then moves into the bark, on which externally visible cankers form. After about two years, pustules appear on the surfaces of these cankers. Wind-borne spores from the pustules can infect only species of *Ribes*, not pines. Thus, both *Ribes* and pines must

Timber trees of the family Cunoniaceae

Edible saxifrages

Woods of the hydrangea family

be present together within a favourable environment in order to perpetuate the fungus. When control measures proved insufficient to halt the spread of the disease after its introduction from Europe in the early 1900s, programs for the systematic eradication of *Ribes* plants, including wild, nursery, and crop plants, were begun in regions in which white pines are of commercial and economic importance. Thus today, in many places in the United States where *Ribes* was once native, wild plants are very difficult to find in nature.

NATURAL HISTORY

Insect-trapping plants. The families Cephalotaceae, Byblidaceae, and Roridulaceae have been reported to be insectivorous. Insectivorous implies the ability of plants to "eat" insects, which, of course, they do not; rather, by a series of mechanisms, insectivorous plants trap insects and externally digest parts of them. Although insectivorous plants doubtless receive some nutrition from the bodies of insects, most can exist quite well without an insect diet. Insectivorous plants usually grow in soils that are deficient in nitrogen salts, which are used by plants in the manufacture of amino acids and proteins. Therefore they require a supplementary source of nitrogen, which they obtain by digesting the proteins in captured insect bodies.

Of the three families of Saxifragales noted above, only Cephalotaceae and Byblidaceae are truly insectivorous in the sense that they both capture and digest insects. Plants of the Roridulaceae, a family restricted to southwestern Africa, are known to trap insects in the resinous secretions of their leaves, but there is no evidence that any form of digestion takes place or that the plants benefit from these accidentally ensnared insects.

Roridula dentata, for example, is known not to digest the insects, which, by incidentally coming into contact with the leaves, become stuck on the plants. Even though these insects apparently do not benefit the plant, they are used as food by a spider of the genus *Synaema*. This spider, which has become adapted to life on *Roridula* plants, is immune to the sticky secretions and is thus able to move without difficulty. The spiders generally hide among the dried leaves or in nests that they build there, awaiting the vibration of a twig, indicating the presence of an ensnared insect, which the spider kills. There thus appears to be a symbiotic relationship between the spider and the plant; clearly the spider benefits from the relationship, but whether the plant is benefitted or not is unknown.

The insectivorous nature of plants of Byblidaceae and Cephalotaceae is more firmly established; apparently, a true capture-and-digest system exists. Byblidaceae consists of one genus, *Byblis*, and two species in western Australia. Plants of *B. gigantea* are shrublets, attaining heights of 50 centimetres (20 inches) and consisting of a woody rhizome bearing in any one season the dying parts of the previous growing season and the growing parts of the present season. These parts consist usually of a main stem, which is sparsely branched near the base. The long, linear, yellow-green leaves of the stems are covered with numerous mucilage glands, which give the leaf a glistening surface. Plants of *B. linifolia* are more delicate than those of *B. gigantea*, and the annual stem and its branches arise from a slender rhizome. These parts are also clothed with mucilage-secreting glands.

The glands are of two kinds, stalked and unstalked. Experiments have shown that minute cubes of coagulated egg albumen—a proteinaceous material such as might be found in insect bodies—placed in contact with the unstalked glands completely disappear after a period of from two to eight days. When this same proteinaceous material is placed in contact with the stalked glands, there is no evidence of digestion.

In other observations, when trapped insects came in contact with unstalked glands, the latter produced a secretion that was much less viscous than that of the stalked glands. The actual mode of digestion of insects by these plants is still not completely known.

Plants of *Byblis* are sometimes infested with a small

wingless **capsid** (members of a family of the insect order Heteroptera). Although other small insects are ensnared in the **mucilage**, **capsids** appear to be able to move unhindered over the surface of *Byblis* leaves.

The family Cephalotaceae consists of one species, *Cephalotus follicularis*, the west Australian pitcher plant, which occurs only in the southwestern corner of Australia. The plant has an underground rootstock from which two kinds of leaves are produced, foliage leaves and pitcher leaves. Foliage leaves and pitcher leaves are produced in a seasonal rhythm: the foliage leaves develop in the autumn, reaching full size and abundance in spring; pitchers grow in winter and spring and are fully formed and functional in summer when the insects they capture are most plentiful.

Foliage leaves attain a maximum length of 13 or 14 centimetres (about five inches); the blade is ovate and pointed at the apex and is equally as long as the petiole (leafstalk). The thick, leathery, and smooth foliage leaves are studded with nectar glands. Pitcher leaves are about five centimetres or more long when fully mature. They measure about two centimetres (about one inch) across and are somewhat compressed front to back. There is an oval opening, wider crosswise than from back to front. The petiole, or leafstalk, is approximately at right angles to the axis of the pitcher; it is attached dorsally below the "hinge" of the lid at about the level of the opening. The mouth of the pitcher is surrounded by a thickened corrugated rim, each ridge of which forms a clawlike tooth that extends into and is directed downward toward the base of the pitcher. Each pitcher has a lid that overhangs the opening and is more or less open, depending upon the age of the leaf. The lid is traversed radially by narrow patches of green tissue between which are clear patches devoid of chlorophyll. The clear patches have the appearance of window-like areas framed in green. To entrapped insects, the clear patches probably appear to be open spaces, and they attempt to escape through them until, eventually exhausted, they fall into the depths of the pitcher.

The interior of the pitcher has two zones. The upper

Pitcher-shaped,
insect-trapping
leaves

zone forms a ridge around the mouth of the pitcher and arches over the internal cavity. The epidermis (surface) of the upper zone is studded with downward pointing hairs, as is the inside of the lid. A smooth, glassy surface characterizes the interior zone of the pitcher, which has a glandular surface. The flask-shaped glands have been reported to be digestive in function. Within the pitcher a shelllike bolster projects inwardly but is not apparent externally; it contains glands, among which are many "water pores," or hydathode-like (water-secreting) structures. The water pores resemble stomates, but the orifice between the guard cells is continuously open. Presumably, the fluid that fills the pitcher is produced from these pores. This action, however, has not yet been proven conclusively.

Some botanists have demonstrated that fluid taken from virgin, or unopened, pitchers can digest animal substances. Others, however, have not been able to find any fluid in unopened pitchers and have reported the presence of fluid only in opened pitchers. In any event, it has repeatedly been observed that pitchers do capture insects, notably ants. Small pitchers catch small insects. That soft parts of these insects undergo dissolution of some sort is evident. There is some question, however, as to whether this dissolution is the result of digestive enzymes secreted by the pitcher glands, by extraneous micro-organisms, or both.

Although pitcher fluid, sterilized to kill any micro-organisms, will digest proteinaceous material in the laboratory, it still cannot be concluded that this digestive process actually takes place in pitchers under normal circumstances. It is presumed, nevertheless, that digestion by pitcher fluid may take place very slowly in the pitchers; available evidence indicates that both the secretions of the pitchers and the actions of micro-organisms contribute to the digestion of insect proteins. Plants grown under laboratory conditions without the presence of insects thrive and flower. The question, therefore, remains concerning the usefulness or necessity of insect protein to insectivorous plants.

Reproductive biology. *Epiphyllous flowers.* Flowers that are borne on or produced from leaves are termed epiphyllous flowers. Flowers and fruits of plants in the genus *Phyllonoma* are borne directly on the upper surface of leaf blades. In *P. ruscifolia*, all stages of flower and fruit development may be found on one plant at any time. The cluster of flowers is produced from the midvein well toward the tip of the mature leaf. From the point of attachment of the cluster of flowers, the leaf narrows rapidly toward the pointed apex. Not all leaves bear flower clusters. There has been some question about the morphological nature of the flower-bearing green leaves. Some botanists have thought them to be expanded stems (cladodes) modified for both photosynthesis and reproduction; others have proposed that the leafstalk and flower stalk represent fused structures. Studies of the minute structure of the leaf indicate, however, that they are true leaves and that a separate flower stalk is not fused to midvein of the leaf.

Pollination processes. Before fertilization can take place in flowering plants, it is necessary for viable pollen to be transferred from stamens (male reproductive organs) and deposited on receptive pistils (female structures). If this transfer takes place within the same flower, it is called self-pollination. Self-pollination, however, is not always accompanied by fertilization and the setting, or producing, of seed, because some plants are not self-compatible; that is, some plants do not have the genetic capacity to produce seed even when the style (the narrow upper portion of the pistil) is dusted with pollen from the same flower. When seed is produced as a result of fertilization by pollen from the same flower, the term self-compatible is used. Cross-pollination refers to the transfer of pollen from flowers of one plant to the pistils in flowers of another plant of the same species in order to effect pollination and subsequently fertilization and the setting of seed.

Species of the family Saxifragaceae apparently have mechanisms that prevent self-pollination. Dichogamy,

for example, is a condition that involves the separate maturing, in terms of time, of stamens and pistils in the same flower. It results when the anthers do not release their pollen at the same time the stigmas (pollen-receptive surfaces of the pistil) are receptive. There are two variations of this arrangement, protandry and protogyny. In protandry, the anthers are ready to liberate their pollen before the stigma of the same flower is structurally and physiologically receptive; in protogyny, the stigma matures before the anthers of the same flower are ready to shed pollen. In the Saxifragaceae that have been studied, protandry is predominant. This condition has also been reported for *Parnassia*, of the family Parnassiaceae. As with many groups of plants, biological phenomena of this kind have not been studied in detail in most families of the order Saxifragales.

Heterostyly is another reproductive phenomenon that has been observed in members of the Saxifragaceae. Heterostylous plants have bisexual flowers of two or three different kinds. They are distinguished from each other by the size and behaviour of the reproductive structures; for example, *Jepsonia heterandra*, a very locally distributed native plant of California, has distylous flowers. Some plants produce long-styled (called pin) flowers, and others produce short-styled (thrum) flowers. Pin flowers also have large stigmas and short stamens that produce many small pollen grains. Thrum flowers have small stigmas and long stamens that produce fewer but larger pollen grains.

Heterostyly is one of the most extraordinary reproductive devices by which cross fertilization is insured in higher plants. Even though a heterostylous flower contains complete and functional structures of both sexes, the plants, because they contain a genetic factor that inhibits self-fertilization, must be cross-pollinated. Although the flowers are bisexual, functionally they are either male or female, and cross-pollination is as obligatory as in species with separate male and female flowers.

Pollination agents. Pollination in saxifragean families is usually by insects. The following account of pollinators in *Jepsonia heterandra* is typical of other species with similar breeding systems. Soon after the opening of anthers in the morning, flowers of *J. heterandra* are visited by flies, especially by several genera of syrphids, as well as by small bees, especially the species *Dialictus orndufi*. The male insects visit flowers to obtain nectar (but not pollen) and to mate with females. In the course of these activities, pollen occasionally adheres to the bodies of the bees and is consequently available for transfer to other flowers. The females, which visit flowers to gather both pollen and nectar, collect abundant quantities of *Jepsonia* pollen on the posterior pair of legs.

Syrphid flies drink nectar from *Jepsonia* flowers but do not crawl into the flowers as do female *Dialictus orndufi*; rather, the flies remain at the entrance to the floral axis and on the styles. From this position the proboscis (elongated mouthparts) is extended down to the nectaries at the base of the petals. When this happens, pollen from the anthers is transferred to the underside of the fly's head, and the proboscis also becomes coated with pollen. During grooming activities, pollen from the head and proboscis is transferred to the forelegs. Flies visiting other flowers transfer the pollen to them, effecting cross-pollination.

Other pollinators of saxifragean plants have been recorded, and flies have been observed transferring pollen of certain species of the family Crassulaceae and *Parnassia*. Most flowers of *Parnassia* have conspicuous nectar-secreting staminodia (sterile, or aborted, stamens), which act as glands and secrete glistening droplets of nectar; flies feeding on this nectar may become dusted with pollen. Pollination in *Roridula* appears to be carried out by small Heteroptera. When the sensitive anthers in *Roridula* are touched by a suitable visitor, they suddenly spring upright, scattering pollen over the insect. The brightly coloured tubular flowers of some Crassulaceae —e.g., *Bryophyllum*—are pollinated by birds. Pollination of *Escallonia* has not been observed in the wild, but the abundant nectar makes insect pollination very likely.

Cross-pollination ensured by flower structure

Flowers growing from leaf surfaces

Flowers of *E. rubra* growing in England have been observed to be visited both by honeybees and bumblebees, the latter even biting their way into closed flowers to secure the nectar (see POLLINATION for additional information about the mechanisms involved in the process).

Ecology. Plants belonging to the order Saxifragales inhabit almost the complete range of environmental conditions on earth. They are to be found growing in deserts and semideserts, under mesic (moist) conditions, and in water; they occur at sea level and in the mountains above the tree line; they grow in humid and dry tropical atmospheres, in the cold of the Arctic and Antarctic, and in the snowy reaches of the European Alps, the Andes, and the Himalayas.

Escallonia, the largest in numbers (60 species) of the seven genera of the family Escalloniaceae, is confined to South America except for one species that reaches Costa Rica. The genus is found predominantly in mountainous regions, but in the southernmost portion of its range in South America, it grows in a temperate climate near the sea. In the cordilleras of Bolivia, Peru, Ecuador, and Colombia, plants of *Escallonia* grow as low shrubs at an elevation in excess of 4,000 metres (13,000 feet), extending above the tree line. The Valdivian rain forests of Chile contain several species of *Escallonia*. In the dry scrub vegetation of central Chile, *Escallonia* grows in company with *Araucaria* (monkey-puzzle tree), *Alnus* (alder), and sclerophyllous shrubs—typically leathery-leaved plants of dry habitats. In such dry areas of Chile, and from Argentina to Venezuela, *Escallonia* species occur at the bases of valleys near sources of underground water. In southeast Brazil, Uruguay, and portions of adjacent Argentina, *Escallonia* occurs in the forest. In other regions of Chile and Brazil, some species of *Escallonia* grow in flooded areas and swamps, but they are rarely found in the shrub-covered *campos* (level, grassy plains areas with scattered trees or shrubs). In the high cordilleras from northwestern Argentina to Peru, *Escallonia* plants are not scarce on the upper cloud forest border, and further north in Colombia, they penetrate the *paramos* (high, treeless plains). The highest cloud forest sites that support the growth of *Escallonia* occur in parts of the southeastern Brazilian coastal ranges and in Costa Rica, where species live in sub-alpine meadows together with numerous members of the family Ericaceae (heaths).

Brunelliaceae, consisting of the single genus *Brunellia*, is another strictly tropical American group of plants. It is distributed along the western side of America from about 23° north latitude in Mexico and the Greater Antilles south to 18° in Bolivia. Like *Escallonia*, most species of *Brunellia* grow in mountain forests, from elevations of about 600 metres (2,000 feet) to 3,800 metres (12,500 feet). One group of *Brunellia* species occurs at low elevations, from 600 to 2,000 metres (2,000 to 6,500 feet). Another group inhabits cold regions and is usually found between 2,800 and 3,200 metres (9,200 and 10,500 feet) elevation. In contrast, *B. hygrothermica* is part of the sea-level vegetation, where temperatures range between 30° and 39° C (86° and 102° F) and the rainfall amounts to 8,000 millimetres (320 inches).

The family Crassulaceae is of cosmopolitan distribution, but species are particularly concentrated in the dry regions of southern Africa, the Macronesian islands (Azores, Canary Islands), and in western North America. Most plants of the Crassulaceae are characterized by their moderate to extreme succulence—thick, fleshy stem and leaf growth—and most members of the family are remarkable for their dry-habitat-adapted structure, particularly mucilaginous water-storage tissues in the leaf and stem. Some species are believed capable of absorbing water directly from the air through special hairs, surface cells, or aerial roots. Bladder hairs of *Crassula falcata*, for example, can take up moisture from the atmosphere. Many plants of the family are of the rosette growth habit. Their crowded, basically disposed leaves are able to retain moisture in the form of dew; absorption of this moisture may take place directly through the leaves or through special hairs. The viviparous habit (*i.e.*, the production of plantlets directly from leaves of the parent

plant) of *Bryophyllum* species may be an adaptation to arid conditions; the plantlets are ready to grow in the presence of the slightest moisture.

The family Saxifragaceae illustrates the entire range of adaptation to differing moisture conditions found in the order. *Saxifraga nutans* is a true aquatic plant, *S. pennsylvanicum* is a bog plant, and *S. micranthidifolia* grows in cold mountain streams and on wet rocks. Other species are more or less adapted to dry conditions (*i.e.*, they are xerophilous), among them *S. fridactyloides*, which stores moisture in small bulblike bodies on the stem (bulbils). Similarly, *S. trifurcata* has a strongly cuticularized (wax-coated) epidermis, *S. globulifera* produces membranous bud scales and hairy stipules, and *S. aspera* stores moisture in its fleshy, heavily cuticularized, long-persistent leaves; all are examples of adaptations to dry habitats. In some saxifrages, leaf rosettes are produced. The bases of the lower leaves in the rosettes are only weakly cuticularized, so that dew accumulating there may be absorbed by the leaves in sufficient quantity to enable the flowering shoot to develop.

Species of the genus *Saxifraga* are known for their tenacious ability to grow and thrive on exposed rocky crags and in fissures of rocks. The name *Saxifraga* literally means "rock breaker." Thus saxifrages grow high in the Alpine regions of the mountains of Europe, in places that are covered with snow and ice for long periods of the year. The plants have tough, wiry root systems and deeply penetrating taproots. In the same harsh environments, some saxifrages (*e.g.*, *S. hirculus*) develop as cushion plants. This involves a considerable reduction in leaf surface (that is, a diminution of the evaporating surface) and a foreshortened shoot. These low cushion plants are also often adaptable to bog conditions.

Most Saxifragaceae species, however, grow in moist, shaded woodlands. Among these are species of *Saxifraga*, *Astilbe*, *Rodgersia*, *Astilboides*, *Peltiphyllum*, and *Boykinia*.

FORM AND FUNCTION

The several families that make up the order Saxifragales are held together by a pattern of overlapping similarities, rather than by characteristics held in common by all families. Perhaps the order is best described by its internal heterogeneity instead of by its homogeneity. Practically all growth forms of plants are found, including trees, shrubs, and woody climbers among the woody types; and annual and perennial herbs among the herbaceous types. Leaves are alternate or opposite, with or without stipules (basal appendages). Sometimes the flowers contain elements of both sexes—that is, stamens (male) and pistils (female)—but in some groups the flowers may be either entirely male or female. The flowers are almost always radially symmetrical. Generally the petals are free; that is, separate and not fused to each other. Stamens vary from few in each flower to many and indefinite in number. The ovule-bearing segments of the pistil (carpels) may be separate, but more often they are fused to each other. All conditions of ovary insertion are present, ranging from ovaries positioned above the other flower parts (superior ovaries) to those wholly enclosed by the fused bases of the sepals, petals, and stamens (inferior ovaries) as well as various intermediate conditions. Seeds usually have abundant nutrient tissues for the developing embryos (endosperm). More homogeneity exists among the anatomical features. The pollen grains, for example, are usually tricolporate, which means they have three germinal pores. Among the woody families, vessel elements (water-conducting cells) have end openings predominantly with ladderlike cross-bars (scalariform perforations), whereas among the herbaceous families, the vessel elements usually have simple perforations.

Several of the families are very distinctive in certain features. The family Phyllonomaceae is characterized by flowers borne directly on the leaves. The family Crassulaceae is well known for its extreme succulence and the presence of crassulacean acid metabolism. Byblidaceae is insectivorous, and Cephalotaceae is distinguished by its

Escallonias
growing
at high
elevations

Saxifrages
growing
on rocks

remarkable urn-shaped leaves and its insectivorous nutrition. The family Francoaceae is distinctive in having a diacytic stomatal apparatus (*i.e.*, stomates, pores in leaf surfaces, with two epidermal cells enclosing the pore so that their common wall is at right angles to the long axis of the stomate). The family Davidsoniaceae is characterized by its irritant hairs. In addition to normal phloem external to the water-conducting xylem, the family Crypteroniaceae also has internal phloem; *i.e.*, food-conducting tissues located within the stem interior, between the pith and the inner surface of the xylem. The families Roridulaceae and Byblidaceae are characterized by the circinate vernation of their leaves; the leaves are rolled lengthwise in the bud, like those of ferns. Pittosporaceae has secretory canals in the axis.

EVOLUTION

Fossil record. Although many species of fossils have been described and assigned saxifragalean names and relationships, it is impossible in many cases to establish with any degree of certainty the veracity of these assignments as far as the real relationships of the fossil plant material is concerned; thus the following examples should be viewed with an understanding of this qualification.

The family Saxifragaceae is represented in the fossil record by *Saxifraga*, found in many European localities in deposits as old as the Tertiary Period (65,000,000 to 2,500,000 years ago), but most have come from the Pleistocene Epoch (which began about 2,500,000 years ago) and more recent deposits. Various fruits and leaves from England, Czechoslovakia, and Germany in Eocene (54,000,000 to 38,000,000 years ago) and more recent deposits, and *Chrysosplenium* from the middle Pliocene of England, are also known from the Saxifragaceae. The family Hydrangeaceae is represented by *Philadelphus*, known from Canada in deposits as old as the Upper Cretaceous; and by *Deutzia*, *Schizophragma*, *Decumaria*, and *Hydrangea* from many European, Central Soviet Union, Japanese, Alaskan, and North American localities of Tertiary age. *Ixerba* of the family Brexiaceae has been found in the Pliocene of New Zealand. *Itea* of the family Iteaceae occurs in Tertiary deposits of Italy. The family Escalloniaceae is known from the Pliocene of New Zealand and Bolivia (*Quintinia* and *Escallonia*, respectively) and is also known from the Pleistocene of New Zealand (*Carpodetus*).

The family Grossulariaceae is known in fossil form by *Ribes*, found in European and North American Tertiary deposits, and by *Riboidoxylon* (wood) from the Upper Cretaceous in California. The family Cunoniaceae is represented by the fossil genus *Cunonioxylon* (wood) from Upper Oligocene deposits in the eastern Alps of Europe. Leaf and stem fossils of the family Crassulaceae are known from France and The Netherlands in Tertiary deposits. A flower of *Billardierites* of the family Pittosporaceae has been found in amber of Miocene age (26,000,000 to 7,000,000 years ago) from the Smaland Peninsula of the Baltic coast.

Several conclusions can be drawn from the above data. Members of the Saxifragales have been present at least since the beginning of the Tertiary Period—that is, from the Paleocene Epoch (which began about 65,000,000 years ago)—and probably even earlier. There are several reports of saxifragalean plants from earlier strata (*e.g.*, *Philadelphus* and *Ribes* from Upper Cretaceous sediments). The occurrence of the wood of *Ribes*, represented by the form genus *Riboidoxylon*, is well dated and based on modern methods. It can probably be accepted as the earliest documented discovery of a saxifragalean plant. The Late Upper Cretaceous deposits of the Panache Formation, in which *Riboidoxylon* occurs, are dated at between 70,000,000 and 80,000,000 years ago.

A comparison of the geographic distribution of fossil forms with modern representatives of the same genera is instructive. Modern species of *Philadelphus* grow in southern Europe, Asia, and North and Central America. The fossil occurrence of *Philadelphus* in what is today northern Germany is thought to indicate a recent contraction of an originally broader range for the genus.

Today, species of *Hydrangea* occur from India to Japan, in the Malay Archipelago, in North and Central America, and in western South America. The fossil range of *Hydrangea* in northern, central, and southern Europe provides evidence that the genus was more widely distributed in geologically earlier times than it is now.

More difficult to explain are the occurrences of other fossil saxifragalean plants in northern latitudes, for example, the *Cunonia*-like wood in the eastern European Alps and the *Billardiera*-like flower in the Baltic region of present-day Germany. The family Cunoniaceae is mostly southern in distribution today and the Pittosporaceae, to which family *Billardiera* belongs, is fundamentally Australian, eight of its nine genera being found on that continent.

These outstanding disjunctive distributions must be viewed with considerable prudence pending other forms of corroborative evidence such as a re-examination of the identifications and a search for other southern plant forms in the beds containing these reputed saxifragalean ancestors. Overall, however, the conclusion that is drawn from presently available data and observations is that present-day distributions of saxifragalean plants are remarkably similar to those that existed as long ago as the Upper Cretaceous Period.

Phylogeny. The fossil record of the order Saxifragales is too fragmentary to enable any conclusions to be drawn concerning its early origins and relationships. All that can be stated with any assurance is that saxifragalean plants appeared in Late Upper Cretaceous times contemporaneously with representatives of many other families of flowering plants. Doubtless, the actual progenitors of plants with saxifragalean relationships were in the process of evolving long before Saxifragales are recorded in fossil-bearing strata. Nothing is known about the real relationships of these ancient plants of saxifragalean alliance nor from which plants they may have evolved.

Information from comparative studies of present-day Saxifragales species seems to point to an origin from ancestors of the order Dilleniales. The order Saxifragales is closely related to the order Rosales, and perhaps its nearest affinities are with members of this group. Although the anatomy of the wood of several families in the Saxifragales is more primitive than that of the most primitive representatives of the Rosales, floral structure in some saxifragalean families reaches a higher level of specialization than that found in any rosalean families. It appears, then, that both the Rosales and Saxifragales owe their origins to forebears of the Dilleniales, perhaps to ancient plants of magnolialean (*i.e.*, the order Magnoliales and its relatives) alliance.

CLASSIFICATION

Distinguishing taxonomic features. In flowering plants, floral characteristics provide the major bases for family delineations. To a lesser extent, vegetative features are used—*i.e.*, the morphology of leaves and twigs, growth habit of the plant, texture of the bark, and sometimes microscopic structure and chemical constituents. Some plant families have unique or almost unique properties, such as insectivorousness or epiphyllous flowers, which enable the plant taxonomist to characterize the family. Usually, however, this is not the case, and families are established on a combination of characteristics; it is this combination of characteristics that sets the family apart from other closely related families.

The generalizations above hold true for the families that comprise the order Saxifragales. Some families have evolved very specialized structural innovations, but most owe their distinctiveness to a combination of characters rather than to any single character. Because the elements that make up the order Saxifragales can be interpreted in various ways, plant taxonomists over the years have assembled different schemes of arrangement; usually the schemes are influenced by their creators' ideas of the features that are the most reliable indicators of relationship and whether larger or smaller groups of plants are more reflective of natural conditions. Nevertheless, the several schemes of arrangement are more or less based on

hydrangea
family

Ancestry
of the
order
Saxi-
fragales

the same data and raw materials. The manner in which these are employed and weighted gives rise to some of the differences in systems of arrangement of saxifragean families.

Among the useful characters employed to subdivide the order Saxifragales into families is the predominant habit (growth form) and duration of the plants—that is, whether the plants are woody or herbaceous, and, if herbaceous, if they are annual or perennial. Using these criteria, the order is divided into two main groups of families, those with mostly woody, perennial plants and those made up mostly of herbaceous species. Herbaceous Saxifragales are usually perennials, but annual plants predominate in a few families. Useful characteristics of the leaves concern phyllotaxy—that is, whether the leaves are alternate, opposite, or whorled on the stem. All three dispositions occur in different parts of the order. The presence or absence of stipules (basal appendages on leafstalks) and of simple or compound leaves have been useful in separating families. Fusion of sepals and petals, and of the carpels (the ovule-bearing segments of the ovary), are pertinent criteria in distinguishing among the families. The number of stamens, whether they are definite or indefinite in number, is also a meaningful character for delineating saxifragean families. Position of other floral parts in relation to the pistil (female organ)—that is, whether sepals, petals, and stamens are attached below, at, or above the attachment to the floral axis of the ovary—is an important means of segregating families in this order. The kind of fruit produced is indicative of familial cohesiveness, as is the number of coats on the seeds.

Annotated classification. The classification of the order Saxifragales into families as presented here incorporates both traditional information from floral structure and vegetative morphology, and ancillary data on the microscopic anatomy of plant parts. This classification, in its broader aspects, conforms to others published in recent years. Unlike some systems, however, which separate the families Philadelphaceae and Hydrangeaceae, these two are united here, and the combined group is considered under the name Hydrangeaceae. Because of the many overlapping characters between the two groups, relationships are better preserved and expressed by joining rather than by separating them.

The family Paracryphiaceae (with Paracryphia as the only genus) is included provisionally within the order, but the relationship is not wholly certain. Lepuropetalon, considered as the basis of a separate family (Lepuropetalaceae) by some plant taxonomists, is tentatively included within the family Parnassiaceae (which has two genera, Parnassia and Lepuropetalon). Unlike the situation with Paracryphia, *Lepuropetalon* has long been included in the family Saxifragaceae, and it seems to be related to this general alliance of plants. Its inclusion as a second genus of Parnassiaceae, however, is a departure from traditional treatments.

A number of the taxa here considered as families are assigned merely to generic status by some taxonomists. In treatments by other taxonomists, all or some of the families included here in the order Saxifragales are put into different orders along with another variety of families. Such dispositions reflect valuation and weighting by different taxonomists and are not to be considered "wrong" on this basis alone; rather, they are legitimate expressions of personal predilections. The classification system presented below is based on that of the Soviet botanist Armen Takhtajan (1969).

ORDER SAXIFRAGALES

Trees, shrubs, lianas (vines), and perennial and annual herbs bearing alternate or opposite, entire or lobed, simple or compound leaves, with or without stipules (basal appendages). Flowers mainly bisexual, sometimes unisexual, radially symmetrical (actinomorphic) or rarely weakly bilaterally symmetrical (zygomorphic), usually both sepals and petals present. Petals free or rarely more or less connate (connate). Stamens (male reproductive organs) few, the same in number as the sepals, twice as many, or numerous. Gynoecium (female flower parts) of separate free carpels (ovule-bearing structures) or more often of fused carpels. Ovary is positioned above the

insertion point of the sepals, petals, and stamens (superior), half-inferior, or inferior (*i.e.*, below the attachment point of the other flower parts). Ovules with 2 outer tissue layers (integuments, or seed coats) or more rarely with only 1 integument. Seeds usually with abundant endosperm (nutrient tissue for developing embryo) and a small embryo. Twenty-eight families, 165 genera, and about 3,340 species with worldwide distribution. Major centres of distribution include New Guinea and Australasia; Australia; Japan, Taiwan, and the Philippines; southern Africa; and tropical and temperate America.

Family Cunoniaceae

Shrubs and trees with opposite or whorled, often pinnately (with leaflets on both sides of a central axis) or trifoliolately (with 3 leaflets) compound leathery leaves, frequently with marginal serrations (notches or teeth) that bear glands. Stipules present, often united in pairs. Flowers small, usually bisexual in compound inflorescences (clusters); receptacle (expanded stem tip bearing the flower parts) usually flat. Sepals 4 or 5. Petals 4 or 5, usually smaller than sepals, often lacking. Stamens 8 to 10, many, or 4 or 5; disc (tissue region from which stamens arise) often annular. Ovary superior, usually of 2 fused carpels, 2-chambered; rarely 2 separate carpels; generally with many to 2 ovules in 2 rows in each chamber; styles (upper narrow part of pistil) free. Fruit usually a capsule, rarely a drupe (single-seeded, bony-pitted, fleshy fruit) or nut. Endosperm usually copious. Twenty-six genera and 250 species, chiefly distributed between 13° and 35° south latitude; most numerous in New Guinea, Australia, and Australasia, but a few north to the Philippines, southern Mexico, and the Caribbean islands; also found in New Caledonia, the Polynesian islands, Fiji, southern Africa, and South America. The largest genera include *Weinmannia* (about 170 species), *Pancheria* (25 species), *Spiraeanthemum* (20 species), *Geissois* (20 species), *Schizomeria* (18 species), *Cunonia* (17 species), and *Larnanonia* (10 species).

Family Davidsoniaceae

Small slender trees bearing irritant hairs. Leaves alternate, pinnately compound, elongated, with large kidney-shaped stipules. Inflorescence a large, lax, stalked panicle (many-branched cluster) or a dense, stalked spike. Bracts (leaflike structures on stem, below flowers or inflorescences) large, clasping the stem. Flowers bisexual. Sepals 4, fused, disposed edge-to-edge, thick. Petals absent. Stamens 10, plus 10 nectar-producing scales inserted on the disc. Ovary superior, of 2 fused carpels, 2-chambered, with 2 free threadlike styles abruptly bent (kneelike) above, and about 7 ovules per ovary chamber. Fruit a large 2-pyrened (pitted) drupe, velvety red when young, covered with a powdery bloom when mature. Seeds 2, large, pendulous, and lacking endosperm. One genus and 1 species (*Davidsonia pruriens*), northeastern Australia.

Family Eucryphiaceae

Trees or shrubs with evergreen, opposite, simple, or pinnately compound leaves and small stipules. Flowers solitary, located in the upper angles between leaves and stems (axillary), regular, bisexual, conspicuous. Sepals 4, rigid, overlapping, cohering at the apex and becoming detached as a caplike unit. Petals 4, large, white, overlapping, sometimes asymmetrical. Stamens numerous in many series (whorls) on a thin disc. Ovary superior, of 4 to 14 fused carpels, 4- to 14-chambered and grooved or furrowed lengthwise, each chamber with pendulous ovules. Styles and mature carpels free but joined by threads to the axis. Fruit a leathery or woody capsule. Seeds few, compressed, winged, fleshy. Endosperm present. One genus (*Eucryphia*) with 5 species, distributed in southeastern Australia, Tasmania, Patagonian Argentina, and southern Chile.

Family Paracryphiaceae

Shrubs or small trees with simple, tooth-margined leaves lacking stipules and in an arrangement on the stem resembling true whorls. Flowers bisexual and separately male, sessile (without a stalk), with 1 bract and 2 early-falling bracteoles (secondary bracts borne on an axis above the main bracts) in terminal rusty-pubescent (hairy) panicles or compound spikes. Sepals and petals absent. Stamens 8 to 11. Ovary superior, with 12 to 15 fused carpels, with few ovules per locule, and 12 to 15 sessile, shortly recurved stigmas (pollen-receptive surfaces at tips of styles). Fruit a 12- to 15-chambered capsule, the segments of which separate from the central axis except at the apex. Seeds unknown. One genus, *Paracryphia*, and 2 species, from New Caledonia.

Family Crypteroniaceae

Trees with 4-angled (more or less square in cross section) branches and opposite, entire, simple, leathery leaves that lack stipules. Inflorescence a true panicle with white- or green-coloured, small, short-stalked, radially symmetrical flowers. Flowers bisexual and unisexual, both occurring on the same plant (*i.e.*, plants polygamodioecious). Sepals fused, forming a

broadly bell-shaped, 4- to 5-lobed calyx. Petals absent. Stamens 4 to 5, alternate with the sepals. Disc absent. Ovary superior, carpels 2, chambers 2, style simple, stigma slightly 2-lobed. Ovules numerous. Fruit a capsule separating into 2 parts that usually remain connected by the style. Seeds many, small, elongated, sometimes winged; embryo cylindrical, endosperm absent. One genus (*Crypteronia*) and 4 species distributed in tropical Asia from northeastern India (Assam) to southeastern Asia, Malaysia, and the Philippines.

Family Brunelliaceae

Tall trees, sometimes spiny, usually tomentose (covered with dense, wooly hairs) throughout. Leaves opposite or whorled, simple, trifoliate or pinnately compound, often with toothed margins, and with small early-falling stipules. Flowers small, regular, with separate male and female flowers on separate plants (*i.e.*, plants dioecious), borne in panicles. Sepals 4 or 5, disposed edge-to-edge, shortly joined below. Petals lacking. Disc cup-shaped, fused to the sepals, 8- to 10-lobed. Stamens 8 to 10 inserted at the base of the disc, with filiform, pubescent filaments. Sterile stamens (staminodia) present in female flowers. Ovary superior, with 5, 4, or 2 free carpels, each gradually tapering into long, awl-shaped, recurved styles and dotlike stigmas. Ovules 2 per ovary chamber. A small, rudimentary female structure (pistillode) present in male flowers. Fruit of 5 to 2 dehiscent follicles (1-carpel, podlike structures that open along one suture or line). Seed 1 or 2 per follicle, with mealy endosperm. One genus (*Brunellia*) and 45 species, distributed in tropical America from Mexico to Peru and on the Caribbean islands.

Family Escalloniaceae

Trees or shrubs with alternate or opposite, simple, evergreen leaves. Leaves often toothed, lobed with small, forward-pointing teeth along lobes, with gland-bearing marginal teeth or with gland-dotted surfaces. Stipules absent. Flowers bisexual, rarely unisexual. Sepals 4 or 5, or calyx of 4 or 5 fused segments. Petals free, 4 or 5, overlapped or edge-to-edge, sometimes clawed. Stamens 4 or 5, sometimes with 4 or 5 sterile stamens. Disc present, the lobes alternating with the stamens. Ovary superior or inferior with 1 to 6 fused carpels, sometimes 1-chambered, with 1 to 6 free styles and many ovules. Fruit a capsule, rarely a drupe or berry. Endosperm copious. Seven genera and about 170 species, distributed in the tropics and southern temperate zone, mostly in South America and Australasia; also Australia, Philippines, New Caledonia, New Zealand, and eastern Himalayas. Genera include *Quintinia* (20 species), *Polyosma* (60 species), *Escallonia* (60 species), *Carpodetus* (10 species), *Argophyllum* (11 species), *Abrophyllum* (2 species), and *Corokia* (6 species).

Family Tribelaceae

Prostrate shrublets with robust flexible stems that produce short, ascending, densely leafy branches. Leaves alternate, simple, sessile (without a leafstalk), partly clasping the stem, smooth-margined but with apex bearing minute teeth, thickish, smooth, more or less covered with a powdery bloom above, lacking stipules. Flowers small, regular, bisexual, solitary at apex of branchlets. Sepals 5, small, shortly fused below, overlapping, persistent. Petals 5, relatively large, elliptical, thickish, slightly clawed, contorted. Stamens 5 alternating with the petals. Disc lacking. Ovary superior, of 3 united carpels with short, simple style and capitate (headlike), 3-lobed stigma. Ovules numerous. Fruit a small, many-seeded, 3-grooved capsule. Seeds shiny, black, remaining attached to floral axis long after capsule opens, with fleshy or oily endosperm. One genus and 1 species (*Tribeles australis*), distributed in temperate South America in southern Chile and Tierra del Fuego.

Family Tetracarpaeaceae

Low shrubs with alternate, simple, doubly toothed, evergreen, strongly incised (deeply slashed around margins) and prominently veined leaves that lack stipules. Flowers regular; bisexual; in erect, persistent, bract-bearing racemes (elongated clusters). Sepals 4 or 5, overlapping, very shortly fused, small. Petals 4, overlapping, round, erose (as though chewed), clawed, falling early. Stamens 8, in 2 whorls of 4 each. Ovary superior, of 4 free carpels. Ovules numerous. Fruit of 4 spindle-shaped follicles. Seeds numerous, with fleshy endosperm. One genus and 1 species (*Tetracarpaea tasmanica*), Tasmania.

Family Iteaceae

Shrubs or trees with simple, toothed or spiny-margined, alternate leaves with stipules. Flowers small, regular, bisexual, or polygamous, with bisexual and unisexual flowers in the same plant. Inflorescence terminal or axillary, densely elongated and raceme-like or short and cymose (more or less flat-topped with central flowers blooming first). Sepals 5, touching at edges or open. Petals 5, disposed edge-to-edge. Stamens 5. Disc annular. Ovary of 2 fused carpels, semi-inferior, often elongated, with few to many ovules; styles 2, joined but becoming free above, though sometimes united by the capitate stigma. Fruit a

narrow or ovoid capsule with few to many oblong or sawdust-like seeds. Embryo large in sparse, fleshy endosperm. Two genera (*Itea* and *Choristylis*) and 17 species, in eastern and northwestern Himalayas to southeastern Asia and the Philippines; also in eastern North America and tropical and southern Africa.

Family Brexiaceae

Shrubs or small trees. Leaves simple, alternate, rarely almost opposite or whorled; smooth-margined, finely toothed, spiny-toothed, or coarsely toothed; leathery. Stipules present in *Brexia*, absent in *Rousseia* and *Ixerba*. Flowers large, solitary or in axillary, few-flowered cymes (flower clusters that mature from top or centre flowers downward). Sepals 4 to 6, overlapping or touching at the edges, deciduous or persistent. Petals 4 to 6, free and overlapping, clawed, or fused and valvate; deciduous or persistent. Stamens 4 to 6 with large anthers. Disc annular or 5-lobed. Ovary superior, of fused carpels, with 4 to 7 chambers, each with 2 to many ovules. Style solitary, with a capitate, lobed, or dotted stigma. Fruit a capsule, drupe, or berry. Three genera and about 11 species, distributed in eastern Africa, Madagascar, the Mascarene and Seychelles islands, and New Zealand.

Family Phyllonomaceae (Dulongiaceae)

Trees or shrubs. Leaves alternate, simple, smooth-margined or toothed; with a long, sharp tip; and with small, fringed or glandular, early-falling stipules. Flowers small, green, borne on the leaves in bundle-like inflorescences. Sepals 5 or 4, open, toothed, persistent. Petals 5 or 4, touching at the margins. Stamens 5 or 4. Disc large, cushion-shaped, positioned within the whorl of stamens and surrounding the ovary. Ovary inferior, of 2 fused carpels, with 1 chamber and many ovules. Styles 2, very short, widely spreading, with small stigmas. Fruit a small, incompletely 2-chambered, 3- to 6-seeded berry. Seeds wrinkled, with endosperm. One genus (*Phyllonoma*) with 8 species, distributed from Mexico to Colombia, Peru, and Bolivia.

Family Pterostemonaceae

Much-branched shrubs with alternate, simple, tooth-margined leaves. Leaves shining, sticky, and resin-producing above; softly pubescent (hairy) below. Stipules small, deciduous. Flowers in few-flowered clusters, regular, bisexual. Sepals 5, touching edge-to-edge. Petals 5, overlapping, conspicuous, pubescent, more or less persistent. Stamens in two whorls of 5 each, the outer whorl fertile, the inner sterile and lacking anthers. Disc absent. Ovary inferior, with 5 fused carpels, 5 chambers, and a shortly 5-lobed style. Ovules 4 to 6 per chamber. Fruit a woody capsule. Seeds few, with tough, gristly outer coats, and without endosperm. One genus (*Pterostemon*) and 2 species, Mexico.

Family Grossulariaceae

Shrubs, sometimes spiny, with alternate, simple, variously lobed leaves, often with resin-producing glands. Stipules absent or connected to the petiole (leafstalk). Flowers regular, bisexual, or male and female and borne on separate plants. Sepals 4 or 5, fused, overlapping or somewhat disposed edge-to-edge, forming a calyx tube, sometimes petallike or coloured, persistent. Petals 5, small, scalelike. Stamens 5, alternate with the petals. Petals and stamens joined to the calyx tube. Disc absent. Ovary inferior, consisting of 2 fused carpels with a single chamber. Styles 2, somewhat connected, with simple stigmas. Ovules few to many. Fruit a juicy berry crowned by the persistent calyx. Seeds many, with endosperm. One genus (*Ribes*, currants and gooseberries) with 150 species, distributed in temperate Eurasia, northwestern Africa, North and Central America, and Pacific South America to Tierra del Fuego.

Family Hydrangeaceae

Small trees, shrubs, lianas (vines), or herbs with horizontal, underground stems (rhizomes). Leaves usually opposite, rarely whorled, simple, and lacking stipules. Flowers usually conspicuous, regular, bisexual, or plants are polygamodioecious—with both unisexual and bisexual flowers on the same plant. Outer flowers of inflorescence sometimes sterile and bilaterally symmetrical with noticeably enlarged petallike sepals. Sepals 4 or 5, occasionally up to 10, fused, or rarely separate. Petals 4 or 5, occasionally up to 10, separate, touching edge-to-edge, overlapping, or contorted. Stamens 4 or 5, or, more often, 8 to 10 to numerous. Ovary superior to partially or wholly inferior, consisting of sometimes 2 but usually 3 to 5 (or more rarely 10) carpels with 1 to usually many ovules in each chamber. Styles free, short, or becoming joined. Stigmas thick. Fruit a capsule or rarely a berry. Seeds with a straight embryo and fleshy endosperm. Nineteen genera and about 260 species, distributed in north temperate regions, the tropics, and the subtropics from Mexico and the Andes to southern Chile, and from southern Europe to eastern Asia, the Philippines, Japan, and Taiwan. Representative genera include *Kirengeshoma* (1 species), *Cardiandra* (5 species), *Philadelphus* (75 species), *Hydrangea* (80 species), *Dichron* (13 species),

Broussaisia (2 species), *Deinanth* (2 species), *Deutzia* (50 species), *Decumaria* (2 species), *Schizophragm* (8 species), *Carpenteria* (1 species), and *Fendlera* (4 species).

Family Montiniaceae

Shrubs or small trees with opposite, subopposite, or alternate, smooth-margined leaves without stipules. Flowers male and female on separate plants (dioecious). Male flowers: sepals 3 to 5, fused, calyx tube cuplike or flattened with smooth or lobed margins; petals 3 to 5, overlapping, slightly fleshy, deciduous; stamens 3 to 5, alternate with the petals; disc flat, discoid. Female flowers: Sepals 4 or 5, fused together and joined to the ovary, forming a short tubular structure with a smooth or minutely toothed margin; petals 4 or 5, overlapping, fleshy, deciduous; sterile stamens present, 4 or 5; disc surrounding ovary, fleshy, 4- or 5-angled. Ovary inferior, consisting of 2 fused carpels and bearing a short, thick, persistent style with 2 large stigmas. Ovules in 1 or 2 series in each chamber. Fruit a capsule. Seeds compressed and winged or more or less globose. Endosperm copious or absent. Two genera (*Montinia* and *Grevea*) and 4 species, distributed in southwestern and tropical eastern Africa and Madagascar.

Family Roridulaceae

Questionably insectivorous shrublets with glands of various lengths on stems, leaves, and sepals. Leaves alternate, elongated, lance-shaped, smooth-margined or with incised lateral margins, rolled lengthwise (circinate) in the bud, without stipules. Flowers regular, bisexual, solitary. Sepals 5, fused at the base, overlapping, persistent. Petals 5, overlapping, broadly elliptical, sharp-tipped. Stamens 5, alternating with the petals. Ovary superior, composed of 3 fused carpels, with short simple style and small, headed stigma. Ovules 1 to several per ovary chamber. Fruit a 3-sectioned capsule. Seeds large, with crustlike outer coat and copious fleshy endosperm. One genus (*Roridula*) and 2 species, southwestern Africa.

Family Pittosporaceae

Trees, shrubs, or twiners (vinelike forms) with elongated, leathery, evergreen, usually smooth-margined leaves that lack stipules. Resin present in large quantities in ducts in outer stem tissue layers. Flowers bisexual, regular, white, blue, yellow, or rarely reddish. Sepals, petals, and stamens 5 each. Petals often with erect claws. Stamens inserted below the ovary, alternating with the petals, free. Ovary of 2, sometimes 3 to 5, fused carpels with 1 to several chambers. Ovules many, arranged in 2 ranks. Style simple. Fruit a capsule or berry. Seeds with endosperm often black, shining, and embedded in a pulp. Nine genera and 200 species, distributed from tropical Africa to the Pacific Islands; in Madeira and Tenerife, Sri Lanka (Ceylon), Japan, and Tasmania; 8 of the 9 genera are endemic (native and restricted) to Australia. Representative genera include *Pittosporum* (150 species), *Marianthus* (16 species), *Billardiera* (9 species), and *Sollya* (2 species).

Family Byblidaceae

Insectivorous herbs or shrublets. Leaves alternate, elongated and linear, round in cross section, crowded, rolled lengthwise in the bud (circinate), bearing both stalked and unstalked capitate glands. Stipules absent. Flowers blue, regular, bisexual, solitary, on long stalks without bracts. Sepals 5, overlapping, fused at the base, persistent. Petals 5, contorted, broadly wedge-shaped, with the narrow end at the point of attachment, the outer edge fringed. Stamens 5, alternating with the petals, sometimes unequal or bent. Ovary superior, with 2 fused carpels, 2 chambers. Style elongated, threadlike, with headlike stigma. Ovules numerous. Fruit a 2-chambered, 2- to 4-sectioned, many-seeded capsule. Seeds with a coarsely warty or nodule-covered coat; endosperm present. One genus (*Byblis*) and 2 species, western Australia.

Family Bruniaceae

Heathlike shrubs and sub-shrubs with clustered, erect, slender branchlets and small, smooth-margined, alternate leaves that lack stipules. Flowers bisexual, small, usually regular, solitary or occurring in dense spikelike or headlike inflorescences. Calyx tube more or less joined to the ovary, with 4 or 5 overlapping segments, persistent. Petals 4 or 5, free, rarely joined below, overlapping, often persistent. Stamens 4 or 5, free or rarely inserted on the corolla (petals) forming a tube, often persistent. Disc rarely present. Ovary mostly half-inferior, rarely completely inferior, of 1 to 3 fused carpels and 1 to 3 chambers, with 2 to 4 pendulous ovules, or 1-chambered with one ovule. Style simple, 2-forked. Fruit a capsule with 2 seeds or a nut with 1 seed. Seeds with fleshy appendages (arils). Endosperm copious, fleshy. Twelve genera and 75 species, distributed in the Cape Region of southern Africa. Representative genera include *Brunia* (7 species), *Lonchostoma* (4 species), *Audouinia* (1 species), *Berzelia* (11 species), *Thamnea* (7 species), *Raspalia* (16 species), and *Staavia* (10 species).

Family Penthoraceae

Perennial herbs with underground stems (rhizomes) and al-

ternate, simple, toothed leaves that lack stipules. Flowers small, regular, bisexual, in one-sided cymes (flower clusters that mature from top or centre flowers downward) at the branch tips. Sepals 5, touching edge-to-edge, persistent. Petals 5 and inconspicuous or, more often, absent. Stamens in 2 whorls of 5 each. Ovary superior with 5 to 8 more or less separate carpels united half their length and slightly sunken in the receptacle, recurved, each with a short style and headlike stigma. Ovules many. Fruit more or less flattened lengthwise, of 5 follicles opening by a line around the middle (lidlike) above their union, containing many sawdust-like seeds with pimple-like projections on their surfaces. One genus (*Penthorum*) and 3 species, distributed in eastern Asia and eastern North America.

Family Crassulaceae

Perennial herbs or sub-shrubs (shrubby in form but woody only at the base or a very low shrub) inhabiting dry, often rocky places and exhibiting structural adaptations to dry habitats. Leaves opposite or alternate, without stipules. Flowers usually in cymes, bisexual or rarely unisexual, very regular. Sepals free or united into a tube, often 4 or 5. Petals of the same number as the sepals, free or variously joined, inserted below the ovary. Stamens as many as or twice as many as the petals. Ovary superior, composed of carpels equal in number to the petals; carpels free or united at the base, 1-chambered. Ovules many or rarely few. Fruit a membranous or leathery follicle. Seeds usually with fleshy endosperm. Thirty-five genera and 1,500 species of cosmopolitan distribution, but mainly in warm, dry regions; especially abundant in southern Africa and Macronesia. Representative genera include *Crassula* (300 species), *Sempervivum* (25 species), *Cotyledon* (40 species), *Kalanchoe* (200 species), *Diamorpha* (2 species), *Pagella* (1 species), *Monanthes* (12 species), and *Bryophyllum* (20 species).

Family Cephalotaceae

Perennial herbs produced from a short, woody rhizome. Lower leaves form stalked, lidded, insect-trapping pitchers; upper leaves flat, elliptical, smooth-margined, and green. Flowers bisexual, regular. Sepals 6, disposed edge-to-edge, coloured. Petals absent. Stamens in 2 whorls of 6 each, those in 1 whorl longer than the others. Disc broad, thick, green, covered with pimple-like projections. Ovary superior, hairy, consisting of 6 free or more or less united carpels, each carpel with 1 ovule. Styles short, recurved, awl-shaped, with simple stigmas. Fruits 1-seeded follicles. Seeds with fleshy endosperm. One genus and 1 species (*Cephalotus follicularis*), distributed in the southwestern corner of Australia.

Family Saxifragaceae

Perennial, rarely annual, herbs with usually alternate leaves that lack stipules. Flowers usually bisexual, regular, 5-parted exclusive of carpels, with male parts usually maturing first (protandrous). Receptacle (expanded axis tip bearing flower parts) flat or hollowed to various depths making stamen and petal positions relative to ovary range from surrounding it (perigynous) to upon it (epigynous). Sepals usually 5, overlapping or touching at the edges and sometimes fused, or absent. Stamens usually in 2 alternating whorls of 5 each, those of the outer whorl opposite the petals (obdiplostemonous). Carpels rarely free, rarely as many as the petals, usually fewer and joined below, often 2. Ovules many, in several rows. Styles free, as many as the carpels. Fruit a capsule. Seed with abundant endosperm. Thirty genera and 580 species, mainly of northern cold and temperate regions, the Andes mountains, and alpine regions generally. A few are found in south temperate regions and Antarctic South America. Representative genera include *Saxifraga* (370 species), *Mitella* (15 species), *Astilbe* (25 species), *Heuchera* (50 species), and *Chrysosplenium* (55 species).

Family Vabliaceae

Erect, branched, sometimes glandular, annual or biennial herbs with opposite, simple, smooth-margined leaves that lack stipules. Flowers regular, bisexual, paired. Sepals 5, touching along the margins. Petals 5, overlapping or open. Stamens 5, alternating with the petals. Disc at upper end of ovary, inconspicuous. Ovary inferior, with 2 or 3 fused carpels, 1 chamber, and many ovules. Styles 2 or 3, thick, widely spreading, with capitate stigmas. Fruit a more or less globular capsule with many minute, appendaged seeds. One genus (*Bistella*) and 5 species, ranging from tropical and southern Africa to northwestern India.

Family Francoaceae

Perennial herbs with hairy surfaces, arising from rhizomes. Leaves crowded or arising from the base of the plant, alternate, without stipules. Flowers in racemes or panicles. Sepals 4, touching along margins, persistent. Petals 4 or 2, overlapping or contorted, sometimes clawed. Stamens 8 or 4, alternating with 8 or 4 sterile stamens. Ovary superior, composed of 4 fused carpels, with 4 chambers, with many ovules and 4 sessile

(unstalked), globose or flattened stigmas. Fruit a capsule, oblong, membranous, erect, 4-lobed, 4-chambered, many-seeded. Seeds very small, with a thin coat and with fleshy endosperm. Two genera (*Francoa* and *Tetilla*) and 2 species, in temperate Chile.

Family Eremosynaceae

Small, annual, hairy herbs, much branched from the base. Leaves alternate, sessile (without stalks), smooth-margined to incised along the sides without stipules. Flowers very small, in terminal 2-forked cymes. Calyx of 5 fused, narrow sepals, deeply lobed. Petals 5, free, narrowly elliptical, spreading. Stamens 5, alternate with the petals, free. Ovary about three-quarters superior, of 2 fused carpels, joined to the calyx at the base, with 1 ovule per chamber and 2 free, slender, divergent styles. Fruit a 2-chambered capsule. Seeds with copious endosperm. One genus and 1 species (*Eremosyne pectinata*), in southwestern Australia.

Family Parnassiaceae

Perennial (*Parnassia*) or very small annual (*Lepuropetalon*) herbs with basally clustered or alternate simple leaves that lack stipules. Flowers solitary, conspicuous or small, bisexual, radially symmetrical. Sepals 5, free or joined together in the lower part, overlapping. Petals 5, overlapping, sometimes fringed, longer than the sepals, minute, or absent. Stamens 5, alternating with 5 sterile stamens. Ovary of 3 or 4 fused carpels, superior, half-inferior, or inferior, 1-chambered, with numerous ovules. Styles 1, 3, or 4, very short, or absent, with 3 or 4 mutually touching stigmas. Fruit a capsule. Seeds with cylindrical embryo and very little or no endosperm. Two genera (*Parnassia* and *Lepuropetalon*) and more than 56 species distributed throughout temperate and subtropical areas of the Northern Hemisphere (*Parnassia*). *Lepuropetalon*, with 1 species, occurs in America from the southeastern United States to Mexico and Chile.

Critical appraisal. In older taxonomic systems, the family Saxifragaceae is placed in the order Rosales along with other families traditionally placed there, such as Hamamelidaceae, Rosaceae, Platanaceae, Crassulaceae, Cunoniaceae, and others. More recent authorities have placed the plant groups included in the traditional Saxifragaceae in different categories and have given different taxonomic importance to the categories themselves.

Among recent systems of classification the older Saxifragaceae (treated as a family in the order Rosales) is, in one system, placed in two different orders: Saxifragales, consisting of the families Crassulaceae, Cephalotaceae, Saxifragaceae, Eremosynaceae, Vahliaceae, Francoaceae, Donatiaceae, Parnassiaceae, and Adoxaceae; and Cunoniales, containing the families Pterostemonaceae, Cunoniaceae, Philadelphaceae, Hydrangeaceae, Grossulariaceae, Oliniaceae, Greyiaceae, Escalloniaceae, Baueriaceae, and Crypteroniaceae. Another recent system treats the older saxifragaceous groups under the order Saxifragales, consisting of the families presented in the annotated classification section above. In still another recently proposed system, the saxifragaceous groups of traditional classification systems are all included in the order Rosales under four families: Hydrangeaceae, Grossulariaceae, Cunoniaceae, and Saxifragaceae. Woody taxa are concentrated in the first three families, the majority falling into Grossulariaceae. The order Rosales in that system contains 17 families and nearly 20,000 species.

Thus, among the several recently proposed systems of classification, there is considerable diversity of opinion as to the taxonomic values and the composition of the groups comprising the Saxifragales.

All of the recombinations, re-evaluations, and reinterpretations appear to be based on little more than a reworking and re-sorting of presently available evidence. Such activities are not productive; a better approach would be taxonomies based on new evidence, thus reducing or even eliminating conjectural aspects. New data can come from intensive studies in plant anatomy, from comparative plant chemistry and cytotaxonomic studies, intensified paleobotanical investigations, and other nontraditional means.

Scales, Musical

Theoretical descriptions of the pitch relationships that exist in music are called musical scales. The specific selection of different tones in any piece of music generally reveals a pattern of relationships among its pitches that can be expressed as a series of fixed distances (intervals) from one pitch to another within the span of an octave. The interval relationships among pitches of a scale are its essential feature, and a particular pattern of intervals defines every scale. Other aspects of pitch usage in music, such as range (distance from the highest pitch used to the lowest), emphasis placed on certain pitches, or the simultaneous (harmonic) and successive (melodic) occurrence of tones, do not alter the identity of the scale, although they may be essential in describing its function.

Although the number of different scales that can be formulated is theoretically nearly infinite, particular scales tend to become conventionalized within any given culture or musical tradition. The scale of a single piece of music may therefore be characteristic of the tone system of a whole culture. In general, the simplest scales can be found in very old music and in the music of nonliterate cultures, while the most complex scales occur in the world's most advanced cultures.

Scale and melody. Scales have proven to be important in the analysis of folk music and the music of nonliterate cultures, but scholars have been obliged to deduce the scales through a study of the actual music, since the creators of the music were not cognizant of scales as theoretical concepts. By contrast, music of the most highly developed cultures (variously described as classical music, art music, cultivated music, and high-culture music) is created in full awareness of rules or conventions pertaining to scale usage.

In view of the wide range of possibilities, a surprisingly small number of scale types predominate throughout the

Non-explicit scales

Other classification systems

world. The intervals found in non-Western music often approximate rather closely the basic whole-step and half-step intervals that are used in Western music. Variations from Western intervals are often expressed as measurements in cents (100 cents = one half step in equal temperament, the pattern of 12 equal half steps used in Western music; cf. TUNING AND TEMPERAMENT, MUSICAL). The task of identifying scales in non-Western music is complicated further by the occasional appearance of highly variable intervals or by singing techniques that produce sounds whose pitches cannot be specified accurately through conventional notation, like the "tumbling strains" (falling melodies) described by musicologist Curt Sachs in the singing of Aboriginal Australians.

Although music performed only on one pitch does exist, the study of scales properly begins with the occurrence of at least two different pitches. Scales consisting of only one or two intervals (*i.e.*, two or three pitches) can be found throughout the world in monophonic music (that consisting of a single unharmonized melodic line), though they are perhaps most numerous in Ceylon, eastern Siberia, California Indian cultures, and in regions near the Ural Mountains. Such scales commonly display a narrow range in which the pitches are separated by a half step, a whole step, or a minor third (one and one-half steps, as, C–E \flat). Larger skips in two- and three-note scales do occur but are less frequent. Some simple scales have probably acquired additional pitches through a tendency to fill in large skips with intervening pitches. Another process by which scales may have expanded is the transposition within a single melody of one characteristic melodic motive (identifiable fragment) to a different pitch level, thus creating additional scale degrees, as in the melody of the Makurap Indians shown below.

From F. Blume (ed.), *Die Musik in Geschichte und Gegenwart*; Bärenreiter-Verlag Kassel, Basel

Occasionally, primitive melodies apparently generated by motivic transposition also contain evidence of emphasis on particular pitches. As an example, the skips in the following Osage Indian melody are arranged so that the pitches G and C are consistently reiterated.

From F. Blume (ed.), *Die Musik in Geschichte und Gegenwart*; Bärenreiter-Verlag Kassel, Basel

The melodic "weight" given to those two pitches could not have been achieved by the simple transposition of motives. Further, weighted scales may also give prominence to certain pitches by using them as range limits or by placing a particular pitch at the ends of sections or the end of a piece.

Scales function somewhat differently in the art-music traditions of highly sophisticated cultures, since they are not only a means of description and analysis but are also pre-existent assumptions for the composer or performer. Within those cultures, knowledge of the characteristics and requirements of various scales is often perpetuated by written treatises on music theory as well as by oral communication from generation to generation. The existence of professional composers and performers also encourages continuity in musical knowledge, even though some cultures, like those of the Western world, advocate

continuous change in musical practices within acceptable limits. Through gradual evolutionary processes, the nature of scales and their functions may change radically over a period of several centuries.

Highly developed, complex systems governing the use of scales exist in a variety of cultures, principally in the Far East, India, Iran, the Muslim world, and the West. The differences in musical styles among those cultures are indeed great, yet there are some similarities in the manner in which scales function in each instance. Each culture has a number of basic scales (interval patterns), called *grāma* in India, *dastgah* in Iran, *maqām* in Muslim cultures. Generally, a basic scale is used to produce a number of different modes, or bases for melodic construction, in which the intervallic structure of the scale remains intact while primary and secondary melodic importance is attached to different pitch degrees (see MODES, MUSICAL). This hierarchy in which modes are generated by basic scale types consequently produces a greater number of modes than there are basic scales. The terms *maqām* and *dastgah* also are used to refer to such modes; the corresponding Indian term is *jāti*. In some art-music traditions the modes serve as the basis for an even larger number of specific melody types, which may again be elaborated further by improvisation in performance. In India the basic melodies are called *rāgas*; in Iran they are *gūsheh*. Although Western art music has a system of scales and modes, the melody types are not used as systematically or as consciously as they are in some of the non-Western traditions.

Common scale types. Pentatonic (five-note) scales are used more widely than any other scale formation. In fact, Western art music is one of the few traditions in which pentatonic scales do not predominate. Their frequency is especially notable in the Far East and in European folk music. The most common varieties of pentatonic scales use major seconds and minor thirds, with no half steps (anhemitonic). A representative type could be spelled C–D–E–G–A, for example. The pentatonic scale is so pervasive that melodies exhibiting tetratonic (four-note) scales often appear to be pentatonic with one pitch omitted. Hexatonic (six-note) scales appear rather rarely in folk music and nonliterate cultures. Examples that are known often seem to be fragments of the seven-note Western diatonic scale.

Heptatonic scales are especially prominent in the world's art-music traditions. The tone systems of India, Iran, and the West are entirely heptatonic, and seven-note scales are also present in the art music of some cultures that do not use such scales exclusively (*e.g.*, the *ritsu* scale in Japan and the *pelog* scale in Java).

With some exceptions in both the distant and the recent past, Western art music has been based largely on one heptatonic scale, known as the diatonic scale. The origins of this scale can be traced to ancient Greece, and it has been formulated to some extent according to acoustical principles (see HARMONY). Since the octave in Western music is normally divided into 12 equal half steps, the characteristic intervals of the diatonic scale can be constructed upon any one of the 12 pitches. Such transpositions of the scale are known as keys.

Before the 17th century, as many as 12 different mode permutations of the diatonic scale were in common use, but only two modes—now called major and minor—have been in general use during most of the past 300 years. The diatonic scale itself consists of five whole steps (W) and two half steps (H), with the half steps dividing the whole steps into groups of two or three. The major scale uses the sequence W–W–H–W–W–W–H, as shown in the first of the following examples, while the intervals in the minor scale are W–H–W–W–H–W–W, as in the second.

In actual music the minor scale is usually altered in one of two ways to create greater emphasis on particular pitches. In the harmonic minor scale (the third example shown) the seventh note is raised one half step, and in the melodic minor scale (the fourth example) both the sixth and seventh notes are raised by one half step in ascending patterns while they are left unaltered in descending patterns (the fifth example).

The diatonic scale

Explicit scale systems

Chromatic,
whole-tone,
and
microtonal
scales

In the 19th and 20th centuries, composers have made increasing use of pitches lying outside the diatonic scale, and that tendency has stimulated a variety of novel scale systems, developed as alternatives to the diatonic scale. Principles for composition within the chromatic scale (consisting of all of the 12 half steps within the octave) were first articulated by the Austrian-born composer Arnold Schoenberg early in this century. Other scales have also been employed on an experimental basis. The whole-tone scale (comprising six whole steps) was used prominently by the French composer Claude Debussy and others, especially in France and England. Microtonal scales requiring intervals smaller than the conventional half step have also appeared sporadically in this century. Among microtonal structures the most important, perhaps, have been scales calling for quarter tones (equal to half the distance of a half step).

Other uses of the term scale. The term scale is sometimes used to describe musical passages consisting of a succession of consecutive scale degrees in ascending or descending patterns. It is also used to describe scalelike exercises that are practiced for the development of technical proficiency on a musical instrument. "Scale" can refer in rare instances to the ordering of some musical element other than pitch. An example is the term *Klangfarbenmelodie* used in some recent music to denote a carefully arranged succession of different tone colours.

Scandinavia, History of

The history of Scandinavia involves five independent nations—Noway, Denmark, Sweden, Finland, and Iceland—with a population in the 1970s of about 20,000,000, tied together by geography, language, and culture. For more than 1,000 years these nations have been bound to each other in political unions of various combinations, but they have also been separated by divergent strategic, economic, and political interests, often resulting in wars and conflicts between them. Yet the common ties outweigh the differences, and it is possible to speak of a common "history of Scandinavia."

From the first appearance of the Scandinavians in Euro-

pean history, as the Vikings, cooperation among them has made them a unit in the eyes of the world. All the Scandinavian countries were politically united only during the period of the Kalmar Union (1397–1523), but in later times Scandinavians have often acted together in the face of external pressure.

Scandinavia has had two periods of profound impact on European history: the Viking Age and the Swedish Age of Greatness. During the Viking Age, the Norsemen ravaged much of Christendom, built a European settlement that extended to the distant North Atlantic islands, and, for a brief moment, touched the shore of North America. During the 17th century, Sweden held the balance of power in Europe and built an empire that stretched deep into Germany. Denmark and Norway too have had periods of empire in the 13th century: Denmark's domain covered the south coast of the Baltic from the Elbe to the Oder and included a base in Estonia, while Norway ruled over Iceland, Greenland, and the Faeroe, Shetland, Orkney, and Hebrides Islands.

For most of its history, however, Scandinavia has been more influenced by the outside world than a power within it. Most developments were late in reaching Scandinavia: the area was the last in western Europe to be Christianized, for example, and industrialization did not begin until the second half of the 19th century. Yet in the last half of the 20th century, the Scandinavian countries have taken their place among the leaders of the modern world.

I. Scandinavia to 1523

THE VIKING AGE: SETTLEMENT ABROAD

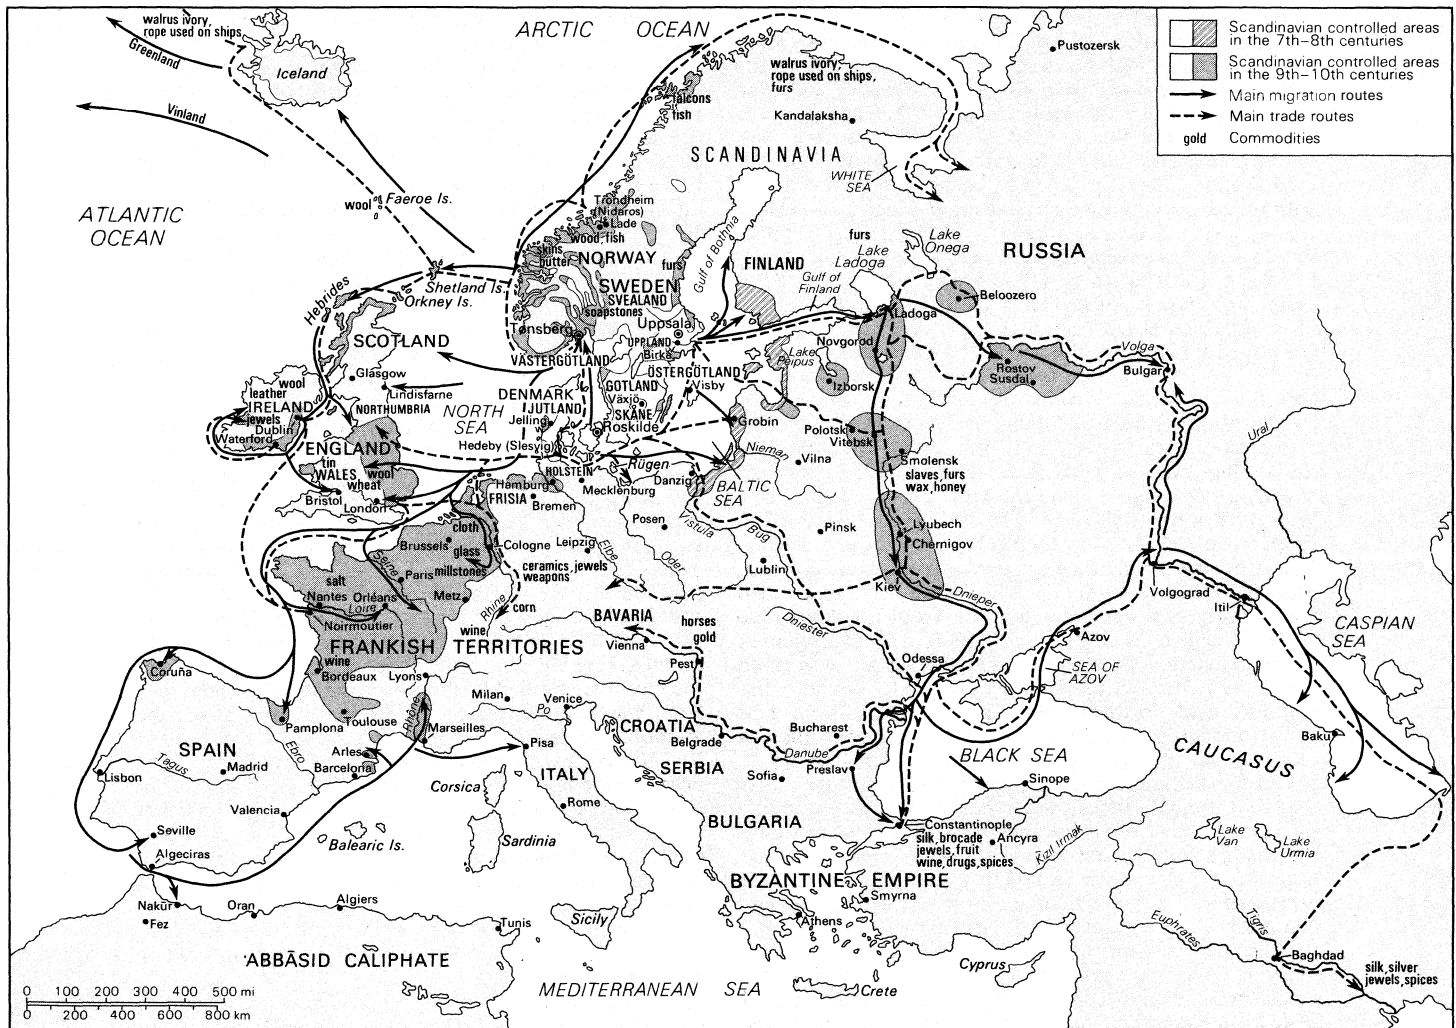

Prehistoric Scandinavia. Prehistoric Scandinavia lasted until the 9th century AD, when writing began to be used in the Nordic lands, at the same time as the inhabitants began to exert an influence on world history through the Viking excursions and the world, in turn, sent emissaries into Scandinavia to introduce Christianity and Western civilization. Written evidence of dwellers in Scandinavia before this time appears only in brief and sometimes controversial mentions in classical sources such as Pythéas, Pliny the Elder, and Tacitus and in runic inscriptions found within Scandinavia that date from the Roman Iron Age (c. AD 1–C.400). Other information comes from archaeological finds, on the basis of which an approximate division into periods can be made.

It appears that the first inhabitants arrived in Scandinavia before the last ice had receded. Finds in Denmark point to possible Neanderthalic hunters in the area (c. 45,000 BC), and two cultures (the Komsa and Fosna) seem to have existed on the northern and western coasts of Norway during the last Ice Age. These groups were apparently isolated phenomena, and links between their members and the Stone Age inhabitants of the area have not been determined. The direction from which the permanent settlers of Scandinavia appeared is generally accepted to have been south and southeast, but their origin is unknown. Some of them seem to have migrated from European Russia over the land bridge between the Gulf of Bothnia and the Arctic Ocean, others through present-day Denmark.

During the Stone Age (Paleolithic, c. 10,000 BC–c. 3000 BC; Neolithic, c. 3000 BC–c. 1500 BC), the population of Scandinavia progressed from existence as hunters and fishers to a more stationary life as agriculturalists, with the help of improved tools and weapons, influenced by and sometimes imported from the lands to the south. It is speculated that major changes of tools, weapons, and burial styles were introduced by new groups of settlers rather than by the innovations of established residents, but controversy on this point continues. Among the more interesting cultures uncovered by archaeologists are the kitchen-midden people (*køkkenmødding*) in Denmark (c. 5000 BC–c. 3000 BC), whose waste heaps attest to the spread of their culture over what is now Denmark, the southern coast of Norway, and the eastern Baltic.

During the Bronze Age (c. 1500 BC–c. 500 BC), most tools were still made of stone, especially flint, with bronze used largely for luxury items. Because copper and tin for the making of bronze had to be imported, trade relations

The
kitchen-
midden
culture

Viking expansion, 7th to 10th centuries.

From *Grosser Historischer Weltatlas*, vol. II, *Mittelalter* (1970); Bayerischer Schulbuch-Verlag, Munich

between Scandinavia and Europe became lively; amber was the principal export. At this time, drawings were made on rocks, especially on the Scandinavian Peninsula, depicting people, tools, ships, animals, and suns, apparently signifying a sun or fertility religion. The former burial methods (in mass and single graves) were replaced by burial above ground in mounds and by funeral pyres.

In the early stages of the Iron Age (pre-Roman, or Celtic, Iron Age, c. 400 BC–c. AD 1; Roman Iron Age, c. AD 1–c. 400; and Germanic Iron Age, c. 400–c. 800), iron ore was imported, until it was discovered that the native bog iron could be exploited. The dominance of the Celts in Europe cut the Scandinavians off from the Mediterranean, until the German tribes and Julius Caesar pushed back the Celts. Exports from Rome flowed into Germany and on to Scandinavia along the rivers to the Baltic and North seas. Gotland became an important trading centre, as attested by hoards of Roman coins that have been found there. (Roman coins have been unearthed throughout Scandinavia, even on Iceland.) Exports from the North were primarily amber, furs, horses, and slaves. During the final stage of the Iron Age, the Swedes established colonies, which were apparently for trading, along the southeast coast of the Baltic at the mouth of the Vistula and in Latvia, as evidenced by building patterns and graves. Hedeby, on the Schlei, attracted traders from as far away as the Arab world. The disruptions of the 4th- and 5th-century migrations of barbarian peoples across Europe and the fall of the Roman Empire were reflected in Scandinavia by internal warfare, shown in the building of fortifications and hoarding of valuables in underground caches and immortalized in the epic of

Beowulf. Place-names indicate much new settlement during the last two centuries of the Iron Age, indicating a return to more peaceful and prosperous conditions, while finds in Sweden indicate contacts with the south Germans and in Norway with Merovingian France.

The Vikings. When the Viking Age began (c. 800), Scandinavia was by no means an isolated, unknown corner of Europe. Trading contacts with other people had existed for centuries, and colonization abroad had been started by the Swedes in one of the directions the Vikings would later take. The cause of the explosion of the Vikings into the world is a matter of much controversy. Obviously, the urge for adventure and desire for loot motivated some of the Vikings, but deeper explanations vary. Some historians posit overpopulation in Scandinavia, while others point to a deteriorating climate that made agriculture less profitable and more difficult. On the other hand, new land was broken at home throughout the age, and a limit to new cultivation was apparently not reached. The deterioration of the Mediterranean trade, caused by conflicts between Muslims and Christians, undoubtedly played a role, with the northern route from east to west becoming an important alternative. Other factors were the lack of organized resistance to the Norse raiders and the superior shipbuilding techniques of the Scandinavians, which made possible the Viking ship, shallow, pointed at both ends, easily manoeuvrable in rivers and bays, and powered by sail and oars. The word Viking is itself controversial: some linguists trace it to the Old Norse *vig* ("battle," "fight"), while a more common theory derives it from *vik* ("bay," "gulf"), making a Viking a person who is tied to bays (with the further meaning of attacking passing ships from the bays).

Cause of
Viking
expansion

Origin
of the
word
Viking

The western route. *The British Isles.* The Viking expeditions went in two general directions—west and east—with the Danes and Norwegians more prevalent in the former and the Swedes in the latter. The Scandinavian states were loose confederations at the beginning of the Viking Age, and the identity of the Vikings as Danes, Norwegians, and Swedes is only approximate. The Viking Age is generally accepted as having begun in 793 with the raid on the English cloister, at Lindisfarne (Holy Island, off northern Britain). Monasteries—isolated, wealthy, and inadequately defended—provided an attractive target for these early Vikings, who were interested in easily won booty and travelled singly or in small groups of ships. After several decades, however, the raiders began to assemble large fleets and to winter abroad. They established camps at strategic places in the British Isles and, later, in France, from which they could make raids into the interior areas; settlements by the Norsemen followed soon after. By 842 half of Ireland was subject to the Vikings, and 11 years later, Olaf the White was the overking of the land where the kingdoms of Dublin and Waterford were established. The Vikings first wintered in England in 851, and in 865 their armies began the overthrow of the Anglo-Saxon kingdoms of Northumbria, Mercia, and East Anglia. In 878 Alfred the Great ceded the territory north and east of a line from London to the northern edge of Wales (about three-fourths of England) to the invaders. This area of Viking settlement was given the name Danelaw; the Danes were predominant in the southern and northeastern parts of the territory, and the Norwegians in the northwest. For more than a century, the Vikings apparently devoted themselves to peaceful settlement and trading in the areas they had won; but around 1000, a new series of raids began, led by the Danish king Sweyn Forkbeard (Svend Tveskæg), and the English were forced to pay tribute (Danegeld) in the hope of avoiding attacks and plundering. In 1013 the attacks reached a peak; all of England submitted, and Denmark and England were joined in one kingdom. But the distance between the two countries and the lack of unifying interests worked to prevent a real unification; when Sweyn died in 1014, it was only through the efforts of his son Canute (Knud) that England remained in the Danish sphere. Canute succeeded his older brother on the Danish throne in 1018, reuniting the kingdoms, and later efforts led to the inclusion of Norway and the Swedish territory of Västergötland in the Danish Empire. Canute devoted most of his attention to England but also sent English missionaries to Christianize Denmark. With the death of Canute's son and successor, Hardekanute (Hardeknud; ruled 1035–42), the Danish empire dissolved. An attempt by the Norwegian king Harald Hårdråde (Norw. Hådråde; 1047–66) to reconquer England in 1066 failed but facilitated the conquest of the island by William I the Conqueror, whose Norman kingdom had been formed out of another wave of Nordic expansion.

The Islands. While Vikings from Norway and Denmark were raiding and, later, settling the British Isles, where they soon became assimilated with the native population, the Norwegians were also travelling to the uninhabited or sparsely inhabited islands west of the Scandinavian peninsula: the Shetland, Hebrides, Orkney, and Faeroe islands; Iceland; Greenland; and, finally, North America. The Shetlands were visited quite early: with a favourable wind, the Vikings could reach them from the Norwegian coast in one day. With the Shetlands as a base, settlers moved on to the Hebrides, Orkneys, and Faeroes and to Iceland, where the few residents, Irish monks, were driven out beginning in 874. Expeditions proceeded to Greenland in c. 986, and around the year 1000, a few Vikings reached Vinland (Wineland) on the North American coast; no settlements were made there, however.

Of these settlements, Iceland is the best known because of medieval Icelandic documents and histories. A West Norwegian chieftain, Ingólfur Arnarson, moved to Iceland in 874 and was followed by settlers, mainly chieftains and their retainers. By 1100 the population was between 70,000 and 80,000. Early local government by the

chieftains led to the establishment of the Icelandic commonwealth in 930, with a national parliament.

The Continent. While some of the Vikings concentrated on the islands and England, others raided the Continent. By the end of the 9th century, Frisia was controlled by the invaders, mainly Danes, and there were attacks on Paris in 845 and 885–887. The lower Loire was also ravaged during the 9th century. Around 900 the Vikings attacked the northern coast of France, and in 911 the French king ceded land on both sides of the mouth of the Seine to the chieftain Rollo and his followers, who in turn promised to prevent attacks by other Norsemen. The territory ruled by the Danes received the name Normandy, and settlers moved in along with the warriors. The attacks, beginning in the 9th century, in Germany, northern Spain, the North African coast, and Italy were more sporadic, and their permanent effects were negligible.

The eastern route. The primary attraction of the eastern route, followed primarily by Swedish Vikings, was the riches of the East, brought to Byzantium and Baghdad along the major East–West trade routes; and because these riches were found in well-established, well-defended states, the primary activity of the Vikings here was trade. Early in the 9th century the Swedes had begun to penetrate into Russia, via the Dnieper River to the Black Sea and Constantinople and via the Volga River to the Caspian Sea and Baghdad; and in the later part of the 9th century, kingdoms (most prominently Kiev and Novgorod) were established by the Swedes in Russia. The native Slavs and Finns in the area were easily conquered; the Swedish settlers were quickly assimilated. The export of Russian and Swedish products (furs, slaves, and weapons) and the import of metals and spices from the Orient brought great wealth to Sweden, and the town of Birka, on an island in Lake Malaren, became an important trading centre during the 9th and 10th centuries; the town disappeared during the 11th century, when the Viking Age was waning. In an attempt to monopolize the northern trade route, the Swedes captured Hedeby (in southern Jutland) in c. 900, which remained in Swedish hands for about 30 years.

The decline of the Vikings. By the mid-11th century, the Viking Age was over; the last eruption was Harald Hårdråde's unsuccessful attempt to win back England in 1066. In the west, the weak states of the 9th century had been replaced by powers no longer defenseless; in the east, the entrance of the Turks produced unease, and the goods of the Orient no longer flowed into Russia as they had a century earlier. Around 1050 the political connections between Sweden and Russia ceased. At the end of the century, the Mediterranean was reopened to the Orient trade by the First Crusade, and the northern route was no longer necessary or attractive. At the same time, Christianity had been established in the Scandinavian countries, and its teachings were inimical to the bold Viking life-style and to the trade of slaves, a prime export. The rise of primitive national states in Scandinavia during the Viking Age also provided an outlet for talents formerly used in trading, settling abroad, or raiding.

THE VIKING AGE: SCANDINAVIA

Denmark. The early centres of Denmark were Roskilde (on the island of Zealand) and Hedeby and Jelling (in southern and northern Jutland, respectively). At the beginning of the Viking Age, the most important seems to have been Hedeby, which served as an outpost against the Frankish empire of Charlemagne; and, after the successes of the Danish kings Godfred (or Gudfred; died 810) and Hemming (died 812) against the Franks, the Eider River became the established southern frontier. To protect the border area and the town of Hedeby (also called Slesvig), the Danevirke, a great rampart south and west of the town, was built, but it proved to be more of a symbol than an adequate defense structure. Louis the Pious, the son of Charlemagne, attempted to Christianize the Danes. He sent a monk, Ansgar, to Hedeby in 826, where his message was resisted. Four years later, the monk visited the Swedish town of Birka, where he met with greater temporary success; the following year he was

made archbishop of Hamburg (later of Bremen, when the Vikings burned the former town), with all of Scandinavia his see. After Ansgar's death, in 865, his successor, Rimbert, wrote a hagiography of him, which is the most important source for 9th-century Danish history.

Unification
under
Harald
Blutetooth

During the 10th century, after internal struggles between rival kings, the centre of power moved to Jelling, where Gorm became king of **Jutland** (c. 940). His son, Harald Bluetooth (Blåtand), attributed to himself the unification of all Denmark, the conquest of Norway, and the Christianization of the Danes. It is possible that he agreed to become a Christian (c. 960) in order to avoid German meddling in Denmark, although he was later forced to protect the southern border from a German attack. Under the King's protection, the new bishops of **Jutland** proceeded with the Christianization of the kingdom, and the gravesite of Harald's pagan parents was made into a Christian shrine. Harald's conquest of Norway was short-lived, and his son Sweyn Forkbeard and grandson Canute were each forced to **rewin** the country. Sweyn, as noted above, also conquered England and formed an Anglo-Danish empire, which his son and grandson continued until the latter's death in 1042. English missionaries were sent into Denmark, to counteract the power of the Hamburg archbishops, but Denmark never left the orbit of the German prelates. Norway elected a native king in 1035, who also ruled in Denmark from 1042 to 1047, when Denmark elected Canute's nephew Sweyn Estridson, who battled with the Norwegian king Harold Hardraade for reunification, with the result that each recognized the other's sovereignty.

Norway. The early local kings and chieftains of Norway ruled over distinct areas, usually with a local assembly or thing. The area around the Oslo fjord was closely tied to Denmark, while the inland areas in southeastern Norway, with the Eidsvating at Eidsvold, were more **influenced** by Sweden. The Gulating on the Sogne fjord was the centre for an aristocratic confederation in the southwestern part of the country, and the **Øreting** at Trondheim was the meeting place for the leaders in the Trondheim fjord area. Farthest north, the earls (*jarls*) of Lade ruled an ancient monarchy and added the Trondheim area to their territory in the 9th century.

At the end of the 9th century, Harald Fairhair (*Hårfagre*) united most of western Norway after the Battle of Hafsrfjord (872, sometimes dated 892). His son and successor, Erik Bloodaxe (*Blóðøx*, so-called because of his murder of seven of his eight brothers) ruled c. 930–935 and was replaced by his only surviving brother, Haakon, who had been reared in England. Haakon was Norway's first missionary king, but his efforts failed; he died in a battle and was followed by Erik's son Harald II Graycloak (*Gråfella*). Harald II killed two of the kings in the Oslo region and the Earl of Lade, and became unpopular because of his prohibition of the public worship of the pagan gods. He was killed c. 970 in a battle against Haakon, son of the Earl of Lade.

Haakon allied himself with Denmark and took over the Gulating area as a Danish fief while the Danish king, Harald Bluetooth, annexed southeastern Norway. Haakon refused to assist in the Christianization of the country and revolted against Harald, becoming sovereign in western and northern Norway until his death during a peasant rebellion in 995. In the same year, Olaf Trygvason, a descendant of Harald Fairhair, returned from England, where he had led a Viking invasion in 991 and had been baptized. Olaf was acknowledged as king along the Norwegian coast; he Christianized those areas, by peaceful means if possible and by force if necessary; he also sent missionaries to Iceland, where the new religion was adopted by the parliament (*Althingi*) in 1000. When Olaf encroached upon Danish territory in Norway, he was challenged by a group of enemies (Sweyn Forkbeard, the Swedish king Olof Skotkonung, and a son of Earl Haakon) and killed in the Battle of Svolder (c. 1000). The Earl of Lade now took power in those parts of Norway not held by Denmark, but when he went to England with Canute (1015), another descendant of Harald Fairhair, Olaf Haraldsson, who had returned from England,

was acknowledged as king throughout Norway, including the inland areas. Olaf worked to increase royal power and to complete the Christianization of the country. In so doing, he alienated the former chieftains, who called on Canute, now ruler of England, for help. Olaf was killed in battle with the Danes and peasant leaders at Stiklestad in 1030. His popularity with the people and the church led to a demand for his canonization; one year after his death, he became St. Olaf, patron saint of Norway.

Canute's rule proved unpopular with the chieftains, and at his death, in 1035, the Norwegians elected **Olaf's** young son **Magnus** as king. In 1042, when Hardecanute died, **Magnus** also became king of Denmark, where he held off an invasion of Wends in **Jutland**. He died in battle in 1047 and was succeeded in Norway by his uncle, Harald Hardraade, with whom he had shared the kingdom since 1046. Denmark chose Canute's nephew, Sweyn Estridson, and after several years of battle between Sweyn and Harald for the rule of Denmark, the two acknowledged each other as king. In 1066 Harald was killed during a vain attempt to conquer England.

Sweden. Several centuries before the Viking Age, the area of Uppland became the most important in Sweden (c. 500). Large grave mounds were raised near the present city of Uppsala over local kings. Political conditions in Sweden before c. 1000 are little known, however, and it is only with the reign of Olof Skotkonung (c. 994–c. 1022) that the political history of Sweden begins.

Uppland

The first attempt to Christianize Sweden was made by the Frankish monk Ansgar in 830. He was allowed to preach and set up a church in Birka, but the Swedes were little interested. A second Frankish missionary was forced to flee. In the 930s another archbishop of Hamburg, Unni, undertook a new mission with as little success. A heathen temple at Uppsala provided a centre for pagan resistance, and it was not until the temple was pulled down at the end of the 11th century that Sweden was successfully Christianized.

The struggle between the old and new religions strongly affected the political life of Sweden in the 11th century. Olof Skotkonung, ruler of all Sweden, was baptized and supported the new religion, as did his sons Anund Jakob (reigned c. 1022–c. 1050) and **Edmund** (c. 1050–60). The missionaries from Norway, Denmark, and even Russia and France, as well as from Hamburg, won converts, especially in Gotland, the area where the royal dynasty made its home and where early English missionaries had prepared the ground. Many pagans refused to abandon their old faith, however, and civil wars and feuds continued. Claimants vied for the throne until the mid-13th century, when a stable monarchy was finally achieved.

Scandinavian society. During the Viking Age, the most important unit of Scandinavian society was the family, and blood feuds were legal and quite common. It appears that the rise of villages was tied to the family, which included the dead. The great majority of people were farmers, and a wide gulf existed between the free men, equal before the law, and the thralls (or slaves), who had extremely limited rights. The chieftains arose from the class of free men by virtue of their wealth and power, and they often combined religious power with secular, serving as local pagan priests. The early kings were chosen by the things (parliaments), comprised of the free men in an area, who also made laws and carried out justice; before the acceptance of Christianity, these kings seem to have been considered holy. The local things became provincial *things* for the lands (provinces) of Denmark and Sweden and the fylker (provinces) of Norway. When a single king won control of each country, he became the link between the provinces, each of which voted on his candidacy; his power in peacetime seems to have been small, but during wars he served as the leader. The three states were electoral monarchies, but the kings were usually chosen from the established royal families.

Already during the Viking Age, the geographic areas of concern and influence of the Scandinavian countries began to emerge. The Norwegians went primarily west, to the British Isles, Iceland, and Greenland; the Danes

Christian-
ization

southwest, to England, France, and northern Germany; the Swedes, east, to Finland and Russia. During the following centuries, Norway continued to concentrate on the west, receiving cultural influences and establishing trade connections with England. Denmark remained the Scandinavian country most closely tied to the Continent and, in its period of empire, concentrated on the south Baltic coast. Sweden's empire began in the Gulf of Finland, and its sovereignty over Finland, which had begun with the trade contacts during the Viking Age, extended from the 13th century to the beginning of the 19th. These early spheres of influence developed into conflicts of interest, especially between Sweden and Denmark, that lasted until the end of the 18th century.

FROM 1050 TO THE UNION OF KALMAR

Denmark. The unification of Denmark had begun in the mid-10th century with Harald Bluetooth and continued under his son Sweyn Forkbeard and grandson Canute, who briefly extended Danish rule to England and Norway. Canute's nephew Sweyn Estridson succeeded in ending the short-lived Norwegian rule of Denmark (1042–47) and, working together with the church, he strengthened royal power. The country was divided into eight bishoprics: Slesvig, Ribe, Arhus, Viborg, Vendyssel, Odense, Roskilde, and Lund. The royal succession remained in the hands of the provincial things. Five of Sweyn's sons succeeded each other on the throne—Harald Hén (1074–80), Knud (1080–86), Oluf (1086–95), Erik Ejegod (1095–1103), Niels (1104–34); and their reigns were marked by battles between the king, the people, and the church over the extent of royal power. Knud (the Holy) was anxious to strengthen royal power, and his bailiffs were ruthless in their treatment of the peasants. A general rebellion in Vendyssel forced the King to flee to Odense, where he was killed in St. Alban's Church. The peasants supported the election of Olaf, but Knud's closest supporter among his brothers, Erik Ejegod, was elected king. Under Erik Scandinavia was recognized as an archbishopric with the seat in Lund (1104).

In order to defend the southern border, Niels made Erik Ejegod's son Knud Lavard duke in South Jutland. Knud's successes against the Wends won him great popularity but cost him the increasing ill will of the King and his supporters, chief among whom was Niels's son Magnus the Strong. In 1131 Magnus killed Knud, precipitating a civil war in which Knud's brother Erik Emune took up the fight against Magnus. In 1134 Erik's army defeated that of Magnus, who was killed along with five bishops and 60 priests. Shortly after the battle, Niels visited Slesvig, a centre of Knud Lavard's support, and was killed by the townspeople; his successor was Erik Emune (1134–37). The civil war continued, and by 1146 the kingdom was divided between the sons of Erik Emune, Magnus the Strong, and Knud Lavard. After continued struggles, Knud's son Valdemar was acknowledged as the single king in 1157.

The Wends continued to be troublesome through attacks on the Baltic trade and the Danish coast; when the Germans began their expansion eastward across the Elbe, Valdemar allied himself with the Saxon prince Henry the Lion against the Wends and acknowledged the Hohenstaufen emperor Frederick Barbarossa as his overlord. With the blessing of the church, represented by Absalon, the bishop of Roskilde (later archbishop of Lund), Valdemar undertook repeated crusades against the Wends; in 1169 he captured Riigen and placed it under Danish rule, beginning the Danish medieval empire. The cooperation of King and church resulted in the crowning of Valdemar's oldest legitimate son, Knud, as king in 1170 by the archbishop, 12 years before Valdemar's death.

At the beginning of the 1180s, north Germany was split among petty counts, and Absalon, who ruled Denmark after Valdemar's death in 1182 during Knud's minority, abandoned Valdemar's subjection to Barbarossa, attacked Pomerania, and annexed it along with part of Mecklenburg to the Danish realm (1184). Knud's brother Valdemar, count of South Jutland, defeated the Count of Holstein, adding the duchy to his own territory.

When Valdemar Sejr became king (1202), the land between the Elbe and the Eider, including Liibeck, was brought under the Danish crown. The empire then extended from the Elbe to the Oder-Vistula. Valdemar began crusades to Estonia in 1219 and established the fortress at Reval (Tallinn), marking the culmination of the Danish empire. In 1223 Valdemar was taken prisoner by one of his north German vassals, bringing the Danish advance to a standstill. Valdemar bought his freedom in 1225, promising to give up all the conquered areas except Estonia and Riigen. A final attempt to win back the lost areas led to his decisive defeat in 1227.

Valdemar's son Erik was crowned during his father's lifetime (1232), and Valdemar made his sons Abel and Christopher dukes: Abel was given South Jutland and Christopher received Lolland-Falster. Soon after Valdemar's death (1241), a struggle broke out between Erik and Abel; Erik was captured and killed in 1250 by his brother's men. Abel succeeded him but was himself killed during an attack on the Frisians in 1252; Christopher became king, and Abel's eldest son became duke of South Jutland, which was soon acknowledged as the only hereditary duchy in Denmark.

Under Christopher I, the former cooperation between church and king ended. The archbishop, Jakob Erlandsen, demanded the full extension of canon law but was opposed by both the King and the peasants. The King had Erlandsen imprisoned, and Denmark was placed under interdict. Erlandsen found support among the South Jutland dukes, the Count of Holstein, and particularly the Prince of Riigen, who attacked Denmark; during the ensuing war Christopher died (1259). The regents for his young son Erik Glipping released the Archbishop, who left the kingdom; after several years, Erlandsen compromised and died on his way back to Denmark.

During Valdemar Sejr's reign, the institution of the *hof* began. As a check against the royal misuse of power, the king was prevailed upon to call together the *hof* composed of the secular leaders and prelates. After the first *hofs* were called under Valdemar, it became the custom for the *hof* to meet at short intervals. When Valdemar's grandson Erik Glipping came of age, a meeting of the *hof* (1282) forced him to sign a coronation charter, in which he agreed to call the *hof* each year, to have no one imprisoned purely on suspicion, and to hold "King Valdemar's law." This charter is the first written constitution of Denmark. The provincial things lost their old power to elect kings, although they retained legislative approval. The *hof* also functioned as the highest court in the kingdom.

In 1286 Erik Glipping was murdered, and the *hof* that elected his 12-year-old son Erik Menved as king (1286–1319) without a charter also appointed a commission to investigate the murder, resulting in the expulsion of a group of leading magnates. The remaining magnates in the *hof* were supporters of the royal policy, and the *hof* decreased in importance. At the same time, the archbishop, Jens Grand, took up his predecessor's policies. The King threw him into prison, and Denmark was again placed under interdict. In 1303 Erik Menved reached a compromise with the Pope in which the King would pay a fine and Jens Grand would be transferred to another see. Erik Menved also tried to take advantage of the weakness of the north German states but was unable to maintain his early gains because of the inability of Denmark's finances to support a mercenary army. At the King's death in 1319, the national finances were chaotic.

The childless Erik was succeeded by his brother Christopher II, who was forced to sign a strict charter. Christopher was the first king who accepted the *hof* as a permanent organ independent of his personal supporters; but he did not abide by the charter, and after a battle with the Danish magnates and the Count of Holstein, he was driven from the kingdom. For a time (1326–30), the young Duke Valdemar of Slesvig ruled under the regency of the Count of Holstein; after Christopher returned, the country was split by a peasant uprising, church struggles, and battle with the Holsteins. The Holstein counts had received almost all of the kingdom in pawn, and even be-

11th-century kings

The reign of Valdemar

Development of the *hof*

Holstein rule

fore Christopher's death in 1332, Skåne rebelled against its Holstein count and joined the Swedish king, Magnus Eriksson, who bought it from its Holstein owner.

For the next eight years (1332–40), Denmark had no king, and the counts of Holstein ruled. In 1340 one of the counts was murdered during a visit to Jutland; several weeks later, Christopher's son Valdemar was chosen as king. After negotiations with the sons of the dead count, it was agreed that Valdemar would be the Danish king, would buy back the pawned areas, and would marry the sister of the South Jutland duke, who for her dowry would present her husband with the northern quarter of North Jutland, which was thus the only kingdom Valdemar began his reign with. He made the reunion of Denmark his first priority: by selling Estonia (1346) and collecting extra taxes, he reclaimed some of the pawned areas, and he brought others back into the kingdom through negotiations or through force of arms. In 1360 he won back the provinces on the east side of the Sound, and Denmark was reunited.

Valdemar also took up the strengthening of the royal power. At a *hof* in 1360, a "great national peace" was agreed between the King and his people. Valdemar was also faced with major economic problems: after the Black Death (1349–50), he confiscated the ownerless estates and seized the royal estates that had been lost during the interregnum. The army was also reorganized: the king's estates became the backbone, and the *lensmænd* (royal representatives), who led civil and military administration from the estates, together with their armed men, became the core of the army. The *hof* was replaced by the *Rigsråde*, a national council of the highest civil servants, bishops, and chiefs at the main castles, and the king's retterting (court of law) became the supreme court.

Valdemar Atterdag's downfall was caused primarily by his foreign policy. In 1361 he attacked Gotland and forced Visby under his rule. Gotland was loosely tied to Sweden and the Hanse cities, and the Hanse declared war on Denmark. Sweden's king, Magnus Eriksson, agreed to the marriage of his son, the Norwegian king Haakon VI, to Valdemar's daughter Margaret and was soon overthrown by the Swedish magnates and replaced by his nephew Albert of Mecklenburg (1363). By 1367 Valdemar, faced with a coalition of the Hanse cities, Sweden, the north German princes, and the Jutland magnates, was forced to flee. Three years later, the council signed the Treaty of Stralsund, which gave the Hanse trading rights in Denmark and pawned western Skåne to them for 15 years. Valdemar returned home and died in 1375.

The royal Danish male line died with Valdemar, and the magnates elected Olaf, the five-year-old son of Margaret and Haakon, on the condition that he sign a charter. When Haakon died, in 1380, Olaf became king of Norway. Margaret served as regent for her son and gained the confidence of Norwegians and Danes, so that when Olaf died in 1387, she became ruler of the two kingdoms.

Norway. At the end of the Viking Age, Norway was an independent kingdom with the right to elect the monarch resting in the lagtings, four district assemblies of the peasants. All royal sons, legitimate or illegitimate, were considered to have equal claims on the crown if they were accepted by a *lagting*. During the 11th and early 12th centuries, it was not unusual for Norway to have two or more joint kings ruling without conflict. Thus Harald III Hardraade's son Olaf III reigned together with his brother Magnus II until the latter died in 1069. Olaf ruled from 1066 to 1093 without being involved in a war; by giving the dioceses (Nidaros, Bergen, Stavanger, and Oslo) permanent areas, he inspired the first Norwegian towns. Olaf's son, Magnus III Barefoot (Barfot) ruled for ten years, during which he undertook three expeditions to Scotland to establish Norwegian sovereignty over the Orkneys and the Hebrides. He was succeeded by his three sons Olaf IV (1103–15), Eystein I (1103–22), and Sigurd I Jerusalemfarer (Jorsalafarer; 1103–30), who ruled jointly and imposed tithes, founded the first Norwegian monasteries, built cathedrals, and incorporated the clergy on the Scottish Isles into the church of Norway.

Following the rule of Magnus III's sons, the increasing power of the church and the monarch contributed to the century of civil war. During the early 12th century, the kings expanded their power over the various provinces, and the family aristocracy in Norway grew discontented. After 1130 interest groups within Norwegian society supported pretenders, and the church was successful in exploiting civil unrest to win independence.

In 1152–53, the English cardinal Nicholas Breakspear (later Pope Adrian IV) visited Norway, resulting in the establishment of an archbishopric in Nidaros (Trondheim). The clergy was exempted from military service. In 1163 the church supported the claims of a pretender, Magnus V, in return for his obedience to the Pope, guarantees for the reforms of 1152, and the issuance of a letter of privileges for the church. Magnus' coronation was the first at which the archbishop presided. The first written law of succession, dating from this coronation, established primogeniture in principle and the prior right of legitimate royal sons to the crown. Instead of election by the things, a representation, dominated by the church, served as the electoral body. The law was never applied, and Magnus was succeeded by Sverrir Sigurdsson, a priest from the Faeroe Islands, who represented himself as a grandson of the first pretender king. After seven years of fighting, Sverrir was acknowledged in 1184 as king of all Norway and set out to bring the church under royal control. He refused to recognize the reforms and privileges made since 1152, and the Archbishop and most of the bishops went into exile; Sverrir was excommunicated. The exiles in Denmark established a rebellious party and allied themselves with the secular enemies of the King, who were opposed to the King's administrative reforms, which included the establishment of the hird as a new aristocracy composed of court officials and the heads of estates. This opposition party won control of the Oslo area and the inland areas and threatened Sverrir's rule until his death in 1202.

Civil war continued until 1217, when Sverrir's grandson Haakon IV became king, beginning the "Golden Age" of Norway. Haakon modernized the administration by creating the chancellor's office and the royal council. He prohibited blood feuds, and a new law of succession was passed by a national assembly (1260) that established the indivisibility of the kingdom, primogeniture, the prior claim of the legitimate royal sons, and, most importantly, the hereditary right of the king's eldest legitimate son to the crown; no election was to be held unless the royal line died out. During Haakon's reign, the northern boundary was regulated by a treaty with Russia. Greenland and Iceland agreed voluntarily to personal unions with the Norwegian king in 1261 and 1262, marking the greatest extent of the Norwegian empire, which included the Faeroes and the Scottish isles. Haakon died during an unsuccessful expedition to the Hebrides in 1263, and in 1266 his successor ceded the Hebrides and the Isle of Man to Scotland in return for recognition of the Norwegian claim to the Orkney and Shetland islands.

Haakon's son and successor, Magnus VI, earned the epithet Lawmender (*Lagabøter*) for his work on Norway's legislation. During his reign (1263–80), a common national law (1274) replaced the earlier provincial laws; Haakon's law of succession was confirmed; and a hereditary nobility, exempted from taxes in return for military service, was established. The king took over the legislative functions, while the things became courts. The towns also received new laws, and the privileges of the church were extended.

Magnus was succeeded by his young son Erik II (1280–99). Erik's regency was led by secular magnates who controlled central power throughout Erik's reign. The rivalry between secular and church leaders caused the regency to negate the political position and the privileges that the church had gained under Magnus' rule. They also tried to limit the rights of the German merchants in Norway but were answered by a blockade from the Hanse cities and were forced to agree to the German demands. Erik was succeeded by his brother Haakon V (1299–1319), who determined to renew the royal power.

Civil war

The
"Golden
Age" of
Norway

He built a series of fortresses, including Akershus in Oslo, marking the shift of political power from the west coast to the Oslo area. Haakon was unable to restore royal power to the extent he wished, however.

Haakon's successor was Magnus, the young son of his daughter Ingeborg and Duke Erik, son of Magnus Ladulbs of Sweden. The child was also elected to the Swedish crown in 1319, creating a personal union between the two countries that lasted until 1355. The countries were to be governed during the King's minority by the two national councils with the King's mother as a member of both regencies. The regency in Norway failed to prevent the increasing power of the magnates, and after the King came of age, he was forced to recognize his younger son Haakon as king of Norway (1343) and to abdicate in his favour when he reached his majority (1355). Magnus' elder son Erik was designated king of Sweden. The Black Death struck Norway in 1349–50 and killed nearly half the population. The upper classes were particularly hard hit: only one of the bishops survived, and many noble families were reduced to the peasantry by the death of their workers and the decrease of their incomes.

Haakon VI's rule (1355–80) reduced the power of the aristocracy, but his royal power was also limited. The casualties of the Black Death among the high civil servants and clergy were replaced by Danes and Swedes. The central government as a whole lost control over the kingdom, and the local areas began to conduct their own affairs.

Haakon VI married Margaret, the daughter of Valdemar Atterdag of Denmark, and their son Olaf was elected king of Denmark in 1375. Olaf also became king of Norway at his father's death (1380), but he died in 1387 at the age of 17, and his mother, who had served as regent in both kingdoms for him, now became the ruler.

Sweden. At the end of the Viking Age, Sweden remained a loose federation of provinces. The old family of kings died out in 1060; after the death of the last of these kings' son-in-law, Stenkil, in 1066, a civil war broke out. Around 1080 Stenkil's sons, Ingi and Halsten, ruled, but Ingi was overthrown by his pagan brother-in-law Blot-sven, who then held the kingship for three years before Ingi regained power. Around 1130, Sverker, a member of a magnate family from Östergötland, was acknowledged as king, and this province now became the political centre of Sweden. Sverker sided with the church and established several cloisters staffed by French monks; he was murdered c. 1156. During the later years of Sverker's reign, a pretender named Erik Jedvardsson was proclaimed king in Svealand; little is known about Erik, but according to legend he undertook a crusade to Finland, died violently c. 1160, and was later canonized as the patron saint of Sweden.

Erik's son Knut killed Sverker's son (1167) and was accepted as king of the entire country. Knut organized the currency system, worked for the organization of the church, and established a fortress on the site of Stockholm. After his death in 1196, members of the families of Erik and Sverker succeeded each other on the throne for half a century. While the families were battling for the throne, the country received its own archbishopric at Uppsala (1164), the country was organized into five bishoprics (Linköping, Skara, Strängnäs, Vasterås, and Vaxjö, joined later by Åbo in Finland), and cloisters were founded. The church received the right to administer justice according to canon law and a separate system of taxation, protected by royal privileges, and the pretenders sought the church's sanction for their candidacies. The first known coronation by the archbishop was that of Erik Knutsson in 1210. The church also gave its sanction to the "crusades" against Finland and the eastern Baltic coast, which combined an attempt at Christianization with an attempt at conquering the areas.

By the mid-13th century, the civil wars were drawing to an end. The most important figure in Sweden at that time was Birger Jarl, a magnate of the Folkung family. The jarls organized the military affairs of the eastern provinces and commanded the expeditions abroad. Birger was appointed *jarl* in 1248 by Erik Eriksson, the last member

of the family of St. Erik, to whose sister he was married. Birger's eldest son, Valdemar, was elected king when Erik died (1250). After Birger defeated the rebellious magnates, he assisted his son in the government of the country and gave fiefs to his younger sons. Birger improved the inheritance rights of women, made laws ordering the peace of the home, women, church, and thing, and began the building of Stockholm. The Hanse merchants in Sweden received privileges, and the establishment of towns blossomed.

Birger died in 1266; in 1275 Valdemar was overthrown by his brother Magnus Ladulbs with the help of a Danish army. Two years later, Valdemar agreed to abandon his claims on the crown and in return received parts of Götaland, which he lost in 1279. In 1280 a law was accepted establishing freedom from taxes for magnates who served as members of the king's cavalry, creating a hereditary nobility; the following year, Magnus Ladulbs exempted the property of the church from all taxes. Under Magnus' reign, the position of *jarl* disappeared and was replaced by the drots (a kind of vice king) and the marsk (marshall), together with the established kansler (chancellor). The export of silver, copper, and iron from Sweden increased trade relations with Europe, especially with the Hanse cities.

Magnus died in 1290 and was succeeded by his ten-year-old son Birger. The regency was dominated by the magnates, especially by the marsk, Torgils Knutsson; even after Birger's coronation in 1302, Torgils retained much of his power. The King's younger brothers Erik and Valdemar, who were made dukes, attempted to establish their own policies and were forced to flee to Norway (1304), where they received support from the Norwegian king; the following year, the three brothers were reconciled. A new political faction was created by the leaders of the church, whom Torgils had repressed, together with a group of nobles and the dukes, and in 1306, the marsk was executed. Birger then issued a new letter of privileges for the church, but his brothers captured and imprisoned him. Two years later the kings of Denmark and Norway attacked Sweden on his behalf. Birger was again recognized king of Sweden in 1310, and transferred half of the kingdom to his brothers as fiefs. Erik's territory, together with his earlier acquisitions, then consisted of western Sweden, northern Halland, southern Bohuslän, and the area around Kalmar and stretched across the borders of the three Scandinavian kingdoms. In 1312 the dukes married two Norwegian princesses, increasing their power and dynastic position; but in December of 1317 the dukes were imprisoned by their brother following a family dinner, and they died in prison. The nobility rebelled against Birger, who was forced to flee to Denmark in 1318, and the King's son was executed.

The magnates now seized control of Sweden and reasserted their power to elect a king. They chose Magnus, three-year-old son of Duke Erik, who had shortly before inherited the crown of Norway. In connection with the election, the privileges of the church and the nobility were confirmed, and the King was not to be allowed to raise taxes without the approval of the council and the provincial assemblies. The magnates now revised the laws of Svealand and by the Treaty of Nöteborg (1323) established the Finnish border with Russia. The Danish province of Skåne was bought and put under the Swedish king; by 1335 Magnus ruled over Sweden, Finland, Blekinge, and Norway, to which he soon added Halland. During Magnus' reign, a national law code was established (c. 1350), providing for the election of the king, preferably from among the royal sons, and a new town law code was written that gave the German merchants considerable privileges. In 1344 Magnus' elder son Erik was elected heir to the Swedish throne, one year after his younger brother Haakon received the crown of Norway. Erik made common cause with the nobility and his uncle, Albert of Mecklenburg, against his father; and in 1356, Magnus was forced to share the kingdom with his son, who received Finland and Götaland. Two years later, Erik died and the kingdom was again united under Magnus' rule.

Albert's
attack on
Sweden

In his struggles with the nobles, Magnus received the support of the Danish king, Valdemar Atterdag, and in 1359 Magnus' son Haakon of Norway was engaged to Valdemar's daughter Margaret. The following year, Valdemar attacked Skåne, and Magnus relinquished Skåne, Blekinge, and Halland in return for Valdemar's promise of help against Magnus' Swedish enemies. In 1361 Valdemar attacked Gotland and captured Visby, an important Baltic trading centre. Haakon, who had been made king of Sweden in 1362, and Margaret were married in 1363. Magnus' opponents among the nobility went to Mecklenburg and persuaded Duke Albert's son, also named Albert, to attack Sweden; Magnus was forced to flee to Haakon's territory in western Sweden. In 1364 the Folking dynasty was replaced by Albert of Mecklenburg. Albert joined in a coalition of Sweden, Mecklenburg, and Holstein against Denmark, and succeeded in forcing Valdemar Atterdag from his throne for several years. Albert was not as weak as the nobles had hoped, and they forced him to sign two royal charters stripping him of his powers (1371, 1383). At the end of the 1380s, Albert had plans to reassert his power, primarily by recalling the royal lands that had been given to the nobles; and in 1388 the Swedish nobles called upon Margaret, now regent of Denmark and Norway, for help. In 1389 her troops defeated and captured Albert, and she was hailed as Sweden's ruler. Albert's allies harried the Baltic and continued to hold out in Stockholm, and it was only in 1398 that Margaret finally won the Swedish capital. In 1396 her great-nephew Erik of Pomerania was hailed as king of Sweden, and in 1397 he was crowned king of Sweden, Denmark, and Norway, marking the beginning of the Kalmar Union.

Expansion. *Finland.* Finland has been populated since the end of the Stone Age; in the 1st millennium AD, Finnish tribes entered the area and pushed the aboriginal Lapps northward. Even before the beginning of the Viking Age, Swedes had settled on the southwestern coast. During the Viking Age, Finland lay along the northern boundary of the trade routes to Russia, and the inhabitants of the area served as suppliers of furs. The Finns apparently did not take part in the Viking expeditions. The end of the Viking Age was a time of unrest in Finland, and Swedish raids were made on the area. No permanent Swedish colonies were established in Finland, and the trading colonies of Swedes, Russians, and Germans were assimilated or returned to their own countries when trade declined.

Russo-Swedish
competition

From the 12th century, Finland became a battle ground between Russia and Sweden. The economic rivalry of the powers in the Baltic was turned into a religious rivalry, and the Swedish expeditions took on the character of crusades. Finland is mentioned together with Estonia in a list of Swedish provinces drawn up for the Pope in 1120, apparently as a Swedish missionary area. The First Crusade, according to tradition, was undertaken c. 1157 by King Erik, who was accompanied by an English bishop named Henry. Henry remained in Finland to organize the affairs of the church and was murdered by a Finnish yeoman; by the end of the 12th century, he was revered as a saint, and he later became Finland's patron. In a papal bull (c. 1172), the Swedes are advised to force the Finns into submission by permanently manning the Finnish fortresses in order to protect the Christianization effort from attacks from the east.

By the end of the 12th century, competition for influence in the Gulf of Finland intensified: German traders had regular contacts with Novgorod via Gotland, and Denmark tried to establish bases on the gulf. The Danes reportedly invaded Finland in 1191 and 1202; in 1209 the Pope authorized the Archbishop of Lund to appoint a minister stationed in Finland. The Swedish king counter-attacked, and in 1216 he received confirmation from the Pope of his title to the lands won by himself and his predecessors from the heathens. He was also authorized to establish a seat for one or two bishops in the Finnish missionary territory. In eastern Finland the Russian church attempted to win converts, and in 1227 Duke Jaroslav undertook a program of forced baptisms, de-

signed to tie Karelia closer to Novgorod. In response the Pope placed Finland under apostolic protection and invoked a commercial blockade against Russia (1229). A large force, led by a Swedish *jarl*, including Swedes, Finns, and crusaders from various countries, was defeated in 1240 by a duke of Novgorod, and the advance of Western Christendom into Russia was halted, while the religious division of Finland was sealed, with the Karelians in the Eastern sphere. The bishop of Finland, Thomas, resigned in 1245, and the mission territory was left without leadership until 1249, when the Dominicans founded a monastery in Turku (Åbo).

Birger Jarl now decided that a full effort was necessary in order to bring Finland into the Swedish sphere; in 1249 he led an expedition to Tavastia, an area already Christianized. Birger built a fortress in Tavastia and some fortifications along the northern coast of the Gulf of Finland, where Swedish settlement on a mass scale began. Swedes also moved to the eastern coast of the Gulf of Bothnia; in both areas, the native population was sparse, and relations between the Swedes and the Finns were peaceful. In 1293 Torgils Knutsson launched an expedition in an attempt to conquer all of Karelia, and built a fortress near the present city of Leningrad. The war lasted until 1323, when the Treaty of Nöteborg drew the boundary between the Russian and Swedish spheres of influence in a vague line from the eastern part of the Gulf of Finland through the middle of Karelia northwest to the Gulf of Bothnia, and the Crusades were ended, with Finland a part of the Swedish realm.

Birger
Jarl's
conquest

The Swedes now began to set up the administration of Finland in accordance with Swedish traditions. Castles were built and taxes were collected, mainly in furs and, later, in grain and money. During the early Middle Ages, Finland was often given to members of the royal family as a duchy. Two new estates, the clergy and the nobility, evolved, with the nobility increased by transplantation from Sweden and the clergy containing a large native element. The first native bishop was appointed in 1291. In 1362 King Haakon of Sweden established the right of the Finns to participate in royal elections and the equal status of Finland with the other parts of the kingdom. Several years later, Haakon was overthrown and Albert of Mecklenburg was crowned. Albert was unpopular with the Finns, and by 1374 a Swedish nobleman, Bo Jonsson Grip, had gained title to all of Finland. Grip died in 1386, and Finland soon after became part of the Kalmar Union.

Iceland. The Norsemen, settling in Iceland between 874 and 930, created an aristocratic commonwealth with all power resting in the local chieftains (*goar*), who also served as pagan priests. The national parliament (*Althingi*), established in 930, was preceded by local assemblies through which the chieftains directed law and order for their districts. After the Althingi was founded, the chieftains and their advisers constituted the *lögretta* (legislature) of the country, and they also held the judicial power. There was no national executive power.

Christian missionaries were sent to Iceland by Olaf Trygvason at the end of the 10th century, and in the year 1000 the new religion was accepted by the Althingi to stop the civil disputes that threatened to tear the country apart. The chieftains retained their religious power: many of them received clerical educations, and the early bishops were ordained chieftains. Most of the churches were also owned or run by the chieftains. The first Icelandic bishop was installed in 1056, and, after 1106, Iceland had two bishoprics. Tithe laws were passed in 1096, and slavery was abolished before 1100. After the Trondheim archbishopric was established in 1152, the Icelandic church belonged to its jurisdiction.

Christian-
ization of
Iceland

Family feuds broke out c. 1200, and some families were completely destroyed. The economy stagnated, with sheep farming, the major industry, having reached its peak under the methods then followed, and the climate deteriorated. Trade increasingly came under the control of Norwegian merchants, and Icelandic shipbuilding declined because of the lack of native wood and iron. In 1262 the Icelandic commonwealth voluntarily agreed to a

personal union with Norway, and the Norwegian king promised to provide regularly for the shipping of important goods to Iceland in return for taxes. The church was given full independence, the chieftains were replaced in administration by the king's officials, and a new set of laws replaced the old. In 1380 the government of Iceland passed to Denmark. The fishing industry progressed, and, when English and German traders and fishermen arrived around 1400, fish became the chief export. In 1402–04, the Black Death ravaged the island.

Greenland. The first Nordic settlers on Greenland reached the island in 985 under the leadership of Erik the Red. Two colonies were established on the western coast, one near Godthåb and one near Julianehåb, where a few thousand Norsemen engaged in cattle breeding, fishing, and sealing. The most important export was walrus tooth. A bishopric and two cloisters were organized on Greenland. The Greenlanders lacked wood and iron for ship-building and could not support communications with Europe; in 1261 they submitted to the Norwegian king, to whom they would pay taxes in return for his acceptance of responsibility for the island's provision through a yearly voyage. After the Crusades, ivory replaced walrus tooth on the European market, and relations with Europe diminished. A worsening of the climate occurred around this time, resulting in a decline in agriculture and livestock breeding, and plagues ravaged the populace: the Black Death alone (mid-14th century) is estimated to have halved the population. When Norway, with Greenland and Iceland, became subject to the Danish king, conditions worsened; the only ships that now sailed to Greenland belonged to pirates. Around 1350 the Godthåb settlement was apparently destroyed by the Eskimo, and in 1379 the Julianehåb area was attacked. The last certain notice of Norsemen on Greenland came in 1410. Sometime during the following 150 years, the Norsemen on Greenland disappeared. It was not until the beginning of the 17th century that Greenland again came into the Danish sphere.

Social and economic conditions. During the Middle Ages, Scandinavia moved from a family society toward a society of estates. Through the production of national law codes and the establishment of royal privileges for various groups in society, the estates were given legal rights and duties. The growth of the church provided an estate of clergymen, while the rise of towns created professional traders and craftsmen. The exemption of the clergy from military service and, later, from taxes was a matter of conflict between the monarch and the church throughout the Middle Ages. The exemption of the nobility from taxes was established in Denmark in the 1240s and in Sweden and Norway in the 1270s. Only Norway had a hereditary monarchy (from c. 1260); Sweden and Denmark remained a blend of elective and hereditary kingdoms, with the national leaders usually electing a king from among the royal sons. Agriculture remained the basis for Scandinavian society throughout the period, and the dominant feature from the Viking Age to the 13th century was new cultivation in connection with the increasing population. Norway could not meet the continually rising native demand for grain, and, from the mid-13th century, imports were drawn from the Baltic area. The usual form of settlement in Denmark was the village, while in Sweden and Norway the single farm predominated. The raising of livestock was common in all three countries and was most important in Norway, where it served in place of grain cultivation as the major source of livelihood. Slavery died out in Denmark and Norway in the early 13th century and in Sweden about a century later. An agrarian crisis occurred in the 14th century, due to the decline in population caused by the Black Death, and many farms were abandoned. Fishing served as an additional source of income for many peasants. The herring catches from the Sound contributed to the expansion of the markets in Skåne, and cod was already main Norwegian export in the 12th century.

Throughout the 12th century, the Scandinavians were the leading traders in the Baltic area. After 1200, however, the Germans began to appear more frequently in

the Baltic, and the city of Lübeck, founded in 1158, competed with Slesvig for the trade from the Baltic to the North Sea. A number of new German cities were founded on the Baltic coast in the 13th century. In the Scandinavian countries, a large number of towns were established at the same time, including Stockholm, and Copenhagen and Bergen grew into important centres of trade. By 1300 the establishment of towns in Scandinavia declined; at the same time the German traders were winning privileges in the existing towns. The Germans were especially interested in fish, and the Skåne towns and Bergen were their main bases, while the ore from the Swedish mines was also exported through the German towns. Norway became most dependent on the Hanse for imports of grain, and the Germans dominated Norwegian trade. Bergen became the site of a German colony, and the merchants there won considerable political influence on the affairs of the kingdom. The battle against the influence of the Hanse continued throughout the Middle Ages.

The primary organ for government in medieval Scandinavia was the assembly of magnates, called the Hof in Denmark, the Hovingmote or Riksmote (assembly of chieftains or national assembly) in Norway, and the Herredag (diet) in Sweden. After the beginning of the 14th century, the functions of these assemblies were taken over by the national council in each country, and the councils in Sweden and Denmark became powerful organs, while in Norway political conditions stunted the council's development. The councils were composed of the bishops and the leaders of the aristocracy and were designed to assist the king's administration, whereby they protected the interests of the aristocracy. A main source of political power was control of the highest local administrative positions, tied to the possession of the royal castles, and the right of the native aristocracy to hold these positions was a source of conflict between the nobles and the kings in each country throughout the Middle Ages. Meetings of the four estates did not win influence until the 15th century.

Adminis-
tration

THE KALMAR UNION

The formation of the union. The Kalmar Union, which from 1397 to 1523 comprised Denmark, Norway, and Sweden, grew out of the dynastic ties between the three countries. In 1319 Magnus Eriksson, son of Duke Erik of Sweden and Princess Ingeborg of Norway, inherited the Norwegian crown and was elected king of Sweden. The Norwegians selected his younger son Haakon as their king (1343), while Magnus' eldest son Erik was elected king in Sweden (1344), thus breaking the personal union of Sweden and Norway when Haakon came of age (1355). After a rebellion of the nobles in Sweden, Haakon and his father ruled that country jointly (1362–63); and in 1363 Haakon married Margaret, daughter of Valdemar Atterdag of Denmark. Shortly afterward, Haakon and Magnus were driven from Sweden, and Albert of Mecklenburg, son of Magnus' sister, was elected king.

When Valdemar Atterdag died in 1375, Olaf, the son of Margaret and Haakon, was elected king of Denmark; and five years later, Olaf succeeded his father to the crown of Norway. Margaret, who served as regent of both Denmark and Norway during her only son's minority, worked to win the crown of Sweden for Olaf, but he died (1387) before she could be successful. After Olaf's death, she was acknowledged as regent in both his kingdoms; and in 1388 rebellious Swedish nobles, unhappy with Albert of Mecklenburg's rule, hailed her as regent in Sweden. The following year, her troops defeated Albert's army and the King was captured; the war continued until 1398, when Stockholm was finally turned over to Margaret.

In order to assure the continuance of the union, Margaret set out to secure the royal succession. In 1389 her sister's grandson, Erik of Pomerania, was acknowledged as king of Norway, and in 1396 the Danes and the Swedes accepted him. The following year, he was crowned king at a meeting in Kalmar, where two documents of union were presented. The first, a letter of homage, contained a

Agricul-
ture and
fishing

Towns
and trade

declaration of fidelity to Margaret and Erik. The second, a letter of union, concerned the conditions for the union, with a common king to be chosen from the sons of the late king and with a common foreign policy, while the internal matters of each country would be determined by the national laws administered by natives. The letter of union is among the most controversial documents in Scandinavian history; present opinion holds that the existing document is a draft and that the provisions contained in it were never accepted.

German
gains in
the Baltic

Along with the dynastic background of the **Kalmar Union**, an important reason for its formation was the geographical position of the Scandinavian states and the growing influence of the Germans in the Baltic. The north German trading centres had joined in the Hanseatic League in the mid-14th century, and these cities engaged in wars, bribes, and financial speculations to defend their markets from competition. The Treaty of Stralsund (1370), with Denmark, gave the Hanse the right of free passage through the Sound, control of the fortresses dominating the herring fisheries, and two-thirds of the revenues of Skåne for 15 years. Norwegian trade was completely under the control of the Hanse, which established an office in **Bergen**; Sweden was ruled by a German king from 1363 to 1389. Throughout Scandinavia, Germans were given important positions and castles. The individual Scandinavian countries were not strong enough to combat the increasing power of the Germans, and it was hoped that a union would enable the Scandinavians to build a common front against the Mecklenburgers, Hanse cities, and Holsteiners.

Scandinavia under **the Union**. The primary objective of Margaret, who ruled the Kalmar Union until her death, in 1412, was to strengthen royal power. In Denmark she avoided calling the national council, left high posts unoccupied, and reduced the privileges of the nobles. The church was a major supporter of the Queen, and she was extremely generous to it in return. The Swedish council had agreed in 1396 to return the royal property it had received since 1363, and Margaret called back much of this property. She placed her supporters in control of castles throughout the kingdoms but managed to win over opinion so that this intrusion in Sweden and Norway did not evoke serious protests. Margaret's foreign policy was based on a desire to keep peace without yielding unnecessarily to the Germans.

Eric of
Pomerania
and
economic
reform

Margaret was succeeded by Erik of Pomerania in 1412. The most successful area of Erik's reign was his economic policy: Erik promoted national trade in Denmark through the founding of towns, especially in the Sound area, and began the Sound toll (1429) to replace the lost revenue from the Skåne market. Erik also gave the Danish towns a monopoly on trade and crafts. He increased the number of Danes appointed to offices in Sweden and Norway, arousing the anger of the native aristocracies, and his effort to control church appointments irritated the clergy. Most aggravating was his foreign policy, however, which consumed great sums of money and great numbers of men. In 1413 he had the Danish **hof** recall the fiefs of the Holsteiners, which started a long war, and in 1426 Lübeck and its allies began a war with Erik over trade privileges. The Hanse cities began a trade blockade of the Scandinavian countries, which especially affected the mining districts of Sweden; in 1434 a rebellion broke out in Bergslagen and Dalarna under the leadership of Engelbrekt Engelbrektsson. After a march through Sweden, Engelbrekt forced the Swedish council to renounce its allegiance to Erik. The Swedish rebellion roused Erik's enemies in Denmark and Norway, and in 1438 Erik went into exile on **Gotland**. The Danish council renounced its allegiance to Erik in 1438, followed in 1439 by his deposition by the Swedish council and in 1442 by the Norwegian.

Erik's nephew, Christopher of Bavaria, was called by the Danish council to become king in 1440. Christopher was accepted by Sweden (1440) and Norway (1442) after he promised to keep the administrations of the countries separate and to appoint only natives to positions. The power was now in the hands of the national council in

each country. When Christopher died without heirs (1448), the union was temporarily dissolved: Sweden elected Karl Knutsson as Charles VIII and hoped that the other Scandinavian countries would accept him as king, while the Danish council elected Count Christian of **Oldenburg**. Norway joined with Sweden (1449) but in the following year was forced to accept Christian I as king.

With Christian I began the revival of the coronation charter for Danish kings, which now included a guarantee for the national council's participation in foreign policy, legislation, taxation, and justice. According to the charters, if the king failed to keep his guarantees, his subjects had the right to renounce him, but this did not prevent the early Oldenburgs from ignoring their charters. Christian attempted to circumvent the position of the council by calling a meeting of the four estates (1468), a practice followed by his successors. After the death of the last male heir to the Holstein counts, Christian reached an agreement with the family making him count of Slesvig and duke of Holstein (1460), with the two areas to be "eternally undivided" and ruled by a royal heir chosen by the local nobility. In paying off a number of princes who had claims on the areas, Christian went into considerable debt, which, together with the costs of the war with Sweden, forced him to pawn the Norwegian Shetland and Orkney islands to the Scottish king in order to provide a dowry for his daughter.

One of the major concerns of the first Oldenburgs was the re-establishment of the union. Danish opinion held that Denmark's position of power depended on the union, and many Swedish nobles desired a union if their influence on Swedish affairs could be maintained. In 1450 a meeting of the Swedish and Danish councils agreed to a renewal of the union under the surviving king, Charles VIII or Christian I, or under a new king when both had died. Charles was not amenable to this agreement, and the Danes attacked Sweden in 1451. The war continued until 1457, when rebellious Swedish nobles drove Charles from the kingdom and hailed Christian as king. In 1464 a new rebellion broke out that Christian's troops failed to conquer, and Karl Knutsson again became the Swedish king (1464). Christian's attempt in 1471 to force the Swedes back into the union was unsuccessful.

Christian died in 1481 and was succeeded by his son Hans (1481–1513), who wanted to reduce the power of the nobility and the Hanse and to create a strong Nordic monarchy with support from the peasants and burghers. Many of Denmark's administrative posts were given to non-nobles, and the King signed trade agreements with the Dutch and English. Hans was acknowledged as Swedish king in 1483, but he was not crowned until 1497, after a war between Sweden and Denmark. Hans ruled in Sweden from 1497 to 1501, when rebellious Swedish nobles called back **Sten Sture**, who had served as regent from 1470 to 1497. Another war between Denmark and Sweden lasted from 1506 to 1513, and from 1510 to 1512 Hans was also involved in a successful war with Lübeck.

Hans' successor was his son Christian II (1513–23). A struggle broke out in Sweden between the Sture party (now led by **Sten Sture the Younger**) and a union party (led by Archbishop Gustaf Trolle); in 1520, after Trolle had been captured by the Stures, a Danish army attacked Sweden and defeated the Sture army. Christian II was crowned hereditary king of Sweden, and 82 people were executed in the "Stockholm Bloodbath." Christian returned to Denmark and left the Swedish government in the hands of the Archbishop and his allies, who were soon met by a rebellion led by Gustav Vasa (*q.v.*). After battles between the Danish army and the Swedish rebels, Vasa was chosen regent of Sweden (1521). In Denmark, Christian attempted to increase the royal power by ignoring the nobles and replacing them with men from the burgher class; he also interfered with the affairs of the church. The opposition to the King grew, and in 1523 the members of the council from **Jutland** renounced allegiance to him and joined his enemies: Liibeck and Christian's uncle, Frederik of Holstein-Gottorp. The burghers and peasants, pressed by high taxes, joined the rebellion. In 1523 Christian abdicated in favour of his uncle **Fred-**

erik, who, as Frederick I, was hailed as king of Denmark and Norway. Sweden elected Gustav Vasa, and the Kalmar Union was permanently dissolved.

Denmark. The major political conflict during the Kalmar Union in Denmark took place between the monarchs and the nobility, both of which were anxious to increase their power. Under Margaret and Erik, the influence of the nobility was diminished by the absolutist policies of the monarchs. Margaret forbade private wars, tore down noble fortresses, and convinced the nobles to promise not to buy taxable peasant land, while Erik favoured the burghers over the nobles. From 1439 the national council reasserted the position of the nobles and took over the government of the kingdom, demanding coronation charters from the kings after 1448. These charters provided for the right of the council to dethrone the monarchs if the power of the council was not respected. Christian I tried to evade the council by calling representatives of the four estates, which later kings used to greater effect. Hans began a policy of appointing non-nobles to important posts in the kingdom, a practice that was increased by Christian II and that together with other misuses of power, led the council to overthrow him.

The peasantry suffered a decline under the Kalmar Union. The towns enticed the young people from the farms, which, together with the loss of the labour force from the plague, led to an increase in abandoned farms. In order to stop this process, landlords in Zealand and Lolland-Falster began the *vornedskabe*, which bound the descendants of tenured peasants to the land and gave the owner the right to recall a dead peasant's heirs to take over the land. By the 16th century, those tenured peasants who lived near the manor worked off a portion of their taxes by service in the manor's fields.

Under the Kalmar Union, Danish towns prospered and the influence of the burghers grew. By 1500 there were approximately 80 towns in the country, most of them fortified. Copenhagen had at most 10,000 inhabitants. The monopoly on internal trade given to the Danish towns by Erik of Pomerania improved the economic position of the burghers, and many German merchants took out citizenship in the towns in order to compete.

During the Kalmar Union, the old *hof* disappeared and the participation of the provincial things in legislation and royal elections ceased, while the people were represented by the estates, which remained unimportant during the period. The national council, composed of the bishops and nobles chosen by the king, including the highest civil servants (the *hofmester*, or master of the court, in charge of finances; the *kansler*, or chancellor; the *marsk*, or marshall, in charge of justice; and the *riksamiral*, or admiral), held the power of legislation and taxation together with the king. The Council's consent was necessary for declarations of war, and, together with the king, it served as the highest court. The entire council was seldom called, and its influence on the daily affairs of administration was negligible. The fiefs were controlled by the king's representatives, who collected taxes and upheld the law, and were never made hereditary.

Norway. Under the Kalmar Union, Norway became an increasingly unimportant part of Scandinavia, politically, and it remained in a union (ultimately as a province) with Denmark until 1814. Margaret and Erik of Pomerania left vacant the highest Norwegian administrative position and governed Norway from Copenhagen. Most appointments made in Norway were given to Danes and Germans. Whereas in Denmark and Sweden national councils took over the government, in Norway the council was unable to assert itself. After the accession of Christian I, Norwegian government was again centred in Copenhagen. The lower estates were also essentially powerless against the Danes, and isolated peasant uprisings had neither good leadership nor clear political goals. In 1448 Norway accepted the Swedish candidate for king, Karl Knutsson, but was forced to acknowledge Christian I of Oldenburg and remain in the union with Denmark. In 1468 Christian pawned the Orkney and Shetland islands to the Scottish king to provide a dowry for his daughter, and the islands were never reclaimed.

The cause of this political impotence in Norway has been a subject of considerable debate. According to one theory, the conscious policy of the kings since the 12th century of crushing the local family aristocracy to strengthen royal power deprived the country of a counterpart to the strong and often rebellious Danish and Swedish aristocracies. A second theory holds that geography was responsible for the absence of a strong aristocracy: the pooriness of the soil prevented economic expansion through the creation of large estates. The most accepted theory, however, attributes the Norwegian decline to the Black Death, which affected Norway more than it did the rest of Scandinavia. Approximately half of the population was lost, and the aristocracy, along with losing many members, was deprived of much of its labour force, which led to the abandonment of farms and the decline of many nobles into the peasant class.

Sweden. Sweden entered the Kalmar Union on the initiative of the noble opponents of Sweden's German king, Albert of Mecklenburg (1363-89). The nobility, many of whom held estates over the national borders, called on Margaret for help; and after a war with the Germans, Margaret was hailed as the regent of Sweden (1389), with her great-nephew Erik of Pomerania as her successor (1396). The national council announced its willingness to return those royal estates that had been given to its members during Albert's reign, and Margaret succeeded in carrying out the recall of this property. She remained popular with the Swedes throughout her reign, but her successor, Erik, appointed a number of Danes and Germans to administrative posts and interfered in the affairs of the church. His bellicose foreign policy caused him to extract taxes and soldiers from Sweden, arousing the peasants' anger. His war with Holstein resulted in a Hanse blockade of the Scandinavian states in 1426, cutting off the import of salt and other necessities and the export of ore from Sweden, and led to a revolt by Bergslagen peasants and miners in 1434. The leader, Engelbrekt Engelbrektsson, formed a coalition with the national council; in 1435 a national meeting in Arboga named Engelbrekt captain of the realm. Erik agreed to change his policies and was again acknowledged as king of Sweden by the council. Erik's agreement was not fulfilled to the Swedes' satisfaction, however, and in 1436 a new meeting at Arboga renounced allegiance to Erik and made the nobleman Karl Knutsson captain of the realm along with Engelbrekt. Soon after, Engelbrekt was murdered by a nobleman; Karl Knutsson became the Swedish regent, and in 1438 the Danish council deposed Erik, followed in 1439 by the Swedish council.

The Danish council elected Christopher of Bavaria as king in 1440, and Karl Knutsson gave up his regency receiving, in return, Finland as a fief, whereupon the Swedish council also accepted Christopher. He died in 1448 without heirs, and Karl Knutsson was elected king (Charles VIII) of Sweden. It was hoped that he would be accepted as the union king, but the Danes elected Christian of Oldenburg. The Norwegians chose Charles as king, but a meeting of the Danish and Swedish councils in 1450 agreed to give up Charles's claims on Norway, while the councils agreed that the survivor of Charles and Christian would become the union king or, if this was unacceptable, that a new joint king would be elected when both were dead. Karl refused to accept this compromise, and war broke out between the two countries. In 1457 the noble opposition, led by Archbishop Jons Bengtsson Oxenstierna, rebelled against Charles, who fled to Danzig. Oxenstierna and Erik Axelsson Tott, a Danish noble, became the regents, and Christian was hailed as king of Sweden. Christian increased taxes, and in 1463 the peasants in Uppland refused to pay and were supported by Oxenstierna, whom Christian then imprisoned. The Bishop of Linköping, a member of the Vasa family, led a rebellion to free the Archbishop, and Christian's army was defeated. Karl Knutsson was recalled from Danzig and again became king, but within six months difficulties between him and the nobles, especially Oxenstierna and Vasa, forced him to leave the kingdom. Oxenstierna served as regent from 1465 to 1466 and was succeeded by

Reappearance of the *hof*

Tott; and the battles between the two families led to the recall of Karl Knutsson, who ruled from 1467 to his death, in 1470.

The period of Charles VIII's reigns was marked by the rivalry of two native parties in Sweden: one, led by the Oxenstiernas and Vasas, contained the old landowning class in central Sweden, including the church and the nobility, who preferred the rule of the council to a strong monarch and felt that a distant union monarch was best; the other, led by the Totts and Karl Knutsson and comprised of representatives for the growing commercial interests who were interested in uninterrupted trade with Lubeck, saw a national monarchy as the best safeguard for their interests. The new leading family in the 1470s, the Stures, represented the anti-union party.

After Karl's death, Sten Sture the Elder was elected regent by the council; and his army, including the Totts and their sympathizers, burghers, and men from Bergslagen, defeated Christian's troops in the Battle of Brunkeberg on the outskirts of Stockholm (1471). During Sten's rule, the University of Uppsala was founded (1477). When Christian I died, in 1481, the matter of the union again arose, and in 1483 Hans was accepted as king of Sweden; but Sten managed to delay his coronation until 1497. In 1493 a new element entered Nordic affairs: Hans formed an alliance with the Muscovite Ivan III Vasilyevich directed against Sweden, which led to an unsuccessful Russian attack on Finland in 1495. The council became discontented with Sten's acquisition of power and, in 1497, called on Hans, whose army defeated Sture's. Hans was crowned and Sture returned to Finland. By 1501 Hans's supporters were discontented with his rule, and Sten Sture was recalled as regent. He died in 1503 and Svante Nilsson Sture became regent. In 1506, a new war with Denmark began, in which Liibeck supported the Swedes. Svante died in 1512, and the council now attempted a reconciliation with Denmark under the regency of Erik Trolle, whose family supported the union. Svante's son, Sten Sture the Younger, led a coup, however, and was elected regent. Peace with Denmark was concluded in 1513.

Last years
of the
Kalmar
Union

The final years of the Kalmar Union were marked in Sweden by the struggle between the archbishop, Gustav Trolle (inaugurated 1516), and Sten Sture the Younger. The Archbishop was head of the council, and he took over the leadership of the pro-union party. A civil war broke out, and in 1517 a meeting of the estates in Stockholm declared Trolle removed from his position. Despite military assistance from Christian II, Trolle was imprisoned. After a defeat by the Swedes, Christian began negotiations and took six noblemen, among them Gustav Vasa, to Denmark as hostages. The Swedish treatment of Trolle brought a papal interdict of Sweden, and Christian could now act as executor. In 1520 the Danish army of mercenaries attacked Sweden, and Sten Sture was mortally wounded in a battle won by the Danes. No leader came forward to replace the regent, and the noblemen and clergy sought a compromise. Christian was acknowledged as king in return for a promise of mercy and constitutional government. The peasants, led by Sten's widow, refused to abandon the war, however, and it was several months before Stockholm capitulated. Christian was then crowned by the Archbishop as hereditary monarch, breaking his promises to the council; and despite promises of amnesty, 82 people, noblemen and clergy who had supported the Stures, were executed for heresy in the Stockholm Bloodbath. The responsibility for this execution has aroused considerable discussion among Swedish and Danish historians; the large part played by Gustav Trolle is now generally accepted.

Christian II now appeared to have Sweden under his control, but not all his opponents were dead or in prison. The nephew of Sten's widow, Gustav Vasa, had escaped from his Danish prison and returned to Sweden in 1520. After the Bloodbath, he went to Dalarna, where the Stures had their staunchest support, and soon a rebellion there was underway, followed by others around the country. By the spring of 1521, the army of men from Dalarna had won its first battle with the Danes, and soon noble-

men were allying themselves with Gustav, who was chosen regent in August. In 1522 he persuaded Lubeck to aid the Swedish rebels; in 1523 the Danish nobility forced Christian to give up the Danish throne and elected Frederick of Holstein-Gottorp as king. Three months later Gustav Vasa was elected Sweden's king by a meeting of the estates, and the Kalmar Union was dissolved.

The balance of power in Sweden shifted during the union from the monarchy to the nobility, who took over the government of the country while the union kings were resident in the other kingdoms. The monarchs' attempts to control the administration by appointing their own supporters from Denmark aroused protests and rebellion from the Swedes. During the later half of the union, a split developed within the nobility between a pro-union and an anti-union faction. The pro-unionists generally owned estates in Denmark or Norway as well as in Sweden and believed that a union monarch would enable the nobility to exercise greater influence; the anti-union nobles preferred a strong national monarchy supported by a strong national nobility. The king and regents elected in Sweden during the union period came from within the ranks of the anti-union nobility.

An important new class in society was composed of the commercial men and miners from Bergslagen, who were interested in the unimpeded export of Sweden's iron and copper. When the Danish interests conflicted with their own, most notably during the wars with the Germans, these men rebelled and supported a strong national monarchy, as did the burghers, who were also interested in the growth of trade. The church, on the other hand, preferred a weak monarch and supported the union.

The great majority of Swedes continued to be peasants, and cultivation was expanded into areas of Norrland and the Finnish wilderness. The major surplus product was butter; from the mid-14th century, a fourth of Sweden's export consisted of this product. As the lands exempt from taxation owned by the nobility and the clergy increased, the burden of taxation on the peasants grew; from the Engelbrekt rebellion in the 1430s through the remaining decades of the union, the peasants fought on the side of the anti-union forces. (H.En.)

II. The 16th and 17th centuries

SEPARATION OF SWEDEN FROM DENMARK-NORWAY

Political and dynastic causes of separation. Until 1523, Denmark, or the Scandinavian Union, was the only important power in northern Europe. The secession of Sweden started a process of disunion lasting for more than 400 years.

The events in the 1520s finally weighed the balance toward Swedish independence. After the Bloodbath of Stockholm in 1520, Sweden in 1521 was moved to revolt against Christian. The King went back to Denmark, only to see another revolt there in 1523, upon which he chose to retire to the Netherlands and the protection of his mighty brother-in-law, the Holy Roman emperor Charles V. But there was no hope for Christian to reconquer Sweden. Although the Swedish bishops had as a rule favoured the union, no Swedish bishop after the Bloodbath could possibly dream of an alliance with Christian—the "tyrant" in the propaganda of Gustav I Vasa, who became king in 1523. The victorious independence faction was an alliance between Swedish high nobility, the farmer-miners of the Dalarna region, and Liibeck, the old enemy of a Scandinavian Union. Gustav, in fact, liberated Stockholm in 1523 with the economic and military help of the Hansa. In his next step toward complete independence, however, Gustav convinced the Diet of Västerås in 1527 to transfer the major part of church property to the crown in order to rid Sweden of Hanseatic influence.

Swedish
independence

Subsequent wars between Sweden and Denmark. For more than a century thereafter, an aim of Danish foreign policy was to re-establish the union. The real issue, however, was the competition for mastery of the Baltic Sea (*Dominium Maris Baltici*). In the 16th and 17th centuries the Baltic region was far more important than either the Mediterranean or the Atlantic, providing Europe's

main source of grain, iron, copper, timber, tar, hemp, and furs. Thus the mastery of the Baltic, in addition to being an internal Scandinavian problem, was vital to the western European powers, which needed free access to the Baltic commodities. These powers, and later Russia, on its ascendancy, wanted a divided but evenly balanced north.

In this perspective, the wars between Denmark and Sweden might be divided into the following periods: (1) the Swedish buildup, 1520–1628; (2) Swedish predominance, 1628–1709; (3) the annihilation of Sweden as a great power (1709–21).

The *Swedish buildup*. Because of Swedish measures against Liibeck after 1523, which aided the Danes, Denmark had no interest in waging war against dissident Sweden. Further, Denmark had to look to the empire and the Emperor, whose nieces claimed the Danish throne. Thus there was peace in Scandinavia until 1560. Perhaps this was due to the wisdom of the Reformation kings—Christian III of Denmark and Gustav Vasa of Sweden. Russians, from the principality of Moscow, advanced toward the part of the Baltic coast east of Poland in the 1550s. Denmark, since 1360 in possession of Gotland off the eastern coast of Sweden, now also bought the island of Ösel, in the northeastern Baltic. In 1560 Sweden decided on the ominous project of crossing the Gulf of Finland from Finland, hoping to annex the harbour of Reval (in northern Estonia; now Tallinn). This established the Swedish strategy for the following 150 years (*i.e.*, to conquer the important Baltic harbours and to control sufficient parts of the hinterland to dominate and tax the Baltic trade). Denmark, with Zealand (Sjælland) and Skåne and the fortifications of Helsingør (Elsinore) and Helsingborg, controlled the Sound; but its offensive strategy was to gain maritime hegemony of the Baltic Sea and to destroy any Swedish harbour in the west. From this point of view, the importance of the Nordic Seven Years' War (1563–70) is that Denmark failed in its aspirations to Baltic hegemony and that the greater part of its navy was sunk off Gotland. Thus Sweden could henceforth transport its armies quite freely in the Baltic area and could not be invaded. This situation remained unchanged until the early 18th century, when Tsar Peter the Great of Russia built Kronstadt, at the eastern end of the Gulf of Finland, and a Baltic fleet.

With its growing mastery of the Baltic area, Sweden needed free access to the Atlantic in order not to depend entirely on the passage through the Sound. Its brief occupation in 1564 of Trondheim, Norway, is an indication of this need, as are Swedish claims to the entire northern half of the Nordic peninsula. These also show that Sweden wanted a harbour in the north, to compete with the Russian harbour of Murmansk. Faced with these pretensions, Denmark decided on a war against Sweden (the Kalmar War, 1611–13), with the ultimate aim of restoring the union. The Danes forced Sweden to accept the occupation of what later became Göteborg harbour until Sweden had paid a huge war tribute, and to give up its pretensions in the north. In four years Sweden had paid the war tribute, chiefly by selling copper on the bourse of Amsterdam. With Dutch support, the harbour of Göteborg grew, thus assuring Swedish access to the Atlantic in case Denmark blocked the Sound.

Swedish predominance. The Thirty Years' War (*q.v.*; 1618–48) and its aftermath brought a different strategic situation. Denmark tried, not very wisely, to stop the Habsburg advance toward the north in 1625–29. Sweden, suddenly seeing its position in the Baltic threatened by the Emperor, concluded the Truce of Altmark (1629) with Poland, gaining possession of much of Livland. Then Sweden went to war against the Emperor, with the blessing and support of France and of Poland. Denmark was now faced with Swedish armies in the south. Sweden attacked through Jutland in 1645, and at the Peace of Bromsebro Denmark lost the islands of Ösel and Gotland in the Baltic and even the old Norwegian provinces of Jamtland and Herjedalen. For the Danes, worse was to follow. At the Peace of Westphalia (1648), ending the Thirty Years' War, Sweden annexed the bishoprics of

Bremen and Verden and established conditions for friendly relations and dynastic alliances with part of the ducal family of the duchies (Holstein–Gottorp). Sweden thus acquired a permanent base south of Denmark.

With things seeming to go badly for Swedish armies in Poland, Denmark desperately tried for revenge in 1657. The effort resulted in a catastrophe. Swedish armies repeated the attack of 1645 through Jutland. In the late winter 1658 the Straits froze—an extraordinary occurrence—so that Charles X Gustavus could lead his armies from Jutland over Fyn to Zealand and toward Copenhagen. In the Peace of Roskilde (1658) Denmark lost all its provinces east of the Sound (notably Skåne), and in addition Norway lost Bohuslän and the county of Trondheim. Still the king of Sweden wanted more. He declared another war late in 1658 to take the rest of the kingdom of Denmark–Norway. Perhaps Sweden could have managed, even with heavy resistance, but the Swedish policy was contrary to the interests of the European powers, notably Holland, which went to the aid of Denmark. The county of Trondheim was recaptured, but Sweden retained Skåne and Bohuslän. The Peace of Copenhagen (1660) thus settled the frontiers between Sweden, Denmark, and Norway at their present boundaries.

The annihilation of Sweden as a great power. It suited European powers that Denmark and Sweden should each have its side of the Sound. Denmark got no support when it tried several times to reconquer the very rich province of Skåne. Nor did the Skånians themselves welcome these attempts. In the Great Northern War (1700–21) Sweden was annihilated as a great power. After the defeat of Charles XII any Swedish hope to rule the Baltic Sea was an illusion. Poland was crumbling. Russia had suddenly made its appearance on the Nordic stage, and Prussia was lurking offstage.

DENMARK–NORWAY

Denmark. The Danish high nobility never accepted Christian II's strong monarchy, and its members were his most bitter enemies. His uncle and successor Frederick I (ruled 1523–33) adopted a careful, *nonprovocative* policy toward the interests of both the nobility and the peasants, and he tried to reconcile the Danish, Dutch, and Hanseatic merchants; thus when Christian II tried to regain his power by invading Norway in 1531–32, there was no national rising. On accession to the throne, Frederick had promised the bishops to fight heresy. Actually, he invited Lutheran preachers to the country, most probably to expand the royal power at the expense of the church.

On the death of Frederick this balance exploded in Denmark's last civil war (the so-called Count's War, 1533–36), over the succession to the throne. The victor was Christian III (ruled 1534–59), Frederick's Lutheran son and ruler of the Duchies. Although Christian had been unacceptable to the bishops and to the Danish and Hanseatic merchants, he was supported by the nobility of the Duchies and by part of the Danish nobility. He was also supported by Gustav Vasa of Sweden because the merchants of Liibeck, Christian II, and the Emperor himself were their common enemies.

Growth of the monarchy. The Danish monarchy was decisively and lastingly strengthened by the civil war, primarily by the confiscation of church property. The nobility no longer had much to gain as an independent political body, and they chose to take part in the politics of the strengthened monarchy. A noble could participate in the council of the realm (*Rigsråde*), govern a county on behalf of the king and the council, or simply cultivate his domain to profit from rising prices on grain and cattle. The merchants of Copenhagen and Malmö had fought Christian III, but they favoured a strong monarchy that would protect their interests in the Baltic trade. Thus the monarchy got the opportunity to build a strong public administration in Copenhagen (Chancery, Rent Chamber), and even in far-off Norway. The real foundations of Danish absolutism were laid during Christian's peaceful reign.

Swedish
and Danish
strategy

Swedish
gains in
the Thirty
Years' War

Denmark's
last civil
war

The strain on the public finances during the reign (1559–88) of Frederick II, resulting from the war with Sweden, was met with stronger taxation on Danish and Norwegian farmers. But the main income came from a duty in the Sound on the constantly increasing trade in the Baltic. Originally a fixed duty per ship, it was changed into a duty on tonnage; it was at the king's own disposal, out of reach of the council. The Sound was considered Danish national waters; this fiction and the Sound duty remained until the 1840s.

These favourable political and economic conditions served as background to the ambitious policies of Christian IV (ruled 1588–1648). As noted above, his foreign policy, perhaps except for the Kalmar War, was a failure. His national policy, however, strengthened the public administration and jurisdiction, and the state actively promoted business and new industries. But the military catastrophes weakened the position of the monarchy, so that the high nobility decided to curtail the powers of his successor, Frederick III (ruled 1648–70).

Introduction of absolutism. Absolutism was nevertheless introduced during Frederick's reign. The nobility proved unable to handle a central government. After the military debacles in 1658–60 the nobles even refused to pay any taxes. The situation in 1660 could thus be exploited by the King's councillors, who drafted a new constitution that eliminated special political privileges of the nobility. The King was proclaimed absolute sovereign. This constitution (and a secret "King's Law" of 1665, which is said to be most absolutist of all European theories of absolutism) lasted until 1848 with only minor modifications.

Denmark's
governing
bureau-
cracy

Actually, after 1660 Denmark was governed by a quite efficient bureaucracy, but the political leaders came from the class of the great privileged landowners. After 1660 wealth, not noble birth, gave access to this class. The government in Copenhagen consisted of "colleges." There were five as a rule—namely the old Chancery, the Rent Chamber, and the new colleges for commerce, war, and navy—and they had their name from a collegiate body, which organized the work of each college. Top decisions were taken by a secret council, in which leaders of the colleges could easily influence the king. Local administration was not much changed after 1660, but the government took pains to see that the new county governors (*amtmand*) never had any military powers. The absolutist kings, very unlike their Swedish colleagues, were rather anonymous, in part because of their feeble mental powers.

After 1660 the crown reduced its properties, so much increased by the Reformation, by massive sales to its bourgeois creditors (who thus made their way to the class of great landowners). The state compensated for loss of income by increasing taxes on the soil, according to the value of the holding that each peasant used. The new assessments made in the period from 1660 to the 1680s served as the bases of taxation in both Denmark and Norway until the 19th century. Until 1660 the king and the council had acted as supreme court: in 1661 the Danish supreme court was created, and appeals could be made to it from the whole kingdom. The last law codifications of Denmark were made in 1683, of Norway in 1687.

Norway. After 1523 the Norwegian council tried to obtain some independence for Norway within the union. But because the bishops dominated the council, they became the losers in the Norwegian parallel to the 1533–36 civil war, which brought about the council's abolition. Nor could the bishops hope for help from Sweden, which did not want to provoke Denmark and whose king was himself leaning toward Lutheranism. Olaf Engelbrektsen, the last Norwegian archbishop and head of the council, left Norway in early 1537 for the Netherlands and the Emperor, taking with him the shrine of St. Olaf.

In Norwegian political history, the year 1536 is a nadir—in Copenhagen, Norway was proclaimed a Danish province forever. Norwegian topography and society, however, were very different from those of Denmark. Thus Norway was allowed to keep most of its ancient

institutions and laws, and new institutions and laws had to be given in a special Norwegian version. From 1550 Norway's natural resources, including fish, timber, iron, and copper—commodities from outside the Baltic area and most useful to all western Europe—were increasingly exploited. Consequently, a new Norwegian bourgeoisie became a political factor. After 1560, Denmark had a constant fear of Swedish plans to occupy Norway. Therefore it was important that the Norwegians should not feel oppressed by the Danish rule. All this may explain the special attention the Danish government had to give to Norway.

Rise of the
Norwegian
bourgeoisie

Most representative of this attitude was Christian IV, who visited Norway often and founded several towns (Kristiansand, with the plan to control the Skagerak; Kongsberg, with its silver mines; Christiania, after a destructive fire in Oslo, 1624). He even went on an Arctic tour to Vardø in 1596, proclaiming the Arctic waters to be the "King's streams." This was part of his reaction to Swedish pretensions.

A certain separatist policy has been attributed to Hannibal Sehested, the King's son-in-law and in the 1640s governor of Norway. He actually created an army (by conscription of peasants) and a separate financial administration, but he may have wanted a platform against the Danish nobility, to work for absolutism. There were no signs of secession in the Norwegian population. When he was deposed in 1651, the financial administration was ruled from Copenhagen.

For almost a generation after 1664, Ulrik Frederik Gyldenløve, the illegitimate son of Frederick III, was governor of Norway. He courted the Norwegian peasants and at the same time gave monopolies on trade and on timber exports to restricted numbers of merchants. By applying such principles the government in Copenhagen and the Danish public servants managed to rule Norway after the Swedish annexations of Skåne and Bohuslän.

SWEDEN

The early Vasa kings, 1521–1611. In the Bloodbath of Stockholm in November 1520 some 80 leading opponents to the Scandinavian Union were put to death or murdered by Christian II and leaders of the Swedish unionist faction. This event became (or was made) a landmark in Swedish history because it compromised the unionist cause beyond recovery. Gustav Eriksson Vasa had lost his father in Stockholm. The next year he began inciting resistance in Dalarna, a mining district north of Lake Mälaren. A rising against Christian "the tyrant" spread from Dalarna to all parts of Sweden. Gustav Vasa was elected protector of the realm in the autumn of 1521. With help from Liibeck, Stockholm and Kalmar were liberated from Christian's rule. In 1523 Gustav I Vasa (ruled 1523–60) was elected king of Sweden.

Gustav Vasa devoted the major part of his reign to the construction of the Swedish state. He convinced the Diet of Västerås (1527) to seize the properties of the church. This, with other annexations, gave the crown direct possession of about 60 percent of Swedish soil before Gustav Vasa died. He has been compared to a landowner in his behaviour toward the crown properties and the state incomes. He personally took part in developing their administration, and he personally and continuously inspected the crown servants. He nominated county governors himself and reserved the most important charges for members of his own family. Money economy had barely come to Sweden, and many state incomes were therefore paid in kind; some of these were used directly to feed and clothe public servants and soldiers, others were sold to foreign merchants. Gustav took great pleasure in literally filling the treasury, in which condition it was handed over to his son. The nobility was allowed no part in state affairs, and the Diet was convened only for royal propaganda, in which Gustav was a master. The fundamental traits of his reign resemble those of Christian III in Denmark. But Gustav was much rougher than Christian. In the 1530s and 1540s the farmers grumbled over taxes and the clergymen complained about interference in church matters. Gustav met opposition from his former friends

Construc-
tion of the
Swedish
state

—e.g., the farmer-miners of Dalarna—with the same ruthlessness as that from other dissenters. Gustav led a careful foreign policy; nevertheless, a considerable army and a strong navy were created during his reign.

Three of Gustav's sons became kings of Sweden—Erik XIV (ruled 1560–68), John III (1568–92), and Charles IX (1599–1611). Erik XIV was an ambitious and warlike politician. He proposed to Queen Elizabeth of England with much ardour and a portrait of himself, which still exists. In addition to his wars with Denmark and expansion south of the Gulf of Finland, he tried to oust his brothers from their positions. He emptied the royal treasury in a few years and murdered some noblemen. Charged with lunacy (perhaps wrongly) in 1568, he was deposed. It has been demonstrated that his death was due to arsenic.

His brother John acceded to the throne with the help of the high nobility. John married a Polish princess and interfered in Polish affairs. Their son Sigismund was elected king of Poland before inheriting the throne of Sweden in 1592. John was a Catholic; this fact was exploited by his uncle Charles, who organized all conceivable Swedish opposition against the recognition of Sigismund. By doing so, Charles made the Diet (and of course the clergy) a political force against the high nobility. The final outcome was the resignation of Sigismund in 1599.

Charles IX was an administrator very much like his father. His foreign policy aimed at dominating the Russian trade routes toward the Kola Peninsula and the White Sea and to grasp as much as possible of the territory (Russian and other) south of the Gulf of Finland. Sweden thus was exposed to Danish attack in 1611; but Charles did not live to experience the defeat in 1613.

nizing the Swedes for the next war. Civil servants and officers were selected exclusively from among the nobility. A standing army was organized. The infantry was conscripted among the peasants and regularly trained by officers who lived on the King's farms among their soldiers; only the cavalry and the navy were professional. Swedish copper and iron were made into the best firearms of the period. The Swedish field artillery proved especially mobile and effective. The army's central administration was professionalized and became a model of efficiency; directing it were members of the high nobility, working together in collegiate bodies.

This war potential was not defensive: it could be used only abroad. It was first directed against the Baltic countries, then against the Emperor himself from 1629. The truce with Poland in 1629 gave Sweden the unique chance to keep most of the coast north of Danzig (Gdansk) and at the same time secure Polish and French support on the German scene. At Breitenfeld, in 1631, a disciplined and mobile Swedish army practically annihilated the imperial army under Graf von Tilly of Bavaria. A year later Gustavus himself fell on the battlefield of Lützen, against imperial forces led by Albrecht von Wallenstein.

Axel Oxenstierna and the Swedish high nobility decided to carry on the war, even though the danger from the Emperor had passed. The enormous cost and debts of the war could be covered only by domination of the Baltic harbours, by French subsidies, and by a continued involvement in Germany. To retire from Germany now would cause the whole Swedish empire to crumble. The tangible results of the peace treaties of the 1640s were Sweden's grip on Denmark and its domination of most of the Baltic harbours.

Reduction of noble possessions. A generation of continuous war had had a profound impact on Swedish society. The Swedish nobility had gained about two-thirds of Swedish and Finnish soil through the transfer of crown property and of royal ground taxes. The nobles wanted to perpetuate this and to introduce the same feudal structure that they had seen and used in their annexations in the Baltic area.

This danger to Swedish and Finnish peasants was not finally averted until the 1680s, when the noble possessions were greatly reduced. The process of reduction had started in the 1650s because of serious financial problems that the peace in Europe brought to Sweden. Comparatively more of the public expenses now had to be met with taxation, but the nobles refused to pay taxes from their enormous possessions. The royalty could then resort to using the non-noble part of the Diet, in which even the peasants had a representation, to obtain consent to reductions. Faced with this threat, the high nobility agreed to pay, and even to minor reductions in their possessions. There then followed, in 1654–60, wars with Poland and with Denmark–Norway and rule by a regency of aristocrats while Charles XI was still a minor during the 1660s. The high nobles were thus able to retain possession of their advantages for yet another generation.

With the reduction of the holdings of the nobility in the 1680s Sweden returned to the political structure of the early Vasa kings. The income of public properties recaptured from the nobility was permanently allotted to public servants, officers, and soldiers. This system, which remained in force throughout the 18th century and far into the 19th, made the crown less dependent on the Diet in matters of finance. The nobles after all made a good deal during the reductions because they were able to rearrange their remaining holdings, thereby creating large contingent domains. The years 1680–1700 were a period of consolidation. It has been called the Carolingian absolutism because it occurred during the reign of Charles XI (ruled 1672–97). But because of the precariousness of the Swedish annexations in the Baltic, the Carolingian absolutism involved a continuous preparation for war.

The successors of Gustavus Adolphus. One of the most fascinating of all the Swedish monarchs was Queen Christina (q.v.), the daughter of Gustavus Adolphus. Count Oxenstierna and the high nobility governed the realm and made war when she was a child. During her

Swedish society under Gustavus II Adolphus

From D. Maland, *Europe in the Seventeenth Century*. Macmillan London Ltd.

The Swedish Empire in 1660.

The Age of Greatness. The early Vasa kings created the Swedish state. Its chief characteristic was a strong monarchy in a rather rustic and backward economy (with the mining industry as a very noteworthy exception). Its chief weaknesses were opposition from the high nobility and a thirst for revenge from Denmark. In the following decades Sweden relegated Denmark to second place in the north and became a most aggressive great power.

The reign of Gustavus II Adolphus. Gustavus II Adolphus (q.v.; ruled 1611–32) was only 16 years old when his father, Charles IX, died; so the actual leadership passed to the aristocrat Axel Oxenstierna (q.v.) and the council. After the Kalmar War the King joined in orga-

Sweden's Carolingian absolutism

reign (1644–54) the transfer of crown property to the nobility continued on an increasing scale. She proved to have a remarkably independent will. She refused to marry. She used the Diet and threat of reductions to get her proposed husband, Charles Gustavus of the Palatinate, recognized as heir to the throne. Then Christina, daughter of the "saviour of Protestantism," abdicated, converted publicly to Catholicism, and went to Rome.

Charles X Gustav (ruled 1654–60) seems to have pursued the abortive idea of uniting Scandinavia under his scepter. His sudden death permitted another government by the high nobility until 1672, during the minority of his son. Charles XI acceded to the throne in 1672 at the age of 17. The Swedish, or Carolingian, absolutism, named after him, was exploited by his son, the most famous of all Scandinavian Kings, Charles XII (ruled 1697–1718).

The reign of Charles XII. Charles XII acceded to the throne at age 15 at a time when, in the hinterland of the Baltic coast, dominated by the Swedes, new states were being formed. Brandenburg and Russia, together with such older states as Denmark and Poland, were natural enemies of Sweden. Denmark, Poland, and Russia made a treaty in 1699, while Prussia preferred to wait and see. War started in 1700, with an overwhelming Swedish victory at Narva. Charles then turned toward Poland (1702–06). In so doing, he gave Peter the Great sufficient time to found St. Petersburg (now Leningrad) and a Baltic fleet and to reorganize the Russian army. Charles XII began his Russian offensive in 1707. The Russians for the first time used a scorched-earth strategy, thus diverting the Swedish armies from Moscow to the Ukraine, where the Swedes suffered a crushing defeat at Poltava in June 1709.

Swedish
defeat at
Poltava
(1709)

Charles spent the next five years in Bender (now Bendery, Moldavian S.S.R.), then under Turkish rule, trying in vain to convince the Turks to attack Russia. The Sultan clearly had no reason to do so, because Peter had turned his attention toward the Baltic. In the years following Poltava, Russia occupied all the Swedish annexations on the Baltic coast and even Finland; Hannover occupied Bremen and Verden; Denmark took Holstein-Gottorp; and Prussia lay waiting for the Swedish part of Pomerania.

Astonishingly, Charles governed Sweden from his residence in Bender during this catastrophe. In 1715 he returned to Sweden (he had left in 1700). He then decided to attack Norway in order to obtain a western alliance against the Baltic powers. On November 30, 1718, during a siege of the fortress of Fredriksten east of the Oslo fjord, Charles was killed by a bullet of either Norwegian or Swedish origin. His death ended the so-called Age of Greatness. By the Peace of Nystad (1721) Sweden formally resigned the Baltic provinces, part of Karelia, and the city of Vyborg (near St. Petersburg) to Russia.

Finland. Under Swedish sovereignty the Finnish tribes gradually developed a sense of unity, which was encouraged by the bishops of Turku. Study in universities brought Finnish scholars into direct touch with the cultural centres of Europe, and Mikael Agricola, the creator of the Finnish literary language, brought the Lutheran faith from Germany. As part of medieval Sweden, Finland had enjoyed, in effect, a semi-independent status, which had been underlined since 1581, when King John III raised the country to the dignity of a grand duchy. In the course of the administrative reforms (1611–32) of Gustavus II Adolphus, Finland became an integral part of the kingdom, and the educated classes thereafter came increasingly to speak Swedish.

On its eastern frontier Finland was harassed by constant warfare, and the danger became more serious when Novgorod, at the end of the medieval period, was succeeded by a more powerful neighbour, the grand duchy of Moscow. In 1595, however, by the Peace of Teusina, the existing de facto boundary, to the Arctic Ocean, was officially recognized by the Russians. By the Peace of Stolbova (1617), Russia ceded Ingermanland and part of Karelia to the kingdom of Sweden–Finland. The population of the ceded territories was of the Greek Orthodox faith, and when the Swedish government began

their forceful conversion to Lutheranism many fled to Russia and were replaced by Lutheran Finns. Though Finnish conscripts played their part in making Sweden a great power, the role of Finland in the kingdom steadily decreased in importance. As a result of the Great Northern War the Finns lost their faith in Sweden's capacity to defend Finland, and the years of hostile Russian occupation during the war gave them a permanent feeling of insecurity.

THE PROTESTANT REFORMATION

As noted above, the last Scandinavian bishops all had tied their fate to losing causes: the Swedish bishops to a union with Denmark, the Danish bishops to Christian II and the Emperor, the Norwegian bishops to Norwegian sovereignty. Rome could give very little moral or political help, if any. The winning cause, as everywhere else in Europe, was the national monarchies.

In Swedish and Danish towns (though not in Norway) some serious attempts were made by preachers in the 1520s to reform the church. These attempts received royal support. At the Diet of Västerås in Sweden (1527), Gustav Vasa convinced the Estates to surrender most of the church territories or properties to the crown and to support the preaching of the "pure gospel." The monasteries were suppressed, but the organization of the Swedish Church remained intact. Only in the 1540s was the church reorganized by royal intervention. But the Lutheran Confession of Augsburg was not adopted in Sweden until 1593, and then only as a reaction against a dynastic alliance with Poland and attempts to re-Catholicize Sweden. The Swedish clergy remained one of the four estates in the Diet until 1866.

In Denmark and Norway the civil war of 1533–36 offered a unique chance for the King to arrange church affairs as it suited him or the state. The old bishops were arrested and the properties of the church were confiscated. The state took over the religious tasks of the church, and the clergy became a body of civil servants. The clergy had no political power of their own, even though new Lutheran bishops were appointed. After 1536–37 there was no archbishop in Denmark or Norway. A special law, the Church Ordinance of 1537–39, regulated the religious activity and the affairs of the clergy. In retrospect from the 19th century, the system was named a "state church." But because it had no independent institutions of its own, it would be more appropriate from an institutional point of view to call it a confessional state.

Because the Reformation enabled the Scandinavian monarchies to increase their powers enormously, Lutheran orthodoxy became a political necessity in the following centuries. This explains the still existing religious homogeneity in the Scandinavian countries and the existence of "the public religion of the state" (first paragraph of the Norwegian constitution).

SOCIAL AND ECONOMIC CONDITIONS

As in most of Europe, agriculture was the main preoccupation in the Scandinavian countries in the 16th and 17th centuries. But rising economic activity in these centuries stimulated a more specialized and commercial exploitation of their natural resources.

Because of the growing demand for cereals and meat in western Europe, Denmark underwent the same change as did the countries east of the Elbe—the domanian system was introduced for commercial agriculture and cattle raising. Sweden and Norway had other resources. Their forests were still virgin, thus providing the indispensable raw materials for European shipbuilding and overseas expansion. Because the trees grew slowly, the wood became hard and well suited also for furniture and tools.

The mining industry in Sweden was founded in the 13th century. In the 16th and 17th centuries copper and iron were the most important exports from Sweden. But Sweden also had its own metallurgical industry, producing weapons especially. The mining industry of Norway was less important, but it supplied Denmark with necessary strategical commodities and with silver from the mines of Kongsberg.

Decline
of the
Scandi-
navian
clergy

The age-old export of western Norway was stockfish, or dried cod. It now had to compete with cod from Newfoundland in North America. All the North Sea countries joined in the herring fisheries.

The Scandinavian countries had very little active foreign trade of their own. Only Dutch and British and to a certain extent German merchants had sufficient capital and foreign relations to organize the export.

The social consequences of these economic changes were profound. In Denmark the free peasant practically disappeared during these centuries. The Danish county population came to consist of serfs and crofters. Correspondingly, the masters of Danish economic and social life were the landlords. But the state was strong enough to assure a public jurisdiction. In contrast to the Swedish nobility, the Danish landlords had more to gain by exploiting their estates than by waging war; the Danish policy of revenge against Sweden was primarily the affair of the crown. Copenhagen was the political and the economic centre of Denmark-Norway; its name means "harbour of merchants," and it was Danish policy to control and profit by the enormous transit through the Sound.

The natural resources of Norway and Sweden gave no economic basis for landlordship. In Norway the peasants remained free. After 1660 most of the crown properties were sold. Although in Denmark they passed over to the landlord class, in Norway the peasants themselves came to buy the farms they used. Characteristic of Norwegian farming was a combination with other activities—farming and fishing along the coast, farming and forestry in the eastern valleys. This latter combination gave rise to a group of most well-to-do farmers, with crofters dependent on them. The naturalization of foreign merchants was also important in these centuries. Thus Norway for the first time in its history got a native bourgeoisie.

The landlordship in Sweden sprang less from economic than from political causes. The Swedish nobility had a vested interest in lifting Sweden from its underdog position of the 16th century. As noted, the nobles acquired strong positions as commanders and administrators in the conquered areas. Thus, in Sweden, they were able to introduce the domanial system on the soil transferred to them during the Age of Greatness. But, in great contrast to Denmark or the conquered areas, serfdom never came to Sweden; the Swedish farmers remained free. Sweden was the only European country in which peasants formed the Fourth Estate in the Diet. Since the Middle Ages royal propaganda had been designed to influence the opinion of the peasants in political matters.

Because Swedish industry was adapted to Sweden's aggressive foreign policy and because exports were in foreign hands, there was little room for an independent bourgeoisie in this period. Social mobility was primarily influenced by the state. Individual careers and personal fortunes could best be made as soldiers, purveyors to the crown, officers, and public servants. In the 16th and 17th centuries the social structure of Sweden also spread to the formerly completely agrarian Finland.

Swedish society had a considerable capacity for assimilation. Although Denmark-Norway did not until 1720 give up hope of recapturing the provinces that had been lost to Sweden around the middle of the 17th century, it could not count on active support from the populations of these provinces.

III. The 18th century

DENMARK-NORWAY

Denmark. The Great Northern War demonstrated that even with alliances Denmark had no hope for recapturing the territories it had lost to Sweden during the preceding century. On the other hand, Sweden no longer had the strength to invade Denmark from the south (Gottorp). Thus, Denmark decided on a careful foreign policy to keep a balance in the north and to safeguard communications between Denmark and Norway. For guarantees, this implied alliances with Russia and the Netherlands and, from time to time, with France. This policy succeeded for the rest of the 18th century, proba-

bly because of the common European need for free access to the Baltic.

Only once in the century did Denmark experience a political nightmare. In January 1762 the lunatic Duke of Gottorp became tsar of Russia as Peter III. He immediately concluded peace with Prussia (thus really saving its King Frederick II in the Seven Years' War) and declared war on Denmark. But with the murder of the Tsar in July and the accession of Catherine to the Russian throne, the clouds disappeared. In the 1770s Denmark managed to bring Gottorp under the Danish throne.

During the 18th century Denmark-Norway acquired an important merchant marine and a navy as well. Freedom of the seas had become a vital issue and a difficult problem, complicated especially by the Norwegian timber export to England. During wars in the middle of the century (1740-63) Denmark-Norway had to bow to the British claim of ruling the seas. But during the U.S. War of Independence (1775-83) the Danish foreign minister A.P. Bernstorff in 1780 organized an armed neutrality treaty with Russia, Sweden, and Holland. Because of a war between England and France, Denmark and Sweden concluded a similar treaty in 1794, which Russia and Prussia joined in 1800. Norwegian export interests would have been threatened, however, if England considered these treaties hostile acts, so in 1780 Bernstorff also concluded a special treaty with England, much to the annoyance of Russia. Such a policy of balance proved to be impossible after 1800.

Denmark, poor in natural resources except for its soil, made no important economic gains in the 18th century. No important industry developed. Following mercantilist theory the government supported trade, to the benefit of Copenhagen merchants. But Denmark had not the political strength to exploit the strategic position of Copenhagen; imports dominated its trade. Except for oxen and meat, Denmark had very little to export. Eastern Norway was made an outlet for Danish grain in the 1730s, but the grain was inferior and normally could not compete with Baltic grain on the western European markets.

The principal reason for Denmark's stagnant economy was the backward state of Danish agriculture in the 18th century. A body of some 300 Danish landlords owned about 90 percent of the Danish soil, grouped in 800-900 estates. The landlords were the real rulers of the country, because their social position gave them privileged positions in filling the leading posts in the administration, the chanceries, and the Rent Chamber.

A price depression beginning in the 1720s enabled the landlords to use their position to impose very strict laws and regulations on the Danish peasants, who lived in villages, renting their farms from landlords whose demesne lands alone covered about 10 percent of the land. To get cheap labour, a compulsory requirement that one live in the village of his birth was extended to all Denmark for all people between four and 40 years of age. When the system was coupled with conscription for military service, the landlord could threaten a young peasant with at least six years of army service if he did not rent a farm. Every tenant had to perform labour on the landlord's domain for an average of three days a week. This work was considered to be the rent of the peasant's holding. A tenant had no right to demand a contract when he took over a holding, nor could he demand payment for improvements he might make on the holding when the lease expired or was lifted by the landlord. Each landlord also had the right of petty jurisdiction on his estate. Even if the landlords got cheap labour and the army received sufficient manpower by this system, Danish agriculture suffered from incredibly low productivity. The farmers performed poorly on the domains of the landlords; they had too little time to cultivate their own holdings; and they had no reason whatsoever to improve them.

Until the 1780s, Danish society seemed stagnant. A financial crisis in the 1760s, after the Russian threats during the Seven Years' War, was solved by a lasting poll tax. But apparently, for economic reasons, no further tax increase was possible. In 1770 a German doctor, Johann Friedrich Struensee, depending on palace intrigues and

The importance of freedom of the seas

Peasant involvement in Swedish politics

Danish society

the queen's bed, gained control of the government through the half-mad king Christian VII (ruled 1766–1808). For a year and a half, freedom of the press and intense reform activity reigned, but mostly on paper. Struensee had no popular support, and he naturally provoked resistance and fury among the landlord class. He was arrested for crime against the majesty and, in April 1772, was tortured to death. His short reign has been classified as another failure of the enlightened despotism of the 18th century. The old men who came back to power led an even more reactionary policy than before, one lasting until a bloodless coup d'état in 1784.

The years between 1784 and 1797 have been called the happiest period in all Danish history. Danish politics of those years were led by A.P. Bernstorff, Ditlev Reventlow, and E.H. Schimmelmann, all from the landlord class, by the benevolent crown prince Frederick (Frederick VI, 1808–39), and by the Norwegian jurist Christian Colbjørnsen. Notable reforms included liberal custom tariffs (1797) and the abolition of the Danish grain monopoly in Norway. But above all, the time was an age of land reforms, beginning in 1786 and lasting until the state suffered financial bankruptcy in 1813. Sixty percent of the Danish peasants became landowners. Compulsory residence, compulsory labour on the domains of landlords, and private jurisdiction were abolished, and the land was redistributed and made into independent farms. The army had to get soldiers by ordinary conscription. Landlords were compensated for the rights they lost, and together with the new landowning farmers they were assured stable labour by strict legislation on the landless crofters. The land reforms were possible because of a continuous rise in grain prices between 1750 and 1815 and because the new men of 1784 had carried out successful reforms on their own estates. As responsible politicians they had an insight into the benefits of a mild inflation and a liberal allocation of state credit, with which they guided the transition to peasant landownership. No doubt the Revolution in France, beginning in 1789, influenced this evolution. The example of the independent French farmers after 1789 hindered an evolution like that in England, with great domains and a numerous class of rural workers. From the land reforms, and from the school act of 1814, which introduced compulsory schooling for all children between ages seven and 14, there stemmed a high standard of Danish agriculture.

The Danish land reforms are remarkable also as the only successful feat of European enlightened despotism.

Norway. Among the common population of Norway there were few signs of unrest during the 18th century. Taxation was reasonable because the Norwegian topography and the status of the free Norwegian peasants made tax collection impossible. For defense against Sweden the Danish government had to rely on the Norwegian peasants themselves, with their own arms, rather than on a professional army. The public servants would not have been able to perform their work surrounded by a hostile population. On the contrary, because Norwegian society was so different, the public servants in Norway could influence Danish decisions regarding Norway by local information and advice. Moreover, Norwegian peasants traditionally complained to "the king in Copenhagen" if the laws were violated by the public servants. This habit was useful for central supervision of the local administration in a thinly populated and distant country.

Real opposition to Danish rule came from the timber merchants and exporters in eastern Norway. For their business, peaceful relations with England were a prerequisite, and banking institutions in Christiania were highly desirable. The first need was met until war with England in 1807–14. The second need was never accepted, however, because of the centralizing economic policy of the government and the interests of the Copenhagen bourgeoisie. The Norwegian exports assured Copenhagen of an important influx of foreign currency and helped to pay the imports to the capital. As long as peace was kept with England, however, the Norwegian and Danish economies were to a large extent complementary, and opposition was only regional.

Romanticists of the later 18th century idealized the Norwegian rural society, with its free peasants in a wild landscape. Certainly, their situation contrasted favourably with that of the Danish tenants; the landowning farmers in eastern Norway, especially, earned sizable incomes from their timber forests. In the east, therefore, and in the region of Trøndelag, the countryside was characterized by a class of rich farmers and a large rural proletariat. Elsewhere in the countryside, social conditions were more nearly equal. The Norwegian population consisted almost exclusively of peasants and fishermen; no city or urban agglomeration exceeded 15,000 inhabitants.

Malthus was the first demographer to see the exceptional possibilities for population studies in the Scandinavian countries, where civic registers were kept by parsons. In 1799, the year following his publication of *An Essay on the Principle of Population*, Malthus went to Norway to confirm his theories about checks on population growth. He found a late marital age, which he ascribed incorrectly to military service and a numerous servant class. In fact, early marriages were hindered by poverty and lack of land. Moreover, Norwegian population statistics of the 18th century indicate years of famine and epidemics, as do Swedish and Danish statistics. Malthus was correct, however, in discerning that demographic evolution in nonindustrialized countries could be studied better in Scandinavia than anywhere else in the world.

Revival of settlement in Greenland. How and why a Norse community in Greenland perished at the end of the Middle Ages is an unsolved and fascinating problem. In the beginning of the 18th century there still was hope of finding Norse descendants among the Eskimos in Greenland. A Norwegian clergyman, Hans Egede, having managed to convince the authorities that such people should be converted to the Lutheran confession, arrived in the Godthåb Fjord (in the southwest), finding only Eskimos, to begin a new European settlement in Greenland. Later in the century another colony was founded at Julianehåb (almost at the southern tip of the island).

Two factors are visible in this activity. First, the Pietist movement, which had a considerable influence in Denmark, demanded religious conversion and stressed an obligation to bring the gospel to the heathens. A Ministry of Missions, founded in 1714, supported Egede in Greenland as it supported missionary activity among the Lapps in northern Norway and among Indians at Tranquebar on the Coromandel Coast.

Second, missionary activity became possible because of a close alliance with commercial interests. Egede himself founded a company in Bergen for trade with Greenland. The trade later passed to the Royal Greenland Trading Company of Copenhagen. The trade with Finnmark (now the northernmost part of Norway) was reserved, in principle, for merchants of Copenhagen as well. Since the 17th century the East India Company (later the Asiatic Company) had been in charge of the trade with the Far East, with a principal port at Tranquebar.

Missionary activity was not extended to Africans. From the end of the 17th century Denmark–Norway had fortifications on the Guinea Coast (Christiansborg at Accra is very well known) to participate in the slave trade. In the 18th century the West India Company bought some sugar-producing islands in the Caribbean Sea (notably St. Croix) and then organized a three-way trade between Africa, the West Indies, and Copenhagen.

The missionary and commercial activities were manifestations of mercantilism. Lasting results were the settlements in Greenland and the Danish trade to the Far East. The Danish islands in the West Indies were sold to the United States in 1916.

SWEDEN

Growth of parliamentary government. Charles XII had no successor. In 1718 his sister Ulrika Eleonora had to convene the Diet in order to be elected. In 1720 she abdicated in favour of her husband, Frederick of Hessen (ruled 1720–51).

This period saw a transition from absolutism to a parliamentary form of government. The real reason for the

Factors in the new European settlement in Greenland

Norwegian opposition to Danish rule

change was the complete failure of the policy of "greatness" connected with the Carolingian absolutism. According to the constitutional laws of 1720–23 the power now rested with the estates. The estates met regularly in the Diet, which designated the council. There the king was accorded a double vote but had no right to make decisions. In the Diet, decision making took place in the "Secret Committee," from which the peasants, or the Fourth Estate, were excluded. The public sessions of the estates in the Diet were reserved for speeches and debates. The three upper estates consisted mainly of state servants. Thus the so-called Age of Freedom until 1772 also was an age of bureaucracy.

Adoption
of the
dual party
system in
Sweden

During this period, a dual party system evolved; the parties were known by the nicknames "Nightcaps" (or "Caps") and "Hats." Both parties were mercantilist, but the Nightcaps were the more prudent. Up to 1738 the Nightcaps were in power. They led a most careful foreign policy so as not to provoke Russia. From 1738 to 1765 power passed to the Hats, who made treaties with France in order to obtain subsidies and support against Russia. War with Russia in 1741–43 led to a temporary Russian occupation of Finland and to a further loss of Finnish provinces northwest of St. Petersburg. A war with Prussia in 1757–62 was very expensive. The Hats attempted to make Sweden a great economic power; but their economic policy and the war costs led to inflation and financial collapse, and their regime came to an end in 1765.

For some years political confusion reigned in Sweden. The Nightcaps received subsidies from Russia, and their negotiations with Prussia and Denmark intensified party struggle in Sweden. Economic chaos, territorial losses, foreign infiltration, and famine in the countryside undermined the parliamentary system. Historians have sometimes stressed these failures too strongly, however, in glorifying the past Carolingian age and the future Gustavian epoch.

Absolutism of Gustav III. At the death of Adolf Fredrick (ruled 1751–71), Gustav III (ruled 1771–92), visiting in Paris, acceded to the throne. Before returning he concluded another treaty with France. In 1772 he used the royal guard and officers of the Finnish army to seize control of the government from the parliament in a bloodless coup d'état. Gustav tried to exploit the Vasa and Carolingian traditions of personal royal power. He could rely on no class of the Swedish society nor on the political institutions of the 18th century, so he had to make the most of royal propaganda to the public. In this he was not without success; the traditional picture of Gustav is that of "King Charming," the promoter of the arts and sciences.

But Gustav's politics were unstable. Until 1786 he put into effect social reforms that belonged to enlightened despotism, thus enmeshing himself in its traditional dilemma: alienating the "haves" without satisfying the "have nots." Even his solution to the dilemma was a traditional one—war. After Turkey attacked Russia in 1787, Gustav went to war against Russia in 1788 to recapture the Finnish provinces. One reason the Swedish attack failed was a conspiracy by noble Swedish officers—the Anjala association—who, during the war, sent a letter to Catherine II of Russia, proposing negotiations. Gustav used the treason of the Anjala association to provoke an outburst of genuine patriotism in Sweden, hoping to channel popular opinion through the Diet, which he convened in 1789. This Diet, however, against his will, abolished practically all the privileges of the nobility (e.g., the nobility no longer had special rights to any posts in the administration nor to any category of Swedish land). In March 1792 the King was mortally wounded by a nobleman and former officer of the royal guards. The last years of the King and especially the days between the assassination attempt and his death (March 29) made him a martyr in the minds of his people, perhaps undeservedly.

The one notable feat in the Swedish economy during the 18th century was a growth in iron production. With growing competition from Russia, Sweden was a main supplier of iron to the European market. Royal manufac-

tures were a failure, however, and there were no Swedish economic innovations during the century.

In the rural population a social change took place. Most of the peasants during the 18th century came to own their farms. This development coincided with the growth of a large rural proletariat, mainly different types of tenants who served as soldiers or labourers to landlords and peasants. The nobility became less exclusive, and money became more useful for social climbing. But noble birth still helped greatly.

Finland. In the course of the Russo-Swedish War of 1741–43, the Russian empress Elizabeth declared her intention of making Finland a separate state under Russian suzerainty. She failed to follow up the idea, however, and at the peace settlement of Turku (Åbo) in 1743 contented herself with annexing a piece of Finland. Meanwhile, her original idea had found favour with some Finns, not so much as a tempting possibility but as a last resort against merging with Russia. During the next Russo-Swedish war (1788–90), a number of Finnish officers involved themselves in the activities of G.M. Sprengtporten, a Finnish colonel who had fled to Russia and wanted to detach Finland from Sweden; but this movement won little support.

IV. Era of revolution

DENMARK–NORWAY

Denmark. The Napoleonic Wars of the early 19th century tore Denmark–Norway out of a peaceful period that had lasted since 1720. The armed neutrality treaty of 1794 between Denmark and Sweden, to which Russia and Prussia adhered in 1800, was considered a hostile act by England. In 1801 a detachment of the English navy entered the Sound and destroyed much of the Danish fleet in a battle in the harbour of Copenhagen. When the English fleet next proceeded to threaten the Swedish naval port of Karlskrona, Russia started negotiations with England. The result was a compromise, which Sweden was forced to adopt in 1802. The neutrality treaty had fallen in ruins. Denmark–Norway, nevertheless, managed to keep outside the wars and to profit from them until 1807.

The Treaty of Tilsit (1807) between France and Russia worsened the situation. In 1805 France had lost its fleet to the English at Trafalgar. England feared that the continental powers might force Denmark to join them so that the Danish navy could be used to invade England. To eliminate this threat, England resorted not to diplomacy but to force. In September English troops occupied Zealand and an English fleet bombarded Copenhagen. Denmark had no choice but to capitulate to the English demands. On October 20 the English commander sailed away with the whole Danish fleet. The "fleet robbery" was severely criticized, even in the British House of Commons. For fear of a French or Russian occupation, Denmark chose what seemed to be the lesser evil and joined the continental alliance against England on October 31. This step also meant war with Sweden. Denmark might have reacted differently if England had used diplomacy, but the events of September had been too much of an affront to the Danish government and especially to the crown prince Frederick (later Frederick VI, ruled 1808–39). An alliance with England was no longer possible.

Norway. The continental blockade of England, which was against Danish interests, was a catastrophe to Norway. Fish and timber exports were stopped, as well as grain imports from Denmark. The consequences were isolation, economic crisis, and hunger. In 1810–13 England consented to some relaxation of its counterblockade against Norway. As a whole, however, the years 1807–14 convinced leading groups in Norway that they needed a political representation of their own.

Swedish foreign policy was erratic during those years (see below), but Denmark–Norway remained an ally of Napoleon until 1814. After Napoleon's defeat at the Battle of Leipzig (1813), Sweden repeated its 17th-century strategy by attacking Denmark from the south. At the Peace of Kiel (January 14, 1814), Denmark gave up all its rights to Norway (but not to the old Norwegian de-

English
humiliation
of
Denmark

Conspiracy
by the
Anjala
association

pendencies of Iceland, the Faeroes, and Greenland) to Sweden.

The Danes did not intend this agreement to end their union with Norway. Officially very loyal to the Treaty of Kiel, the Danish government worked for the eventual return of Norway. This probably is why the crown prince Christian Frederick, governor of Norway, in collusion with the Danish king, organized a rising against the Treaty of Kiel. In doing so he needed support in Norway, and he thus came to rely on two political forces, each with regionalist aims. The larger faction consisted of public servants and peasants, with traditional opposition to the centralizing policy of Copenhagen. The other was the small but important group of timber merchants in eastern Norway, who wanted independence from Copenhagen for their trade with western Europe. Since 1809 they even had conspired for a union between Sweden and Norway.

This was the main background of a constituent assembly, called by Christian Frederick to meet at Eidsvoll, 40 miles north of Christiania. It drew up a constitution on May 17, 1814 (which still exists), and elected Christian Frederick to the throne of Norway.

Norwegian independence got no support from the great powers, and Sweden attacked Norway in July 1814. After a fake war of 14 days, Christian Frederick resigned. Jean Bernadotte, the Swedish crown prince, accepted the fait accompli of the Norwegian constitution, and in so doing could no longer argue on the basis of the Treaty of Kiel. This was of the greatest political importance to the Norwegians. As a constitutional monarchy, Norway entered the union with Sweden in November 1814; only minor modifications were made in its constitution—the king and the foreign policy would be common; the king would be commander in chief of Norway's armed forces, which could not be used outside Norway without Norwegian consent; a government in Christiania (with a section in Stockholm) and the Storting (Norwegian parliament) would take care of national affairs.

SWEDEN

Royalist reaction. A fear of influences from revolutionary France dominated the Swedish government during the last decade of the 18th century and the first of the 19th. These fears were reflected in major economies in public finances, the legislation of land reforms, and the censoring of French literature. Gustav IV (ruled 1792–1809), unlike his father, Gustav III, was pious and superstitious. He considered events in France to be insults to moral order. A deep aversion toward the revolutionaries and Napoleon characterized his foreign policy. Of decisive importance was his resolution in 1805 to join the coalition against France. When France and Russia signed the Treaty of Tilsit in 1807, Gustav stubbornly accepted war, even with Russia. Denmark, which had sided with France in October 1807, declared war against Sweden in 1808. England, at the moment busy in Spain, could offer little help. Sweden thus became politically isolated, with enemies in the east, south, and west. The Swedish army defended Finland poorly, reaching its nadir when the strong fortress of Sveaborg near Helsingfors was handed over to the Russians by treason. The Russians advanced as far as Umeå in Sweden. Finally, in 1809, a bitter peace was made at Frederikshavn, in which Sweden surrendered Finland and the Åland Islands (northeast of Stockholm) to Russia.

In March 1809 Gustav IV was deposed by a group of high officials and officers. More than anything, a widespread longing for a quick and cheap peace brought the men of 1809 to power, but they were unable to save Finland. A new constitution was made, embodying the principle of separation of powers. The division of the Diet in four estates remained. Charles XIII (ruled 1809–18), the uncle of Gustav IV, was elected king. That he was senile and childless opened the question of succession to the throne.

With the consent of Denmark, the commander in chief of the Norwegian army, Christian August (at the moment waging war against Sweden), was elected crown

prince, and took the name Charles August. Behind this decision were thoughts of a Scandinavian confederation. This solution was cherished by Denmark and even by Napoleon.

In 1810 Charles August died, and the question of the succession to the throne was reopened. A Swedish lieutenant, Baron Carl Otto Mörner, was sent to Paris to explain the situation to Napoleon. At the same time he worked for his own plans—to pick one of Napoleon's commanders for the throne of Sweden. The choice fell on the prince of Pontecorvo, the marshal Jean-Baptiste Bernadotte. This choice pleased Napoleon, though he may have preferred the Swedish throne to be taken over by his ally King Frederick VI of Denmark–Norway. Meanwhile the French consul in Göteborg and the francophile Swedish foreign minister, Engeström, managed to persuade the Diet to set aside the Danish alternative and to name Bernadotte as crown prince of Sweden in August 1810.

Bernadotte. From his arrival in Sweden in October 1810, Bernadotte, who took the name Charles John, became the real leader of Swedish politics. In designating him for the crown, the Swedes hoped that he would somehow reconquer Finland and the Åland Islands. When Napoleon attacked Russia in 1812, Charles John personally negotiated with Tsar Alexander, offering help against Napoleon if the Tsar would permit Sweden to occupy Finland or even only Åland. The Tsar declined. Quite soon Russia needed no foreign help against Napoleon.

Charles John then turned to the West. In March 1813 he negotiated a treaty with England by which, for participating in the final offensive against Napoleon, Charles John was to obtain Norway. Thus Charles John became commander in chief of the northern allied army, consisting of Prussian, Russian, and Swedish soldiers. He used this army sparingly, especially the Swedish contingent, even at the Battle of Leipzig in October 1813, because he cherished a hope of succeeding Napoleon and also because he needed troops to attack Denmark. After Leipzig, Charles John refused to cross the Rhine; instead he led the northern army against Denmark. The result was the Peace of Kiel, whereby Norway was surrendered.

By accepting a constitution in Norway, Charles John became heir, peacefully, to his second throne in four years and consequently gained a more independent position in Sweden. He hoped, moreover, to impress favourably liberal circles in France.

The cession of Finland to Russia. In the words of Swedish historian, Sten Carlsson, in 1969, "The loss of Finland was the price of the long and still unbroken period of peace that was to begin in 1814." The statement implies that the possession of Finland in the past centuries forcibly brought Sweden in collision with other powers in the Baltic area. When Peter the Great founded the new Russian capital at St. Petersburg and the harbour of Kronstadt at the bottom of the Gulf of Finland in the first decade of the 18th century, the danger became much more serious. It is significant that Russia acquired wide Finnish areas around St. Petersburg in 1721 and in 1743.

As a part of the Swedish monarchy, Finland had been accorded practically no institutions of its own, but from the middle of the 18th century the majority of officials and intellectuals were of Finnish origin. In those circles there was a growing feeling that Finland had to bear the cost of Swedish extravagances in foreign policy. The feeling was not unfounded. Swedish strategic directives of 1785 implied that in case of Russian attack, Swedish forces should retire from the frontier, leaving Finnish detachments behind, and that under extreme danger the whole of Finland should be evacuated. This strategy was put into effect in 1807–09. Even the treachery of the Åjala association in 1788 was repeated in 1808, when Sveaborg near Helsingfors capitulated to the Russians. The feeling that the Finns could trust nobody other than themselves was born in the end of the 18th century. In 1809 the Finns themselves had to carry the responsibility of coming to terms with Russia. Tsar Alexander offered to recognize constitutional developments in Finland and to give it autonomy as a grand duchy under his throne.

Surrender
of Finland
to Russia

When Sweden surrendered Finland in 1809, it even had to give up the Åland Islands northeast of Stockholm. "Russia would not take a trunk (Finland) without the keys." (G.Sa.)

V. The 19th century

DENMARK

Economic development and the liberal reform movement. *Economic consequences of the war.* The Napoleonic Wars had proved a national catastrophe for Denmark, both economically and politically. The policy of armed neutrality had failed, and the fleet had been destroyed or surrendered. Copenhagen, the capital, which was the country's commercial and administrative centre, had been devastated by the bombardment of 1807, while Norway had been lost at the Treaty of Kiel in 1814. Trade had been hard-hit by the blockade, and the widespread overseas connections that formerly had played so large a part in the economic life of Denmark could not be resumed. Copenhagen's role as an international financial and trading centre was taken over by Hamburg, and even a considerable part of Danish home trade was controlled from there. Inflation further contributed to the crisis. The state was forced to make a formal declaration of bankruptcy, and not until an independent national bank with sole rights to issue banknotes was established in 1818 was economic stability slowly re-established. It was 20 years, however, before the coinage rose to parity with the silver standard, and banknotes were first redeemable in 1845.

The economic crisis was worsened by low corn prices. The loss of Norway and the high import duties on corn that Great Britain imposed at this time meant that Denmark was deprived of its surest markets for its corn export. The period from 1818 to 1828 was characterized by an agricultural crisis that resulted in the compulsory auctioning of many estates and farms, forcing the agrarian reform to a complete standstill.

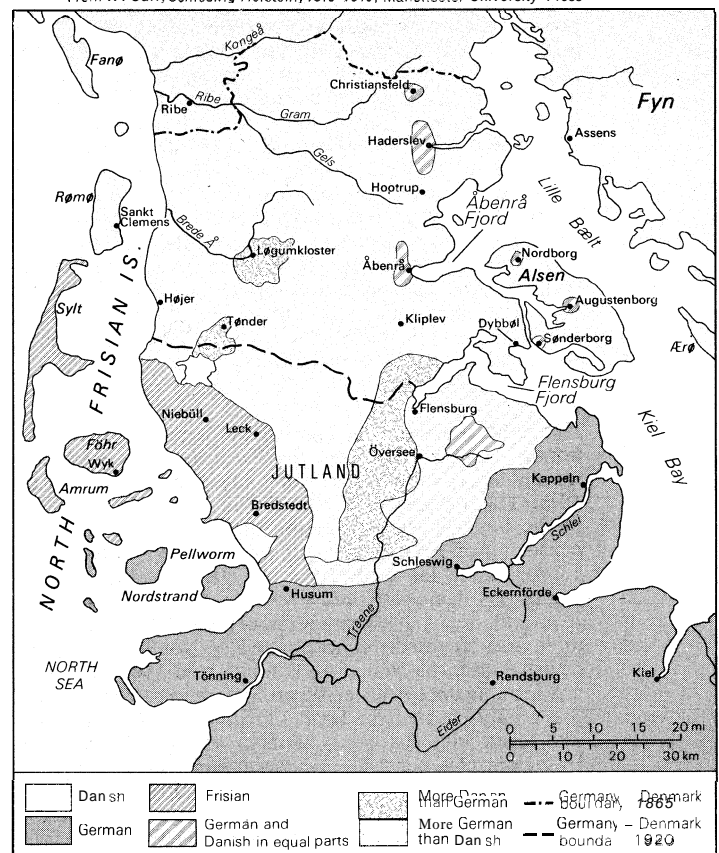

In about 1830 economic life took a turn for the better with, among other things, more stable prices for agricultural products, increased trade, and the first signs of industrialization.

The liberal movement. Denmark's government under Frederick VI (ruled 1808–39) could be described as a patriarchal autocracy. In the Privy Council, which was regularly convened after 1814, Poul Christian Stemann became the leading figure and was responsible for the government's strongly conservative policies until 1848. His close colleague, Anders Sandøe Ørsted, pleaded for a somewhat more liberal policy, at least on economic questions. After the July Revolution in France, a demand was made in Denmark for a liberal constitution. The government was forced to make concessions, and in 1834 four provincial consultative diets (or assemblies) were created, two in the kingdom itself, one in Schleswig (Slesvig), and one in Holstein. These had merely an advisory function, but both the eligibility and the right to vote were fairly extensive. Simultaneously, the liberal movement grew in strength, especially in the academic world and among the middle classes. The liberal press whose leading journal was *Fædrelandet* ("The Fatherland," established in 1834), subjected the absolute monarchy and its conservative administration to severe criticism. When Frederick VI, the popular monarch, died in 1839 the liberals had great hopes of his successor Christian VIII (ruled 1839–48), who, during his youth as regent in Norway, had appeared as the spokesman for a liberal government. Over the years, however, he had become much more conservative and as king of Denmark did not consider the time ripe to dissolve the absolute monarchy. He confined himself, therefore, to modernizing the administration, especially in establishing local government by municipal laws between 1837 and 1841, granting some independence to parishes and counties. Parallel with the liberal movement ran the farmers' movement. This started as a religious movement but soon became dominated by social and political ideas, with agitators such as Jens Anderson Hansen leading the way. When the government intervened, the liberals and farmers joined forces against the common adversary. In 1846 the farmers' case re-

ceived support when a group of liberal reformers led by Anton Frederik Tscherning founded the Bondevenne selskabet (Society of the Friends of the Peasant), which developed into the Venstre (the liberal farmer's party).

The 1849 constitution. After the death of Christian VIII in January 1848 and under the influence of the February Revolution in Paris and the March Revolution in Germany, the new king Frederick VII (ruled 1848–63) installed the March Cabinet, in which the National Liberal leaders Orla Lehmann and Ditlev Gothard Monrad were given seats. After a constituent assembly had been summoned, the absolute monarchy was abolished and was replaced by the June constitution of 1849. Together with the king and his ministers there was now also a Parliament with two chambers, the Folketing and the Landsting, both elected by popular vote but with a property-owning qualification as a prerequisite for a seat in the Landsting. Parliament, together with the king and government, shared legislative power while the courts independently exercised judicial power. The constitution also secured the freedom of the press, religious freedom, and the right to hold meetings and form associations.

From W. Carr, *Schleswig-Holstein, 1815–1848*; Manchester University Press

Language distribution in Schleswig-Holstein, 1849.

The National Liberals and the Schleswig-Holstein question. Nationalism was, together with liberalism, the most important movement in the 19th century. In Denmark, national feelings were inflamed by the conflict with Germany on the Schleswig-Holstein question. After the loss of Norway, the Danish monarchy consisted of three main parts: the kingdom of Denmark and the duchies of Schleswig and Holstein, the last of which was a member of the German Confederation. Whereas Holstein was German, Schleswig was linguistically and culturally divided between a Danish and a German population. When the liberal German-speaking population in Schleswig opposed autocratic rule and demanded a free constitution and affiliation to Holstein and the German Confederation, a Danish National Liberal movement emerged and demanded that Schleswig be incorporated in Denmark (the Eider Policy, named for the Eider River, which formed the southern boundary of Schleswig). When the

The Eider Policy

National Liberal Government officially adopted this policy in 1848, the Schleswig-Holsteiners resorted to arms. As the rebellion received military aid from Prussia, the Danish Army could not suppress it. The war, which lasted three years, ended in the agreements of 1851 and 1852 in which Denmark pledged to take no measures to tie Schleswig any closer to itself than to Holstein. The Eider Policy was thus abandoned, and the June constitution of 1849 applied only to Denmark. The National Liberal government was succeeded in 1852 by a Conservative government under Christian Albrecht Bluhme.

Under the influence of the Pan-Scandinavian movement and the German Confederation's constant interference in constitutional matters in Schleswig and Holstein, the Eider Policy again won ground, and the Conservative government was replaced in 1857 by a moderate National Liberal government led by Carl Christian Hall. This government introduced a number of reforms of which the most important was a law of freedom of enterprise in trade and industry. In 1863, in the belief that Prussia was preoccupied with the Polish rebellion against Russia and in expectation of support from Sweden, the government separated Holstein from the rest of the state and conferred a joint constitution on the kingdom and Schleswig. This "November constitution" meant that Schleswig was annexed to Denmark, in contravention of the agreements of 1851 and 1852.

Prussia, however, under the leadership of Otto von Bismarck, reacted immediately, and in February 1864 war broke out between Denmark on the one side and Prussia and Austria on the other. After the Danish defeat at Dybbøl and the consequent occupation of the whole of Jutland, Denmark was forced by the Treaty of Vienna to surrender the whole of Schleswig and Holstein to Prussia and Austria.

The conservative regime. *Realignment of political factions.* The defeat in 1864 led to the fall of the National Liberal government. Under Christian IX (ruled 1863–1906) a Conservative government was appointed, and in 1866 a new constitution followed that introduced electoral rules giving the Landsting a distinct conservative leaning, with great landowners and civil servants as the dominating elements. The National Liberal Party was swallowed up by the Conservative Party. As a counterweight, the various groups that represented the farmers combined together in 1870 to form The United Left, (Det forenede Venstre), which in 1872 secured a majority in the Folketing. Venstre demanded that the 1849 June constitution be reintroduced together with a number of other reforms. With Jacob Brønnum Scavenius Estrup, a great landowner, as prime minister (1875–94), however, a strictly conservative policy was pursued. Despite the opposing parliamentary majority, the government forced its policy through by means of provisory law and with support from the king. The result was that all reforms came to a standstill. Not until the "compromise" of 1894 was the crisis solved, at which time Estrup himself left the government. The demand for parliamentary democracy was not granted, however, until the 1901 election, when Venstre came to power, and what has become known in Denmark as the "Change of System" was introduced.

Social and economic change. The progress of Venstre and the formation of the Social Democratic Party in the 1870s must be viewed against the background of the great economic and social changes. During the 1850s and 1860s a network of railroads was created, industrialization began, agrarian reforms were introduced, and a number of technical improvements in corn production were effected. In the years between 1870 and 1901 the urban population increased from 25 percent to 44 percent of the total population. The rapid development of harbours, ships, and foreign trade meant that the shortage of raw materials, such as iron and coal, did not hinder the development of industry to any essential degree. There was a steady stream of foreign capital to Denmark. Trade unions and employers' federations were established at this time and spread nationwide by 1899. The fall in the world market price of corn after 1875 resulted in an

increased production of butter and bacon. England became even more the main market for agricultural products. Even the smallest farm arranged its production with exports in mind, while at the same time foodstuffs were imported. Standardization of butter and bacon and their export was arranged by the farmers themselves on a co-operative basis and with a view to the existing struggle with townsmen and the great landowners. The cooperative movement won ground in rural areas. Culturally, the farmers gathered around the folk high schools, educational institutions with a mainly liberal arts program, inspired the ideas of N.F.S. Grundtvig, the writer, educationist, and theologian.

SWEDEN

Population, agriculture, and industry. The population of Sweden, which in 1815 was barely 2,500,000 reached 3,500,000 by 1850 and 5,100,000 by 1900. During the period 1815 to 1900, therefore, the country's population had more than doubled, despite a loss of 850,000 emigrants (mainly to North America) during the period 1840 to 1900.

Until the last quarter of the 19th century, Sweden was a predominantly agricultural country. In 1850, 90 percent of the population lived off the land. By 1900 the figure was still as high as 75 percent. At the beginning of the 19th century, rural dwellings were clustered together in the villages, and the fields were cultivated under an old open-field system. The basis for an agricultural modernization was laid down by a statute of 1827 on enclosures (Laga skifte), which stated that when possible the fields of the individual farm should be assembled together in a compact area. Enclosures of lands, which took place throughout the 19th century, changed the face of the countryside. Villages were split up, and scattered farms became the predominant type of dwelling in Sweden. The move away from the village system brought about a widespread reclamation of wasteland and the modernization of agriculture, which accounted in part for the increase in population.

During the first half of the 19th century, trade and industry were still restricted by regulations and guild rules. The middle of the 19th century saw the beginning of industrial organization, primarily in the timber trade, and in the last quarter of the 19th century the industrial revolution began in earnest with the advent of new methods in iron and steel production and the birth of a number of specialized industries, such as those of machines and machine tools. During the greater part of the 19th century, however, Sweden was a poor and overpopulated country.

The Conservative Era (1815–40). At the conclusion of the Napoleonic Wars, Sweden was hard-hit by an economic slump that lasted until 1830, characterized by abortive attempts to reestablish the value of the currency. After devaluation in 1834, the currency was finally stabilized. Crown Prince Charles John (Carl Johan), who was king under the name of Charles XIV John (ruled 1818–44), pursued a strictly conservative policy. The king's power, invested in him by the constitution, was exploited to the limit; and the ministers were recruited from his henchmen without regard to the wishes of Parliament. In the 1820s the liberal opposition steadily increased its demands for reforms, and 1830 was the year in which liberal opinion made a breakthrough. In Sweden this was indicated by the establishing of a newspaper, *Aftonbladet*, which with Lars Johan Hierta as editor, became the leading journal of the liberal opposition. Simultaneously, the king's one-man-rule, which was exercised through his powerful favourite Magnus Brahe, became even more emphatic. The struggle against the growing liberal opposition, which reached its climax at the end of the 1830s, was characterized by actions against the freedom of the press and indictments of high treason and countered by the liberals with sharp criticism, demonstrations, and street riots.

The liberal reform period. The pressure of the opposition, however, at last forced the king to yield, and the 1840 Parliament, in which the liberal opposition had the

Enclosures

The United Left

majority, forced through the "departmental reform," which meant that the ministers actually became the heads of their own ministries. Another reform of great significance was the introduction in 1842 of compulsory school education. When Charles XIV John died in 1844 and was succeeded by his son Oscar I (ruled 1844–59), the liberal reform period had already gained momentum.

Principal reforms. Among the most important of the reforms was the introduction of free enterprise in 1846, which meant the abolition of the guilds. They were now replaced by free industrial and trade associations. Simultaneously, the monopoly of trade that the towns had held since the Middle Ages was also abolished. Finally, by the introduction of a statute in 1864, complete freedom of enterprise became a reality. The lifting of almost all bans on exports and imports in 1847, together with a reduction in customs duties, was the first step toward free trade. A number of other liberal reforms were introduced: equal rights of inheritance for men and women (1845), unmarried women's rights (1858), a more humane penal code through a number of reforms (1855–64), religious freedom (1860), and local self-government (1862). Another significant step was the decision in 1854 that the state should be responsible for the building and management of main-line railroads.

Parliamentary reform. Oscar I, who took the initiative himself in many of these reforms, became more conservative after the disturbances in Stockholm in 1848. When he was succeeded by his son, Charles XV (ruled 1859–72), the power had in reality gradually passed into the hands of the Privy Council, which, under the leadership of the minister of finance, Baron Johan August Gripenstedt, and the minister of justice, Baron Louis De Geer, completed the reforms. From the beginning of the 19th century the most important of the liberal demands had been for a reform of the system of representation. It was not until 1865–66 that agreement was reached to replace the old Riksdag with its four Estates of nobility, clergy, burghers, and peasantry with a parliament consisting of two chambers with equal rights. The members of the first were chosen by indirect vote and with such a high eligibility qualification that it bore the stamp of an upper chamber representing great landowners and commercial and industrial entrepreneurs. The members of the second were chosen by direct popular vote, which was limited, however, by a property qualification and therefore gave the farmers an advantage.

Political stagnation (1866–1900). The reform of the representative system marks the end of the liberal reform period. During the following 20 years, Swedish politics were dominated by two issues: the demand for an abolition of ground tax, which had been levied from ancient times, and the defense question, where the demand was for an abolition of the military system of *indelningsverket* (that is to say, an army organization in which the soldiers were given small holdings to live on). The defense system was to be modernized by an increase in conscription. The First Chamber's demand for rearmament, however, was impossible in view of the Second Chamber's demand for the abolition of the ground tax. As these issues had been linked together in the 1873 compromise, they were not resolved until 1892, when it was decided to abolish the ground tax and replace the old army organization with a larger and better trained conscripted army. The latter was completed through the defense reform of 1901, which introduced a conscripted army with a 240-day period of service.

The heavily falling prices of corn on the world market in the 1880s gave rise to a serious agricultural crisis. In 1888 a moderate tariff was introduced that was gradually raised in the following years. The Second Chamber, which, since the electoral reform had been dominated by the farmers' party, was at this time split into a protectionist faction and a free-trade faction. With the appearance of the Social Democrats in 1889, the Liberal factions in the Riksdag merging into the Liberal union in 1900, and the Conservative groups forming a united election organization in 1904, there came into being the parties that still dominate Swedish politics today.

Foreign policy. Until the end of the 19th century, foreign policy was still regarded as the monarch's personal province. Already, as crown prince, Charles John had concluded an alliance with Russia against almost unanimous opposition and by so doing initiated the Russia-oriented policy that characterized the whole of his reign. The succession of Oscar I to the throne in 1844 brought no immediate alteration. The only deviation was in his somewhat carefully demonstrated sympathy for the growing Pan-Scandinavian movement. When the German nationals rebelled against the Danish king in 1848, Oscar I aligned himself with Frederick VII and contributed, together with the tsar, to a cease-fire and armistice.

Change in alliance policy. During the negotiations on Schleswig-Holstein, Oscar I was still on the side of Tsar Nicholas I of Russia, aligned more or less against the radical nationalism in Germany. But in reality he endeavoured to extricate Sweden from the conservative Russia-orientated policy that Charles John had initiated in 1812. The opportunity came during the Crimean War (1853–56), when Oscar I adopted a friendly attitude to the Western powers and, among other things, opened Swedish harbours to English and French warships, and tried to induce the Western powers, with the help of Swedish troops, to attack St. Petersburg. With this intention, he signed the November Treaty with the Western powers in 1855. The peace treaty that was concluded in Paris shortly afterward, however, ended the hopes cherished in Sweden of winning Finland, or at least Åland, back again. All that was gained was the Åland Convention, which forbade Russia to build fortifications or have other military installations on Åland.

Pan-Scandinavianism. During the 1840s and 1850s the idea of a united Scandinavia had won great support among students and intellectuals. Crown Prince Charles had spoken out enthusiastically in favour of this ideal, and, after his succession to the throne in 1859, he assured the Danish king of Sweden's solidarity with Denmark, promising Swedish support in 1863 to defend the frontier at the Eider—the southern boundary of Schleswig. Encouraged by these promises, Denmark embarked upon the policy that led to the Danish-Prussian War of 1864. In the event, the Swedish government reluctantly refused to honour the king's pledge. Scandinavian unity therefore suffered a decisive defeat and ceased to be the guiding light of Swedish foreign policy.

Neutrality and friendship with Germany. In the wars between Prussia and Austria in 1866 and between Germany and France in 1870–71, Sweden was officially neutral, even if in the latter the king's personal sympathies were with France. Oscar II (ruled in Sweden 1872–1907) reoriented the country's foreign policy. The new German Empire under the leadership of Otto von Bismarck excited his admiration and sympathy. At the same time, connections with Germany became much closer, and from the mid-1870s Swedish politics were influenced by a close friendship with Germany that was even more emphasized during the last years of the 19th century by the growing fear of Russia.

The Swedish-Norwegian Union. From the Swedish viewpoint the union with Norway was a disappointment. Instead of an alliance of the two countries, the incompatibilities grew, and the union remained a personal one, on the whole confined to a joint monarch and foreign policy. One of the few positive results of the union was an 1825 statute that abolished or greatly reduced tariffs between the countries. The union also had an important influence on Sweden's domestic affairs, and Norway served as a model for Swedish radicals who demanded parliamentary democracy.

As crown prince in the 1850s, Charles XV had promised the Norwegians that on his succession to the throne he would abolish the post of governor general, which in Norway was regarded as a sign of the country's subordinate position in the union. In reality, this question was relatively unimportant, as the post of governor general had not been occupied by a Swede since 1829 and had been vacant since 1855. When Charles XV succeeded to the throne, however, and tried to honour his pledge to

coopera-
tion with
Denmark

The
governor-
general
question

abolish the post, the Swedish Parliament and the government headed by the powerful minister of finance, Baron J.A. Gripenstedt, opposed the resolution. Charles XV was forced to give way and withdraw his support for the abolition of the post. The government, with support from Parliament, had thus strengthened its position over the king. The governor-general question marked the beginning of the struggle for power between king and Parliament that characterized Sweden's internal politics for the latter part of the 19th century. In 1905 the union question again influenced Swedish domestic affairs. With the dissolution of the union, the king's power was usurped, and a government chosen by the majority parties in Parliament and headed by the right-wing leader Christian Lundeborg was appointed to negotiate with Norway. Thus the dissolution of the union led to the first real parliamentary government in Sweden.

NORWAY

For Norway the Treaty of Kiel (1814) meant secession from Denmark and the forming of its own separate state with complete internal self-government. The history of Norway during the 19th century is marked by the struggle to assert its independence of Sweden within the union and its attempts to emancipate itself from Danish cultural influences.

Population, trade, and industry. *Population.* Norway's population grew more rapidly during the 19th century than in any other period of its history. The population rose from 883,000 in 1801 to 2,240,000 in 1900. Whereas the urban population was only 8.8 percent in 1800, it had reached 28 percent by 1900. After Ireland, Norway had the highest relative emigration of all European countries in the 19th century. From 1840 to 1914 about 750,000 people emigrated.

Economic conditions. Norway was also severely hit by the economic crisis that followed the Napoleonic Wars. Norway's exports consisted mainly of wooden goods to Great Britain and, to a certain extent, of glass and iron products. After the war, when the British introduced preferential tariffs on articles of wood from Canada, Norwegian forest owners and sawmills and export firms were badly hit. Iron and glass exports also met with marketing difficulties. Fish, which after timber was the country's most important export commodity, was only lightly hit by the slump; and by the 1820s the herring fisheries on the west coast enjoyed a period of vigorous expansion. From the 1850s on, agriculture developed rapidly. Modern methods were adopted and an emphasis was laid on cattle breeding. Simultaneously, the building of railroads began ending the isolation of the small communities and opening the way for the sale of agricultural products. It was, however, above all the great expansion of merchant shipping (especially between 1850 and 1880) that gave the most powerful boost to the country's economy. Norway's percentage of world tonnage rose from 3.6 percent to 6.1 percent: and at the end of the century Norway possessed, after the United Kingdom and the United States, the largest merchant navy in the world. The economic resources that merchant shipping brought to the country laid the basis for industrialization. From 1860 Norway's industry expanded rapidly, especially in the timber trade and in engineering. Socially and economically this expansion was a springboard for ship-owners, manufacturers, and businessmen, all of whom began to play a much greater role in politics toward the end of the 19th century.

The age of bureaucracy (1814–59). The economic development in the decades immediately after the Napoleonic Wars meant a reduction in the power of the big business concerns and great estates. The decision to abolish the nobility in 1821 was indicative of the greatly reduced social and economic circumstances of the upper classes. At the same time, the position of the bureaucrats was strengthened, and from then until the latter part of the 19th century they controlled the political power of the country. Apart from the bureaucrats, there were only two other political factors of any importance in Norway at this time: the farmers and the monarch.

Parliamentary authority. The Eidsvoll constitution of 1814 gave Parliament greater authority than parliamentary bodies had in any other country except the United States. The king retained executive power and chose his own ministers, but legislation and the imposition of taxes required the participation of the Storting (Parliament). The Storting had the power to initiate legislation, and the king had only a suspension veto. When the union's monarch Charles XIV John (ruled 1818–44) demanded the right of absolute veto, the Storting categorically refused, despite the King's attempt to intimidate them with shows of military strength. Faced with this unanimous resistance, the King was forced to abandon his struggle, and the Storting's dominant position became the firm defense against Swedish attempts to unite the two countries. As a national demonstration, Norway began in the 1820s to celebrate May 17, the date of the Eidsvoll constitution, as a national day. The King's attempt to outlaw the celebration resulted in violent demonstrations, and during the 1830s he conceded this point also.

Monetary problems. Norway had at the same time many major problems to resolve on the domestic front. The war, which had been to a great extent financed by an increased issue of banknotes, had brought about a reduction of the riksdaler to one-fifteenth of its original value. To ward off inflation, a severe sterling tax was imposed, and in 1816 a new bank of Norway was established that had the monopoly of issuing banknotes. In spite of strong precautionary measures, however, it was not until the currency reform of 1842 that finances were stabilized. From an economic point of view, the bureaucratic rulers were decidedly liberal, and the guild system and old trade regulations were abolished during the 1840s and 1850s. By 1842 it was decided to reduce tariffs, a decision that gradually made Norway a free-trade country.

Political change. The influence that the vote gave to the farmers was not exploited at first, and they continued to elect bureaucrats as their parliamentary representatives. About 1830, however, a demand was raised for a decrease in expenditure, and under the leadership of Ole Gabriel Ueland, a more deliberate "class" policy began to be conducted in the Storting. The farmer's policy, which led to sharp conflicts with influential groups of bureaucrats, became a struggle for political power, resulting in the passing of a bill on local government in 1837. Under pressure from both a radical labour movement, which arose after 1848 under the leadership of Marcus Moller Thrane, and the later mounting tension in the relationship with Sweden, the farmers allied themselves in the 1850s and 1860s with the Venstre Party, which had been founded during the 1850s by the middle classes and minor civil servants. The party's intensely nationalistic attitude was expressed in its attempts to strengthen national culture and language. The struggle for the introduction of the vernacular as the official language instead of the bureaucrats' Danish influenced tongue became an important item of the party's policy.

The union conflict (1859–1905). As the union's king usually resided in Sweden, he was represented in Norway by a governor general. This gave rise to the governor-general conflict, which was not resolved until 1873, when Sweden yielded to Norway's main demands. The result was that in Norway the king was regarded as purely Swedish, and his right to nominate the government in Norway was considered a danger to the country's autonomy. The conflict revolved around the question of the Storting's confidence in the government. During the reign of Oscar II (ruled in Norway 1872–1905), matters came to a head when a Conservative government refused to pass a bill that the Storting had three times accepted. After a trial before the court of impeachment (Riksretten) the government was forced to resign. The Storting and not the king had thus acquired the decisive influence on the government, and Norway became the first country in Scandinavia to be governed by parliamentary means. Although Norway had won full self-government on the domestic front, the union was still represented externally by the Swedish-Norwegian king, and the country's foreign policy was conducted by the Swedish foreign minis-

shipping

ter. From the 1880s, therefore, there was an increasing demand for an independent Norwegian foreign minister. In 1891, Venstre won an impressive majority at the polls with the Foreign Minister question, among other things, on its program. In spite of this, the Venstre government headed by Johannes Steen, which the King had appointed after the election, did not take up the foreign minister question but raised instead a more limited demand for a Norwegian consular service. Even this was flatly refused by Sweden in 1892. When the Norwegian Parliament attempted to carry out this reform independently, it was forced under threat of military action to negotiate with Sweden on a revision of the whole question of the union. Though Sweden soon showed its readiness to be most compliant, the incompatibilities had become so marked that there was no real chance of a compromise. The negotiations collapsed in 1898, and Norway at the same time demonstrated its independence by abolishing the union emblem on its merchant flag, despite the king's veto. New negotiations were opened in an attempt to solve the more limited demand for an independent consular service, but when these negotiations also failed Norway took the matter into its own hands, and the Storting passed a bill establishing Norway's own consular service. When the king refused to sanction the bill, the coalition government, under the leadership of Christian Michelsen, resigned. As, under the circumstances, it was impossible for the king to form a new Norwegian government, the Storting declared "the Union with Sweden dissolved as a result of the King ceasing to function as Norwegian King," on June 7, 1905. The Swedish Parliament refused, however, to accept this unilateral Norwegian decision. Under threat of military action and partial mobilization in both countries, Norway was forced to submit and enter into negotiations on the conditions for the dissolution of the union. A settlement was reached in Karlstad in September 1905, which embodied concessions from both sides. The Swedish-Norwegian union was thus legally dissolved, and shortly afterward Prince Charles of Denmark was chosen as Norway's king and came to the throne under the name of Haakon VII.

of
the union

FINLAND

Authoritarian government (1809–63). On its separation from Sweden in accordance with the Treaty of Fredrikshamn (Hamina, 1809) Finland had a population of over 900,000. As elsewhere in Scandinavia, population growth was rapid, and by 1908 the figure had exceeded 2,000,000. The bulk of the population lived off the land. Manufacture of wooden articles, export of timber, shipbuilding, and merchant shipping were practiced to a certain extent in the small coastal towns.

Political organization. The political framework was laid down by the Porvoo (Borgå) Diet (Valtiopaivat) in 1809, at which time the Russian tsar Alexander I promised to respect the religion and fundamental laws of Finland, as well as the privileges and rights of the inhabitants (that is to say, the Swedish constitution of 1772 as amended in 1789 by which the regent alone had the executive power, while the consent of the Diet "Lantdag" was required for legislation and the imposition of new taxes). The grand duke (the tsar) was not obliged to convene the Lantdag at regular intervals, and the result was that it did not meet until 1863. From 1809 to 1863 Finland was ruled by a bureaucracy chosen by the tsar, though, with the exception of the governor-general, this was solely Finnish. The highest administrative organ during the period was the Senate, which consisted of a judicial department and an economic department. The former was the country's supreme court, while the latter became a sort of ministry. A ministerial state secretary in St. Petersburg represented Finnish affairs to the tsar.

Russian reforms and repression. Despite the strongly authoritarian form of government, a number of important reforms were implemented. In 1812 the tsar was induced to restore those areas of Finnish territory that Sweden had ceded to Russia by the treaties of Nystad (Uusikaupunki) 1721 and Abo (Turku) 1743. Furthermore, in 1812 the town of Helsingfors (Helsinki) was

chosen as the capital, and the monumental buildings in its centre stem from this period. The vast rural population and purely agrarian structure prevented the spread of liberal and national ideas to any great extent during the first part of the 19th century. The reaction reached its climax with the Finnish language ordinance of 1850, which forbade the publication in Finnish of books other than those that aimed at religious edification or economic benefit. Since Finnish was the only language understood by the majority of the population, the ordinance smacked of an attempt to maintain class differences and was well suited to preserve the existing bureaucracy.

The
Finnish
language
ordinance

Language controversy and political reforms. **The language problem.** As late as the mid-19th century, Swedish was the only language allowed within the Finnish administration. There was an almost total lack of literature in Finnish, and teaching at both the secondary and university levels was in Swedish. The division between the two languages became not only of national and cultural significance but also a social distinction. This is one of the reasons why the language controversy in Finland created such bitterness. To begin with, the advocates of a Finnish-speaking Finland, or Fennomans, were successful. By recording folksongs and writings, a Finnish literature was developed during the latter part of the 19th century. The first purely Finnish-speaking grammar school appeared in 1858. In 1863 Alexander II (ruled 1855–81) issued a decree stating that after a 20-year interim period, Finnish was to be placed on an equal footing with Swedish in the administration and in the law courts, as far as their relations with the public were concerned. Swedish, however, remained the language of internal administration, and it was not until 1902 that Swedish and Finnish were placed on an equal footing as official languages.

Reform of the Diet. During the reign of Alexander II other reforms were begun. The most important was his convening of the Diet (Lantdag) in 1863, and the promulgation of a new act in 1869 providing that the Diet thereafter should be convened regularly. The next great reform period came after the Russian defeat in the war against Japan (1904–05). The most important action was the Parliamentary reform of 1906, which replaced the old Diet of the Four Estates by a one-chamber Eduskunta (Riksdag) elected by universal and equal franchise for both men and women. Thus, from having one of Europe's most unrepresentative political systems, Finland had, at one stroke, acquired the most modern. The Parliamentary reform polarized the political factions, and the ground was laid for the modern party system. The introduction of universal and equal suffrage meant that the farmers and workers potentially commanded a great majority. Social and economic problems came to the fore. The breakthrough in democracy, made possible by this reform, was an important prerequisite for Finland's success in winning its independence in 1917–18.

Adoption
of the
universal
and equal
franchise

Relations with Russia. Until the 1890s, Russia respected Finland's special position within the Russian Empire in all essentials. During the reign of Alexander II (ruled 1855–81), the country's independent position was strengthened still further. In addition to the Lantdag ordinance of 1869, the country acquired its own monetary system (1865), and a law on conscription, which laid the foundations for the Finnish Army, was passed in 1878.

Russian expansion. Pan-Slavism's pressure for a Russian expansionist policy and the sharpening clashes between the great powers, brought about a change in Russia's policy toward Finland. During the 1890s an attempt was made to "russianize" Finland, with, for example, the introduction of Russian postal, toll, and monetary systems. The appointment of Nicolay Bobrikov as governor general in 1898 signified an acute intensification of Russian policy. In the February Manifesto of 1899 it was decreed that all legislation would be instituted by the Russian authorities. In 1901 a new law was passed dissolving the Finnish national army and making it possible to conscript Finnish nationals to serve in Russian units. In Finland a fierce independence movement grew in reaction to Russian policy, and in 1904 Governor General Bobrikov was assassinated. The Russo-Japanese War saved Finland

from an immediate Russian reaction and led instead to the 1906 reform. After a few years, however, "russianization" was resumed in earnest. In 1910 it was decreed that all important laws should be passed by the Russian Duma (Parliament). By late autumn 1914 a program for Finland's annexation to Russia was announced.

The *struggle for independence*. During World War I the Finnish liberation movement sought support from Germany, and a number of young volunteers received military training and formed the Jagar Battalion. After the Russian Revolution in March 1917, Finland obtained its autonomy again, and a Senate, or coalition government, took over the ruling of the country. By a law of July 1917 it was decided that all the authority previously wielded by the tsar (apart from defense and foreign policy) should be exercised by the Finnish Diet. After Russia was taken over by the Bolsheviks in November 1917 the Diet issued a declaration of independence for Finland on December 6, 1917.

ICELAND

The Treaty of Kiel (1814). By the Treaty of Kiel in 1814, when Denmark ceded Norway to Sweden, it was explicitly decided that Iceland, Greenland, and the Faeroe Islands, which belonged to the united Danish-Norwegian kingdom, should remain under the Danish crown. As these outlying lands, especially Greenland, were formerly considered as belonging to Norway, Norway protested against the decision. The Treaty of Kiel did not change the status of Iceland. The country remained under the king of Denmark and was ruled by a landsfoged (governor) nominated by him. When Denmark introduced provincial consultative diets in 1834, Iceland was represented by two members in the Roskilde Diet. In 1838, however, a separate council of higher civil servants was established in Reykjavik, and in 1843 a separate provincial advisory body, which took the old Icelandic name Althing, was set up.

Demands for self-government. Under the influence of the National Liberal movement in the 1830s and 1840s, a nationalistic Icelandic movement arose and, under the leadership of Jón Sigurdsson, demanded a much more independent position for Iceland. During the drawing up of the 1849 Danish constitution, Iceland demanded complete internal self-government and a union consisting only of a joint monarchy and a common foreign policy. In 1851 an Icelandic national meeting was held to discuss the question of the country's relations with Denmark, but no positive result was reached. After long-drawn-out negotiations, Denmark resolved in 1871 to implement a provisional solution by which Iceland was declared an integral part of the Danish kingdom but with special internal rights. Iceland refused to accept this decision and continued to press for complete internal self-government.

This policy was shortly afterward crowned with success. When Christian IX visited Iceland in 1874, on the occasion of the country's 1,000-year jubilee, he granted Iceland its own constitution, which in all essentials fulfilled the demand for home rule. Icelandic affairs still continued under the supervision of a special minister in the Danish government, however, and this led to repeated conflicts during the 1880s and 1890s between the Althing and the Danish government.

It was not until 1903, two years after the "Change of System" (the year when parliamentary democracy made its breakthrough in Denmark) that Iceland was granted its own national government by the establishment of a separate ministry for Iceland in Reykjavik. Under the leadership of Hannes Hafstein a number of social and economic reforms were carried out during the years preceding World War I. These included the modernization of the fishing fleet, which was implemented during the 1890s and the first decade of the 20th century. The old farming community began to be replaced by an organized industrial way of life. The demand for complete internal self-government was not realized, however, before the Act of Union of 1918, which made Iceland a completely independent state, united with Denmark solely by the monarchy and a common foreign policy.

VI. The 20th century

DENMARK

Liberal rule. The Venstre government that came to power under the "Change of System" in 1901 went swiftly to work on a number of reforms. A free-trade law that corresponded to the agricultural export interests was passed; in conformity with the ideas of the 18th-century theologian N.F.S. Grundtvig, the state church was transformed into a folk church with parochial church councils; the educational system was democratized; and changes in the system of taxation were effected so that income and not land was the main criterion for taxation. After the victory over the Conservatives (*Højre*) it became apparent that it was impossible for Venstre, led by J.C. Christensen, to remain united. In 1905, therefore, the radical faction broke away to become the Radical-Liberal Party (Det Radikale Venshe), the most important members of which were Peter Munch and Ove Rode. Between 1913 and 1920 the Radicals, supported by the Social Democrats, were in power. In 1915 the constitution was revised, and the privileged franchise to the Landsting was revoked, although the electoral qualifying age of 35 was retained. At the same time, the franchise to both the Folketing and the Landsting was extended to women, servants, and farm hands. The right-wing majority in the Landsting agreed to the constitutional reform on condition that the single-member constituency be replaced by proportional representation. There followed a number of reforms, including a judicial reform introducing trial by jury and a land reform bill that aimed to redistribute land from the large estates to increase the size of smallholders' farms.

Foreign policy and World War I. After the Franco-German War (1870–71), Danish foreign policy was developed along strictly neutral lines. There were strong differences of opinion between *Højre* and Venstre on the way in which this should be carried out. *Højre* demanded a strong defense policy and J.B.S. Estrup carried through by provisory law the fortification of Copenhagen. Within Venstre itself there was disagreement on the lines the neutrality should take. The most radical viewpoint was held by Viggo Hørup, who wanted complete disarmament. After the split within Venstre in 1905, the Radical Liberal Party continued Hørup's ideas. In the years before 1914, it became increasingly important to define Germany's intended attitude to Denmark in the event of a European conflict. The Germans were well aware that the Schleswig affair had left a good many Danes with a loathing for everything German, while the constant friction between the Danish minority and the German administration in Schleswig added fuel to the flames. Successive Danish governments after 1901 made persistent efforts to assure Germany of Denmark's benevolent neutrality, but there was wide disagreement between the parties on the means Denmark should employ to maintain its neutrality. At the outbreak of war, Germany forced Denmark to lay mines in the Store Bælt in August 1914, and as the British fleet made no serious attempts to break through, neutrality was maintained.

World War I gave Denmark, together with a number of other neutral countries, an extremely good export market to the belligerent countries but an inevitable shortage of supplies. With a widespread overseas trade, the country's economic life was exceedingly vulnerable and became especially so after Germany opted for unrestricted submarine warfare from 1917 on. Denmark's exports to Great Britain were, to a certain extent, reoriented to Germany. There was a shortage of raw materials in both agriculture and industry, and the government rationed a number of consumer goods and controlled the country's economic life to a certain extent.

The interwar period. By the Treaty of Versailles it was decided that part of Schleswig should revert to Denmark in accordance with the principle of self-determination. The boundary was determined by a plebiscite in 1920. The discontent that arose as a consequence of the drawing of the boundary, coupled with labour unrest and dissatisfaction with remaining wartime restrictions, led to the fall of the government in the same year. It was suc-

ceeded by a Venstre (Liberal Democratic) government supported by the Conservatives. From 1924 to 1926 the Social Democrats, under the leadership of Thorvald Stauning and supported by the Radicals, were in power. The years 1926 to 1929 saw Venstre in power again, supported by the Conservatives. The recurring problem for the governments of the 1920s was the critical economic conditions that followed World War I. In 1922 the country's largest private bank, Landmandsbanken, failed. At times unemployment reached a high level. The Social Democrats scored a great victory at the polls in 1929, and a coalition government was formed with the Radical Party under the leadership of the Social Democrat Stauning, with Peter Munch as foreign minister.

Economic crisis. The Great Depression of the early 1930s led to unemployment, which in 1933 affected 40 percent of the organized industrial workers. When Great Britain went off the gold standard in 1931, Denmark followed suit. The greatest blow to the Danish economy, however, was the system of preferential Commonwealth tariffs established in 1932. To cope with the crisis, the government subjected foreign trade to stringent control by the establishment of a "currency centre," and won the support of Venstre in the "Kanslergade compromise," by which it was agreed to devalue the krone and to freeze existing wage agreements by law. In addition, Venstre supported social reforms that included old-age pensions and health, unemployment, and accident insurance. A number of measures were also adopted in support of agriculture. The general election of 1935 returned the Social Democrats again, and after the elections to the Landsting in 1936 the government coalition of Social Democrats and Radicals held the majority in both the Folketing and the Landsting. Trade improved, and during the late 1930s industry again began to expand.

Foreign policy. Denmark had joined the League of Nations in 1920 and had worked for a peaceful solution to international problems during the whole of the inter-war period. When Adolf Hitler came to power and Germany began to rearm, Denmark's position was again very vulnerable. Although Germany had never recognized the alteration in its boundary as laid down by the Treaty of Versailles, Hitler did not raise the matter. Under Foreign Minister Munch's leadership, Denmark tried in vain during the 1930s to obtain recognition of the boundary, and at the same time it avoided all measures that might possibly offend its powerful neighbour. When in the spring of 1939 Hitler offered nonaggression pacts to those countries that might feel threatened by Germany's expansionist policy, Denmark, in contrast to the other Scandinavian countries, accepted the offer.

Denmark during World War II. On the outbreak of war in 1939 Denmark, in common with the other Nordic countries, issued a declaration of neutrality. On April 9, 1940, German troops crossed the border, and after token resistance the Danish government submitted to a military occupation of the country. Formally, however, Denmark remained a sovereign state until August 29, 1943, and in this its position differed from the other occupied countries of Europe. A coalition government was formed by the major parties, with Thorvald Stauning as leader, and in July 1940 Erik Scavenius became foreign minister. When Germany attacked the Soviet Union, the Danish government was forced to allow the formation of a Danish volunteer corps and at the same time to forbid all Communist activity in the country. In November 1941, Denmark signed the Anti-Comintern Pact.

Stauning died suddenly in May 1942 and was succeeded by Vilhelm Buhl, who was forced to resign in November of the same year under pressure from the Germans. He was succeeded by Erik Scavenius. The elections of 1943 proved to be a great national demonstration that the people were united in support of the four old democratic parties and the fight against Nazism. At the same time, the resistance movement was organized, and Germany's military defeats paved the way for demands for an open breach with the powers of occupation. Dissatisfaction caused by consumer shortages and inflation, combined

with the growing opposition to German occupation, led to a series of strikes in the summer of 1943 that in August culminated in actions aimed directly at the Germans. When the Danish government refused to introduce the death penalty for sabotage, allow persecution of Jews, or use force against the strikers, the Germans declared a state of emergency. The Danish government ceased to function and the German *Reichskommissioner* assumed political control. The Danish army and navy were disbanded but not before many of the ships were scuttled by their own crews.

In September 1943 the Danish Freedom Council was formed, and under its leadership the resistance movement was organized, mainly in the form of illegal newspapers, a comprehensive intelligence service, and numerous acts of sabotage. During the last year of the war, closer cooperation began between the Freedom Council and leading politicians. When the Germans surrendered, on May 5, 1945, a government was formed consisting half of representatives of the Freedom Council and half of politicians from the old political parties. After elections in the autumn of 1945, a Venstre government came to power, led by Knud Kristensen.

The postwar period. The first task after the liberation was to take legal proceedings against German collaborators. By a retroactive law these persons were brought to trial and sentenced to death or given long-term prison sentences. Another consequence of the war was that the Schleswig question arose once more. The Nazi dictatorship and the great numbers of refugees fleeing from eastern Germany to South Schleswig caused a reaction that won the Danish faction strong support among the local population. In Denmark opinion was divided, but when the United Kingdom in the autumn of 1946 made inquiries about Denmark's opinion on the boundary, all the parties agreed in the October Note of 1946 to reject any alteration to the boundary. After the elections of 1947, when Knud Kristensen's government was replaced by a Social Democratic minority government led by Hans Hedtoft, all plans to pursue an active policy concerning the boundary question were abandoned.

Defense policy. When the tensions between the great powers grew in 1948, the question of affiliation to a defensive alliance became urgent. Sweden took the initiative in proposing the formation of a Nordic defense union. Denmark, under the leadership of Hedtoft, was favourably disposed, but because of differences between Sweden and Norway it came to nothing. Denmark thus became a member of the North Atlantic Treaty Organization (NATO) in April 1949. Denmark's military defense later was considerably strengthened by statutes in 1950 and 1951 and was further complemented by armaments from the United States. Denmark nevertheless rejected a request by the United States to establish air bases on Danish territory. With the Federal Republic of Germany's admission to NATO, Denmark succeeded in obtaining guarantees—confirmed in the Bonn Protocol of 1955—for the rights of the Danish minority in South Schleswig.

Domestic affairs. The domestic scene was dominated during the early 1950s by economic difficulties resulting from inflation. The 1950 coalition government of Venstre and the Conservatives, under the leadership of Erik Eriksen, fought the crisis with greatly increased taxation and various forms of compulsory savings. The constitution was revised in 1953, abolishing the Landsting. The Danish national legislature now consisted of only one chamber, the Folketing, the membership of which was increased to 179. King Frederick IX, who had succeeded Christian X in 1947, signed the new constitution on June 5, 1953.

After the election of 1953, the Radicals declined to support the government, which was replaced by the Social Democrats led by Hans Hedtoft and, after his death in 1955, by H.C. Hansen. The election of 1957 resulted in a very complicated parliamentary situation, as no single party was able to form a government. After a prolonged crisis, a coalition of Social Democrats, Radicals, and the small Georgist, or Single-Tax, Party (Retsforbund) was formed. The Georgist Party left the government in 1960

Rise of
GermanyMember-
ship
in NATO

and the Radicals in 1964, but the Social Democrats remained in power under Jens Otto Krag. The election of 1968 resulted in a coalition of the Venstre, Conservatives, and Radicals. After the 1971 elections Krag formed a new Social Democratic government. He resigned in October 1972 and was replaced by Anker Jørgensen. Frederick IX, who died in 1972, was succeeded by his daughter, Margrethe II.

Economic issues. Among the main issues in Danish politics during the 1950s and '60s were the frequently negative balance of payments, the labour market, and the country's trade policy. During the early '50s, the Danish economy suffered a large deficit in the trade balance. The situation improved during the later '50s as the result of lower import prices for raw materials, a considerable increase in industrial production, and the stabilization of prices of agricultural export products. The period 1957 to 1965 was marked by rapidly rising prosperity. During the 1960s, however, the balance of payments deficit became larger, and the government was forced to intervene in an attempt to control rising consumption. This was done by a purchase tax in 1962, by compulsory savings, by intervention in labour conflicts, and by the regulation of wages and prices. Within the framework of the Organization for European Economic Co-operation (OEEC) Denmark, during the 1950s, abolished most of the regulations that had restricted its foreign trade, and it was one of the countries that became a member of the European Free Trade Association (EFTA) on its formation in 1959. Negotiations for Danish membership in the European Economic Community (EEC), or Common Market, were conducted in 1961–63 and 1970–72. Denmark was offered, and accepted, EEC membership in 1972, effective January 1, 1973.

After 1973, rising oil prices and the international depression affected the Danish economy badly and led to an increase of unemployment, up to 10 to 14 percent of the organized labour force.

Political development during the 1970s. Because of controversy between the left-wing parties, the Folketing rejected a tax bill introduced by the government in 1973, leading to dissolution of the Folketing. In the following election, in December, all five of the old parties incurred heavy losses; the victors were two new parties, Fremskridtspartiet (Progress Party), on the extreme right wing, and Centrums Demokraterne (Democratic Centre), consisting of the right-wing faction of the Social Democrats. The non-Socialist parties gained a solid majority, and the Social Democratic government resigned and was replaced by a Venstre government with Poul Hartling as prime minister. Despite being a minority government, holding only 22 seats in the Folketing, Venstre succeeded in conducting a firm policy, resulting in a harsh savings program. The demand for drastic measures to prevent further increase of unemployment, however, caused the fall of the government, and new elections were held in January 1975. In spite of the great success of Hartling's own party (Venstre), he was forced to resign when the government suffered defeat in the Folketing on January 28, and Anker Jørgensen formed a Social Democratic government. This government strengthened its position in the election of February 1977, without, however, gaining a majority in the Folketing. As a consequence the government was reorganized in 1978 as a coalition, including representatives of Venstre, under the leadership of Jørgensen.

SWEDEN

The introduction of parliamentary democracy. The economic expansion that started in the early 19th century laid the foundations for internal developments in Sweden during the 20th century. The turning point came during and immediately after World War I. There was suddenly a worldwide demand for Swedish products such as steel and pulp, matches and ball bearings, telephones and vacuum cleaners. The composition of the population underwent a decisive change, and Sweden was transformed from an agricultural to a modern industrial country.

Political reform. Politically, the economic develop-

ment meant that a universal and equal franchise was more and more vociferously demanded. The issue was solved in 1907 by a compromise submitted by a Conservative government under the leadership of Amund Lindman. The motion granted a universal and equal franchise for the Second Chamber, a certain democratization of the First Chamber, and proportional representation for elections to both chambers of the Riksdag. The elections to the Second Chamber in 1911 produced a landslide victory for the Liberal Party (Liberala Samlingspartiet) and Gustav V (ruled 1907–50) was forced to ask Karl Staaff to form a Liberal government.

Defense policy. One of the most important points of Liberal policy in 1911 was a decrease in military expenditure. The realization of this demand led to sharp conflicts between Gustav V and Staaff. As the tension between the Great Powers grew, a farmers' rally was organized, and 30,000 farmers from all over the country sought out the King and demanded that the country's defenses be strengthened. In his reply (Borggrädstalet, the Courtyard Speech) the King promised to reinforce the military defenses. As he had given this pledge without having consulted the government, it resigned, and the King appointed a civil servant government with Hjalmar Hammarskjöld as prime minister.

Policy during World War I. During World War I, Sweden attempted to remain neutral and to assert its right to trade with the belligerent countries. For Great Britain, the blockade was an important weapon, and Sweden's demand to import freely favoured Germany exclusively. As a result, the Allies stopped a large percentage of Sweden's trade. This, however, not only affected Sweden's exports to Germany but from 1916 caused a severe shortage of food. The situation was worsened by unrestricted submarine warfare and by the entry of the U.S. into the war in 1917. Hammarskjöld was forced to resign; he was followed by a Conservative government and shortly afterward by a Liberal one, both of which conducted a more diplomatic trading policy with the Allies. In May 1918 an agreement was reached with Great Britain and the U.S. that allowed Sweden again to import produce from the West, on condition that exports to Germany be limited and that a large part of Sweden's merchant fleet be put at the Allies' disposal.

The Social Democrat–Liberal coalition. In the general election of 1917, the left-wing parties (the Social Democrats and Liberals) secured a further increase in their majority in the Second Chamber, and the King was obliged to choose a Liberal–Social Democratic government. Under Nils Edén, the new government, as one of its first measures, amended the constitution. The main issues were woman suffrage and the introduction of a universal and equal franchise for elections to the First Chamber and in local elections.

Domestic policy (1918–45). *Party politics.* From 1920 onward, a line was drawn between the Socialist parties on one side and the Liberals and Conservatives on the other. The regrouping of the parties in Swedish politics did not produce any dynamic changes. From 1920 to 1932 the parties held power alternately, but no government—whether Social Democratic, Liberal, or Conservative—had any chance of gaining firm support for its policy in the Riksdag. From a political viewpoint the 1920s were a period of stagnation.

The economic climate. From an economic point of view, however, the picture was quite different. The 1920s were marked by steadily improving trade conditions, and in this boom period Sweden was one of the countries that prospered significantly.

Like other countries, Sweden suffered severely during the Great Depression of the early 1930s. Unemployment rose, and reductions in wages caused a series of harsh labour conflicts. The election of 1932 brought a considerable advance to the Social Democratic Party, and to some extent to the Farmers' Party as well, and led to a Social Democratic administration under the leadership of Per Albin Hansson. It offered a comprehensive policy to fight the crisis, including extensive public works and a number of moves in support of agriculture. This policy

Trade
deficits

The
Courtyard
Speech

The
Great
Depression

was subjected to scathing criticism by the right-wing parties, but an agreement reached with the Farmers' Party in 1933 made it possible to implement the program. The economic crisis of the '30s was overcome more rapidly in Sweden than in most other countries. As early as 1936, wages had reached their old level, and by the end of the decade unemployment had become insignificant.

From a political point of view, the '30s were a time of preparation, when a series of bills for radical reforms was worked out. The whole program could be summarized in the term *folkhemmet*, in which society is viewed as a "home" for the people, taking care of their needs in unemployment, sickness, and old age, but with the advent of World War II in 1939, reforms were postponed because of rising military expenditure and supply difficulties.

Foreign policy (1918–45). When World War I ended, Russia and Germany were among the defeated nations, and Sweden thus found itself in an unusually good position regarding external security. In 1925 military expenditure was considerably reduced. Problems regarding foreign policy were confined to Sweden's application for membership in the League of Nations, which was granted in 1920, and to its relationship with Finland.

When the Civil War in Finland ended, the problem of Åland re-emerged. The inhabitants of the Åland Islands (Finnish *Ahvenanmaa*) were purely Swedish-speaking, and a plebiscite revealed that almost all were in favour of affiliation to Sweden. The League of Nations, however, decided in 1921 to award Finland the sovereignty of the islands, though with certain conditions pertaining to internal self-government and limiting the right to fortify or otherwise utilize the islands for military purposes.

Hitler's rise to power resulted in a re-examination of Sweden's defense policy, which in 1936 was amended to strengthen the country's defenses. Sweden followed a strictly neutral course, in close collaboration with the other Scandinavian countries and The Netherlands, Belgium, and Switzerland. As a consequence, Hitler's proposal in the spring of 1939 for a nonaggression pact was rejected. Sweden's attempt to form a Nordic defense union or, if that could not be achieved, a Swedish–Finnish defense alliance led to nothing, primarily because the Soviet Union objected.

On the outbreak of war in 1939 Sweden declared itself neutral. When the Soviet Union shortly afterward launched an attack on Finland, Sweden gave Finland aid in the form of vast material supplies and a volunteer corps organized with the support and consent of the authorities. On the other hand, Sweden, in common with Norway, refused the request made by the Allies to march through Sweden in order to intervene in the war. After the German occupation of Denmark and Norway in 1940, however, Sweden was forced by German military superiority to allow the transit of German troops through Sweden to Norway. Many Norwegians and Danes sought refuge in Sweden, the majority of them with the intention of fleeing to England. When Germany attacked the Soviet Union in June 1941, transit facilities were demanded for a division of German troops from Norway to Finland, and Sweden acquiesced under threat of military reprisals. In 1943 the agreement concerning the transit of German troops was revoked. Toward the end of the war, Norwegian and Danish police were trained and equipped in Sweden. Immediately after the war, Sweden was granted membership in the United Nations, without having relinquished its principally neutral foreign policy.

The welfare state. The coalition government that was formed in 1939 was replaced shortly after the end of the war in 1945 by a Social Democratic government under the leadership of Per Albin Hansson. After his death in 1946, Tage Erlander became prime minister, a post that he held until his resignation in 1969. He was succeeded by Olof Palme, who took over the leadership of the government without any other changes being made in its composition.

The period of social reform. The period 1946 to 1950 may justly be called the great period of reform, during which new, comprehensive laws were adopted concerning

old-age pensions, child allowances, health insurance, rent allowances, educational reforms, and the expansion of universities and other institutions of higher education and research. Those parts of the Social Democrats' postwar program that aimed at nationalization of industry were not, however, carried through. By tax reorganization the government tried, however, to achieve wider distribution of wealth.

Surprisingly, the years after World War II had been marked by stable trading conditions and a scarcity of labour. During the Korean War, the boom reached its climax, entailing large price rises and rapid inflation. A recession followed at the end of 1951. In Sweden this meant that the upward movement of prices and incomes was interrupted, and for the first time since World War II there was a rise in unemployment. Even though the crisis of 1951–52 was neither serious nor long, it drew attention to the problems of economic stability. The Social Democrats now became primarily preoccupied with securing the advances already achieved. They began to collaborate with the Farmers' Party, and in the autumn of 1951 the Social Democratic government was replaced by a coalition government consisting of Social Democrats and Farmers, which lasted until 1957.

In the late 1950s the question of a compulsory pension for all employees became a principal political issue. The opposition fought it energetically, mainly because it was feared that control of the pension fund would create a latent risk of complete Socialism; the government finally enacted the bill in 1959.

New constitution. In 1955 a committee to review the constitution of 1809 (the Instrument of Government) was appointed. On its recommendations, the old two-chamber Riksdag was replaced in 1971 by a one-chamber Riksdag composed of 350 members elected by proportional representation. The new Instrument of Government, which entered into force on January 1, 1975, reduced the membership of the Riksdag to 349 (to minimize the risk of evenly divided votes) and the voting age to 18. It also further curtailed the powers and duties of the king, to a point merely ceremonial. King Carl XVI Gustaf, who succeeded Gustav VI Adolf in 1973, was the first king to serve under the new constitution.

Foreign policy. Sweden's foreign policy since 1945 has remained strictly neutral. When the international situation became tense in 1948 during the Berlin blockade, the Swedish government took the initiative in negotiations on a defense alliance between Sweden, Norway, and Denmark. Sweden insisted that the alliance should be truly independent of the great powers, while Norway wanted cooperation with the Western powers, and so negotiations fell through. In accordance with its policy of neutrality, Sweden has not applied to join the European Economic Community (EEC). Trading policy has been aimed at liberalizing trade, and this has been pursued in close connection with the United Kingdom, with which Sweden participated in the establishment of the European Free Trade Association (EFTA) in 1959. Although the Nordic defense alliance was not achieved, Scandinavian collaboration has been intensified by the Nordic Council, formally inaugurated in 1952. Among the important results of the council's work, passports are not required between the countries, a free labour market was created, and a far-reaching coordination of economic and social legislation took place. Conversely, the plans for a Scandinavian customs union, which were discussed during the 1960s, led to no result.

Domestic affairs during the 1970s. In the election of 1970, the Social Democrats lost the absolute majority they had held since 1968, but in spite of this the Social Democratic government of Olof Palme continued in office with the support of the Communists. Social Democrats remained in office until the election of 1976, when the non-Socialist parties won a majority. *Palme's* resignation brought an end to 44 years of Social Democratic domination. The non-Socialists formed a coalition government, consisting of the Moderata Samlingspartiet (Moderate Coalition Party; conservative), Folkpartiet (Liberal Party; liberal), and Centerpartiet (Centre

The

question

The
retirement
pension
controversy

Party; agrarian), with Thorbjörn Fälldin (Centerpartiet) as prime minister.

The international economic crisis after 1974 caused considerable unemployment, and in consequence the rapid growth of the Swedish standard of living ceased. Political discussion focussed on demands for industrial democracy, conservation, and the energy problem, above all the question of nuclear power. It was the last that brought down Fälldin, who had campaigned for cessation of building nuclear power plants, who had been forced to compromise on the issue, whose coalition was rent with dissension, and who resigned on October 5, 1978. He was succeeded on the 13th by Ola Ullsten, leader of the Folkpartiet, who formed a minority government in which one-third of the ministers were women.

NORWAY

Economic and industrial growth. The period 1905 to 1914 was characterized by rapid economic expansion in Norway. The development of the merchant fleet, which had begun during the second half of the 19th century, continued, and at the outbreak of World War I Norway's merchant navy was the fourth largest in the world.

From about the turn of the century, Norway's immense resources of waterpower provided a base for great industrial expansion. The large number of waterfalls bought by Norwegian and foreign companies gave rise to grave concern that the country's natural resources were falling into foreign hands or becoming monopolized by a small number of capitalists. In 1906 three-quarters of all developed waterpower in Norway was owned by foreign concerns. Venstre and the growing Norwegian Labour Party pressed for legislation to protect the natural resources of the country. The proposed bill on concessions (later known as the Concession Laws) played a dominating role in Norwegian politics from 1905 to 1914. It led to a split in the Venstre, but the majority of Venstre supported the bill, which was passed by the Storting in 1909 and remained in force despite continued criticism. In 1887 the Norwegian Labour Party (Det Norske Arbeiderpartiet, or DNA) was founded, and universal suffrage was one of the principal points in the party program. In the 1890s Venstre likewise adopted this policy, and in 1898 universal male suffrage was introduced. By new reforms in 1907 and 1913 the vote was extended to women. One consequence of industrialization and the introduction of universal suffrage was the growing influence of the DNA. A number of social reforms were enacted: a factory act, which included protection for women and children, accident insurance for seafaring men, health insurance, and in 1915 a law on a 10-hour working day.

Norway in World War I and the interwar years. *World War I.* With the outbreak of war in 1913, Norway, like Sweden and Denmark, issued a declaration of neutrality. Norway was badly injured by the war at sea, about half of Norwegian merchant shipping being lost. As the Allied powers could almost totally control Norway's foreign trade, they forced it to break off exports of fish to Germany, and at the same time they forbade exports of iron pyrites and copper, which were important commodities for the German war industry. Because of the many casualties caused by submarine warfare, public feeling in Norway was strongly anti-German. The government, however, under the leadership of the Venstre politician Gunnar Knudsen, insisted upon maintaining the appearance of neutrality. The war brought a distinct boom to Norway, although prosperity was unevenly distributed. The steeply rising prices imposed hardships on the working classes and the lower income civil servants. Within the DNA, the left wing formed the majority in 1918, and in 1919 the DNA, unlike the other Social Democratic parties in western and central Europe, joined the Comintern (Third Communist International). The DNA, however, was unwilling to submit to the centralization that Moscow demanded, and in 1923 it withdrew.

The Great Depression. In the years up to 1935 the various governments—formed alternately by the Conservatives, the Liberals (Venstre), and the Farmers'

Party—pursued, by and large, a liberal economic policy. After the inflation caused by World War I and the post-war years, the main aim during the 1920s was to guide the currency (the krone) back to its former value. Norway received only an insignificant share in improved world market conditions, and by 1927 the unemployment figures were as high as 20 percent of the organized labour force. The Great Depression in the early 1930s increased unemployment still further, and by 1933 at least 33 percent of the work force, including many civil servants, was unemployed.

The government, led by the Farmers' Party (1911–33) and Venstre (1933–35), tried to combat the crisis with extensive reductions in governmental expenditure but refused to consider an expansionist financial policy or the emergency relief measures that the Norwegian Labour Party demanded. The DNA thus enjoyed great success in the elections of 1933, although failing to gain a majority in the Storting. When the DNA formed the government in 1935, with Johan Nygaardsvold as prime minister, it needed the support of at least one other party. By a compromise with the Farmers' Party, which included a number of measures in support of agriculture, the DNA received support for a social program that included old-age pension reform, revision of the factory act, statutory holidays, and (some years later) unemployment insurance financed by increased taxation. State investments were also greatly increased. Although the situation was improved, unemployment in Norway was still as high as 20 percent of the organized labour force in 1938.

Despite economic difficulties, the high rate of unemployment, and the many labour conflicts, the interwar years were a period of vigorous expansion and the country's industrial production was increased by 75 percent during the years 1913 to 1938.

Foreign policy. During the 1920s, Norway acquired Svalbard and Jan Mayen, and Norwegian hunters and fishermen occupied an area on the east coast of Greenland. Denmark's demand for sovereignty of the area led to a conflict that was settled in the Permanent Court of International Justice in The Hague in 1933 in Denmark's favour. As the League of Nations in 1936 had proved ineffective at keeping the peace, Norway's foreign minister, Halvdan Koht, made strenuous efforts within the framework of the League to coordinate the policy of the smaller states in an effort to preserve peace. Norway continued to pursue a strictly neutral policy and declined Germany's invitation to join in a nonaggression pact in 1939.

Norway during World War II. With the outbreak of hostilities in 1939 Norway declared itself neutral. On April 9, 1940, German troops invaded the country and occupied Oslo, Bergen, Trondheim, and Narvik. In contrast to Denmark, the Norwegian government rejected the German ultimatum regarding immediate capitulation. The Norwegian Army, which received help from an Allied expeditionary force, was unable to resist the superior German troops, however. After three weeks the war was abandoned in southern Norway. The Norwegian and Allied forces succeeded in recapturing Narvik but withdrew again on June 7, when the Allied troops were needed in France. Some days later the Norwegian troops in northern Norway capitulated, and the King and the government fled to London. The Norwegians in London were augmented considerably by the Norwegian merchant navy—directed from the Norwegian Shipping and Trade Mission (Nortraship) in London—which played an important part during the war. The war, however, caused the loss of half of the merchant fleet.

In Norway, Vidkun Quisling, leader of the small Norwegian Nazi party (Nasjonal Samling, or National Union), proclaimed on April 9 his intention of forming a national government. This aroused such strong resistance, however, that the Germans thrust him aside and organized an administrative council instead, consisting of apolitical civil servants. Political power was wielded by the German commissioner, Josef Terboven. In September 1940 the administrative council was replaced by a number of "commissarial counsellors" who in 1942 formed a

Social reforms

The German invasion

Concession Laws

Dependence on foreign trade

Nazi government under the leadership of Quisling. The "nazification" attempt aroused strong resistance. To begin with, this took the form of passive resistance and general strikes, which the Germans countered with martial law and death sentences. At the same time, the resistance movement became more firmly organized and undertook large-scale industrial sabotage, of which the most important was that against the production of heavy water in Rjukan in southern Norway.

At the end of the war, the German troops in Norway capitulated without offering resistance. Only the most northerly part of the country was ravaged by the German retreat from Finland in the winter of 1944–45.

The postwar period. The liberation was followed by trials of collaborators; 24 Norwegians, including Quisling (whose name has gone down in history as a byword for a traitor), were sentenced to death and executed, and 19,000 received prison sentences. By a strict policy that gave priority to the reconstruction of productive capacity in preference to consumer goods, Norway quickly succeeded in repairing the damage caused by the war. By 1949 the merchant fleet had attained its prewar size, and the figures for both industrial production and housing were greater than in the 1930s. During the postwar period, until the mid-1970s, Norway enjoyed full employment and a swiftly rising standard of living.

Political and social change. After the liberation in 1945, a coalition government was formed under the leadership of Einar Gerhardsen. The general election in the autumn of 1945 gave the Norwegian Labour Party a decisive majority, and a purely Labour government was formed with Gerhardsen as prime minister. The DNA governed from 1945 to 1965 except for a few weeks in 1963 when a right-wing government came to power. The various Labour governments continued the social policies initiated in the 1930s. A law on a general retirement pension was passed in 1956 and a law on social welfare replaced the former "poor law" in 1964.

The election of 1965, however, resulted in a clear majority for the four right-wing parties—Høyre (Conservative), Venstre (Liberal), Senterpartiet (Centre), and Kristelig Folkeparti (Christian People's), which formed a coalition government under the leadership of Per Borten. In the spring of 1971 there was a split within the coalition government, and the DNA again came to power, headed by Trygve Bratteli.

As a consequence of the referendum on the EEC (1972; see below), the Labour government resigned and was followed by a non-Socialist coalition government under the leadership of Lars Korvald. After the election of 1973, which resulted in a majority for the Socialist parties, the DNA returned to power with Bratteli again as prime minister. When he resigned as leader of the party and prime minister in 1976, he was succeeded by Odvar Nordli. The election of 1977 resulted in a majority of only one seat for the two Socialist parties (DNA and the Socialist Left Party, or Sosialistisk Venstreparti), but Nordli decided to stay in office. In the 1970s the main question in Norwegian politics was how to exploit the rich oil deposits in the Norwegian part of the North Sea. The oil industry has not been as prosperous as expected, however, and it has also caused a sharp rise in the domestic price level.

Postwar foreign policy. When the antagonisms between the great powers came to a head in 1948, Norway took part in the negotiations set in motion by Sweden on a Nordic defense union. Norway, however, was not willing to participate unless a clear guarantee of help from the Western powers was obtained, while Sweden stood firm on a neutral policy. In 1949 Norway and Denmark joined the newly formed North Atlantic Treaty Organization (NATO), within the framework of which Norway's defense system was greatly reinforced though NATO was not allowed to establish airfields or to stockpile atomic weapons on Norwegian territory.

Another aspect of foreign policy was the question of Norway's proposed membership in the European Economic Community (EEC). Since 1959 Norway has been a member of the European Free Trade Association

(EFTA). In 1972 it rejected the invitation to join the EEC after a referendum on the issue.

Foreign policy during the later 1970s was dominated by disputes with the Soviet Union over concessions at Spitsbergen and over the boundary between Norway and the Soviet Union in the Barents Sea of the Arctic Ocean. The latter problem, once merely an esoteric legal issue, took on great importance when it was discovered that extensive deposits of petroleum and natural gas probably lay beneath the shallow waters.

FINLAND

Between the wars. *The Civil War.* With its declaration of independence, Finland was recognized as an independent state in 1918. Although the liberation from Russia occurred peacefully, Finland was unable to avert a violent internal conflict. After the revolutionaries had won control of the Finnish Social Democratic Party, they went into action and on January 28, 1918, seized Helsinki and the larger industrial towns in southern Finland. The right-wing government led by Pehr Evind Svinhufvud of the National Coalition Party fled to the western part of the country, where a counterattack was organized under the leadership of Gen. Carl Gustaf Mannerheim. At the beginning of April the White Army under his command won the Battle of Tampere (Tammerfors). German troops also came to the aid of the government, and by May the rebellion had been suppressed. It was followed by trials in which harsh sentences were passed.

Political change. When the Civil War ended, it was decided, during the summer of 1918, to make Finland a monarchy, and in October the German prince Frederick Charles of Hessen was chosen as king. With Germany's defeat in the war, however, General Mannerheim was designated regent, with the task of submitting a proposal for a new constitution. As it was obvious that Finland was to be a republic, the struggle now concerned presidential power. The liberal parties wanted power to be invested in the Eduskunta (Parliament), while the conservatives wanted the president to have powers independent of the Eduskunta. The strong position held by the conservatives after the Civil War enabled them to force through their motion that the president should be chosen by popularly elected representatives, independent of the Eduskunta, and also that he should possess a great deal more authority, especially regarding foreign policy, than at that time was usual for a head of state. After the new constitution had been confirmed on July 17, 1919, Kaarlo Juho Ståhlberg, a member of the National Progressive Party, was elected first president of Finland.

Agrarian reform. During the interwar years Finland, to a much greater extent than the rest of Scandinavia, was an agrarian country. In 1918, 70 percent of the population was employed in agriculture and forestry, and by 1940 the figure was still as high as 57 percent. Paper and wooden articles were Finland's most important export commodities. By the Smallholdings Law of 1918 and by a land reform in 1922, which allowed the expropriation of estates of more than 495 acres (200 hectares), an attempt was made to give tenant farmers and landless labourers their own smallholdings. More than 90,000 smallholdings were created, and since then the independent smallholders, who form the majority of the Agrarian Party (now the Centre Party, or Keskustapuolue), have been a major factor in Finnish politics.

Political parties. During K.J. Ståhlberg's period as president (1919–25), the right-wing parties and the Agrarian Party held power by means of coalitions. During this period the president tried determinedly to minimize the recriminations of the Civil War, and in the course of time he granted amnesty to those who had received long terms of imprisonment. At the same time, the Finnish Social Democratic Party was reorganized under the leadership of Vaino Tanner with an exclusively reformist program. When Tanner in 1926 formed a Social Democratic minority government, which granted a general amnesty, the old differences from the Civil War had been almost eliminated. Lauri Kristian Relander, the Agrarian Party's candidate, was elected president in 1925.

Labour
govern-
ment

The new
constitution

The
Lapua
Movement

As a reaction to the growing Finnish Communist Party, the Lapua (Lappo) Movement emerged, which in the years 1929–32 attempted to force its demands through by actions against Communist newspapers, acts of terrorism against individual citizens, and mass demonstrations. These actions, which were supported by the conservatives and many members of the Agrarian Party, were at first successful. After the election of 1930, an anti-Communist law was forced through that resulted in the banning of public activity by the Finnish Communist Party. In 1931 P.E. Svinhufvud was elected president with the help of the Lapua Movement. When the Lapua Movement shortly afterward turned its activities against the Social Democrats, too, and tried to seize power by force in the Mantsala Rebellion in 1932, the president intervened and crushed the rebellion. Another failure at this time was the law on the total prohibition of alcohol, introduced in 1919. As in the United States, the law resulted in a sharp increase in organized crime and smuggling, and after a referendum in 1932 it was repealed.

The language question. The constitution of 1919 provided that both Finnish and Swedish should be the national languages. A younger radical generation now raised the demand for the supremacy of Finnish. The language controversy, which during the interwar period was a very bitterly fought issue, caused the position of the Swedish language to be progressively weakened toward the end of the 1930s. After World War II the laws governing language were revised, first in 1947 and again in 1961. They now embody certain guarantees for the Swedish language.

Foreign policy. After the recognition of Finland as a sovereign state, two problems had to be faced. The first was in connection with the eastern boundary, where influential groups wished to annex East Karelia. By the Treaty of Tartu (Dorpat) in 1920, however, the boundary was unchanged except in the north, where Finland acquired a route to the Arctic Ocean and the harbour of Petsamo. The other problem concerned the Åland Islands (Finnish Ahvenanmaa). The demands of the population of Åland to be united with Sweden were firmly rejected. The League of Nations settled the question in 1921 in accordance with Finland's wishes.

Finland's main security problems resulted from the threat from the Soviet Union. An attempt to solve this by a defense alliance with Estonia, Latvia, and Poland in 1922 failed when the Eduskunta refused to ratify the agreement, and in 1932 a Finnish–Soviet nonaggression pact was signed. During the second half of the 1930s a Finnish–Swedish defense association was planned that, among other things, would have brought about the rearming of the Åland Islands, but the Soviet Union objected to these plans and they could not be realized.

Finland during World War II. *Defeat by the Soviet Union.* After Poland's defeat in the autumn of 1939, the Soviet Union, wishing to safeguard Leningrad, demanded from Finland a minor part of the Karelian Isthmus, a naval base at Hanko, and some islands deep in the Gulf of Finland. When Finland rejected the demand, the Soviet Union launched an attack on November 30, 1939. Immediately after the attack a coalition government was formed under Risto Ryti. Despite courageous resistance and a number of successful defense actions, the defense of the Karelian Isthmus broke down and Finland had to initiate peace negotiations. By the Treaty of Moscow of March 12, 1940, Finland surrendered a large area of southeastern Finland including the city of Viipuri (Viborg), and leased the peninsula of Hanko (Hangö) to the Soviet Union for 30 years. (The Russo-Finnish war is discussed at greater length in *WORLD WARS: World War II*.)

Cooperation with Germany. After the Treaty of Moscow the plan for a Nordic defense union was resumed. The Soviet Union still objected, however, and the plan was abandoned. In December 1940 Pres. Kyösti Kallio resigned, and Risto Ryti was elected in his place. When the tension between Germany and the Soviet Union grew in spring 1941, Finland approached Germany but did not conclude a formal agreement. Nevertheless, Finland,

like Sweden after Norway's capitulation, allowed the transit of German troops. When Germany attacked the Soviet Union on June 22, 1941, therefore, German troops were already on Finnish territory, and after a few days Finland was drawn into the war. The "War of Continuation" (1941–44) began with a successful Finnish offensive that led to the capture of large areas of East Karelia. From the winter of 1942–43, however, German defeats gave rise to a growing demand for peace in Finland. After the breakthrough of the Red Army on the Karelian Isthmus in June 1944, President Ryti resigned on August 1. He was succeeded by Marshal Carl Gustaf Mannerheim, who immediately demanded the evacuation of the German troops and began negotiations for an armistice. This was signed on September 19, 1944, on condition that Finland recognize the Treaty of Moscow of 1940. A pledge was given, moreover, to cede Petsamo; lease an area near Porkkala, southwest of Helsinki, for a period of 50 years (in place of Hanko); and within six years pay the equivalent of \$300,000,000 in goods for war reparations. In the meantime, however, the German Army refused to leave the country, and in a series of clashes that followed, it devastated great areas of northern Finland in its retreat. The final peace treaty that was signed in Paris on February 10, 1947, reiterated the conditions of the armistice agreement.

The postwar period. After the armistice in 1944 a coalition government was formed under the leadership of Juho Kusti Paasikivi. When conditions had been stabilized, Marshal Mannerheim resigned, and Paasikivi was elected president in his place in 1946. In 1956 the leader of the Agrarian Party, Urho Kekkonen, who acted as prime minister a number of times during the period 1950 to 1956, was elected president. He was subsequently re-elected four times.

Foreign policy. Under the leadership of Paasikivi and Kekkonen, relations with the Soviet Union were stabilized by a consistently friendly policy on the part of Finland. A concrete expression of the new foreign policy—designated the Paasikivi–Kekkonen line—was the Agreement of Friendship, Cooperation, and Mutual Assistance concluded between Finland and the Soviet Union in the spring of 1948. After war reparations had been paid in full, trade with the Soviet Union continued, rising to more than 20 percent of the country's total. Further signs of the détente showed when the Soviet Union returned its base at Porkkala in 1955, did not protest at Finland's associating with EFTA in 1961, and opened the reconstructed Saimaa Canal (partly on Finnish, partly on Soviet territory) in 1968.

Relations with the Soviet Union, however, have not been entirely without complications. After the elections of 1958, a coalition government under the leadership of the Social Democrat Karl August Fagerholm was formed, in which certain members considered anti-Soviet were included. The Soviet Union responded by recalling its ambassador and cancelling credits and orders in Finland. When the Finnish government was reconstructed, relations were again stabilized. During the autumn of 1961, when international relations were severely strained because of the Berlin crisis, the Soviet Union requested consultations in accordance with the Agreement of Friendship, Cooperation, and Mutual Assistance. President Kekkonen succeeded—during a personal meeting with the Soviet leader N.S. Khrushchev—in inducing the Soviet Union to abandon its request.

Finland has participated in the work of the Nordic Council since 1955. The proposal for a Nordic customs union failed because of Finland's last-minute refusal to take part. Finland is unique in having links with both the EEC and its Communist parallel, Comecon.

Domestic affairs. During the postwar period, Finland's domestic affairs have been marked by economic difficulties. After World War II the country was left with the task of absorbing about 300,000 refugees from the areas ceded to the Soviet Union and at the same time paying war reparations. Despite these obstacles, Finland quickly recovered. The war reparations brought about rapid expansion in the metal and shipbuilding industries, and the

The
Treaty
of Moscow

timber trade soon resumed exporting and quickly exceeded its prewar level. The rebuilding and colonization required to resettle the refugees, however, were such a drain on the country's economic resources that inflation could not be avoided; as a result Finland has had to devalue its currency on a number of occasions.

In the government that was formed after the armistice, the new Finnish Communist Party held a strong position, which it retained in the following government. When in the spring of 1948 it was revealed that the party had planned a coup, the Eduskunta forced the Communist minister of the interior to resign. After parliamentary elections in the autumn of 1948, a Social Democratic government came to power under the leadership of K.A. Fagerholm. During the 1950s the governments changed rapidly and consisted of various party coalitions, usually under the leadership of the Agrarian Party or the Social Democrats. During this period, however, both the conservative National Coalition Party and the leftist Finnish People's Democratic League (SKDL) were excluded from the government.

Forming and keeping a government in Finland is very difficult because of the proliferation of political parties, which means that no one party, and often no party group, can command a majority in the Eduskunta. In consequence, there have been many nonpolitical cabinets composed of civil servants appointed by the president. The Social Democrats have won the most seats in practically every Finnish election since 1907 and thus are needed by any coalition government, but they have rarely commanded a majority. The left-centre Cabinet (headed by the Social Democrat Kalevi Sorsa) that held office from September 4, 1972, to June 4, 1975, was the second longest lived in Finnish history. In the first 59 years after independence there were 59 governments. The elections of 1975 did nothing to change this situation. The elections of March 1979 resulted in a victory for the conservative parties, but a new coalition government was formed under the leadership of the Social Democrats.

ICELAND

The union (1918–43). The modernization of Iceland's trade and industry continued during the interwar period. The trawler was introduced in the fisheries, the communications system was improved, and the country acquired its own merchant fleet.

After 1918 the government in Reykjavik consisted of a ministry headed by three elected members, while legislative power lay jointly with the king and the Althing (Parliament). The Althing was composed of three major parties: the Progressive Party (a liberal party that had evolved from the old Farmers' Party), the Independence Party (a conservative right-wing party), and the Social Democratic Party. The Progressive Party was in power for most of the interwar years and, supported by the Social Democrats, effected a number of economic and social reforms.

When the Germans occupied Denmark in 1940, connections between Iceland and Denmark were broken off, and the Icelandic government took over all governmental functions. In May 1940, Iceland was occupied by British troops, who were later replaced by Americans. During the whole of World War II, Iceland was used as a strategic air base. In 1941 Sveinn Björnsson was elected regent and assumed all the authority that had formerly been the king's. In March 1944 the Althing accepted a constitution making Iceland a republic, a decision confirmed by an overwhelming majority in a plebiscite in May. On June 17, 1944, Iceland was proclaimed a republic, and Sveinn Björnsson was elected its first president.

The Republic of Iceland. *Domestic affairs.* World War II brought severe inflation, which caused great political unrest in Iceland. Shortly after the country became a republic, the bureaucratic government that had functioned since 1942 was replaced by a coalition consisting of the Socialist parties and the right-wing Independence Party, whose leader, Ólafur Thors, became prime minister. During the postwar period, power has been held

by one of the three major parties, often in the form of a coalition between two of them.

In the late 1950s the Independence and Social Democratic parties established a coalition that lasted till the election of 1971, when it was supplanted by a leftist coalition. In 1974 a more conservative coalition was formed between the Independence Party and the Progressive Party, with the Independence Party leader, Geir Hallgrímsson, as prime minister. After the election of 1978, which brought spectacular gains for the left, a left-wing government was formed by the Progressive Party, together with the two Socialist parties, with the Progressive leader Ólafur Jóhannesson as prime minister.

Sveinn Björnsson was re-elected president in 1945 and remained in power until his death in 1952. Asgeir Asgeirsson was his successor in 1952–68. Kristján Eldjárn was elected in 1968 and again in 1972 and 1976.

Immediately after World War II there was a period of vigorous economic expansion characterized by large investments in the modernization of the agricultural and fishing industries and a comprehensive building program. As a consequence of shrinking prices and smaller fish catches, however, Iceland was again faced with great economic problems, and, as a result, the króna has been repeatedly devalued.

Foreign relations. The question of United States air bases in Iceland became the dominating issue in postwar foreign policy. After lengthy negotiations, an agreement was reached in 1946 that entailed the withdrawal of the American troops from Iceland within six months. Permission was granted, however, to use the air base at Keflavik for a further five-year period, especially in respect of flights to West Germany. In 1949 Iceland became a member of the North Atlantic Treaty Organization (NATO). In 1951, in the East-West crisis, it was agreed that U.S. troops should be stationed in Keflavik. Since then, opinion has changed in favour of U.S. withdrawal.

The other great political issue has concerned the right to fish in Icelandic waters. When Iceland extended its territorial waters from a three- to a four-mile limit in 1952, the United Kingdom and other countries protested. In 1958 the fishing limit was extended from four to 12 miles. The United Kingdom refused to recognize Iceland's decision, and when Iceland announced its intention of confiscating British trawlers that fished within the 12-mile limit, the United Kingdom responded by sending gunboats to protect its fishing vessels. A series of minor incidents followed between Icelandic coast guard cutters and British trawlers and frigates. In 1972 Iceland again unilaterally extended its fisheries limit—this time to 50 miles. This provoked strong protests from other nations, particularly Britain and West Germany, and led to increased tension in the so-called "cod war" involving the Royal Navy.

Despite a decision of the International Court of Justice in The Hague, which declined to recognize the demand for a 50-mile limit, the Icelandic government decided in 1975 to claim a 200-mile limit. This led to a series of incidents between British and Icelandic trawlers, to military actions between units of the two navies, and finally in February 1976 to the breaking of diplomatic relations between Great Britain and Iceland. Under Norwegian mediation the conflict was settled in June 1976, and the British government recognized the 200-mile limit.

Scarlatti, Domenico

One of the major keyboard composers of all times, Domenico Scarlatti, in his 555 sonatas for harpsichord,

dazzlingly expanded the technique of the keyboard, and his innovations of harmony and form enhance one of the most strikingly original styles of the 18th century.

Son of the composer of vocal music Alessandro Scarlatti,

Domenico Scarlatti, engraving by an unknown artist. Ziolo

Giuseppe Domenico was born in Naples on October 26, 1685, in the same year as Bach and Handel. Domenico Scarlatti's career demonstrates aspects both of precocity and of delayed maturity. More than the entire first half of his life was devoted to the composition of vocal music that seldom shows any independence from the all-pervading influence of his father. But nearly all those keyboard works in which he developed his own almost totally unprecedented style appear to date from the period subsequent to his father's death and to his own departure from his native Italy. In fact, the majority of them appear to date from the very last years of his life.

Early life and vocal works: Italy. Scarlatti began the first half of his career at the age of 16 with the production in Naples in 1703 of his first operas, *Ottavia restituita al trono* and *Il Giustino*. The librettos and part of the music still survive. In 1705 his father sent him away from Naples, reputedly to study with the then famous pedagogue and composer of opera Francesco Gasparini, musical director at the Ospedale della Pietà in Venice, where the composer Antonio Vivaldi also served.

While in Venice, Domenico met a young Irishman, Thomas Roseingrave, who later became the founder of an English Scarlatti cult that lasted throughout the century. Many years later he described Domenico's harpsichord playing to the English musicologist Charles Burney as sounding as if "ten hundred d. . . s had been at the instrument; he had never heard such passages of execution and effect before." At about the same time, Domenico formed a friendship with Handel, who was only a few months older than himself. Although they never again met after Domenico's establishment in Rome and Handel's departure from Italy in 1709, they spoke of each other for the rest of their lives with affection and admiration.

By the spring of 1709 Domenico had taken over his father's position in Rome as musical director and composer to the exiled Queen Maria Casimira of Poland. Until her departure in 1714, he composed a series of operas and occasional pieces, all of them on texts by the Queen's secretary, Carlo Sigismondo Capeci. Many of these had set designs by the young Filippo Juvarra, one of the last of the great Italian Baroque architects. Their grandiose perspectives, as shown in surviving drawings, quite belied the size of the Queen's tiny theatre in the Palazzo Zuccari. Some of the music has survived, but, were it not for the reflected glory cast upon it by the later harpsichord sonatas, this music would inspire little interest today.

By 1713 at least, Domenico had established relations

First

Musical
director at
St. Peter's

with the Vatican, and from 1714 to 1719 he held the position of musical director at St. Peter's. Of the surviving church music that appears to date from this time, only the ten-voice *Stabat Mater* gives a hint of the genius that was to find its long-delayed flowering in the harpsichord sonatas.

During these years Domenico brought to an end his apparently never-too-successful career as an opera composer with *Ambeto* (1715); it had an intermezzo, *La Dirindina*, which, because of the liberties of its text, was withdrawn from performance in Rome. His endeavours also produced *Berenice, regina di Egitto* (1718), with music by both Scarlatti and Nicola Porpora. More promising for the future were his relations with the Portuguese embassy, for which in 1714 he composed a cantata in honour of the birth of a crown prince of Portugal.

In September 1719 Domenico abandoned his post at the Vatican, and the records indicate a departure for England, but no substantiating evidence of a visit to the British Isles has ever been discovered. By the end of 1720, if not earlier, he was in Lisbon, and his serenata *La Gioiosa delle Stagioni* (of which half the *Concerto* was performed at the royal palace in Lisbon on September 6. He had become musical director to that flamboyant and extravagant monarch John V of Portugal, as well as music master to the King's younger brother Don Antonio and to the Princess Maria Bárbara de Bragança, who was to remain his patroness and for whom most of the harpsichord sonatas were later written. The production of serenades and church music continued, most of it adequate but hardly distinguished, if judged by surviving pieces. But a major change was taking place in Scarlatti's life. In 1725 his father died; in 1728 he made his last visit to Italy to marry at the unusually late age of 43 a young Roman, Maria Catalina Gentili, by whom before her death in 1739 he was to have five children (four more were born to his second marriage, with the Spanish Anastasia Maxarti Ximenes); and in 1729 his pupil Maria Barbara married the Spanish crown prince the future Ferdinand VI, and Scarlatti followed the royal pair to Spain.

Later life and keyboard works: Spain. There he was to spend his remaining years, first in Seville, perhaps already listening to Spanish popular music and imitating, as Burney tells us, "the melody of tunes sung by carriers, muleteers, and common people," and after 1733 in the royal residences of Madrid and at the nearby palaces of La Granja, Escorial, and Aranjuez. Many links with the past seem to have been cut, and an emancipation seems to have taken place that permitted the extraordinary stylistic development of the harpsichord sonatas. Scarlatti virtually disappears as a composer of vocal music, and there is no evidence of his participation in the extravagant opera productions directed by his friend the castrato singer Farinelli, whose singing in 1737 had so charmed the half-mad Philip V that he rose to a position of unparalleled eminence and power at the Spanish court.

Scarlatti is seldom mentioned, and the fullest surviving record of his life and character is to be found in the series of harpsichord sonatas that begins with the sumptuous publication of the *Essercizi per gravicembalo* (Exercises) in 1738, preceded by a dedication to his former patron John V of Portugal, doubtless in acknowledgment of the knighthood in the Order of Santiago that he had received from him earlier that year. The series of harpsichord sonatas continues brilliantly with manuscript volumes copied out for Maria Barbara in 1742 and 1749. She became queen of Spain in 1746, and the musical activities of the Spanish court became more lavish than ever, always under the direction of Farinelli. But the principal evidence of Scarlatti's own activity continues to reside in the final great series of harpsichord sonatas copied out for the Queen from 1752 to 1757, the year of Scarlatti's death.

This music ranges from the courtly to the savage, from an almost saccharine urbanity to an acrid violence. Its gaiety is all the more intense for an undertone of tragedy. Its moments of meditative melancholy are at times overwhelmed by a surge of extrovert operatic passion. Most particularly he has expressed that part of his life which

was lived in Spain. There is hardly an aspect of Spanish life, of Spanish popular music and dance, that has not found itself a place in the microcosm that Scarlatti created with his sonatas. No Spanish composer, not even Manuel de Falla in the 20th century, has expressed the essence of his native land as completely as did the foreigner Scarlatti. He has captured the click of castanets, the strumming of guitars, the thud of muffled drums, the harsh bitter wail of gypsy lament, the overwhelming gaiety of the village band, and above all the wiry tension of the Spanish dance. (R. K.: *Domenico Scarlatti*)

There are also abundant echoes of the festivities of the Spanish court, of the wind instruments and drums of state processions, of the horns and oboes of the royal hunt, of fireworks and artillery salvos, and of the music from the royal barges that floated over the waters of the Tagus during the summer embarks at Aranjuez.

All of this does not find expression merely in loosely knit impressionistic program music, but is assimilated and distilled with all the rigour that Scarlatti had learned from his 16th century ecclesiastical masters, and is given forth again in a pure musical language that extends far beyond the domain of mere harpsichord virtuosity. All is assimilated into an unflinching sense of the larger context. In those last five years as he wrote sonata after sonata Scarlatti was reliving his entire life, living it more intensely than ever before, bringing it to fruition. (*Zbid.*)

A consistent development is perceptible in Scarlatti's harpsichord music, essentially characterized by an expansion of simple binary dance form through elaborations of thematic organization and extensions of tonal range. Spectacular innovations in keyboard virtuosity are often accompanied by audacious dissonances, unconventional voice leading, and far-flung modulations. The predominance of fast movements in the earlier sonatas gives way to a greater frequency of slow movements in the middle period, to a wider range of lyricism, and in the later sonatas to a leaner, more concentrated style.

Beginning with the Queen's volume of 1749, an increasing number of sonatas are arranged in pairs, contrasting slow movements with fast, coupling complementary fast movements, or extending the total tonal range of a pair conceived as a unit. Nearly 400 of the later sonatas appear arranged in pairs, and there are at least a dozen sonatas arranged in triptychs. A general absence of recognition of this organization of Scarlatti sonatas into a larger context has provided a serious obstacle to the appreciation of their true stature.

The instrument for which most of the late sonatas were composed appears to have been a one-manual harpsichord of the traditional Mediterranean kind, in cedar and cypress, with an extended compass of five octaves and with two eight-foot registers. Queen Maria Barbara was supplied with such instruments in each of the three principal royal residences, Buen Retiro (in Madrid), Aranjuez, and Escorial. On a background of such simplicity and seeming limitation of resources, Scarlatti imposed the variety and contrasts of sonorities and textures that elevate his writing for the harpsichord to a level comparable to that of Chopin and Liszt for the piano.

Shortly before his death, Scarlatti returned at least once more to vocal music, with a *Salve Regina* for soprano and strings, perhaps the most beautiful of his vocal compositions and one of the few meriting survival. He died at Madrid on July 23, 1757.

Personal verbal utterances of Scarlatti have survived only in his preface and dedication of the *Essercizi*, in a letter to the Duke of Alba (1752), and indirectly in a few legal documents. Known samples of his handwriting are less than a dozen, and no autographs of the harpsichord sonatas have been found. A handsome portrait by Domingo Antonio de Velasco was in the possession of Scarlatti descendants until 1912 and is now in the municipal museum of Alpiarça, Portugal.

Except for 18th-century English publications, mainly of his earlier sonatas, and for a few continental reprints, the bulk of Scarlatti's keyboard music was hardly known beyond his immediate circle and can have exercised very little direct influence on his Italian successors (with the exception of one of his editors, the composer Muzio Cle-

Organiza-
tion of
the
sonatas

The
harpsi-
chord
sonatas

menti), or on those German and Austrian composers such as C.P.E. Bach, Haydn, Mozart, and Beethoven, many of whose stylistic features it anticipates.

It was not until the edition prepared by the Italian pianist Alessandro Longo (began in 1906) that virtually all the harpsichord sonatas became available, and, even then, serious flaws in this and other editions prior to 1953 severely hampered any serious understanding of their stylistic development and coherence. Only with the respective complete editions of Ralph Kirkpatrick and Kenneth Gilbert, which maintain the chronological order and pairwise arrangement of sources, can an unobstructed view of Scarlatti's keyboard work at last generally be obtained.

MAJOR WORKS

HARPSICHORD MUSIC: The main body of Scarlatti's work consists for the most part of one-movement sonatas for the harpsichord. There are 555, of which the majority are grouped in pairs.

OPERAS: Scarlatti wrote over a dozen operas. These include: *Tolomeo et Alessandro, ovvero La corona disprezzata* (1711); *Tetide in Sciro* (1712); *Amor d'un ombra, e gelosia d'un aura* (1714, produced in London in 1720, under the title *Narciso*); and *Ambleto* (1715).

OTHER WORKS: The rest of his output comprises cantatas and church music, including a mass, two settings of *Salve Regina*, and a *Stabat Mater*.

BIBLIOGRAPHY. The definitive biographical and critical study, including the most complete existing catalog of compositions, a comprehensive bibliography, and an account of sources, is RALPH KIRKPATRICK, *Domenico Scarlatti* (1953; paperback edition, 1968). It is supplemented by DOMENICO SCARLATTI, *Sixty Sonatas . . .*, ed. with a preface by RALPH KIRKPATRICK, 2 vol. (1953) and also recorded by him. Superseding all previous editions are DOMENICO SCARLATTI, *Complete Keyboard Works in Facsimile from the Manuscript and Printed Sources*, ed. by RALPH KIRKPATRICK, 18 vol. (1971); and *Complete Keyboard Works*, ed. by KENNETH GILBERT, 9 vol. 1971–).

(R.Ki.)

Schelling, Friedrich

Friedrich Wilhelm Joseph von Schelling was one of the three towering figures whose works, in the period following the death of Immanuel Kant (early 19th century), comprised the movement that marks the climax of classical German philosophy—that of German Idealism. The other two figures were Johann Fichte, an ethical, subjective Idealist, and G.W.F. Hegel, a dialectical, absolute Idealist. Schelling himself was an aesthetic, objective Idealist: for, spurning Fichte's starting point in the human ego, Schelling grounded his metaphysics (on the nature of being) instead in objective nature, which he reconciled with mind through the aesthetic creativity that they both share. Schelling's philosophy of nature, which was intensely Romantic, and his philosophy of man, which discerned the darker, irrational recesses of man's being, foreshadowed the 19th-century reaction against the shallow confidences of the Enlightenment and has even been seen by some as a harbinger of 20th-century Existentialism.

Early life and career. Schelling was born on January 27, 1775, in Leonberg, a small town in the Württemberg, where his father was a Lutheran minister. In 1777 his father became a professor of Oriental languages at the theological seminary in Bebenhausen, near Tübingen. It was there that Schelling received his elementary education. He was a highly gifted child, and he had already learned the classical languages at the age of eight. On the basis of his rapid intellectual development, he was admitted, at the age of 15, to the theological seminary in Tübingen, a famous finishing school for ministers of the Württemberg area, where he lived from 1790 to 1795. Among his fellow students were G.W.F. Hegel, later to become the foremost philosopher of the 19th century, and J.C.F. Holderlin, later to become one of the greatest German poets. The youth at Tübingen were inspired by the ideas of the French Revolution and, spurning tradition, turned away from doctrinal theology to philosophy. The young Schelling was inspired, however, by the

Schelling, oil painting by Joseph Karl Stieler (1781–1858). In the Bayerische Staatsgalerie, Munich. By courtesy of the Bayerisches Nationalmuseum, Munich

thought of Immanuel Kant, who had raised philosophy to a higher critical level, and by the Idealist system of Fichte, as well as by the pantheism of Benedict de Spinoza, a 17th-century Rationalist. When he was 19 years old Schelling wrote his first philosophical work, *Über die Möglichkeit einer Form der Philosophie überhaupt* (1795; "On the Possibility and Form of Philosophy in General"), which he sent to Fichte, who expressed strong approval. This work was followed in 1795 by *Vom Ich als Prinzip der Philosophie* ("Of the Ego as Principle of Philosophy") and by an article, "Philosophische Briefe über Dogmatismus und Kritizismus" (1796; "Philosophical Letters on Dogmatism and Criticism"). One basic theme governs all of these works—the Absolute. This Absolute cannot be defined, however, as a God who stands over the world; each person is himself the Absolute as the Absolute ego. This ego, eternal and timeless, is apprehended in a direct intuition, which, in contrast to sensory intuition, can be characterized as intellectual.

From 1795 to 1797 Schelling acted as a private tutor for a noble family, who had placed its sons under his care during their studies in Leipzig. The time spent in Leipzig marked a decisive turning point in the thought of Schelling. He attended lectures in physics, chemistry, and medicine. He acknowledged that Fichte, whom he had previously revered as his philosophical model, had not taken adequate notice of nature in his philosophical system, inasmuch as Fichte had always viewed nature only as an object in its subordination to man. Schelling, in contrast, wanted to show that nature, seen in itself, shows an active development toward the spirit. This interpretation becomes especially obvious in the organic forms of nature: a plant, according to Schelling, is an interlacing tendency of soul. This philosophy of nature, the first independent philosophical accomplishment of Schelling, made him known in the circles of the Romantics and won the approval of the famous writer Johann Wolfgang von Goethe.

Period of intense productivity. In 1798 Schelling was called to a professorship at the University of Jena, the academic centre of Germany at the time.

Career at Jena. The foremost intellects of the time—Goethe, the writer Friedrich Schiller, the Romantics Friedrich and August Wilhelm Schlegel, the writer and critic Ludwig Tieck, and, from 1801, Hegel—were all together at Jena. During this period Schelling was extremely productive: he developed his philosophy of nature through lectures and books; and between 1797 and 1800 he published in rapid succession several works on the philosophy of nature, notably *Ideen zu einer Philosophie der Natur* (1797; "Ideas Toward a Philosophy of Nature") and *Von der Weltseele, eine Hypothese der höheren Physik zur Erklärung des allgemeinen Organismus* (1798; "On the World Soul, a Hypothesis of Advanced Physics for the Interpretation of the General

Early works on the Absolute

Organism"). It was Schelling's desire, as attested by his famous work *System des transzendentalen Idealismus* (1800; "System of Transcendental Idealism"), to unite his concept of nature with Fichte's philosophy, which took the ego as the point of departure. Schelling saw that this unity of the natural and the spiritual spheres was given by art. Art mediates between these spheres insofar as, in artistic creation, the natural (or unconscious) and the spiritual (or conscious) productions are united. In this work it became evident that Schelling had drawn up a pantheism of historical development. Naturalness and spirituality are explained as emerging from an original state of indifference, in which they were submerged in the yet-undeveloped Absolute, and as rising through a succession of steps of ever-higher order. Schelling explicates this statement especially in an article, "Darstellung meines Systems der Philosophie" (1801; "An Exposition of My System of Philosophy").

Fichte did not acknowledge this concept, however, and the two writers attacked each other most sharply in an intensive correspondence from the years around 1800. Fichte reproached Schelling for not acknowledging in his speculations the only sure foothold of philosophy, the certitude of the ego; and Schelling, in his turn, asserted that Fichte had never risen to the true origin of all philosophy, the Absolute, which comprehends both nature and spirit. Their correspondence ended without result in 1802.

Marriage
to
Caroline
Schlegel

The time spent in Jena was important for Schelling also in a personal respect: there he became acquainted with Caroline Schlegel, who was among the most gifted women in German Romanticism. Caroline was born in 1763, the daughter of a professor in Göttingen, and she married a physician, Wilhelm Bohmer, at the age of 21. After his death she lived in Mainz in the house of a librarian, Georg Forster, who was a partisan of the French Revolution. There she met a French officer, to whom she bore a child. In 1796 she married August Wilhelm von Schlegel, a poetical translator and a leader of the new Romantic criticism, and moved with him to Jena. There she met Schelling and was immediately enthusiastic about him both as a person and as a thinker. Thus they soon came to love one another. The death, in 1800, of Auguste, Caroline's daughter (from her marriage with Bohmer), whom Schelling had treated in her last illness, drew Schelling and Caroline even closer together. Through Goethe's intervention, Caroline obtained a divorce from Schlegel in May 1803 and married Schelling in the same year. The unpleasant intrigues that accompanied this marriage reached their climax when Schelling was held responsible for the death of Auguste. It was rumoured that Schelling had treated her according to Brunonian theories, which regarded all disease as due to either deficient or excessive stimulation. Such personal difficulties and the dispute with Fichte caused Schelling to leave Jena, and he accepted an appointment at the University of Würzburg in 1803.

Career at Würzburg and Munich. At first, Schelling lectured at Würzburg on the philosophy of identity, conceived in his last years in Jena, in which he tried to show that, in all beings, the Absolute expresses itself directly as the unity of the subjective and the objective. It was just on this point that Hegel initiated his criticism of Schelling. As attested in Hegel's work *Differenz des Fichte'schen und Schelling'schen Systems der Philosophie* (1801; "Difference Between the Philosophical Systems of Fichte and Schelling"), Hegel had at first taken Schelling's side in the disagreement between Schelling and Fichte. A complete unanimity seemed to exist between Hegel and Schelling, and in 1802 the *Kritisches Journal der Philosophie* ("Critical Journal of Philosophy") appeared in Jena, with Hegel and Schelling as coeditors. In the following years, however, Hegel's philosophical thought began to move significantly away from Schelling's. Hegel's famous work *Phänomenologie des Geistes* (1807; Eng. trans., *The Phenomenology of Mind*, 1910) contained strong charges against Schelling's system, without, however, mentioning his name. To Schelling's definition of the Absolute as an indiscriminate unity of the subjective and

Hegel's
criticisms

the objective, Hegel replied that such an Absolute is comparable to the night, "in which all cows are black." Besides, Schelling had never explicitly shown how one could ascend to the Absolute; he had begun with this Absolute as though it were "shot out of a pistol."

This criticism struck Schelling a heavy blow. The friendship with Hegel that had existed since their time together at the seminary in Tübingen broke up. Schelling, who had been regarded as the leading philosopher of the time until the publication of Hegel's *Phänomenologie*, was pushed into the background by Hegel, whose philosophy was now generally regarded as the authoritative system.

This situation caused Schelling to retreat from public life. From 1806 to 1841 he lived in Munich, where, in 1806, he was appointed as general secretary of the Academy of Plastic Arts. He lectured from 1820 to 1827 in Erlangen. Caroline died on September 7, 1809. This sad event, which dealt a heavy blow to Schelling, led him to write a philosophical work on immortality. The text on Caroline's gravestone, which Schelling himself wrote, ends with the words "Every sensitive being stands with devotion here, where the husk that once enclosed the most noble heart and beautiful spirit slumbers." In 1812 Schelling married Pauline Gotter, a friend of Caroline. In a letter to Pauline, written shortly after Caroline's death, Schelling declared that, if the dead had any awareness of the sorrows of the survivors, Caroline would thank Pauline Gotter for everything she would do for Schelling. The marriage was calm and harmonious, but the great passion that Schelling had felt for Caroline was unrepeatable.

During the years in Munich, Schelling tried to consolidate his philosophical work in a new way, producing a revision that was instigated by Hegel's criticism of his philosophy of identity. Schelling questioned all Idealistic speculations built on the assumption that the world presents itself as a rational cosmos. Were there not also irrational things, he asked, and was not evil the predominant power in the world? In his *Philosophische Untersuchungen über das Wesen der menschlichen Freiheit* (1809; Eng. trans., *Of Human Freedom*, 1936), Schelling attempted to explore this question. In this important work he declared that the freedom of man is a real freedom only if it is freedom for good and evil. The possibility of this freedom is founded on two principles that are active in every living thing: one, a dark primal foundation that manifests itself in carnal desire and impulse; the other, a clearheaded sensibleness that governs as a formative power. Man, however, has placed the dark stratum of impulse, which was meant only to serve the intellect as a source of power, above the intellect and has thus subordinated the intellect to the impulses, which now rule over him. This reversal of the right order is the occurrence known in the Bible as the Fall from grace, through which evil came into the world. But this perversion of man is revoked by God, who becomes man in Christ and thus re-establishes the original order. In addition to Schelling's obvious use of Christian dogma in this work, the influence of Jakob Bohme, a theosophical thinker, can also be seen. Schelling adopted Bohme's thought that God must give birth to himself by raising himself from the dark ground of nature into the light.

Period of the later, unpublished philosophy. The position developed in the work on freedom forms the basis of Schelling's later philosophy, covering the time from 1810 until his death, which is known only through a draft of the unpublished work *Die Weltalter* (written in 1811; partial Eng. trans., *The Ages of the World*, 1942) and through the manuscripts of his later lectures. In *Die Weltalter* Schelling wanted to relate the history of God. God, who originally is absorbed in a quiet longing, comes to himself by glimpsing in himself ideas through which he becomes conscious of himself. This self-consciousness, which is identical to freedom, enables God to project these ideas from himself—i.e., to create the world.

This conception was adopted and, at the same time, significantly extended in the "Vorlesungen zur Philosophie der Mythologie und der Offenbarung" ("Lectures on the Philosophy of Mythology and of Revelation"), a se-

Consoli-
dation
of his
philosophy

of the
World*

ries that Schelling repeated several times. Through them he hoped to develop a great public interest once more, as he had done during his time in Jena. His appointment to the University of Berlin in 1841 gave him this opportunity. It had been brought to the attention of the Prussian king of that time, Frederick William IV, that Schelling had deviated from Idealistic thought and had turned to the primary Christian truths—i.e., to the doctrines of the defection of man from God and the reconciliation of man with God through Christ. The King hoped that Schelling would combat the so-called dragon's seed of Hegelianism in Berlin, where Hegel had been working until his death in 1831. Schelling's first lecture in Berlin manifested his self-consciousness. Schelling declared that in his youth he had opened a new page in the history of philosophy and that now in his maturity he wanted to turn this page and start yet a newer one. Such notables as Friedrich Engels, the Marxist theoretician, Søren Kierkegaard, a Danish religious thinker, Jakob Burckhardt, a German historian, and Mikhail Bakunin, a Russian revolutionary agitator, were in his audience. Schelling, however, was denied any great success in his appearance in Berlin. Moreover, he was embittered when his lectures were plagiarized in a publication by one of his opponents, H.E.G. Paulus, who wanted to submit the positive philosophy of Schelling, now finally disclosed in these lectures, to the public for examination. Schelling initiated a legal suit but lost the case. Resigned, he discontinued lecturing.

The content of these lectures, however, represented the definitive climax of Schelling's creative activity. Schelling now divided philosophy into a *negative* philosophy, which developed the idea of God by means of reason alone, and, in contrast, a *positive* philosophy, which showed the reality of this idea by reasoning a posteriori from the fact of the world to God as its creator. Schelling then explained (referring to his work on freedom) that man, who wanted to be equal to God, stood up against God in his Fall into sin. But God was soon elevated again as the principle. During the era of mythology, God appeared as a dark power. During the era of revelation, however, God emerged in history as manifestly real in the figure of Christ. Thus, the complete history of religion should be conveyed through philosophical thought.

In 1854 Schelling travelled to Switzerland to recover from a cold in Bad Ragaz, where on August 20, he died. The king of Bavaria, Maximilian II, erected a gravestone there for him as the foremost thinker of Germany.

Personality and significance. Schelling is described as a man of thickset build, and, according to favourable reports, his high forehead and sparkling eyes were impressive. Opponents of his philosophy, however, such as Karl Rosenkranz, a disciple of Hegel, spoke of a sharp and piercing look. His character was unbalanced. Schelling has been described as nervous, unpredictable, and deeply sensitive in his proud fashion. Particularly striking was his unwavering consciousness that it was his mission to bring philosophy to a definite completion.

In order to understand Schelling's life, two periods must be clearly discerned: the first, from his philosophical beginnings to 1809 (his composition of the work on freedom); the second, from 1809 until his death. During the first period Schelling stood in the limelight. He knew personally the most important people of his time and was recognized by them as a genius. Stimulated by his fame, Schelling was able to achieve, especially during the time at Jena, a productivity that was truly amazing. In the works of this time, however, Schelling quickly changed his philosophical concepts; thus, in the earlier Schelling studies he is spoken of as the Proteus of Idealism—an infinitely changing being.

The second period was of a completely different character. It was introduced by certain occurrences: Caroline's death and Hegel's criticism. Schelling no longer published any extensive works, even though he repeatedly announced new books. Evidently, he was convinced that, due to the influence of Hegelianism, his philosophy would not receive proper consideration. This belief was decisively strengthened when his appearance in Berlin, which he had hoped would enhance the evaluation of his

thinking, was a failure. His feeling for life was significantly changed in comparison with the first period of his life, for he now declared that melancholy and sadness are the true moods to which man inevitably is exposed. He attempted, however, to overcome this pessimistic view of life by drafting a metaphysics that was defined by recourse to the personal God of the Christian revelation. At the end of his "Vorlesungen zur Philosophie der Offenbarung," he declared that: "The highest is, indeed, to acknowledge and worship God in spirit; but in order that this might happen in truth as Christ demands, it is also true that what we worship must be the real God as revealed by deeds, and not some abstract Idol." For Schelling, recourse to the God of revelation meant that despair cannot be the last word.

Great philosophical influence was denied to Schelling. The philosophical situation at the time was determined not by the few disciples of Schelling but by the Hegelians. The right-wing Hegelians occupied all of the philosophical professorial chairs and handed down the tradition of Hegel's system. The left-wing Hegelians explained that, even to suspend Hegel's system, an analysis of Hegel's philosophy was necessary. Thus, in tracing the development of German Idealism, the early and middle Schelling—that is, the Schelling who drew up the philosophy of nature and the philosophy of identity—has been placed between the Idealism of Fichte, who started from the ego, and Hegel's system of the Absolute spirit.

The independence of Schelling and his importance for philosophy are only now being recognized, and that in connection with Existential philosophy and philosophical anthropology, which conceive themselves as counteracting the philosophy of absolute reason. The later Schelling now turns out to have been the first thinker to illuminate Hegel's philosophy critically. In particular, Schelling's insight that man is determined not only by reason but also by dark natural impulses is now valued as a positive attempt to understand the reality of man on a level more profound than that attained by Hegel.

BIBLIOGRAPHY

Works: Schelling's works have been published by his son, K.F.A. SCHELLING (ed.), *Sämtliche Werke*, 14 vol. (1856/61; reprinted unchanged as the "Münchener Jubiläumsdruck," entitled *Werke*, ed. by MANFRED SCHROETER, 12 vol. (1927–54). The Schelling-Kommission, which existed for a time at the Bayerischen Akademie der Wissenschaften in Munich, prepared a critical new edition of his works that includes the unpublished manuscripts. His instructive and often intimate correspondence with influential men and women was edited by GUSTAV L. PLITT, *Aus Schellings Leben: In Briefen*, 3 vol. (1869–70). Because this edition is out of date, HORST FUHRMANS has planned a new collection of the letters, with detailed commentaries, of which only one volume had appeared by the early 1970s: *Schelling: Briefe und Dokumente* (1962). Important for Schelling's thought is his correspondence with Johann Gottlieb Fichte: WALTER SCHULZ (ed.), *Fichte-Schelling: Briefwechsel* (1968), which presents the philosophical development that characterized his position in German Idealism.

Studies: For an older classical work see KUNO FISCHER, *Geschichte der neuern Philosophie*, 4th ed., vol. 7 (1923), which details Schellings's life and interprets his individual writings. KARL JASPERS, *Schelling: Grosse und Verhängnis* (1955), is an important work that achieves a critical understanding of Schelling from the standpoint of Existentialism. Two works by HORST FUHRMANS, *Schellings letzte Philosophie* (1940) and *Schellings Philosophie der Weltalter* (1954), provide guidance on the salient problem of whether Schelling changed from the building of a system of Idealism to espousing a philosophy of freedom that also recognizes the irrational. See also WALTER SCHULZ, *Die Vollendung des deutschen Idealismus in der Spätphilosophie Schellings* (1955). From the standpoint of art, which played an essential role in his philosophy, DIETER JAEHNIG, *Schelling: Die Kunst in der Philosophie*, 2 vol. (1966–69), is important. The entire Schelling literature is cited in the two bibliographies: GUNDO SCHNEEBERGER, *Friedrich Wilhelm Joseph von Schelling* (1954), listing publications from 1797 to 1953; and HANS-JORG SANDKUEHLER, *Friedrich Wilhelm Joseph Schelling* (1970), which brings it up to 1969.

The two
periods of
Schelling's
thought

Schiller, Friedrich

One of the greatest German dramatists, poets, and literary theorists, Johann Christoph Friedrich von Schiller (ennobled in 1802) exemplifies in his life and work the triumph of man's spirit over adverse circumstance. In one of his last letters (April 2, 1805) he said to his friend Wilhelm von Humboldt: "After all, we are both idealists, and should be ashamed to have it said that the material world formed us, instead of being formed by us." The pursuit of beauty was to him a matter of greatest moment in human affairs; his devotion to his literary work was his personal religion. Thomas Carlyle recognized this when he wrote: "As Schiller viewed it, genuine Literature includes the essence of philosophy, religion, art; whatever speaks to the immortal part of man."

In the Staatliche Museen, Berlin.

Schiller was born at Marbach on the River Neckar on November 10, 1759, the second child of Lieutenant Johann Kaspar Schiller and his wife, Dorothea. His father saw much strenuous service in Bavarian, French, and Swabian regiments; when his campaigning days were over, he devoted himself to horticulture and was appointed superintendent of the gardens and plantations at Ludwigsburg, the residence of Duke Karl Eugen of Württemberg. Johann Kaspar gave his only son what he himself had been denied, a sound grammar school education until the age of 13 when, in deference to what amounted to a command from his despotic sovereign, he reluctantly agreed to send his boy to the Military Academy (the Karlsschule), an institution founded and personally supervised by the Duke. Against the wishes of the parents, who had hoped to have their son trained for the ministry, the Duke decreed that young Friedrich was to prepare for the study of law; later, however, he was allowed to transfer to medicine. Having endured the irksome regimentation at the academy for eight years—during which period he was virtually cut off from his family and the outside world—Schiller left to take up an appointment as an assistant medical officer (noncommissioned) to a Stuttgart regiment, a post that brought him no prestige and very little pay.

Early drama. His adolescence under the rule of a petty tyrant confronted Schiller with the problem of the use and abuse of power, a theme that recurs in most of his plays. His resentment found expression in some of his early poems (published in the *Anthologie auf das Jahr* 1782) and especially in his first play, *Die Räuber* (*The Robbers*, printed at his own expense and with borrowed money in 1781), a stirring protest against stifling convention and corruption in high places. The hero, Karl Moor, a young man of fiery spirit and abundant vitality, has led a somewhat disorderly life at the university. His villainous younger brother Franz (modelled on Shakespeare's Iago, Edmund, and Richard III) poisons their

aged father's mind against the prodigal elder son. When the old Count Moor disowns Karl, the young man turns brigand and defies all established authority at the head of a band of outlaws, until, before long, he discovers that however corrupt the existing order may be, violence and anarchy do not offer a workable alternative and society cannot be reformed by terrorism and crime. He decides to give himself up to justice, thus submitting to the law that he had flouted. Schiller could therefore claim to have written in defense of law and morality. At the same time, Karl Moor is represented as a "sublime criminal," and the play is a scathing indictment of a society that could drive so fundamentally noble a character to a career of crime.

In order to have the play accepted, Schiller had to prepare a stage version in which the rebellious ardour of his original text was toned down. Nevertheless, the first performance (January 13, 1782) at the National Theatre at Mannheim in the neighbouring state of the Palatinate created a sensation; it was a milestone in the history of the German theatre and, incidentally, in the career of August Wilhelm Iffland, who appeared in the role of Franz Moor and who was destined to become the leading German actor of his time. Schiller travelled to Mannheim without the Duke's permission in order to be present on the first night. When the Duke heard of this and of a subsequent secret visit, he sentenced the poet to a fortnight's detention and forbade him to write any more plays. To escape from this intolerable situation, Schiller decided to cut himself adrift. It meant giving up his livelihood, such as it was, his home ties, and the prospect of a reasonably secure future; but he was determined to follow his literary bent, whatever the cost. In the company of a loyal friend, the musician Andreas Streicher, he fled from Stuttgart at night, crossed the frontier that separated Duke Karl Eugen's territory from the neighbouring state, and set out for Mannheim, in the hope of receiving help from Heribert Baron von Dalberg, the director of the theatre that had launched his first play. He brought with him the manuscript of a new work, *Die Verschwörung des Fiesco zu Genua* (*Fiesco: or, the Genoese Conspiracy*), subtitled "a republican tragedy": the drama of the rise and fall of a would-be dictator, set in 16th-century Genoa, picturing, in Schiller's own phrase, "ambition in action, and ultimately defeated."

The new play proved an ill-starred venture. It was rejected, and when Schiller prepared a revised version for the Mannheim stage, with a different ending, this was rejected, too. Baron Dalberg, not anxious to provoke a diplomatic incident by sheltering a deserter, kept the embarrassing visitor at arm's length. For some tense weeks Schiller led the hand-to-mouth life of a refugee, until he found a temporary home with Henriette von Wolzogen, whose sons had been fellow students of his and who invited him to stay at her house at Bauerbach in Thuringia. There he finished his third tragedy, *Kabale und Liebe*, and started work on *Don Carlos*.

As the title suggests, *Kabale und Liebe* is a tragedy of love thwarted by intrigue. In this play about the love of a young aristocrat for a girl of humble background, Schiller's innate sense of drama is seen at its best. The appeal of its theme—the revolt of elemental human feeling against the artificialities of convention—the vigour of its social criticism, the vitality of dialogue and characters, and the shapeliness of its structure all combine to make *Kabale und Liebe* great theatre.

About six months after Schiller's flight from Stuttgart, Dalberg judged it safe to re-establish contact with his former protégé. He eventually offered Schiller an appointment as resident playwright with the Mannheim theatre. Schiller accepted and had the satisfaction of seeing *Kabale und Liebe* score a resounding success; but his hopes of clearing his debts and gaining a measure of financial security were doomed to disappointment. There were other worries as well, chief among them a serious illness that attacked him soon after he had arrived in Mannheim. Applying in his own case the rather violent methods that had made him notorious among his patients in his Stuttgart days, he tried to control successive bouts of fever by taking vast quantities of quinine. After several

heim
theatre

Success
of *Die
Räuber*

relapses, the trouble finally abated; but the damage done to his health at that time probably prepared the way for the illness that was to be the constant companion of his later life. When his contract expired after a year, it was not renewed; and once again Schiller needed the help of friends to extricate him, from both his financial predicament and from an emotional crisis caused by his attachment to a married woman, the charming but unstable Charlotte von Kalb. Four unknown admirers wrote to him from Leipzig and finally invited him to join them there. One of them, Christian Gottfried Körner, became his close and lifelong friend; being a man of some substance, he was able to support Schiller during his two years' stay in Saxony, toward the end of which *Don Carlos*, his first major poetic drama, was published in book form (parts had appeared in his journal *Thalia*).

Classical drama. *Don Carlos* marks a turning point in Schiller's development as a dramatist. The first sketch had been in prose; this was recast in verse, and what had originally been conceived as "a domestic drama in a royal house" (as Schiller put it in 1784) evolved into a play about large political issues. The domestic drama concerns the relations between the aging King Philip II of Spain, his third consort, Elizabeth of Valois, and his son by his first marriage, Don Carlos, who is in love with his stepmother. The conflict between father and son is not confined to their private lives; it has political implications as well. The change of focus from the domestic to the political sphere produced a play of inordinate length (the original version runs to 6,280 lines) and a tortuous plot. But there are positive qualities to compensate for these faults: a wealth of exciting and moving scenes and a wide range of sharply individualized characters, the most memorable being the complex, brooding, and tragic figure of King Philip. The characteristically resonant note of Schiller's blank verse is heard here for the first time. Blank verse had been used by German playwrights before, notably Gotthold Lessing in *Nathan der Weise* (published 1779), but it was Schiller's *Don Carlos*, together with Goethe's *Iphigenie auf Tauris* (both published after extensive revision in 1787), that definitely established it as the recognized medium of German poetic drama.

Schiller had accepted Körner's generous offer of hospitality and financial help in the spirit in which it was made. In the congenial circle of his new friends he experienced a sense of contentment and joyous confidence such as he had not known before. He gave jubilant expression to this mood in his hymn "An die Freude," which Beethoven was to use for the choral movement of his *Ninth Symphony*. He could not stay with Körner indefinitely, however, and the moment came when he felt he had to make another bid for independence. In July 1787 he set out for Weimar, in the hope of meeting some of the men who had made Weimar the literary capital of Germany. He soon established friendly relations with Johann Gottfried Herder and especially with Christoph Martin Wieland, in whose journal *Der deutsche Merkur* he published the long poem "Die Künstler" ("The Artists"), a meditation on the role of the arts as the great civilizing force in human evolution. Goethe, who was in Italy at the time, returned to Weimar in the following year. At first Goethe's studied aloofness prevented any close personal contact, but in the long run the older man could not resist the magnetism of Schiller's personality. A chance meeting in 1794 and the ensuing exchange of letters mark the beginning of their friendship, a union of opposites that forms an inspiring chapter in the history of German letters. Their fascinating correspondence is a worthy memorial to a momentous literary partnership.

Historical studies. In spite of his initial antipathy, Goethe had recommended Schiller for appointment to a professorship of history at the University of Jena. Schiller having presented the requisite credentials in his history of the revolt of the Netherlands (*Geschichte des Abfalls der vereinigten Niederlande von der spanischen Regierung*, 1788). His history of the Thirty Years' War (*Geschichte des dreissigjährigen Krieges*, 1791–93) further enhanced his prestige as a historian; it also provided him with the material for his greatest drama, *Wallenstein*,

published in 1800 and brilliantly translated into English by Samuel Taylor Coleridge, who thought it "not unlike Shakespeare's historical plays—a species by itself." While Schiller does not rank with such later masters as Theodor Mommsen and Leopold von Ranke, his contribution to German historiography is not to be underrated. He wrote at a time when modern methods of historical research had not yet been perfected, but he applied a critical mind to the sources accessible to him; he had a dramatist's eye for character and motive, and he handled his subjects with literary skill. What he offered to his readers was history seen through the medium of his own individuality, presented with all the verve and eloquence of his distinctive prose style.

Although Schiller's academic post was unremunerative, he felt sufficiently confident about his prospects to embark upon matrimony: in 1790 he married Charlotte von Lengefeld, a cultured young woman of good family, who bore him two sons and two daughters. Schiller was an affectionate husband and father, and Charlotte proved her devotion in all the trials that lay ahead. In the second year of their married life, Schiller's health gave way under the strain of perpetual overwork. For a time he lay critically ill, and although he rallied after several relapses, he never fully recovered. He was under no illusions. With the scientific detachment of the medical man, he analyzed his own condition, a combination of chest trouble and digestive disorder, which, as he suspected, proved intractable. He commented, in a letter to Körner, "My mind, by the way, is serene, and I shall not be found lacking in courage, even though the worst may befall." The rest of his life was a losing battle, fought with superb fortitude, against the inexorable advance of disease.

Philosophical studies. Calamitous as his illness was, it produced a piece of great good luck. To give him time to recuperate at leisure, without worrying about publishers' contracts or tradesmen's bills, two Danish patrons—Prince Friedrich Christian of Schleswig-Holstein-Augustenburg and Heinrich Ernst, Count Schimmelmann—granted him a generous pension for three years. Schiller decided to devote part of this time to studying the philosophy of Immanuel Kant—a project he had had in mind ever since his arrival in Weimar. As he proceeded to assimilate Kant's views, he soon felt the urge to formulate his own. The encounter with Kant's philosophy thus produced between 1793 and 1801 a series of essays in which Schiller sought to define the character of aesthetic activity, its function in society, and its relation to moral experience: his essays on moral grace and dignity, "Über Anmut und Würde," and on the sublime, "Über das Erhabene," as well as the celebrated essay on the distinction between two types of poetic creativity, "Über naive und sentimentalische Dichtung." The latter, like his letters on the aesthetic education of man, "Briefe über die ästhetische Erziehung des Menschen," first appeared in *Die Horen*, an ambitious but short-lived literary periodical edited by Schiller and published by Johann Friedrich Cotta, one of Germany's leading publishers, whom Schiller had met during a visit to his native Swabia in 1793–94. Cotta became a personal friend and a trusted adviser. This period of critical stocktaking also produced some exquisite reflective poems: "Das Ideal und das Leben" ("Life and the Ideal"), "Der Spaziergang" ("The Walk"), "Die Macht des Gesanges" ("The Power of Song"). These are "philosophical lyrics" in the true sense: not versified philosophy, but poetic utterance inspired by an intellectual experience. They contain the quintessence of Schiller's philosophical and critical thinking, and they are among his best poems, but they are poems for the few. On the other hand, the ballads written in 1797 (including "Der Handschuh" ["The Glove"], "Der Taucher" ["The Diver"], and "Die Kraniche des Ibykus" ["The Cranes of Ibycus"]) are among his most popular productions. In these poems and in the famous "Lied von der Glocke" ("The Song of the Bell") Schiller shows how to make poetry accessible to the man in the street without debasing it. Popularity, he insists in his review of Gottfried August Bürger's poems, need not and should not mean pandering to vulgar taste.

Reflective
poetry

Historical drama. In the *Wallenstein* cycle—a work on the grand scale, consisting of a prefatory poem, a dramatic prologue, and two five-act plays—Schiller reached the height of his powers as a dramatist. Against the sombre background of the Thirty Years' War there rises the sinister figure of the emperor Ferdinand II's commander in chief, who in his secret heart is meditating high treason: by joining forces with the enemy, he hopes to make himself the arbiter of the empire. Wallenstein sees himself as a privileged being, a superman beyond good and evil, the man of destiny. While these traits repel, his bearing in the hour of crisis compels admiration and even wins a measure of sympathy. His portrayal is a profound study of the lure and the perils of power.

Working against time, Schiller produced four mole plays in quick succession (apart from his adaptations of *Macbeth* and of the Italian dramatist Carlo Gozzi's *Turandot* for the German stage and his fine translation from the French of Jean Racine's *Phèdre*): *Maria Stuart* (first performed in 1800); *Die Jungfrau von Orléans* (1801; a "romantic tragedy" on the subject of Joan of Arc, in which the heroine dies in a blaze of glory after a victorious battle, rather than at the stake like her historical prototype, who was burned to death in 1431 as a witch and a heretic); *Die Braut von Messina* (1803; *The Bride of Messina*, written in emulation of Greek drama, with its important preface, Schiller's last critical pronouncement); and *Wilhelm Tell* (1804; probably Schiller's most popular play; picturing the revolt of the Swiss forest cantons against Habsburg rule and the assassination of a tyrannous Austrian governor by the hero, it deals with the justifiability of violence in political action). Each one of these later plays has its own distinctive merit, but as a piece of dramatic craftsmanship *Maria Stuart* is superior to the rest. The action is compressed into the last three days in the life of Mary, queen of Scots, before her execution at Fotheringhay; all the antecedents—her French marriage, her brief and troubled Scottish reign, her long and increasingly strait imprisonment in England—emerge by means of retrospective analysis: a striking example of what Schiller called "the Euripidean method." Although Schiller treated his subject with the freedom of the artist, repeatedly diverging from the recorded facts, his play is anything but a travesty of history; on the contrary, it shows a profound grasp of the historical situation. It offers a disturbing analysis of the problems that arise whenever political expediency masquerades as justice and judges are subjected to the pressures of power politics or ideological conflict. Schiller's heroine turns outward disaster into inward triumph by accepting the verdict of the English tribunal—which she regards as both unjust and ultra vires—in expiation of sins committed in former days; by giving to the decree of her judges a meaning that they had not intended, she rises superior to their jurisdiction, a sinner redeemed and transfigured. This conforms to Schiller's theory of tragedy, which turns on the hero's moral rebirth through an act of voluntary self-abnegation.

Death overtook Schiller at Weimar (May 9, 1805) while he was working at a new play on a Russian theme, *Denzetrius*. Judging by the noble fragments that remain, it might well have developed into a masterpiece.

Correspondence. In any account of Schiller's life and works, his letters deserve special attention, whether read as an autobiography, as a running commentary on his plays and poems, as a supplement to his critical writings, or as reflections on German intellectual life in the second half of the 18th century. They are as rich in self-revelation as they are in portraits of contemporaries, and they show the author's personality from all angles: free and easy with intimates, ceremonious when the occasion demands it, clear and precise in matters of business, affectionate to his wife, coolly incisive when provoked, with a touch of humour even in adversity. As one would expect, literary and philosophical topics predominate, but not to the exclusion of other matters; Schiller's letters reflect the whole range of his interests, from the most important to the most trivial: the future of German drama and the price of tobacco, society gossip and the French Revolution,

the philosophy of Immanuel Kant and his children's teething troubles. When Goethe was editing his correspondence with Schiller for publication, he described the letters Schiller had addressed to him as "perhaps the greatest treasure he possessed."

Assessment. In one of the first of those letters the writer, then 34 years old, sized up his prospects:

Now that I have begun to know and to employ my spiritual powers properly, an illness unfortunately threatens to undermine my physical ones. . . . However, I shall do what I can, and when in the end the edifice comes crashing down, I shall perhaps have salvaged what was worth preserving.

He was as good as his word. "The idea of freedom," Goethe said to his young friend Johann Peter Eckermann, "assumed a different form as Schiller advanced in his own development and became a different man. In his youth it was physical freedom that preoccupied him and found its way into his works; in later life it was spiritual freedom." Schiller's early tragedies are attacks upon political oppression and the tyranny of social convention; his later plays are concerned with the inward freedom of the soul that enables a man to rise superior to the frailties of the flesh and to the pressure of material conditions; they show the hero torn between the claims of this world and the demands of an eternal moral order, striving to keep his integrity in the conflict. In his reflective poems and in his treatises, Schiller sets out to show how art can help man to attain this inner harmony and how, through the "aesthetic education" of the individual citizen, a happier, more humane social order may develop. His reflections on aesthetics thus link up with his political and historical thinking.

Schiller's thought has sometimes been called escapist, a retreat into an ivory tower; and yet he has also been charged with trying to press art into the service of morality or social reform. Both criticisms are unjust. Nowhere does Schiller advocate an ascetic or cowardly withdrawal from ordinary experience; on the contrary, he boldly faces the problems of modern life: the disintegration of the human personality in a highly mechanized civilization, the loss of individual freedom under forms of government that put a premium on conformity. Nor does he deny the autonomy of art: far from postulating any direct influence of art on private morals or public affairs, he insists that its effect can only be a mediate and long-term one.

One of the most striking features of Schiller's *oeuvre* is its modernity, its startling relevance to the life of the 20th century. Although for a time he fell out of favour with the German intelligentsia, the enduring value of his work is not likely to be obscured by fashions in criticism.

MAJOR WORKS

PLAYS: *Die Räuber* (1781; *The Robbers*, trans. by A.F. Tytler, Lord Woodhouselee, 1792; and the Rev. W. Render, 1799); *Die Verschwörung des Fiesco zu Genua* (1783; *Fiesco*; or *The Genoese Conspiracy*, trans. by G.H. Noehden and J. Stoddart, 1796); *Kabale und Liebe* (1784; first trans. as *Cabal and Love*, 1795; *The Minister*, trans. by M.G. Lewis, 1798); *Don Carlos, Infant von Spanien* (1787; first trans. 1798; also trans. by J. Kirkup in *The Classic Theatre*, vol. 2, 1959); *Wallenstein, ein dramatisches Gedicht* (1800; trans. by C.E. Passage, and in *Schiller's Tragedies: The Piccolomini and the Death of Wallenstein*, trans. by S.T. Coleridge, 1840); *Maria Stuart* (1801; first trans. 1801; also by L.A. Rhoades, 1894; and *Mary Stuart*, trans. by S. Spender, 1959); *Die Jungfrau von Orléans* (1801; *The Maid of Orléans*, first trans. 1835; also trans. by L. Filmore, 1882); *Die Braut von Messina oder die feindlichen Brüder* (1803; *The Bride of Messina*, first trans. 1837; also trans. by A. Lodge, 1841, and, in English verse, by E. Allfrey, 1876); *Wilhelm Tell* (1804; first trans. 1829; rev. trans. by W. Peter, 1968); *Demetrius* (unfinished) (1805; trans., together with part of *The Bride of Messina* by C. Hodgcs, 1836).

VERSE: *Anthologie auf das Jahr 1782* (1782); *Xenien*, with Goethe (1796; both trans. in the *Complete Works*, trans. by S.T. Coleridge et al., with careful revision and new translation, C.J. Hempel, 2 vol., 1870); *Gedichte*, 2 vol. (1800–03). Many of Schiller's poems are collected in *The Poems of Schiller*, trans. by E.P. Arnold Forster (1901), and *The Ballads and Shorter Poems of Frederick v. Schiller*, trans. by G. Clarke (1901), as well as in the *Complete Works*.

NOVELS: *Der Verbrecher aus Infamie* (1786, later pub. as *Der Verbrecher aus verlorener Ehre*, 1802; *The Criminal from Lost Honour*, trans. by J. Oxenford and C.A. Feiling, 1844); *Der Geisterseher* (1789; *The Apparitionist*, trans. by T. Roscoe in *The German Novelists*, vol. 3, 1826).

HISTORICAL: *Geschichte des Abfalls der vereinigten Niederlande von der Spanischen Regierung* (1788; *The History of the Defection of the United Netherlands from the Spanish Empire*, trans. by E.B. Eastwick, 1844); *Geschichte des dreissigjährigen Krieges*, 2 vol. (1791–93; *The History of the Thirty Years War in Germany*, trans. by Capt. Blaquiére, 1799); *Belagerung von Antwerpen* (1794; trans. in the *Complete Works*).

PHILOSOPHICAL: "Über den Grund des Vergnügens an tragischen Gegenständen" (1792); "Über die tragische Kunst" (1792); "Über Anmut und Würde" (1793); "Über das Pathetische" (1793); all trans. in the *Complete Works*; "Briefe über die ästhetische Erziehung des Menschen" (1795; "On the Aesthetic Education of Man," trans. by E.M. Wilkinson and L.A. Willoughby, 1967); "Über naive und sentimentalische Dichtung" (1795–96); "Über das Erhabene" (1801); "Über den Gebrauch des Chors in der Tragödie" (1803); all trans. in the *Complete Works*.

BIBLIOGRAPHY. For detailed bibliographical information, see WOLFGANG VULPIUS, *Schiller-Bibliographie*, 1893–1958 (1959); and R. PICK (comp.), "Schiller in England, 1787–1960: A Bibliography," *Publications of the English Goethe Society*, vol. 30 (1961). The largest collection of Schilleriana is housed in the Schiller-Nationalmuseum at Marbach. The *Jahrbuch der Deutschen Schillergesellschaft* is mainly devoted to the study of Schiller.

Two of the principal modern editions of Schiller's works are the centenary edition, the *Säkular-Ausgabe*, ed. by EDUARD VON DER HELLEN, 16 vol. (1904–05); and the *Horenausgabe*, ed. by C. SCHUDEKOPF and C. HOFER, 22 vol. (1910–26), which presents Schiller's *oeuvre*, including most of his letters, in chronological order. The letters were edited by F. JONAS, 7 vol. (1892–96). Supplementary material that has since come to light is incorporated in the comprehensive *Nationalausgabe*, ed. by JULIUS PETERSEN *et al.* (1943–), a major critical edition designed to consist of about 40 volumes.

Schiller's style does not readily lend itself to translation into English; most of the existing English versions of his works do not rise above mediocrity. *Wallenstein* is the outstanding exception: *Die Piccolomini* and *Wallensteins Tod* were translated by Coleridge, at a time (December 1799–April 1800) when the poet, who had just returned from his visit to Germany, was still at the height of his powers. Among later contributions, a translation of the letters *On the Aesthetic Education of Man* by E.M. WILKINSON and L.A. WILLOUGHBY (1967, with elaborate commentary), deserves to be specially mentioned.

Of the many critical biographies, see THOMAS CARLYLE, *Life of Friedrich Schiller* (1825), the earliest monograph on Schiller of any lasting value; JAKOB MINOR, *Schiller*, 2 vol. (1890); OTTO HARNACK, *Schiller* (1898); EUGEN KUHNEMANN, *Schiller* (1905); KARL BERGER, *Schiller*, 2 vol. (1905–09); HERBERT CYSARZ, *Schiller* (1934); WILLIAM WITTE, *Schiller* (1949); MELITTA GERHARD, *Schiller* (1950); REINHARD BUCHWALD, *Schiller*, 2 vol., rev. ed. (1953–54); BERNHARD ZELLER, *Schiller, eine Biographie* (1958), richly illustrated; GERHARD STORZ, *Der Dichter Friedrich Schiller* (1959); BENNO VON WIESE, *Schiller* (1959); EMIL STAIGER, *Friedrich Schiller* (1967). The biographies by Carlyle and Witte are in English; all others are in German.

Various special aspects of Schiller's work and personality are treated in the following: LUDWIG BELLERMANN, *Schillers Dramen*, 2 vol. (1888–91); HEINRICH DUNTZER, *Schillers lyrische Gedichte*, 3rd rev. ed. (1893); *Schillers Gesprache*, ed. by JULIUS PETERSEN (1911); MAX HECKER, *Schillers Tod und Bestattung* (1935); E.L. STAHL, *Friedrich Schiller's Drama: Theory and Practice* (1954); THOMAS MANN, *Versuch über Schiller* (1955); W.F. MAINLAND, *Schiller and the Changing Past* (1957); WILLIAM WITTE, *Schiller and Burns, and Other Essays* (1959); *Schiller Bicentenary Lectures*, ed. by FREDERICK NORMAN (1960). The reception of Schiller's works and the history of his posthumous fame up to his first centenary are richly documented in *Schiller: Zeitgenosse aller Epochen*, pt. 1, ed. by NORBERT OELLERS (1970).

(W.Wi.)

Schleiermacher, Friedrich

Friedrich Schleiermacher, widely known during his lifetime as theologian, preacher, classical philologist, and shaper of Prussian church life and culture, is generally

recognized as the founder of modern Protestant theology and the most influential Protestant theologian of the 19th century. His best known work, *The Christian Faith*, is a Christian dogmatics expounding the Christian religion as an individual formation of the "feeling of absolute dependence," the original unity of knowledge and action. Through this dogmatics and other works on theology, ethics, philosophy, and art, Schleiermacher has continued to contribute to the discussion of particular problems in theology and philosophy and to present a vision of the unity of religion and culture.

By courtesy of the Staatsbibliothek, Berlin

Schleiermacher, engraving by F. Lehmann, middle of the 19th century.

He was born November 21, 1768, in Breslau, Lower Silesia (now Wrocław, Poland), the son of Gottlieb and Katharina-Maria (*née* Stubenrauch) Schleiermacher. His father, a Reformed (Calvinist) military chaplain, and his mother both came from families of clergymen. He had an older sister, Charlotte, and a younger brother, Carl.

Childhood and education

From 1783 to 1785 he attended a school of the Moravian Brethren (Herrnhuters), an influential Pietistic group, at Niesky. In this milieu, individualized study was combined with a piety based on the joy of salvation and a vividly imaginative relation with Jesus as Saviour, rather than (as in the Pietism centred in Halle) on a struggle to feel sorrow and repentance. Here Schleiermacher developed his lifelong interest in the Greek and Latin classics and his distinctive sense of the religious life. Later he called himself a Herrnhuter "of a higher order."

Yet the lifeless and dogmatic narrowness of the Moravian seminary at Barby, which he attended from 1785 to 1787, conflicted with his increasingly critical and inquiring spirit. He left in 1787 with the reluctant permission of his father, who had at first harshly rebuked him for his worldliness and accused him of hypocrisy; and at Easter he matriculated at the University of Halle. There he lived with his maternal uncle, Samuel Stubenrauch, a professor of theology, who could understand his restlessness and skepticism.

A diligent and independent student, Schleiermacher began, along with his theological studies, an intensive study of Immanuel Kant's philosophy. In his epistemology (theory of knowledge), though not in his ethics and religion, he remained a Kantian throughout his life. After two years he moved to Drossen (Ošno), near Frankfurt an der Oder, where his uncle had assumed a pastorate, and began preparing for his first theological examinations. Though he read more in ethics than in theology, he took his examinations in Reformed theology in 1790, achieving marks of "very good" or "excellent" in all fields except dogmatics, the one in which he was later to make his most original contribution.

Schleiermacher then took a position as tutor for the family of the Graf (Count) zu Dohna in Schlobitten, East Prussia. Besides tutoring, he preached regularly,

Early career

chiefly on ethical themes, and continued his philosophical study, particularly of the question of human freedom. After taking his second theological examinations in 1794, the same year in which his father died, Schleiermacher became assistant pastor in Landsberg and then, in 1796, pastor of the *Charité*, a hospital and home for the aged just outside Berlin. In that city he found his way into the circle of the German Romantic writers through the creator of early Romanticism, Friedrich von Schlegel, with whom he shared an apartment for a time, began a translation of Plato's works, and became acquainted with the new Berlin society.

In *Über die Religion. Reden an die Gebildeten unter ihren Verächtern* (*On Religion: Speeches to Its Cultured Despisers*), written in 1799 as a kind of literary confession, Schleiermacher addressed the Romantics with the message that they were not as far from religion as they thought; for religion is the "feeling and intuition of the universe" or "the sense of the Infinite in the finite," and Christianity is one individual shaping of that feeling. This work, perennially attractive for its view of a living union of religion and culture, greatly impressed the young theologians of the time. The *Monologen* (1800; *Soliloquies*), written in a somewhat artificial rhythmic prose, presented a parallel to religion in the view of ethics as the intuition and action of the self in its individuality. The individuality of each human being is here seen as a unique "organ and symbol" of the Infinite itself.

A six-year courtship of Eleonore Grunow, unhappily married to a pastor in Berlin, ended in 1802, when Schleiermacher accepted a call to a small Reformed congregation in Stolp, Pomerania (now *Ślupsk*, Poland), and she decided to remain with her husband; but until 1805 he continued to hope she might still consent to become his wife. In this pastorate he became aware of the deep cleavage between a church preacher and a modern man, but at the same time he came to acquire a great fondness for preaching.

In 1804 he accepted a call to be university preacher and extraordinary professor of theology at the University of Halle. As the first Reformed theologian on that Lutheran theological faculty and as a spokesman for Romantic Idealism, he met a cool reception. But the situation changed, and after a year he was made ordinary professor of theology.

In *Die Weihnachtsfeier* (1805; *Christmas Celebration*), written in the style of a Platonic dialogue, Schleiermacher adopted the definition of religion he later incorporated into *The Christian Faith*. Instead of speaking of religion as "feeling and intuition," he now called it simply "feeling"—namely, the immediate feeling that God lives and works in us as finite human beings.

Napoleon's invasion of Prussia forced Schleiermacher to leave Halle in 1807. He moved to Berlin, giving lectures on his own and travelling about to encourage national resistance; he also assisted Wilhelm von Humboldt in laying plans for the new university to be founded in Berlin. He married Henriette von Willich, the widow of a close friend of his, in 1809. In that same year he became pastor of Dreifaltigkeitskirche (Trinity Church) in Berlin and, in 1810, professor of theology at the new university, this latter position one that he retained to the end of his life.

His activities in the years following were many and varied. He lectured on theology and philosophy; he preached in Dreifaltigkeitskirche almost every Sunday until the end of his life; he was a member (from 1800) and permanent secretary of the Berlin Academy of Sciences; he carried on an extensive correspondence; and he was active in promoting the Prussian Union, which brought Lutheran and Calvinist churches into one body. His major publications during this period were the *Kurze Darstellung des theologischen Studiums* (1811; *Brief Outline of the Study of Theology*), presenting a curriculum in which the function of theology is to shape and direct the church as a religious community, and *Der christliche Glaube* (1821-22; 2nd ed. 1831; *The Christian Faith*), an original and impressively systematic treatment of Christian dogmatics.

His relations with the Prussian king were tense until 1831, partly because of differences of view concerning the Prussian constitution and the relation between church and state, and partly because of machinations of his personal rivals. At one stage, an edict of banishment was issued against him, but it was not carried out.

He preached his last sermon on February 2 and gave his last lecture on February 6, 1834. On February 12 he died from inflammation of the lungs. His death stirred the populace of the whole city; Leopold von Ranke, a famous historian, estimated that there were from 20,000 to 30,000 people in the long funeral procession through the streets of Berlin. He was buried in the cemetery of Trinity Church.

Schleiermacher's thought continued to influence theology throughout the 19th century and the early part of the 20th. Between about 1925 and 1955 it was under severe attack by followers of the "kerygmatic" theology of the Word of God (founded by Karl Barth and Emil Brunner) as leading away from the gospel toward a religion based on human culture. Since then, however, there has been a renewed study and appreciation of Schleiermacher's contributions, partly because the critique was one-sided, and partly because of a new interest in 19th-century theology.

BIBLIOGRAPHY. Schleiermacher's works, *Samtliche Werke*, have been published in 30 volumes in three parts: 1. *Theologie*, 2. *Predigten* (sermons), 3. *Philosophie* (1835-1864). The best available study of his life and thought is MARTIN REDEKER, *Friedrich Schleiermacher* (1968), a thorough and readable work (in German) based on meticulous research. A brief and charmingly personal biography is that of MARY F. WILSON, "Biographical Sketch," in *Selected Sermons of Schleiermacher*, pp. 1-37 (1890). HUGH ROSS MACKINTOSH, *Types of Modern Theology*, pp. 31-100 (1937), contains a critical study of Schleiermacher's thought ("The Theology of Feeling") from the point of view of a "kerygmatic" theology of the Word. TERENCE TICE, *Schleiermacher Bibliography* (1966), includes over 1900 items with introductions and annotations.

(R.P.S.)

Schleswig-Holstein

The most northerly *Land* (state) of the Federal Republic of Germany, Schleswig-Holstein has an area of 6,052 square miles (15,676 square kilometres), which constitutes 6.3 percent of the whole country. The *Land* was the home of about 2,500,000 people by the early 1970s. Less than half were urbanized and just over a quarter were of refugee origin; both factors help shape the personality of the contemporary *Land*, which is also the most Protestant in the republic. Extending from the lower course of the *Elbe* River and the *Land* of Freie und Hansestadt Hamburg northward to Denmark, Schleswig-Holstein occupies the southern half of the *Jutland* Peninsula. Its eastern coast is on the Baltic Sea and its western coast on the North Sea; on the mainland it is bounded on the east by the German Democratic Republic. This northerly location has also lent considerable character to the region. Throughout much of European history, Schleswig-Holstein has straddled strategically vital routes between Scandinavia and the south of Europe, and also those running east-west across the great expanses of the continent's northern plain. The important Kiel Canal, linking the Baltic and North seas, and the associated modern four-lane highway reflect a continuation of this role. The *Land* also includes *Fehmarn*, the island in the Baltic; and, in the North Sea, the islands of *Sylt*, *Föhr*, *Amrum*, *Pellworm*, *Nordstrand*, *Helgoland*, and lesser islets known as *Halligen*, all of the North Frisian group. The capital is at Kiel. For related information, see the articles GERMANY, HISTORY OF; BALTIC SEA; and GERMANY, FEDERAL REPUBLIC OF.

History. The history of the area is well-known for its complexity. The two areas of Schleswig and Holstein, without much in the way of natural resources except some arable land, have at times been subject to the claims and counterclaims of Denmark, Sweden, the Holy Roman Empire, Prussia, and Austria. Internally, with Dan-

ish minorities in predominately German areas and German minorities surrounded by Danes, Schleswig-Holstein's history has been one of internal conflicts and, more recently, accommodations.

It took centuries for the two areas, separated by the Eider River, to grow together and become a unified and independent entity. Jutish, Frisian, and Saxon legal traditions existed side by side, a situation that, to some extent, continued up to 1900. This resulted in complicated social and political problems in a land confusedly divided between different forms of government but having a typically European social and constitutional structure, in which princes, the Church, nobility, towns, and peasantry all played parts of varying importance.

The histories of Schleswig and Denmark were closely connected; in the 12th century Schleswig became a dukedom and remained a fief associated (but not without dispute) with Denmark until 1864. Holstein, on the other hand, developed more independently, belonging first as a county, and then (from 1474) as a dukedom, to the Holy Roman Empire. After 1815, Holstein was incorporated in the newly formed German Federation.

During the 1840s, issues relating to the rights of the various national minorities, to the succession rights of the Danish royal family, and to Denmark's interests in the two duchies resulted in their political future becoming involved in larger questions of European politics, particularly the rivalry between Austria and Prussia for the leadership of Germany. The result was that both the duchies were incorporated into Prussia as a single province by the Peace of Prague (1866). The incorporation was not exactly trouble free, because many Schleswig-Holstein people had hoped to set up a German state of their own. The Danish population of North Schleswig was equally discontent under Prussian rule. At the turn of the century the nationality quarrels in North Schleswig reflected similar struggles throughout Europe. The conflict lasted past World War I, until, in 1920, a plebiscite, fixed by the Treaty of Versailles, led to the establishment of borders corresponding very nearly to differences of nationality. An area of North Schleswig voted for incorporation into Denmark. The German minority in this area was consequently a cause of much unrest during the interwar years.

After World War II, Schleswig-Holstein was organized as a Land. The first Landtag, or Diet (legislative assembly), was elected in 1947, and a Social-Democratic government was formed. After 1950 there followed different coalitions led by the Christian Democratic Union.

Landscape. The surface features of Schleswig-Holstein were largely formed by the deposition of glacial drift as a result of the southern advance of Scandinavian ice sheets during the Pleistocene Ice Age some 2,000,000 years ago. Glacial moraines (small hills of ice-carried debris) and outwash plains with stretches of alluvium and sea marshes characterize the landscape. A rough division into eastern, central, and western regions is nevertheless possible. The hilly eastern countryside, a young moraine landscape, is rich in lakes. The loamy soil in this area brings one of the best wheat harvests in Germany. Along the Baltic coast are sheer cliffs, indented by fjords.

In the middle of the state lie the uplands, an old moraine area. The soil is so poor in this area that only in the last two centuries has it been cultivated.

In the west is flat, marshy, treeless land, which can only be partly cultivated. It is known for its numerous ditches, dikes, and ponds. West of the marshes are shallows and flats, which are exposed to the tides, creating a hazard for shipping. Some tidal flats and marshes have been reclaimed, planted to grass, and used for livestock grazing. The east coast, however, is always losing land through exposure to wind, tide, surf, and storm.

Climatically, Schleswig-Holstein lies in an area affected by the Gulf Stream. It has mild winters and temperate summers (yearly average temperature 46° F [8° C]). A high degree of humidity and high rainfall (yearly average 30 inches) make for strong vegetation growth. Strong winds, however, lead to a drying out and drifting of the upland soil.

The people. Schleswig-Holstein has about 2,500,000 inhabitants (412 per square mile [159 per square kilometre]). Thirty percent of the population is urbanized, being concentrated in Kiel (272,000), the main town and the administrative and industrial centre; and also in Lübeck, Neumünster, and Flensburg. The end of World War II brought difficult social problems as retreating army units and more than 1,000,000 evacuees and refugees (many from the east) raised the population about 50 percent above the pre-war level. Unemployment at one time reached 21 percent, but reconstruction programs and aid from the federal government have helped overcome major economic problems. There is a tendency for young workers to migrate away from the state, particularly to Hamburg.

The composition of the population has been greatly altered since World War II through the residual effects of the influx of people from Mecklenburg, East Prussia, and similar areas. This has led to a decline of dialects, although Holsteiner *Platt* (or Plattdeutsch [Low German]) is still spoken. In the north of the state, there is still a small Danish-speaking minority with its own schools. In the border districts, however, nationalistic tendencies seem to have been relaxed as an awareness of the necessity for a united western Europe has gained ground.

Schleswig-Holstein contains the highest proportion of Protestants in the German Republic—over 86 percent; Roman Catholics make up only 6 percent of the population.

The economy. Agriculture accounts for less than 10 percent of the state's net economic output, but Schleswig-Holstein still uses almost 75 percent of its total area (which is not, as a whole, well endowed by nature) for agricultural purposes. The farms of the area have been forced to rationalize their structure, partly as a result of foreign competition, and much land reform and crop specialization has taken place since 1945. Wheat, sugar beets, and potatoes are among the more common arable crops. Livestock provides a far higher proportion of farm incomes, however: a third of farm sales are derived from milk and milk products; nearly a half from pigs; and 16 percent from cattle breeding. The integration of farms, food-processing plants, and marketing concerns in one organization is increasingly characteristic of the agricultural system. Although the state is low in forest reserves, its importance as a supplier of nursery plants for the forests of other regions has caused it to be called "the cradle of German forests."

Industries are increasingly important to the Land's economy. Major branches include shipbuilding, machine construction, and electrical engineering—all important in Kiel—as well as paper, textile, and clothing industries. Recently, there has been a large increase in tourism, notably from the various urban and industrialized regions in the south.

Its long coastline and strategic location have, for centuries, made the area a focus of sea traffic. The Baltic fjords contain the large harbours of Lübeck, Kiel, and Flensburg, and the Kiel Canal, traversing Schleswig-Holstein to connect the North Sea and the Baltic, is the most heavily used in the world. About 80,000 ships pass through it annually.

Air traffic is less important, but a large airport is planned at Kaltenkirchen, near Hamburg, to meet the needs of supersonic air travel.

Administration and education. Since the 1960s there have been problems of area planning and of adjustment to the European Economic Community, of which Germany is a member. Schleswig-Holstein has begun a number of administrative reforms, including reform of its legal system. Under a 1970 reform, the number of *Landkreise* (rural districts) was reduced to 12 and that of municipalities to just under 1,300. As a result, Schleswig-Holstein has, on the average, counties with the largest area within the Federal Republic. Constitutionally, and within the federal framework, the state is headed by a chief minister, assisted by ministers who are responsible to the 73-seat legislative assembly.

The Peace of Prague (1866)

The three topographic zones

Main industries

The *Land* is noted for a high standard of education. The centre of the system is the historic University of Kiel, founded in 1665; a Medical Academy, in Lübeck, was added in 1964. There are also two teacher-training colleges and a number of other specialized institutions of higher learning. At a lower level, cooperative secondary schools have been built to serve the needs of scattered villages.

Cultural life and institutions. As elsewhere in the republic, the state offers generous support to several theatres and orchestras. There are also about 50 significant museums primarily concerned with local and state history. Adult education and libraries enjoy a special tradition and promotion. The Institute for World Economies at Kiel is one of the oldest economic research institutes in Europe and has a very large special library for political economy.

Schliemann, Heinrich

Fascinated from childhood by Greek history and Homeric epics, the German businessman and archaeologist Heinrich Schliemann retired at a relatively early age, after making a fortune in international trade, in order to devote himself to the archaeology of Greece and Turkey. He discovered the sites of the ancient cities of Troy and Mycenae, and his excavations there revealed Bronze Age civilizations hitherto entirely unknown. A pioneer of Greek prehistoric archaeology, he was one of the first excavators on a major scale and one of the first to make the results of his findings widely known to the general public.

BY courtesy of the Deutsche Staatsbibliothek, Berlin

Schliemann, engraving by A. Weger, after a photograph.

Born on January 6, 1822, at Neubukow, in Mecklenburg-Schwerin (now in East Germany), Schliemann was the son of a poor pastor. A picture of Troy in flames in a

history book his father had given him when he was seven years old remained in his memory throughout his life and sustained his fervent belief in the historical foundations of the Homeric poems. At the age of 14 he was apprenticed to a grocer, and it was in the grocer's shop that he heard Homer declaimed in the original Greek. After several years in the shop, ill health forced him to leave, and he became a cabin boy on a ship bound from Hamburg to Venezuela. After the vessel was wrecked off the Dutch coast, he became office boy and then bookkeeper for a trading firm in Amsterdam. He had a passion and a flair for languages, as well as a remarkable memory; these factors, combined with great energy and determination, enabled him to learn to read and write fluently between eight and 13 languages—accounts vary, but his competence certainly included Russian and both ancient and modern Greek.

In 1846 his firm sent him to St. Petersburg as an agent. There he founded a business on his own and embarked, among other things, on the indigo trade. In 1852 he married Ekaterina Lyschin. He made a fortune at the time of the Crimean War, mainly as a military contractor. In the 1850s he was in the United States and became a U.S. citizen, retaining this nationality for the rest of his life. Returning to Russia he retired from business at the age of 36 and began to devote his energies and money to the study of prehistoric archaeology, particularly the problem of identifying the site of Homeric Troy. To train himself, he travelled extensively in Greece, Italy, Scandinavia, Germany, and Syria and then went around the world, visiting India, China, and Japan (he wrote a book about the last two countries). He also studied archaeology in Paris.

In 1868 Schliemann took his large fortune to Greece, visiting Homeric sites there and in Asia Minor, and the following year he published his first book, *Ithaka, der Peloponnes und Troja* ("Ithaca, the Peloponnese, and Troy"). In this work he argued that Hisarlik, in Asia Minor, and not Bunarbashi, a short distance south of it, was the site of Troy and that the graves of the Greek commander Agamemnon and his wife, Clytemnestra, at Mycenae, described by the Greek geographer Pausanias, were not the *tholoi* (vaulted tombs) outside the citadel walls but lay inside the citadel. He was able to prove both theories by excavation in the course of the next few years. He had divorced his Russian wife, Ekaterina, and married in 1869 a young Greek schoolgirl named Sophia Engastromenos, whom he had selected through a marriage bureau.

Although some isolated discoveries had been made before he began digging, Schliemann has rightly been called "the creator of prehistoric Greek archaeology." The French geologist Ferdinand Fouqué dug at Santorin in 1862 and found fresco-covered walls of houses and painted pottery beneath 26 feet (eight metres) of pumice, the result of the great eruption that divided the original island into Thera (modern Thira) and Therasia (modern Thirasia). Geologists at that time dated the Santorin eruption to 2000 BC, which suggested a great antiquity for Fouqué's finds and the existence of prehistoric cultures hitherto unknown in the Aegean. The English archaeologist Frederick Calvert had dug at Hisarlik, and in 1871 Schliemann took up his work at this large man-made mound. He believed that the Homeric Troy must be in the lowest level of the mound, and he dug uncritically through the upper levels. In 1873 he uncovered fortifications and the remains of a city of great antiquity, and he discovered a treasure of gold jewelry, which he smuggled out of Turkey. He believed the city he had found was Homeric Troy and identified the treasure as that of Priam. His discoveries and theories, first published in *Trojanische Altertümer* (1874), were received skeptically by many scholars, but others, including the prime minister of England, William Ewart Gladstone, himself a classical scholar, and a wide public, accepted his identification.

When he proposed to resume work at Hisarlik in February 1874, he was delayed by a lawsuit with the Ottoman government about the division of his spoils, particularly

Business

Discovery
of
Homeric
Troy

the gold treasure, and it was not until April 1876 that he obtained permission to resume work. In 1874–76 Schliemann dug instead at the site of the Treasury of Minyas, at Orchomenus in Boeotia, but found little except the remains of a beautiful ceiling. During this delay he also published *Troja und seine Ruinen*, (1875) and began excavation at Mycenae. In August 1876, he began work in the *tholoi*, digging by the Lion Gate and then inside the citadel walls, where he found a double ring of slabs and, with that ring, five shaft graves (a sixth was found immediately after his departure). Buried with 16 bodies in this circle of shaft graves was a large treasure of gold, silver, bronze, and ivory objects. Schliemann had hoped to find—and believed he had found—the tombs of Agamemnon and Clytemnestra, and he published his finds in his *Mykena* (1878).

After an unsuccessful excavation in Ithaca in 1878, he resumed work at Hisarlik the same year. He conducted a third excavation at Troy in 1882–83 and a fourth from 1888 until his death. In his first season he had worked alone with his wife, Sophia. In 1879 he was assisted by Emile Burnouf, a classical archaeologist, and by Rudolf Virchow, the famous German pathologist, who was also the founder of the German Society for Anthropology, Ethnology, and Prehistory. In his last two seasons Schliemann had the expert assistance of Wilhelm Dorpfeld, who was a practical architect and had worked at the German excavations at Olympia. Dorpfeld brought to Troy the new system and efficiency of the German classical archaeologists working in Greece, and he was able to expose the stratigraphy at Troy more clearly than before and to revolutionize Schliemann's techniques. In 1884, Schliemann, together with Dorpfeld, excavated the great fortified site of Tiryns near Mycenae.

Toward the end of his life, Schliemann suffered greatly with ear trouble and travelled in Europe, visiting specialists and hoping for a cure. None was forthcoming. In great pain and alone, on December 25, 1890, while walking across a square in Naples, he collapsed; he died the next day, December 26.

Schliemann's work of discovery in archaeology is easy to assess. He discovered Homeric Troy as well as a city that existed long before Homer—a prehistoric Bronze Age civilization in Turkey; this was also what he discovered at Mycenae. Hitherto, ancient historians had thought of four empires: Greece, Rome, Egypt, and Babylon-Assyria; Schliemann discovered two new civilizations and enormously lengthened the perspective of history. He nearly discovered a third, namely that of prehistoric Crete.

He had long thought that there must have existed in the Mediterranean a civilization earlier than Mycenae and Bronze Age Hisarlik, and he guessed that it might be in Crete. At one time he contemplated excavation in Crete, but he could not agree to the price asked for the land; thus, the discovery of the pre-Mycenean civilization of Minoan Crete was left to Sir Arthur Evans ten years after Schliemann's death.

Schliemann was one of the first popularizers of archaeology. His books and his dispatches to *The Times*, the *Daily Telegraph*, and other papers kept the world informed and excited by his archaeological discoveries as no one previously had been able to do. It has been said that "every person of culture and education lived through the drama of discovering Troy." Schliemann became a symbol not only of the new archaeological scholarship of the second half of the 19th century but also of the romance and excitement of archaeology. Scholars and the public were inspired by him, and, when he died, Sir John Myres, Camden Professor of Ancient History at the University of Oxford, said that to many it seemed that "the spring had gone out of the year."

When Schliemann began excavating, no corpus of accepted practice existed for archaeological fieldwork. Like Sir Flinders Petrie and Augustus Pitt-Rivers, he was a pioneer. Stratigraphy had been observed and understood in the Danish peat bogs, the Jutland barrows, and the prehistoric Swiss lake dwellings, but Hisarlik was the first large dry-land man-made mound to be dug. It is not

surprising that Schliemann was at first puzzled by what he found, but, eventually, with the assistance of Dorpfeld, he was able to untangle the stratigraphy. There is a wide variation in the assessment of his technique as an excavator. He did extremely well for someone starting to dig in the 1870s, yet he is often unfairly criticized by those who are excavating similar mounds in the Near East 100 years later.

BIBLIOGRAPHY. Schliemann's own books, *Ilios* (1880) and *Troy and Its Remains* (1875), deserve reading not only for their account of his own reconnaissances and excavations but also for the autobiographical material contained. CARL SCHUCHHARDT, *Schliemann-Ausgrabungen im Lichte der heutigen Wissenschaft* (1889; Eng. trans., *Schliemann's Excavations and Archaeological and Historical Studies*, 1891), is a contemporary assessment of his role in the development of archaeology. STANLEY CASSON, *The Discovery of Man* (1939); JOHN MYRES, *The Cretan Labyrinth: A Retrospect of Aegean Research* (1933); and GLYN DANIEL, *A Hundred Years of Archaeology* (1950), give more recent assessments of his work. EMIL LUDWIG, *Schliemann of Troy: The Story of a Gold-Seeker* (1931); and ROBERT PAYNE, *The Gold of Troy* (1958), are popular and slightly sensationalized biographies. For a more balanced picture, containing much new information, see LYNN and GRAY POOLE, *One Passion, Two Loves: The Story of Heinrich and Sophia Schliemann, Discoverers of Troy* (1966).

(G.E.D.)

Schoenberg, Arnold

"Whether right or left, whether forward or backward—one must always go on without asking what lies before or behind one. That should be hidden; you ought to—nay, must—forget it, in order to fulfill your task." These words, spoken by the Angel Gabriel in Arnold Schoenberg's *Jakobsleiter* (*Jacob's Ladder*), might well describe the composer's entire career. Of himself he said, "I am a conservative who was forced to become a radical." Beginning as an imitator of Johannes Brahms and, even more, of Richard Wagner, he discovered and developed a principle—the method of composition with 12 tones related only to one another—that changed the course of 20th-century music.

Pictorial Parade

Schoenberg.

Schoenberg was born on September 13, 1874, in Vienna. His father, Samuel, owned a small shoe shop in the Second, then predominantly Jewish, district. Neither Samuel nor his wife Pauline (*née* Nachod) was particularly musical, although, like most Austrians of their generation, they enjoyed music. There were, however, two professional singers in the family—Heinrich Schoenberg, the composer's brother, and Hans Nachod, his cousin. Nachod, a gifted tenor, was the first to sing the role of Waldemar in Schoenberg's *Gurrelieder*.

Before he was nine years old, Schoenberg began composing little pieces for two violins, which he played with

Childhood
composi-
tions

his teacher or with a cousin. A little later, when he acquired a viola-playing classmate, he advanced to the writing of string trios for two violins and viola. His meeting with Oskar Adler (later the famed astrologer and author of *Das Testament der Astrologie*) was a decisive one. Adler encouraged him to learn the cello so that a group of friends could play string quartets. Schoenberg promptly began composing quartets, although he had to wait for the "S" volume of *Meyers Grosses Konversations-Lexikon* (an encyclopaedia that his family was buying on the installment plan) to find out how to construct the sonata-form first movement of such works. Until about his 18th year he had no models for composition other than violin duets, opera potpourris, and band music played in parks and beer gardens.

Schoenberg's father died in 1890. To help the family finances, the young man worked as a bank clerk from 1891 to 1895. During this time he came to know Alexander von Zemlinsky (1872–1942), a rising young composer and conductor of the amateur orchestra *Polyhymnia* in which Schoenberg played cello. The two became close friends, and Zemlinsky gave Schoenberg instruction in harmony, counterpoint, and composition. This resulted in Schoenberg's first publicly performed work, the *String Quartet in D Major* (1897). Highly influenced by the style of Brahms, the quartet was well received by Viennese audiences during the 1897–98 and 1898–99 concert seasons.

First major works. A great step forward took place in 1899, when Schoenberg composed the string sextet *Verklärte Nacht* (*Transfigured Night*), a highly romantic piece of program music (unified by a nonmusical story or image). Based on a poem of the same name by Richard Dehmel (1863–1920), it was the first piece of program music to be written for such an ensemble. Its programmatic nature and its harmonies, surpassing even the harmonic extremes of Wagner, outraged conservative program committees. Consequently, it was not performed until 1903, when it was violently rejected by the public. Since then it has become one of Schoenberg's most popular compositions, both in its original form and in Schoenberg's later versions for string orchestra.

First
move to
Berlin

In 1901 Schoenberg decided to move to Berlin, hoping to better his financial position. He married Mathilde von Zemlinsky, his friend's sister, and began working as musical director at the *Überbrettel*, an intimate artistic cabaret. He wrote many songs for this group, among them, *Nachtwandler* (*Sleepwalker*) for soprano, piccolo, trumpet, snare drum, and piano (published 1969). Schoenberg did not find this position sufficiently rewarding, either artistically or materially. The German composer Richard Strauss (1864–1949) helped him to get a job as composition teacher at the Stern Conservatory and used his influence to secure him the Liszt stipend awarded by the Allgemeiner Deutscher Musikverein, or Society for German Music. With the encouragement of Strauss, Schoenberg composed his only symphonic poem for large orchestra, *Pelleas und Melisande* (1902–03), after the drama by the Belgian writer Maurice Maeterlinck (1862–1949).

Back in Vienna in 1903, Schoenberg became acquainted with the Austrian composer Gustav Mahler (1860–1911), who became one of his strongest supporters. Schoenberg and Zemlinsky induced Mahler to become the honorary president of their Verein Schaffender Tonkünstler, or Society of Creative Musicians, founded in March 1904. Although the society lasted but one season, it gave a number of important concerts, including the first performance of *Pelleas und Melisande* under the composer's direction; this was a landmark performance, founded by Schoenberg in Vienna after World War I.

Schoenberg's next major work was the *String Quartet No. 1 in D Minor*, Opus 7 (1904). The composition's high density of musical texture and its unusual form (the conventional four movements of a "classic" string quartet blended into one vast structure played without interruption for nearly 50 minutes) caused difficulties in comprehension at the work's premiere in 1907. A similar form

was used in the more concise *Chamber Symphony in E Major* (1906), a work novel in its choice of instrumental ensemble. Turning away from the "monster" post-Romantic orchestra, Schoenberg wrote for a chamber-like group of 15 instruments: flute, oboe, English horn, three clarinets, bassoon, contrabassoon, two horns, and string quintet.

During these years, Schoenberg's activity as a teacher became increasingly important. The young Austrian composers Alban Berg (1885–1935) and Anton Webern (1883–1945) began studying with him in 1904; both gained from him the impetus to their notable careers. As Webern wrote in 1912:

Importance as a
teacher

People think Schoenberg teaches his own style and forces the pupil to adopt it. That is quite untrue—Schoenberg teaches no style of any kind; he preaches the use neither of old artistic resources nor of new ones. . . . Schoenberg does in fact educate his student as a creator. With the utmost energy, he tracks down the pupil's personality, seeking to deepen it, to help it break through—in short, to give the pupil the courage and the strength to find an attitude to things which will make everything he looks at into an exceptional case, because of the way he looks at it. It is an education in utter truthfulness with oneself. (From Willi Reich, *Schoenberg: A Critical Biography*; English translation 1971, Longman Group Limited.)

In turn, Schoenberg benefitted greatly from the intellectual stimulation of his loyal disciples. He stated at the beginning of his *Harmonielehre* ("Theory of Harmony"; 1911), "This book I have learned from my pupils." His great gifts as teacher are manifest in this work as well as in his textbooks—most of them, unfortunately, published only after his death: *Models for Beginners in Composition* (1942), *Structural Functions of Harmony* (1954), *Preliminary Exercises in Counterpoint* (1963), and *Fundamentals of Musical Composition* (1967).

Evolution away from tonality. Until this period all of Schoenberg's works had been strictly tonal; that is, each of them had been in a specific key, centred upon a specific tone. However, as his harmonies and melodies became more complex, tonality became of lesser importance. The process of "transcending" tonality can be observed at the beginning of the last movement of his *Second String Quartet* (1907–08). This work is innovative in another respect, too: it is the first string quartet to include a vocal part (soprano; texts of last two movements by Schoenberg's contemporary, the poet Stefan George). The opening words of the Finale, "Ich fühle Luft von anderen Planeten" ("I feel air from another planet"), have often been symbolically interpreted in the light of Schoenberg's breakthrough to a new world of sound.

On February 19, 1909, Schoenberg finished his piano piece Opus 11, No. 1, the first composition ever to dispense completely with "tonal" means of organization. Such pieces, in which no one tonal centre exists and in which any harmonic or melodic combination of tones may be sounded without restrictions of any kind, are usually called "atonal." Schoenberg himself disliked this negative-sounding term, preferring "pantonal"; but "atonal" is still more widely used. Atonal instrumental compositions are usually quite short; in longer vocal compositions, the text serves as a means of unification. Schoenberg's most important atonal compositions include *Five Orchestral Pieces*, Opus 16 (1909); the monodrama *Erwartung* (*Expectation*), a stage work for soprano and orchestra, Opus 17 (1924); *Pierrot Lunaire*, 21 recitations ("melodramas") with chamber accompaniment, Opus 21 (1912); *Die glückliche Hand* (*The Hand of Fate*), drama with music, Opus 18 (1924); and the unfinished oratorio *Die Jakobsleiter* (begun, 1917).

Atonal
composi-
tions

Schoenberg was aware that his new style would not be understood. As he wrote in the program notes for the first performance of his piano pieces Opus 11 and songs Opus 15, on January 14, 1910:

Now that I have set out along this path once and for all, I am conscious of having broken through every restriction of a bygone aesthetic; and though the goal toward which I am striving appears to me a certain one, I am, nonetheless, already feeling the resistance I shall have to overcome; I feel how hotly even the least of temperaments will rise in revolt, and suspect that even those who have so far believed

in me will not want to acknowledge the necessary nature of this development. . . . I am being forced in this direction not because my invention or technique is inadequate, nor because I am uninformed about all the other things the prevailing aesthetics demand, but because I am obeying an inner compulsion, one stronger than any upbringing: that I am obeying the formative process which, being the one natural to me, is stronger than my artistic education. (Also from *Schoenberg: A Critical Biography*.)

Schoenberg's earlier music was by this time beginning to find recognition. On February 23, 1913, his *Gurrelieder* (begun in 1900, orchestration completed in 1911) was first performed in Vienna. This gigantic cantata calls for unusually large vocal and orchestral forces: six solo singers (soprano, mezzo-soprano or contralto, two tenors, bass, and speaker), three four-part men's choirs, one eight-part mixed choir, and a huge orchestra of 25 woodwinds, 25 brasses, 16 percussion (including several large iron chains), and 84 strings. Along with Mahler's *Eighth Symphony* (*Symphony of a Thousand*), the *Gurrelieder* represents the peak of the post-Romantic monumental style. This music was received with wild enthusiasm by the audience, but the embittered Schoenberg could no longer appreciate or acknowledge their response.

In 1911, unable to make a decent living in Vienna, he had moved to Berlin. He remained there until 1915, when, because of wartime emergency, he had to report to Vienna for military service. He spent brief periods in the Austrian Army in 1916 and 1917, until he was finally discharged on medical grounds. During the war years he did little composing, partly because of the demands of army service and partly because he was meditating on how to solve the vast structural problems that had been caused by his move away from tonality. He wanted to find a new principle of unification that would help him to control the rich harmonic and melodic resources now at his disposal. Near the end of July 1921, Schoenberg told a pupil, "Today I have discovered something which will assure the supremacy of German music for the next 100 years." This was the method of composition with 12 tones related only to one another. Schoenberg had just begun working on his *Piano Suite*, Opus 25, the first 12-tone piece.

In the 12-tone method, each composition is formed from a special row or series of 12 different tones. This row may be played in its original form, inverted (played upside down), played backward, or played backward and inverted. It may also be transposed up or down to any pitch level. All of it, or any part of it, may be sounded successively as a melody or simultaneously as a harmony. In fact, all harmonies and melodies in the piece must be drawn from this row.

Although such a method might seem extremely restrictive, this did not prove to be the case. Using this technique, Schoenberg composed what many consider his greatest work, the opera *Moses und Aron* (music begun in 1930, second act finished in 1932; music for third act never composed). Music and text vividly contrast the personalities of Moses, possessed of a vision yet powerless to communicate it to his people, and Aaron, glib and fluent, who manipulates and misrepresents Moses' ideas for his own ends. Some writers have seen in this an allegory of Schoenberg and his disciples, although Schoenberg was never inarticulate.

For the rest of his life, Schoenberg continued to use the 12-tone method. Occasionally he returned to traditional tonality, for, as he liked to say, "There is still much good music to be written in C major." Among these later tonal works are the *Suite for String Orchestra* (1934); the *Variations on a Recitative for Organ*, Opus 40 (1940); and the *Theme and Variations for Band*, Opus 43A (orchestral version, Opus 43B; 1943). Schoenberg thought of school groups when writing the *Suite* and *Band Variations*, but their difficulty and sophistication make them accessible to only the best of these.

After World War I Schoenberg's music won increasing acclaim, although his invention of the 12-tone method aroused considerable opposition. Tragedy came in 1923, when his wife Mathilde died after a long illness. A year later he married Gertrud Kolisch, the sister of the violin-

ist Rudolf Kolisch (1896–). His success as a teacher continued to grow. In 1925 he was invited to direct the master class in musical composition at the Prussian Academy of Arts in Berlin. The Viennese, who began to feel that they had been neglecting Schoenberg, deplored his departure. But he desired no publicity, for, as he wrote to a journalist who wanted to interview him, "My most pressing need is to depart from Vienna as unnoticed as I have always been while I was here."

It seemed that Schoenberg had reached the peak of his career. His teaching was well received, and he was writing important works: the *Third Strinz Quartet*, Opus 30; the opera *Von Heute auf Morgen* (*From Today to Tomorrow*), Opus 32 (1928–29, first performed in 1930); the *Accompaniment to a Film Scene*, Opus 34 (1929–30); the *Cello Concerto after G.M. Monn* (1932–33); and the *Concerto for String Quartet and Orchestra after Handel* (1933). But political events proved his undoing. The rise of National Socialism in Germany in 1933 led to the extirpation of Jewish influence in all spheres of life. Schoenberg was dismissed from his post at the academy. He emigrated to the United States via Paris, where he formally returned to the Jewish faith, which he had abandoned in his youth. In November 1933 he took a position at the Malkin Conservatory in Boston, Massachusetts. Although he had talented pupils there, he was disappointed in the smallness of the institution, and the northern climate was detrimental to his health. In 1934 he moved to California, where he spent the rest of his life, taking U.S. citizenship in 1941. He held major teaching positions at the University of Southern California (1935–36) and at the University of California at Los Angeles (1936–44).

Schoenberg's major American works show ever-increasing mastery and freedom in the handling of the 12-tone method. Some of the outstanding compositions of his American period are the *Violin Concerto*, Opus 36 (1934–36); the *Fourth String Quartet*, Opus 37 (1936); the *Piano Concerto*, Opus 42 (1942); and the *Fantasia for violin with piano accompaniment*, Opus 47 (1949). He wrote a number of works of particular Jewish interest: *Kol Nidre* for mixed chorus, speaker, and orchestra, Opus 39 (1938); *Prelude to the Genesis Suite* for orchestra and mixed chorus, Opus 44 (1945); *A Survivor from Warsaw* for speaker, male chorus, and orchestra, Opus 46 (1947); *Dreimal tausend Jahre* (*Thrice a Thousand Years*), for mixed chorus a cappella, Opus 50A (1949); and *De Profundis* (Psalm 130, set in Hebrew), also for mixed chorus a cappella, Opus 50B (1950). It was a deep disappointment to him that, because of ill health and other problems, he was unable to complete either *Die Jakobsleiter* or *Moses und Aron*.

During the last years of his life Schoenberg wrote a series of texts called "Modem Psalms." There are 16 of them, dealing with various religious and ethical problems faced by modem man. Schoenberg was able to compose only part of one of the Psalms. The unfinished work was published as *Modern Psalm*, Opus 50C.

On July 2, 1951, Hermann Scherchen, the eminent conductor of 20th-century music, conducted the "Dance Around the Gold Calf" from *Moses und Aron* at Darmstadt, West Germany, as part of the program of the Summer School for New Music. The telegram telling of the great success of this performance was one of the last things to bring Schoenberg pleasure before his death. Eleven days later, he died at his home in Los Angeles.

In 1912 Schoenberg had prophesied concerning his own work: "The second half of this century will spoil by overestimation whatever the first half's underestimation left unspoiled." Certainly, no overestimation occurred after Schoenberg's death. Rather, there was a more just appraisal of the historic importance of his music and teaching. He did not live to see the revolution in electronic music, yet it could not have taken place without his horizon-expanding activities. To him can be applied (as did his pupil Alban Berg) the words of the German musical historian Hugo Riemann on J.S. Bach:

One of the greatest masters of all times, one of those who cannot be surpassed because in them is embodied the musical feeling and thinking of an entire epoch. He gains a spe-

Emigration to the United States

Twelve-tone method

cial importance, an unexampled greatness because in him the styles of two different ages reached their peak, so that he stands between them like a towering landmark.

MAJOR WORKS Orchestral music

Pelleas und Melisande, symphonic poem, op. 5 (1902–03); First Chamber Symphony, op. 9 (1906); Second Chamber Symphony, op. 38 (1906–39); Five Orchestral Pieces, op. 16 (1909); Variations for Orchestra, op. 31 (1928); Suite for String Orchestra (1934); Violin Concerto, op. 36 (1934–36); Piano Concerto, op. 42 (1942).

Chamber music

STRING SEXTET: *Verklärte Nacht*, op. 4 (1899).

STRING QUARTETS: *Quartet in D Major* (1897); No. 1 in D Minor, op. 7 (1905); No. 2 in F Sharp Minor, op. 10 (1907–08), with soprano voice in the last movement; No. 3, op. 30 (1927); No. 4, op. 37 (1936).

STRING TRIO: op. 45 (1946).

CHAMBER ENSEMBLE: Wind Quintet, op. 26 (1923–24); Suite for Seven Instruments, op. 29 (1925).

VIOLIN AND PIANO: *Fantasia*, op. 47 (1949).

PIANO SOLO: Three Piano Pieces, op. 11 (1909); Five Piano Pieces, op. 23 (1920–23); Piano Suite, op. 25 (1921–23).

Vocal music

STAGE WORKS: *Erwartung*, monodrama, op. 17 (1924); *Die glückliche Hand*, drama with music, op. 18 (1924); *Von Heute auf Morgen*, opera in one act, op. 32 (1930); *Moses und Aron*, opera (unfinished; begun 1930).

VOICE AND ORCHESTRA: *Gurrelieder* (1900–11); *Pierrot Lunaire*, op. 21 (1912); *Die Jakobsleiter*, oratorio (unfinished; 1917); *Kol Nidre*, for speaker, mixed chorus, and orchestra, op. 39 (1938); *A Survivor from Warsaw*, for speaker, chorus, and orchestra, op. 46 (1947).

VOICE AND INSTRUMENTS: *Das Buch der hangenden Gärten*, for voice and piano (on poems by S. George), op. 15 (1908–09); *Herzgewachse*, for soprano, celesta, harmonium, and harp, op. 20 (1911); *Serenade*, for bass voice and seven instruments, op. 24 (1923); *Ode to Napoleon Buonaparte*, for speaker, string quartet, and piano, op. 41 (1942).

CHOIR: *Four Pieces for Mixed Chorus*, op. 27 (1925); *Three Satires for Mixed Chorus*, op. 28 (1925); *Six Pieces for Male Chorus*, op. 35 (1930).

SONGS: *Four Songs*, op. 2 (1898–1900), including "Erhebung," no. 3; *Six Songs*, op. 3 (1898–1900), including "Warnung," no. 3; "Hochzeitslied," no. 4; and "Geibtes Herz," no. 5; *Eight Songs*, op. 6 (1905), including "Mädchenlied," no. 3; "Verlassen," no. 4; and "Ghasel," no. 5.

Literary works

Harmonielehre (1911; *The Theory of Harmony*, 1947); "Compositions with Twelve Tones" in *Style and Idea*, ed. by DIKA NEWLIN (1941); *Models for Beginners in Composition* (1942); *Structural Functions of Harmony* (1954); *Preliminary Exercises in Counterpoint* (1963); *Fundamentals of Musical Composition* (1967).

BIBLIOGRAPHY. JOSEF RUFER, *Das Werk Arnold Schönbergs* (1959; Eng. trans., *The Works of Arnold Schoenberg*, 1962), a catalog of Schoenberg's compositions, writings, and paintings, lists both published and unpublished materials. Schoenberg bequeathed many manuscripts and letters to the Library of Congress, Washington, D.C. Among them is the original manuscript of his *Quartet in D Major*. The North Texas State University, Denton, Texas, holds the Schoenberg-Nachod Collection, which comprises correspondence between Schoenberg and his cousin Hans Nachod, as well as many early manuscript compositions. A partial description of the collection is found in DIKA NEWLIN, "The Schoenberg-Nachod Collection: A Preliminary Report," *The Musical Quarterly*, 54:34–41 (1968).

Correspondence: ERWIN STEIN (ed.), *Arnold Schönberg: Ausgewählte Briefe* (1958; Eng. trans., *Letters*, 1964), provides a good selection of the correspondence.

Biographical and critical studies: DIKA NEWLIN, *Bruckner-Mahler-Schoenberg* (1947), a standard work, is the first study in English of the relationship among these composers. EGON WELLESZ, *Arnold Schönberg* (1921; Eng. trans., 1925, reprinted 1969), the first biography of the composer, covers his works through 1923 (the first 12-tone compositions). This version must be used with caution because of many mistakes in translation. H.H. STUCKENSCHEIDT, *Arnold Schönberg* (1951; Eng. trans., *Arnold Schoenberg*, 1959), is sketchy, but the first biography to cover Schoenberg's entire life. WILLI REICH, *Arnold Schönberg* (1968; Eng. trans., *Schoenberg: A Critical Biography*, 1971), has no musical examples, but is especially rich in citations of contemporary documents. RENE LEIBOWITZ, *Schoenberg et son école* (1947; Eng. trans.,

Schoenberg and His School, 1949, reprinted 1970), introduced French readers to the music of the Neo-Viennese School. KARL H. WÖRNER, *Gotteswort und Magie, die Oper "Moses und Aron"* von Arnold Schönberg (1959; Eng. trans., *Schoenberg's "Moses and Aaron,"* 1963), is a thorough study of both the musical and philosophical-theological aspects. MERLE ARMITAGE (ed.), *Schoenberg: A Symposium* (1937), contains essays varying greatly in quality, but provides some interesting insights into the composer. ARNOLD SCHOENBERG, *Style and Idea*, trans. and ed. by DIKA NEWLIN (1950), comprises essays from many periods of Schoenberg's life, including "Composition with Twelve Tones," which has not been surpassed as a lucid and economical presentation of its subject.

(D.N.)

Scholasticism

From the time of the Renaissance until at least the beginning of the 19th century, the term "Scholasticism," not unlike the name "Middle Ages," was used as an expression of blame and contempt. The medieval period was widely viewed as an insignificant *intermezzo* between Greco-Roman antiquity and modern times, and Scholasticism was normally taken to describe a philosophy busied with sterile subtleties, written in bad Latin, and above all subservient to the theology of popery. Even the German Idealist Hegel, in his *Vorlesungen über die Geschichte der Philosophie* (1833–36; Eng. trans., *Lectures on the History of Philosophy, 1892–96*), declared that he would "put on seven-league boots" in order to skip over the thousand years between the 6th and 17th centuries; and having at last arrived at Descartes, said that now he could "cry land like the sailor." In those same first decades of the 19th century, on the other hand, the Romantics swung the pendulum sharply to the opposite side, to an indiscriminate overestimation of everything medieval.

Today, scholars seem better able to confront the medieval epoch, as well as Scholasticism—i.e., its philosophy (and theology)—without prejudgments. One reason for this state of affairs is the voluminous research which has been devoted to this era and which has revealed its true nature, not only as a respectable continuation of the genuinely philosophical tradition but also as a period of exemplary personalities quite able to stand comparison with any of the great philosophers of antiquity or of modern times.

NATURE AND SIGNIFICANCE

Scholasticism is so much a many-sided phenomenon that, in spite of intensive research, scholars still differ considerably in their definition of the term and in the emphases that they place on individual aspects of the phenomenon. Some historians, seeming almost to capitulate to the complexity of the subject, confine themselves to the general point that Scholasticism can only be defined denotatively as that kind of philosophy that during the European Middle Ages was taught in the Christian schools. The question of its connotation, however, remains, viz., What kind of philosophy was it?

The answer that Scholasticism was "school" philosophy and, in fact, "Christian" school philosophy can be understood only by examining the historical exigencies that created the need for schools. The search thus leads the inquirer back to the transition from antiquity to the Middle Ages—a point which, according to Hegel, was marked by the symbolic date AD 529, when a decree of the Christian emperor Justinian closed the Platonic Academy in Athens and sealed "the downfall of the physical establishments of pagan philosophy." In that same year, however, still another event occurred, which points much less to the past than to the coming age and, especially, to the rise of Scholasticism, viz., the foundation of Monte Cassino, the first Benedictine abbey, above one of the high-ways of the great folk migrations. This highly symbolic fact suggests not only the initial shift of the scene of the intellectual life from places like the Platonic Academy to the cloisters of Christian monasteries, but it marks even more a change in the *dramatis personae*. New nations were about to overrun the Roman Empire and its Hellenistic culture with long-range effects: when, centuries lat-

Barbarians need for school learning

er, for example, one of the great Scholastics, Thomas Aquinas, was born, though he was rightly a southern Italian, his mother was of Norman stock, and his Sicilian birthplace was under central European (Hohenstaufen) control.

It was a decisive and astonishing fact that the so-called barbarian peoples who penetrated from the north into the ancient world often became Christians and set out to master the body of tradition that they found, including the rich harvest of patristic theology as well as the philosophical ideas of the Greeks and the political wisdom of the Romans. This learning could be accomplished only in the conquered empire's language (*i.e.*, in Latin), which therefore had to be learned first. In fact, the incorporation of both a foreign vocabulary and a different mode of thinking and the assimilation of a tremendous amount of predeveloped thought was the chief problem that confronted medieval philosophy at its beginnings. And it is only in the light of this fact that one of the decisive traits of medieval Scholasticism becomes understandable: Scholasticism above all was an unprecedented process of learning, literally a vast "scholastic" enterprise that continued for several centuries. Since the existing material had to be ordered and made accessible to learning and teaching, the very prosaic labour and "schoolwork" of organizing, sorting, and classifying materials inevitably acquired an unprecedented importance. Consequently, the writings of medieval Scholasticism quite naturally lack the magic of personal immediacy, for schoolbooks leave little room for originality. It is therefore misleading, though understandable, that certain polemicists have wrongly characterized Scholasticism as involving no more than the use of special didactic methods or a narrow adherence to traditional teachings.

First of all, if the major historical task of that epoch was really to learn, to acquire, and to preserve the riches of tradition, a certain degree of "scholasticity" was not only inevitable but essential. It is not at all certain that today's historians would have direct intellectual access to Plato, Aristotle, and Augustine had the Scholastics not done their patient spadework. Besides, the progress from the stage of mere collection of given sentences and their interpretation (*expositio*, *catena*, *lectio*), to the systematic discussion of texts and problems (*quaestio*, *disputatio*), and finally to the grand attempts to give a comprehensive view of the whole of attainable truth (*Summa*) was necessarily at the same time a clear progression toward intellectual autonomy and independence, which in order to culminate, as it did in the 13th century, in the great works of Scholasticism's Golden Age, required in addition the powers of genius, of men like Albertus Magnus and Thomas Aquinas.

On the other hand, the moment had to come when the prevalent preoccupation with existing knowledge would give way to new questions, which demanded consideration and answers that could emerge only from direct experience. By the later Middle Ages, procedures for exploiting and discussing antecedent stocks of insight had been largely institutionalized, and it was an obvious temptation to perpetuate the dominion of those procedures—which could lead only to total sterility. It is widely agreed that this is almost exactly what did happen in the 14th century in what is called the "decline" and disintegration of Scholasticism.

HISTORY AND ISSUES

Roots of Scholasticism. From the beginning of medieval Scholasticism the natural aim of all philosophical endeavour to achieve the "whole of attainable truth" was clearly meant to include also the teachings of Christian faith, an inclusion which, in the very concept of Scholasticism, was perhaps its most characteristic and distinguishing element. Although the idea of including faith was expressed already by Augustine and the early church fathers, the principle was explicitly formulated by the pivotal, early 6th-century scholar Boethius. Born in Rome and educated in Athens, Boethius was one of the great mediators and translators, living on the narrow no-man's-land that divided the epochs. His famous book,

The Consolation of Philosophy, was written while he, indicted for treachery and imprisoned by King Theodoric the Goth, awaited his own execution. It is true that the book is said to be, aside from the Bible, one of the most translated, most commented upon, and most printed books in world history; and that Boethius made (unfinished) plans to translate and to comment upon, as he said, "every book of Aristotle and all the dialogues of Plato." But the epithet that he won as "one of the founders of Scholasticism" refers to quite another side of his work. Strictly speaking, it refers to the last sentence of a very short tractate on the Holy Trinity, which reads, "As far as you are able, join faith to reason"—an injunction which in fact was to become, for centuries, the formal foundation of Scholasticism. Instead of "faith," such concepts as revelation, authority, or tradition could be (and, indeed, have been) cited; and "reason," though unambiguously meant to designate the natural powers of human cognition, could also be granted (and, in fact, has been granted) very different meanings. In any case, the connection between faith and reason postulated in this principle was from the beginning and by its very nature a highly explosive compound.

Boethius himself already carried out his program in a rather extraordinary way: though his *Opuscula sacra* ("Sacred Works") dealt almost exclusively with theological subjects, there was not a single Bible quotation in them: logic and analysis was all.

Though called the "first Scholastic," Boethius was at the same time destined to be for almost a millennium the last layman in the field of European philosophy. His friend Cassiodorus, author of the *Institutiones*, an unoriginal catalog of definitions and subdivisions, which (in spite of their dryness) became a source book and mine of information for the following centuries, who, like Boethius, occupied a position of high influence at the court of Theodoric and was also deeply concerned with the preservation of the intellectual heritage, decided in his later years to quit his political career and to live with his enormous library in a monastery. This fact again is highly characteristic of the development of medieval Scholasticism: intellectual life needs not only teachers and students and not only a stock of knowledge to be handed down; there is needed a certain guaranteed free area within human society as well, a kind of sheltered enclosure, within which the concern for "nothing but truth" can exist and unfold. The Platonic Academy, as well as (for a limited time) the court of Theodoric, had been enclosures of this kind; but in the politically unsettled epoch to come "no plant would thrive except one that germinated and grew in the cloister."

The principle of the conjunction of faith and reason, which Boethius had proclaimed, and the way in which he himself carried it out were both based on a profound and explicit confidence in man's natural intellectual capacity—a confidence that could possibly lead one day to the rationalistic conviction that there cannot be anything that exceeds the power of human reason to comprehend, not even the mysteries of divine revelation. To be sure, the great thinkers of Scholasticism, in spite of their emphatic affirmation of faith and reason, consistently rejected any such rationalistic claim. But it must nonetheless be admitted that Scholasticism on the whole, and by virtue of its basic approach, contained within itself the danger of an overestimation of rationality, which recurrently emerged throughout its history.

On the other hand, there had been built in, from the beginning, a corrective and warning, which in fact kept the internal peril of Rationalism within bounds, viz., the corrective exercised by the "negative theology" of the so-called Pseudo-Dionysius, around whose writings revolved some of the strangest events in the history of Western culture. The true name of this protagonist is, in spite of intensive research, unknown. Probably it will remain forever an enigma why the author of several Greek writings (among them *On the Divine Names*, "On the Celestial Hierarchy," and *The Mystical Theology*) called himself "Dionysius the Presbyter" and, to say the least, suggested that he was actually Denis the Areopa-

cism

Boethius
and
Cassio-
dorus

The
Pseudo-
Dionysius

gite, a disciple of Paul the Apostle (Acts). In reality, almost all historians agree that "Pseudo-Dionysius," as he came to be called, was probably a Syrian Neoplatonist, a contemporary of Boethius. Whatever the truth of the matter may be, his writings exerted an inestimable influence for more than 1,000 years by virtue of the somewhat surreptitious quasi-canonical authority of their author, whose books were venerated, as has been said, "almost like the Bible itself." A 7th-century Greek theologian, **Maximus the Confessor**, wrote the first commentaries on these writings, which were followed over the centuries by a long succession of commentators, among them **Albertus Magnus** and **Thomas Aquinas**. The main fact is that the unparalleled influence of the Areopagite writings preserved in the Latin West an idea, which otherwise could have been repressed and lost (since it cannot easily be coordinated with rationality)—that of a negative theology or philosophy that could act as a counterpoise against Rationalism. It could be called an Eastern idea present and effective in the Occident. But after the Great Schism, which erected a wall between East and West that lasted for centuries, **Denis** the Areopagite, having become himself (through translations and commentaries) a Westerner "by adoption," was the only one among all of the important Greco-Byzantine thinkers who penetrated into the schools of Western Christendom. Thus negative theology was brought to medieval Scholasticism, as it were, through the back door.

The most important book of **Denis**, which dealt with the names that can be applied to God, exemplified his negative theology. It maintained first of all the decidedly biblical thesis that no appropriate name can be given to God at all unless he himself reveals it. But then **Denis** showed that even the revealed names, since they must be comprehensible to man's finite understanding, cannot possibly reach or express the nature of God; and that in consequence, every affirmative statement about God requires at once the corrective of the coordinate negation. The theologian cannot even call God "real" or "being," because he derives these concepts from the things to which God has given reality; and the Creator cannot possibly be of the same nature as that which he has created. Thus, *The Mystical Theology* concluded by finally relativizing also the negations, because God surpasses anything that man may possibly say of him, whether it be affirmative or negative.

Scholasticism certainly could have learned all of this also from Augustine, who repeatedly warned that "Whatever you understand cannot be God." But probably an authority of even greater weight than Augustine was needed to counteract a reason that was tending to overrate its own powers; and this authority was attributed, although falsely, to the works of **Denis** the Areopagite. This impact could, of course, not be restricted to the idea of God; it necessarily concerned and changed man's whole conception of the world and of existence. The influence of **Denis** is reflected in the noteworthy fact that **Thomas Aquinas**, for instance, not only employed more than 1,700 quotations from **Denis** the Areopagite but also appealed almost regularly to his work whenever he spoke, as he often did (and in astonishingly strong terms), of the inexhaustible mystery of being. **Thomas Aquinas**, however, who also wrote a remarkable commentary on **Denis'** book *On the Divine Names*, is mentioned here only as an example, albeit a most telling example.

At the very end of the medieval era of Scholasticism, the Areopagite emerged once more in the work of a 15th-century cardinal, **Nicholas of Cusa**, also known as a mathematician and advocate of experimental knowledge, in whose library there are preserved several translations of the Areopagite writings—replete, moreover, with marginal notes in the Cardinal's handwriting. But even without this concrete evidence, it would be quite plain that **Cusanus'** doctrine of "knowing nonknowing" is closely linked to the Areopagite's conviction that all of reality is unfathomable.

The translation into Latin of the *Corpus Areopagiticum*, which was made in the 9th century—i.e., some 400 years

after the death of its author—by **John Scotus Erigena**, is itself worthy of mention, especially because the translator was one of the most remarkable figures of early medieval philosophy. After generations of brave and efficient collectors, organizers, and schoolmasters had come and gone, **Erigena**, in his *De divisione naturae* ("On the Division of Nature"), developed the Dionysian Neoplatonism on his own and tried to construct a systematic conception of the universe, a more or less pantheistic world view, which (as **Gilson** says) for a moment offered the Latin West the opportunity—or the temptation—to choose the way of the East once and for all. The church, though not until centuries later, condemned the book, apparently convinced that any counterpoise to its own position can become dangerous in itself.

Early Scholastic period. If there was any philosophical-theological thinker of importance during the Middle Ages who remained untouched by the spirit of the Areopagite, it was the 11th-century Benedictine **Anselm** of Canterbury, a highly cultivated Franco-Italian theologian who for years was prior and abbot of the abbey **Le Bec** in Normandy and then became, somewhat violently, the archbishop of Canterbury. In **Anselm's** entire work there is not a single quotation from **Denis**; not even the name is mentioned. Consequently, **Anselm's** thinking, thus freed from the corrective embodied in the Areopagite's negative theology, displayed a practically unlimited confidence in the power of human reason to illuminate even the mysteries of Christian faith; he thus frequently approached a kind of Rationalism, which did not shrink from the attempt to demonstrate, on compelling rational grounds, that salvation (for example) through God incarnate was philosophically necessary. To be sure, a theologian such as **Anselm** certainly would never have subscribed to the extreme thesis that nothing exists that is beyond the power of human reason to comprehend: the two famous phrases, coined by him and expressing again, in a grandiose formulation, the principle of **Boethius**, "faith seeking to be understood" and "I believe in order to understand," clearly proclaim his faith in the mysteries of revelation as comprising the very basis of all reasoning. Nevertheless, in the case of **Anselm**, the very peculiar conjunction of faith and reason was accomplished not so much through any clear intellectual coordination as through the religious energy and saintliness of an unusual personality. It was accomplished, so to speak, rather as an act of violence, which could not possibly last. The conjunction was bound to break up, with the emphasis falling either on some kind of Rationalism or on a hazardous irrationalization of faith.

That this split did actually happen can be read to some extent in the fate of the "Anselmic argument," which **Kant**, 700 years later, was to reject as the "ontological proof of God"—connecting it, however, not with the name of **Anselm** but with that of **Descartes**, the earliest modern philosopher. It is, in fact, significant that **Descartes**, in his proof of the existence of God, imagined that he was saying the same thing as **Anselm**, and that, on the other hand, **Anselm** would scarcely have recognized his own argument had he encountered it in the context of **Descartes's** *Discours de la méthode* (1637; *Discourse on Method*, 1950), which claims to be "pure" philosophy based upon an explicit severance from the concept of God held by faith. But given **Anselm's** merely theoretical starting point, that severance was not only to be expected; it was almost inevitable.

But, also within the framework of medieval Scholasticism, a dispute was always brewing between the dialecticians, who emphasized or overemphasized reason, and those who stressed the suprarational purity of faith. **Berengar** of Tours, an 11th-century logician, metaphysician, and theologian, who was fond of surprising formulations, maintained the pre-eminence of thinking over any authority holding, in particular, that the real Presence of Christ in the Eucharist was logically impossible. His contemporary the Italian Hermit-monk and cardinal **Peter Damian**, however—who was apparently the first to use the ill-famed characterization of philosophy as the "handmaid of theology"—replied that, if God's omnipotence

Anselm's belief in human reason

Bernard
and
Abelard

acts against the principle of contradiction, then so much the worse for the science of logic. Quite analogous to the foregoing controversy, though pitched on a much higher intellectual level, was the bitter fight that broke out almost one century later between a Cistercian reformer, Bernard of Clairvaux, and a logician and theologian, Peter Abelard. Bernard, a vigorous and ambivalent personality, was in the first place a man of religious practice and mystical contemplation, who, at the end of his dramatic life, characterized his odyssey as that of *anima quaerens Verbum*, "a soul in search of the Word." Although he by no means rejected philosophy on principle, he looked with deep suspicion upon the primarily logical approach to theology espoused by Abelard. "This man," said Bernard, "presumes to be able to comprehend by human reason the entirety of God."

Logic was at that time, as a matter of fact, the main battleground of all Scholastic disputations. "Of all philosophy, logic most appealed to me," said Abelard, who by "logic" understood primarily a discipline not unlike certain present-day approaches, the "critical analysis of thought on the basis of linguistic expression." From this viewpoint (of linguistic logic), Abelard also discussed with penetrating sharpness the so-called "problem of universals," which asks, Is there an "outside" and objective reality standing, for example, not only for the name "Socrates" but also for such common names as "man," "canineness," and the like? Or do common concepts ("universals") possess only the reality of subjective thought or perhaps merely that of the sound of the word? As is well known, it has been asserted that this was the principal, or even the only, subject of concern in medieval Scholasticism—a charge that is misleading, although the problem did greatly occupy philosophers from the time of Boethius. Their main concern from the beginning was the whole of reality and existence.

The advance of medieval thought to a highly creative level was foreshadowed, in those very same years before Peter Abelard died, by Hugh of Saint-Victor (an Augustinian monk of German descent), when he wrote *De sacramentis Christianae fidei* ("On the Sacraments of the Christian Faith"), the first book in the Middle Ages that could rightly be called a *summa*; in its introduction, in fact, the term itself is used as meaning a comprehensive view of all that exists (*brevis quaedam summa omnium*). To be sure, its author stands wholly in the tradition of Augustine and the Areopagite; yet he is also the first medieval theologian who proclaims an explicit openness toward the natural world. Knowledge of reality is, in his understanding, the prerequisite for contemplation; each of the seven liberal arts aims "to restore God's image in us." "Learn everything," he urged; "later you will see that nothing is superfluous."

It was on this basic that the university—which was not the least of the achievements of medieval Scholasticism—was to take shape. And it was the University of Paris, in particular, that for some centuries was to be the most representative university of the West. Though there are usually a variety of reasons and causes for such a development, in this case the importance of the university—unlike that of Bologna and also of Oxford—lay mainly in the fact that it was founded in the most radical way upon those branches of knowledge that are "universal" by their very nature: upon theology and philosophy. It is, thus, remarkable, though not altogether surprising, that there seems to have existed not a single *summa* of the Middle Ages that did not, in some way or other, derive from the University of Paris.

Strangely enough, the classical theological-philosophical textbook used in the following centuries at the universities of the West was not the first *summa*, composed by Hugh of Saint-Victor, but was instead a work by Peter Lombard, a theologian who probably attended Abelard's lectures and who became *magister* at the cathedral school of Notre-Dame and, two decades later, bishop of Paris. Lombard's famous *Four Books of Sentences*, which, though written one or two decades later than Hugh's *summa*, belonged to an earlier historical species, contained about 1,000 texts from the works of Augustine,

which comprise nearly four-fifths of the whole. Much more important than the book itself, however, were the nearly 250 commentaries on it, by which—into the 16th century—every master of theology had to begin his career as a teacher. In view of this wide usage, it is not astonishing that Lombard's book underwent some transformations, at the hands, for instance, of its most ingenious commentator, Thomas Aquinas, but also (and even more so) at the hands of Duns Scotus in his *Opus Oxoniense*, which, in spite of being a work of extremely personal cast, was outwardly framed as a commentary on the "Master of Sentences."

Maturity of Scholasticism. Clearly, the world view of Western Christendom, on the whole Augustinian and Platonic in inspiration and founded upon Lombard's "Augustine breviary," was beginning to be rounded out into a system and to be institutionalized in the universities. At the very moment of its consolidation, however, an upheaval was brewing that would shake this novel conception to its foundations: the main works of Aristotle, hitherto unknown in the West, were being translated into Latin—among them his *Metaphysics*, the *Physics*, the *Nicomachean Ethics*, and the books *On the Soul*. These writings were not merely an addition of something new to the existing stock; they involved an enormous challenge. Suddenly, a new, rounded, coherent view of the world was pitted against another more-or-less coherent traditional view; and because this challenge bore the name of Aristotle, it could not possibly be ignored, for Aristotle's books on logic, translated and equipped with commentaries by Boethius, had for centuries been accepted as one of the foundations of all culture. During the lifetime of Abelard the full challenge of the Aristotelian work had not yet been presented, though it had been developing quietly along several paths, some of which were indeed rather fantastic. For instance, most of the medieval Latin translations of Aristotle stem not from the original Greek but from earlier Arabic translations.

Within the Western Christendom of the 2nd millennium, a wholly new readiness to open the mind to the concrete reality of the world had arisen, a view of the universe and life that resembled the Aristotelian viewpoint. The tremendous eagerness with which this new philosophy was embraced was balanced, however, by a deep concern lest the continuity of tradition and the totality of truth be shattered by the violence of its assimilation. And this danger was enhanced by the fact that Aristotle's works did not come alone; they came, in fact, accompanied by the work of Arabic commentators and their heterodox interpretations.

The most influential Arabic commentators were an 11th-century polymath, Avicenna, a Persian by birth, and a 12th-century philosopher, Averroes, born in Spain. Avicenna, personal physician to sovereigns, but also a philosopher and theologian, read—according to his own account—Aristotle's *Metaphysics* 40 times without understanding it, until he learned the text by heart. F.C. Copleston has called him "the real creator of a Scholastic system in the Islamic world." In the view of Averroes, who was not only a philosopher but also a jurist and a doctor, Aristotle's philosophy represented simply the perfection of human knowledge; and to the West, he himself was to become *the* commentator. A third great commentator was a 12th-century orthodox Jewish philosopher, Moses Maimonides, also born in Spain, who wrote his main works in Arabic. Maimonides was at the same time a vigorous adherent of the Aristotelian world view and was, thus, confronted by the same unending task that preoccupied the great teachers of medieval Christendom. At first sight it appears strange that none of these three thinkers had any appreciable influence within his own world (neither Islam nor Judaism knew of any such thing as a "discovery" of Aristotle), whereas on almost every page of the 13th-century Christian *summae* the names of Avicenna, Averroes, and Maimonides are found.

The first theologian of the Middle Ages who boldly accepted the challenge of the new Aristotelianism was a 13th-century Dominican, Albertus Magnus, an encyclo-

pedic scholar. Although he knew no Greek, he conceived a plan of making accessible to the Latin West the complete works of Aristotle, by way of commentaries and paraphrases; and, unlike Boethius, he did carry out this resolve. He also penetrated and commented upon the works of the Areopagite; he was likewise acquainted with those of the Arabs, especially Avicenna; and he knew Augustine. Nevertheless, he was in no wise primarily a man of bookish scholarship; his strongest point, in fact, was the direct observation of nature and experimentation. After having taught for some years at the University of Paris, he travelled, as a Dominican superior, through almost all of Europe. Not only was he continually asking questions of fisherman, hunters, beekeepers, and birdcatchers but he himself also bent his sight to the things of the visible world. But amidst the most palpable descriptions of bees, spiders, and apples, recorded in two voluminous books on plants and animals, Albertus formulated completely new, and even revolutionary, methodological principles: for instance, "There can be no philosophy about concrete things," or, "in such matters only experience can provide certainty."

With Albertus, the problem of the conjunction of faith and reason had suddenly become much more difficult, because reason itself had acquired a somewhat new meaning. "Reason" implied, in his view, not only the capacity for formally correct thinking, for finding adequate creatural analogies to the truths of revelation, but it implied, above all, the capacity to grasp the reality that man encounters. Henceforth, the Boethian principle of "joining faith with reason" would entail the never-ending task of bringing belief into a meaningful coordination with the incessantly multiplying stock of natural knowledge of man and the universe. Since Albertus' nature, however, was given more to conquest than to the establishment of order, the business of integrating all of these new and naturally divergent elements into a somewhat consistent intellectual structure waited for another man, for his pupil Thomas Aquinas.

Thomas
Aquinas

To epitomize the intellectual task that Aquinas set for himself, the image of Odysseus' bow, which was so difficult to bend that an almost superhuman strength was needed, is fitting. As a young student at the University of Naples, he had met in the purest possible form both extremes, which, though they seemed inevitably to be pulling away from one another, it was nevertheless his life's task to join: one of these extremes was the dynamic, voluntary poverty movement whose key word was "the Bible"; and the second phenomenon was the Aristotelian writings and outlook, which at that time could have been encountered nowhere else in so intensive a form. And "Aristotle" meant to Thomas not so much an individual author as a specific world view, viz., the affirmation of natural reality as a whole, including man's body and his natural cognitive powers. To be sure, the resulting *Summa theologiae* (which Thomas himself chose to leave incomplete) was a magnificent intellectual structure; but it was never intended to be a closed system of definitive knowledge. Thomas could no longer possess the magnificent naïveté of Boethius, who had considered it possible to discuss the Trinitarian God without resorting to the Bible, nor could he share Anselm's conviction that Christian faith so completely concurred with natural reason that it could be proved on compelling rational grounds.

In the meanwhile, the poles of the controversy—the biblical impulses, on the one hand, and the philosophical and secular ones, on the other—had begun to move vigorously apart, and partisans moving in both directions found some encouragement in Thomas himself. But in his later years he realized that the essential compatibility as well as the relative autonomy of these polar positions and the necessity for their conjunction had to be clarified anew by going back to a deeper root of both; that is, to a more consistent understanding of the concepts of creation and createdness. At Paris, he had to defend his own idea of "a theologically based worldliness and a theology open to the world" not only against the secularistic "philosophism" of Siger of Brabant, a stormy member of the faculty of arts, and against an aggressive group of hetero-

dox Aristotelians around him, but also (and even more) against the traditional (Augustinian) objection that by advocating the rights of all natural things Thomas would encroach upon the rights of God, and that, besides, the theologian needs to know only that part of creation that is pertinent to his theological subject. The latter idea was supported also by the Italian mystical theologian Bonaventura, who, in his earlier days as a colleague of Thomas at the university, had likewise been enamoured of Aristotle, but later, alarmed by the secularism that was growing in the midst of Christendom, became more mistrustful of the capacities of natural reason. Thomas answered this objection in somewhat the following way: The benefit that the theologian may derive from an investigation of natural reality cannot be determined in advance, but, in general, faith presupposes and therefore needs natural knowledge of the world; at times, an error concerning the creation leads men astray also from the truth of faith. This may sound like an optimistic Rationalism; but the corrective of negative theology and philosophy was always present in the mind of Thomas, as well. Not only, as he argued in his treatise on God, does man not know what God is, but he does not know the essences of things either.

Late Scholastic period. Thomas did not succeed in bridging the faith–reason gulf. When he left Paris (1272) and after his death (1274), the gulf became much more radical; and on March 7, 1277, the Archbishop of Paris, in fact, formally condemned a list of sentences, some of them close to what Thomas himself had allegedly or really taught. This ecclesiastical act, questionable though it may have been in its methods and personal motivations, was not only understandable; it was unavoidable, since it was directed against what, after all, amounted in principle to an antitheological, rationalistic secularism. Quite another matter, however, were the factual effects of the edict, which were rather disastrous. Above all, two of the effects were pernicious: instead of free disputes among individuals, organized blocks (or "schools") now began to form; and the cooperative dialogue between theology and philosophy turned into mutual indifference or distrust. Nonetheless, the basic principle itself ("join faith with reason") had not yet been explicitly repudiated. This was to happen in the next generation.

The negative element, as formulated in the theology of the Areopagite, proved to be insufficient as a corrective to counter the overemphasis of reason, for reason seemed to imply the idea of necessity; Anselm's asserted "compelling grounds" for revealed truths, for example, were akin to such a necessitarianism. A second corrective was therefore demanded and this took the name of "freedom"—which indeed was the battle cry of an important Franciscan, Duns Scotus, known as the "subtle doctor," who lived at the turn of the 14th century. Scotus used "freedom" primarily with reference to God; consequently, since redemption, grace, and salvation as well as all of creation were the work of God's groundless, absolute freedom, there could be no "necessary reasons," if indeed any reasons at all, for anything. It was therefore futile to attempt to coordinate faith with speculative reason. Clearly, Scotus' theological starting point made the conjunction of what man believes with what he knows every bit as difficult as it had been in Siger of Brabant's secularistic "philosophism." From both positions there was only one step to the doctrine of a "double truth"—a step that in fact was taken in the 14th century by the Nominalist William of Ockham, also a Franciscan, to whom singular facts alone are "real," and their coherence is not; this mere factuality, he held, can neither be calculated nor deduced, but only experienced; reason therefore means nothing but the power to encounter concrete reality. And upon such soil only a consistently "positive" theology could thrive. Any collaboration with speculative reason must be rejected as untheological. Faith is one thing and knowledge an altogether different matter; and a conjunction of the two is neither meaningfully possible nor even desirable. Inexorably, and justified by reasons on both sides, a divorce was taking place between faith and reason—to the connection of which the energies of al-

Duns
Scotus
and

of Ockham

most a thousand years had been devoted. What was occurring was the demise of medieval Scholasticism.

ENDURING FEATURES

But not all of Scholasticism is specifically medieval and therefore definitively belonging to the dead past; there are perennial elements that are meant for every age, the present one included, three of which may be here distinguished. First, not only has Scholasticism held true to the normal historical rule that ideas, once thought and expressed, remain present and significant in the following time; but the medieval intellectual accomplishments have surpassed the rule and exerted, though more or less anonymously, a quite exceptional influence even on philosophers who consciously revolted against Scholasticism. New historical investigations clearly show that the classical modern philosophers Descartes, Locke, Spinoza, and Leibniz owe much to medieval ideas. Of Descartes, for instance, it has been said, contrary to the usual view, that he could quite well have been "included with the later Scholastics"; and even Charles Sanders Peirce, the originator of 20th-century American Pragmatism, refers not too rarely to Scholastic maxims. Secondly, there have been explicit attempts to go back to Scholastic thinkers and inspire a renaissance of their basic ideas. Two chief movements of this kind were the Scholasticism of the Renaissance (called *Barockscholastik*) and the Neoscholasticism of the 19th and 20th centuries, both of which were primarily interested in the work of Thomas Aquinas.

Renaissance Scholasticism received its first impulses from the Reformation. One of its leading figures, a Dominican, Cardinal Thomas de Vio (16th century), commonly known as Cajetan, had some famous disputations with Martin Luther. Cajetan's great commentary on Thomas Aquinas, published again in a late edition of the *Summa theologiae* (1888–1906), exerted for at least three centuries an enormous influence on the formation of Catholic theology. He was much more than a commentator, however; his original treatise on the "Analogy of names," for example, can even pass as a prelude to modern linguistic philosophy. The so-called Silver Age of Scholastic thought, which occurred in the 16th century, is represented by two Spaniards: Francisco de Vitoria of the first half and Francisco Suárez of the last half of the century were both deeply engaged in what has been called the "Counter-Reformation." Though likewise commentators on the works of Thomas Aquinas, the Renaissance Scholastics were much less concerned with looking back to the past than with the problems of their own epoch, such as those of international law, colonialism, resistance to an unjust government, and world community. Though Suárez was for more than a hundred years among the most esteemed authors, even in Protestant universities, Renaissance Scholasticism was eradicated by Enlightenment philosophy and German Idealism. This, in turn, gave rise in due time to the Neoscholasticism of the 19th century, one of the most effective promoters of which was a German Jesuit, Joseph Kleutgen, who published a voluminous scholarly apology of patristic and Scholastic theology and philosophy, and was also responsible for the outline of the papal encyclical *Aeterni Patris* of Leo XIII (1879), which explicitly proclaimed the "instauration of Christian philosophy according to St. Thomas." The result, fed of course from many different sources, was that all over the world new centres of Scholastic research and higher learning (universities) arose—some more traditionalistic, some from the start engaged in the dialogue with modern philosophy and science, and some primarily devoted to historical studies and the preparation of critical editions of the great medieval Scholastics—and that a multitude of periodicals and systematic textbooks were produced. It is too early for a competent judgment on this enterprise to be made. Its immeasurable educational benefit for several generations of students, however, is undeniable as the unique contributions of some Neoscholastic thinkers to current intellectual life. A weak point, on the other hand, seems to be a somewhat "unhistorical" approach to reality and existence. In any case, it is scarcely a matter of mere chance that, after World War

II, the impact of Existentialism and Marxism caused a noticeable decline in Neoscholasticism and that the positions of "Scholastic" authors active in the 1970s is already beyond Neoscholasticism.

The third and most important aspect of the enduring significance of the Scholastic movement implies the acceptance of the following fundamental tenets: that there exist truths that man knows, and also revealed truths of faith; that these two kinds of truth are not simply reducible to one another; that faith and theology do not, by means of symbols and sensuous images, merely say the same as what reason and science say more clearly by conceptual argumentation (Averroes, Hegel); that, on the other hand, reason is not a "prostitute" (Luther), but is man's natural capacity to grasp the real world; that since reality and truth, though essentially inexhaustible, are basically one, faith and reason cannot ultimately contradict one another. Those who hold these convictions appear quite unable to refrain from trying to coordinate what they know with what they believe. Any epoch that addresses itself to this interminable task can ill afford to ignore the demanding and multifarious paradigm of Scholasticism; but to the problems posed it will have to find its own answer.

BIBLIOGRAPHY. For the latest and most detailed bibliography, see W. TOTOK, *Handbuch der Geschichte der Philosophie*, vol. 2, *Mittelalter und frühe Neuzeit* (1970). Among the most reliable, best-grounded presentations of the whole period are: E. GILSON, *History of Christian Philosophy in the Middle Ages* (1955); F. COPLESTON, *A History of Philosophy*, vol. 2, *Mediaeval Philosophy*, vol. 3, *Late Mediaeval and Renaissance Philosophy* (1950, 1953; paperback edition, 1962, 1963); M. DE WULF, *Histoire de la philosophie médiévale*, 6th ed., 3 vol. (1934–47; Eng. trans. of vol. 1, 1951); and E. BREHIER, *La Philosophie du moyen âge*, 2nd ed. (1949). Still indispensable, though obsolete in some details is: F. UEBERWEG, *Grundriss der Geschichte der Philosophie*, vol. 2, B. GEYER, *Die patristische und scholastische Philosophie*, 11th ed. (1928). Lucidly arranged and divided is the 13th volume of FLICHE-MARTIN, *Histoire de l'Église: Le Mouvement doctrinal de XI^e au XIV^e siècle* (1951), which includes contributions by A. Forest, F. van Steenberghe, and M. de Gandillac. M. GRABMANN'S masterpiece, *Die Geschichte der scholastischen Methode*, 2 vol. (1909–11, reprinted 1956), covers only the time until the first years of the 13th century. For a first introduction for the general reader, see J. PIEPER, *Scholastik* (1960; Eng. trans., *Scholasticism*, 1960). Special problems concerning the continuing influence of medieval Scholasticism are treated in the following monographs: A. KOYRE, *Descartes und die Scholastik* (1923); A. TELLKAMP, *Das Verhältnis John Locke's zur Scholastik* (1927); and J.O. FLECKENSTEIN, *Scholastik, Barock, exakte Wissenschaften* (1949). The following are sources on Neoscholasticism: J.P. GOLINAS, *La Restauration du Thomisme sous Leon XIII et les philosophies nouvelles* (1959); GIOVANNI ROSSI, *Le origini del Neotomismo nell'ambiente di studio del Collegio Alberoni* (1957); A. VIEL, "Le Mouvement thomiste au XIX^e siècle," *Revue Thomiste* (1909–10); E. BETTONI, *La Situation actuelle de la philosophie parmi les catholiques dans les divers pays* (1948), a survey of centres of study, institutes, and publications; and J.S. ZYBURA (ed.), *Present-Day Thinkers and the New Scholasticism: An International Symposium* (1926).

(Jf.Pi.)

Schopenhauer, Arthur

Arthur Schopenhauer, called "the philosopher of pessimism," was a discoverer of the irrational impulses of life arising from the will, an opponent of the absolute Idealism of G.W.F. Hegel and of the rationally determined awareness of progress and of the present in the 19th and 20th centuries, and a pioneer of the new "life" philosophy.

Early life and education. Schopenhauer was born on February 22, 1788, the son of a wealthy Danzig merchant, Heinrich Floris Schopenhauer, and his wife Johanna, who later became famous for her novels, essays, and travelogues. In 1793, when Danzig came under Prussian sovereignty, they moved to the free city of Hamburg.

Young Arthur enjoyed a gentlemanly, urbane education. He spent two years (1798–1800) in the home of one of his father's business friends in Le Havre, France, in order to learn the French language. After his return, he

attended a private business school, where he became acquainted with the spirit of the Enlightenment and was exposed to a Pietistic attitude sensitive to the plight of man. During this time, the Pietistic phrase that characterized life as a "vale of tears" became as familiar to him as did the writings of the German lyric poet Matthias Claudius, known as the Wandsbeck Messenger. In 1803 he accompanied his parents for a year on an extensive journey through Belgium, England, France, Switzerland, and Austria. Again, predominantly negative impressions prevailed: the sight of such want and misery as that at the *Bagno* (prison) in Toulon, France, with its 6,000 galley slaves, reinforced his tendency toward a pessimistic outlook on life. According to the wishes of his father, he reluctantly entered a business apprenticeship in 1805.

The sudden death of his father in April 1805, however, precipitated a decisive change in his life. His mother and his young sister Adele moved to Weimar, where his mother succeeded in joining the social circle of the poets Goethe and Christoph Martin Wieland (often called the German Voltaire). Arthur himself had to remain in Hamburg for more than a year, yet with more freedom to engage in the arts and sciences. *Phantasien über die Kunst* (1799; "Reveries on Art"), a work by Wilhelm Wackenroder, known for his writings on old German art and music, provided the young man with a significant initiation into literature. Here music was depicted as the liberating counterbalance to man's base existence, and it was from this fundamental mood that Schopenhauer's philosophy of music later arose. In May 1807 he was finally able to leave Hamburg. During the next two years, spent in Gotha and Weimar, he acquired the necessary academic preparation for attendance at a university.

In the fall of 1809 he matriculated as a student of medicine at the University of Göttingen and mainly attended lectures on the natural sciences. As early as his second semester, however, he transferred to the humanities. On the advice of the famous author of the *Aenesidemus*, Gottlob Ernst Schulze, a critic of Kantianism, Schopenhauer concentrated first on the study of Plato and Kant. This course proved to be of great consequence to his intellectual growth, for it caused him to reject the post-Kantian development, as expounded by the Idealists J.G. Fichte, F.W.J. von Schelling, and G.W.F. Hegel, that was to be the predominant philosophical current for a long time to come. In the fall of 1811, Schopenhauer went to the University of Berlin. For one semester he attended the lectures of Fichte, at first with appreciation, later with mocking indignation. The philosopher Friedrich Schleiermacher, one of the fathers of modern theology, could likewise offer him little. What the professors of philosophy were lacking—results that were clarifying and, in their lucidity, convincing—he found instead in

the representatives of classical philology (Friedrich August Wolf and August Bockh) and in a long series of lectures on the natural sciences. The war situation eventually constrained him to leave Berlin. In Rudolstadt, during the summer of 1813, he finished his dissertation, *Über die vierfache Wurzel des Satzes vom zureichenden Grunde* (Eng. trans., *On the Fourfold Root of the Principle of Sufficient Reason*, 1889), which earned him the doctor of philosophy degree from the University of Jena.

Active maturity. The following winter (1813–14) he spent in Weimar, in intimate association with Goethe, who invited his assistance with some problems concerning his *Farbenlehre* ("theory of colours"). Schopenhauer was able to "profit immensely" from his conversations with the poet, which covered the most varied philosophical topics. In that same winter, however, the Orientalist Friedrich Majer, a disciple of Johann Gottfried Herder, introduced him to the teachings of Indian antiquity—the philosophy of Vedanta and the mysticism of the Vedas (Hindu scriptures). Later, Schopenhauer considered that the *Upanishads* (philosophic Vedas), together with Plato and Kant, comprised the foundation on which he erected his own philosophical system.

In May 1814 he left his beloved Weimar after a quarrel with his mother, whose frivolous way of life he disapproved of. He then lived in Dresden until 1818, associating occasionally with a group of writers for the *Dresdener Abendzeitung* ("Dresden Evening Newspaper"). For some time he kept in close contact with the panentheist philosopher K.C.F. Krause, proponent of a "league of mankind," with whom he shared a love for Indian antiquity. Schopenhauer finished his treatise *Über das Sehn und die Farben* (1816; "On Vision and Colours"), supporting Goethe against Newton; yet he did not receive the poet's approbation.

His next three years were dedicated exclusively to the preparation and composition of his main work, *Die Welt als Wille und Vorstellung* (1819; Eng. trans., *The World as Will and Idea*, 1883–86). The fundamental idea of this work—which is condensed into a short formula in the title itself—is developed in four books comprising two comprehensive series of reflections that include successively the theory of knowledge, the philosophy of nature, aesthetics, and ethics. The first book begins with Kant. The world is my representation, says Schopenhauer. It is only comprehensible with the aid of the constructs of man's intellect: space, time, and causality. But these constructs show the world only as appearance, as a multiplicity of things next to and following one another—not as the thing in itself, which Kant considered to be unknowable. The second book advances to a consideration of the essences of the concepts presented. Of all the things in the world, only one is presented to a person in two ways, viz., the person himself: he knows himself externally as body, as appearance and, internally, directly as part of the primary essence of all things, as will—in the general sense that Schopenhauer gave to the concept. The will is the thing in itself; it is unitary, unfathomable, unchangeable, beyond space and time, without causes and purposes. In the world of appearances, it is reflected in an ascending series of realizations. From the blind impulses in the forces of inorganic nature, through organic nature (plants and animals) to the rationally guided actions of men, an enormous chain of restless desires, agitations, and drives stretch forth—a continual struggle of the higher forms against the lower, an eternally aimless and insatiable striving, inseparably united with misery and misfortune. At the end, however, stands death, the great reproof that the will-to-live receives, posing the question to each single person: Have you had enough?

Whereas the first two books present the will in an affirmative mode, the last two, dealing with aesthetics and ethics, surpass them by pointing to the negation of the will as a possible liberation. Evoking as their leading figures the genius and the saint, who illustrate this negation, these books present the "pessimistic" world view that values non-being more highly than being. The arts summon man to a will-less way of viewing things, in which

Work on
*The World
as Will
and Idea*

the play of the passions ceases. To the succession of levels achieved by the realizations of the will corresponds a gradation of levels in the arts—from the lowest—the art of building (architecture)—through the art of poetry to the highest—music. But the arts liberate a person only momentarily from the service of the will. A genuine liberation results only from breaking through the bounds of individuality imposed by the ego. Whoever feels acts of compassion, of selflessness, of human kindness, and the suffering of other beings as his own is on the way to the abnegation of the will to life, achieved by the saints of all peoples and times in asceticism. Schopenhauer's anthropology and sociology do not, in the manner of Hegel, commence with the state or with the community; they focus upon man—patient, suffering man who toils by himself—and show him certain possibilities of standing his ground and of living together with others, possibilities with which modern sociology has yet to become thoroughly and fruitfully conversant.

The book, published in December of 1818, marked the summit of Schopenhauer's thought. In the many years thereafter, no further development of his philosophy occurred, no inner struggles or changes, no critical reorganization of basic thoughts. From then onward, his work consisted merely of more detailed exposition, clarification, and affirmation.

Schopenhauer then embarked on his first journey through Italy; indeed, he was one of the last such travelers to perceive the monuments of classical antiquity with a sensitivity comparable to that of Johann Joachim Winckelmann, author of an epoch-making history of ancient architecture.

In March 1820, after a triumphant dispute with Hegel, he qualified to lecture at the University of Berlin. Though he remained a member of the university for 24 semesters, only his first lecture was actually held; for he had scheduled (and continued to schedule) his lectures at the same hour when Hegel lectured to a large and ever-growing audience. Clearly, he could not successfully challenge a persistently advancing philosophy. Even his book received scant attention. For a second time Schopenhauer went on a year-long trip (1822–23) to Italy, and this was followed by a year of illness in Munich. In May 1825 he made one last attempt in Berlin, but in vain. He now occupied himself with secondary works: a translation of *El oraculo manual* (1647; Eng. trans., *The Oracle*, 1953) by the Spanish Jesuit Baltasar Gracian, which appeared only posthumously; plans (which were never realized) for translations of Hume into German and Kant into English; and a rendering of his treatise on colours into Latin (*Theoria Colorum Physiologica*; 1830).

Scholarly retirement in Frankfurt. During his remaining 28 years (after 1833), he lived in Frankfurt, which he felt to be free from the threat of cholera, and left the city only for brief interludes. He had finally renounced his career as a university professor and lived henceforth as a recluse, totally absorbed in his studies and writings.

Pursuit of cultural interests. The natural-science collections of the city afforded him the opportunity to observe and inform himself of progress in the empirical sciences, and he attended plays and concerts; but he took little interest in what he considered the trivial events of everyday life. The classical authors Plato, Aristotle, Horace, and Seneca; the major writers of more recent times, such as Shakespeare and the Spaniard Calderón de la Barca; the leading spirits of mysticism; the French moralists and psychologists; and the influential exponents of the Enlightenment—these were his familiar companions. Thus, he progressively lost contact with his former connections, and his social life was restricted almost exclusively to conversations with fellow patrons at the dinner table.

His life now took on the shape that posterity first came to know: the measured uniformity of the days; the strict, ascetic life-style modelled after Kant; the old-fashioned attire; the tendency to gesticulative soliloquy; the brisk walks with an accompanying poodle. Brief excursions to nearby locations and to the Rhine and occasional re-

unions with early friends were for a long time the only diversions in a life of continued robust health and mental alacrity.

Publication and continuing obscurity. His leisure was not idle. Despite the disappointments engendered by his indifferent contemporaries, he relied on the eventual triumph of truth, as presented by his life's accomplishments: "The truth can wait," he wrote, "for it lives a long time." Thus, in 1836, after 19 years of "silent indignation," he published his short treatise *Über den Willen in der Natur* (Eng. trans., *On the Will in Nature*, 1889), which skillfully employed the queries and findings of the rapidly expanding natural sciences in support of his theory of the will. The preface for the first time openly expressed his devastating verdict on the "charlatan" Hegel and his clique. During the years from 1837 to 1839, he entered two academic competitions sponsored by the Norwegian and Danish societies of the sciences. The treatise *Über die Freiheit des menschlichen Willens* (submitted 1839; Eng. trans., *On the Freedom of the Will*, 1960) won him a first prize, whereas the treatise *Über das Fundament der Moral* (submitted 1840; *On the Basis of Morality*, 1903) did not—a fact that Schopenhauer expressly noted on the title page of a volume that included both essays under the title *Die beiden Grundprobleme der Ethik* (1841; "The Two Main Problems of Ethics").

The treatise *On the Will in Nature* and the *Ethics* were intended as supplements to the second and fourth books of *The World as Will and Idea*, with which they were to share, for the time being, the fate of remaining unnoticed. Even the second edition of his main work (1844), which included an additional volume of great significance, failed to break what he called "the resistance of a dull world"—despite the fact that, by then, Schopenhauer's first disciples, whom he jokingly called "apostles" and "evangelists," had gathered. Notable among these followers was a convert from Hegelianism, Julius Frauenstadt, who later became his literary executor. The little weight that Schopenhauer's name carried became evident when three publishers rejected his latest work. It was Frauenstadt who in the end persuaded a rather obscure Berlin bookseller to accept the manuscript without remuneration.

In this book Schopenhauer turned to significant topics hitherto not treated individually within the framework of his writings: the work of six years yielded the essays and comments compiled in two volumes under the title *Parerga und Paralipomena* (1851; selective Eng. trans., *Essays from . . .*, 1951). The *Parerga* ("Minor Works") include fragments concerning the history of philosophy; the famous treatise "Über die Universitäts-Philosophie"; the enigmatically profound "Transzendente Spekulation über die anscheinende Absichtlichkeit im Schicksale des Einzelnen" ("Transcendent Speculation on the Apparent Premeditation in Personal Fate"); the "Versuch über das Geistersehn und was damit zusammenhangt" ("Essay on Ghost-seeing and its Related Aspects")—the first investigation, classification, and critical reflection concerning parapsychology; and the "Aphorismen zur Lebensweisheit" ("Aphorisms on Practical Wisdom"), a serene and brilliant account garnered from his long life. The *Paralipomena* ("Remnants"), or as Schopenhauer called them ". . . separate, yet systematically ordered thoughts on various subjects," included essays on writing and style, on women, on education, on noise and sound, and on numerous other topics.

Worldwide recognition. After the stormy events of the Revolution of 1848 had subsided (condemned by Schopenhauer as an eruption of man's primitive nature), the *Parerga und Paralipomena* brought the beginning of worldwide recognition. In April 1853 John Oxenford, an English critic, writing in *The Westminster Review*, broke the ice with an influential attack on Hegelian philosophizing, entitled "Iconoclasm in German Philosophy." Reviews, essays, and more extensive treatises on Schopenhauer and his theory followed in rapid succession. Already in 1857, in Bonn and in Breslau, the first lectures on his philosophy were given; the University of Leipzig

proposed the first scholarly competition on his teachings; initial translations and eulogies appeared in French; Italy's foremost critic, Francesco de Sanctis, in a dialogue written with Neapolitan verve, drew a parallel between Schopenhauer and Italy's own poet of pessimism, Count Giacomo Leopardi. Suddenly, the hermit of Frankfurt drew admiration and visitors. Richard Wagner sent him (in 1854) *The Ring of the Nibelung*, bearing a dedication "in veneration and gratitude." He was visited by the later founder of characterology, Julius Bahnsen (1856); by the dramatist Friedrich Hebbel (1857); and by the French statesman Foucher de Careil. Other, mostly younger, academicians sought his acquaintance at the dinner table of the "Englischer Hof." Famous artists arrived to preserve his features on canvas for posterity. "The Nile has reached Cairo," he came to say.

During the last years of his life, he added the finishing touches to most of his works. Even a third edition of his main work, containing an exultant preface, appeared in 1859 and, in 1860, a second edition of his *Ethics*. On the morning of September 21, 1860, he succumbed to a sudden and painless death.

Soon thereafter, Julius Frauenstädt published new and enlarged editions, with many handwritten additions, of the *Parerga and Paralipomena* (1862), the Fourfold Root (1864), the essay *On the Will in Nature* (1867), the treatise on colours (1870), and finally even a fourth edition of his main work (1873). Later that same year Frauenstädt published the first complete edition of his works in six volumes.

Influence. During this time, the actual impact and influence of Schopenhauer began to spread. By turning away from spirit and reason to the powers of intuition, creativity, and the irrational, his thought has affected—partly via Nietzsche—the ideas and methods of vitalism, of life philosophy (Dilthey, Bergson), of Existential philosophy, and of anthropology. Through his disciple Julius Bahnsen and through Eduard von Hartmann's philosophy of the unconscious, the connection to modern psychology and to Sigmund Freud and his school can be established. The philosophy of history of Jacob Burckhardt, a Swiss cultural historian, also proceeds from Schopenhauer. Within the German cultural realm, Schopenhauer's influence on music and literature brings to mind such names as the opera composers Richard Wagner and Hans Pfitzner; Wilhelm Busch, a humorous artist and poet; the dramatists Gerhart Hauptmann and Frank Wedekind; and Thomas Mann, the greatest of modern German novelists. Since 1911, the Schopenhauer Society in Frankfurt am Main has been dedicated to the study, exposition, and dissemination of Schopenhauer's philosophy.

MAJOR WORKS

Über die vierfache Wurzel des Satzes vom zureichenden Grunde (1813, reissued 1847; *On the Fourfold Root of the Principle of Sufficient Reason*, 1889); *Über das Sehnen und die Farben* (1816, rev. 1854 after Latin adaptation, *Commentatio Exponens Theoriam Colorum Physiologicam, Eandemque primariam*, 1830); *Die Welt als Wille und Vorstellung: vier Büchlein, nebst einem Anhang der die Kritik der Kantischen Philosophie enthält* (1819; augmented editions 1844 and 1859; *The World As Will and Idea*, 3 vol., 1883–86; *The World As Will and Representation*, 2 vol., 1958); *Über die Freiheit des menschlichen Willens* and *Über das Fundament der Moral*, published together as *Die beiden Grundprobleme der Ethik* (1841; *The Basis of Morality*, 1903, 1965; first section, *On the Freedom of the Will*, 1960); *Parerga und Paralipomena*, 2 vol. (1851; selections trans. as *Religion: A Dialogue*, 1889; *The Wisdom of Life*, 1890; *Counsels and Maxims*, 1890; *Studies in Pessimism*, 1891; *The Art of Literature*, 1891; *Essays from the Parerga and Paralipomena*, 1951). *Der hmdschrifflcher Nachlass* ("Manuscript Remains"), selections 1864 and 1891–93, critical edition (vol. 1–3, 5, 1966–70; vol. 4 in prep.), the first complete edition of the *Nachlass* manuscripts, including the marginal inscriptions in Schopenhauer's private library; trans. *Baltasar Gracians Hand-Orakel und Kunst der Weltklugheit* (many German editions).

BIBLIOGRAPHY

Editions: Collections of Schopenhauer's *Werke* are nu-

merous; the edition by JULIUS FRAUENSTAEDT, 6 vol. (1873–74), has been re-edited several times; it is, like the one by EDUARD GRISEBACH, 6 vol. (1891), now out of date. PAUL DEUSSEN (ed.), *Sämtliche Werke*, 16 vol. (1911–42, unfinished), contains Schopenhauer's correspondence, ed. by ARTHUR HUEBSCHER (vol. 14–16). ARTHUR HUEBSCHER (ed.), *Sämtliche Werke*, 2nd ed., 7 vol. (194650; 3rd ed., 1972–), is the standard edition based on new research.

Biographies: ARTHUR HUEBSCHER, *Arthur Schopenhauer: Ein Lebensbild*, 2nd ed. (1949), a comprehensive evaluation of research results up to its date of publication; and *Schopenhauer: Gespräche* (1971), an authentic source for his life and work history; WILHELM VON GWINNER, *Arthur Schopenhauer aus persönlichem Umgang dargestellt*, 3rd ed. (1910, reprinted 1963), a description of a personal acquaintance with Schopenhauer; PATRICK GARDINER, *Schopenhauer* (1963), an English-language biography.

Studies: KUNO FISCHER, *Geschichte der reuerm Philosophie*, vol. 8, *Arthur Schopenhauer*, 4th ed. (1934), a biased account; JOHANNES VOLKELT, *Arthur Schopenhauer*, 5th ed. (1923); and HEINRICH HASSE, *Schopenhauer* (1926), both thorough descriptions in German; ARTHUR HUEBSCHER, *Schopenhauer: Gesfren-Heufe-Morgen* (1973), on his importance and influence.

(Ar.Hü.)

Schrodinger, Erwin

Erwin Schrodinger, with the physicists Albert Einstein, Niels Bohr, Max Born, Werner Heisenberg, Wolfgang Pauli, Louis de Broglie, and P.A.M. Dirac, developed quantum mechanics in the late 1920s and shared the Nobel Prize in Physics with Dirac in 1933. In 1926 Schrödinger discovered the partial differential equation that is the basic equation of quantum mechanics and bears the same relation to the mechanics of the atom as Newton's equations of motion bear to planetary astronomy. Adopting a proposal made by de Broglie in 1924 that particles of matter have a dual nature and in some situations act like waves, Schrödinger introduced a theory describing the behaviour of such a system by a wave equation. The solutions to Schrodinger's equation, unlike the solutions to Newton's equations, are wave functions that can only be related to the probable occurrence of physical events. The definite and readily visualized sequence of events of the planetary orbits of Newton is, in quantum mechanics, replaced by the more abstract notion of probability. This aspect of the quantum theory made Schrödinger and several other physicists, including Einstein, profoundly unhappy, and Schrodinger devoted much of his later life to formulating philosophical objections to the generally accepted interpretation of the theory that he had done so much to create.

Schrodinger was born in Vienna on August 12, 1887. An only child, he was brought up in a family devoted to scientific and cultural activity. He was privately tutored until the age of 11, when he entered a Gymnasium. Schrodinger received a broad classical education that served as the basis for his lifelong interest in languages, philosophy, and literature.

Schrodinger entered the University of Vienna in 1906 and remained there, with brief interruptions, until 1920; he saw military service in World War I. His work in physics during this period was distinguished, but hardly of the calibre of his later discoveries in atomic wave mechanics. Indeed, late in his life, he wrote that in 1918 he had more or less decided to abandon theoretical physics for philosophy, when it appeared that he would get an academic post in Czernowitz, Romania, now Chernovtsy, Ukrainian S.S.R. Czernowitz was taken from Austria after the war, and instead Schrodinger went to Zürich in 1921, where he remained for the next six years. There, in a six-month period in 1926, at the age of 39, a remarkably late age for original work by theoretical physicists, he produced the papers that gave the foundations of quantum wave mechanics. In 1927 he accepted an invitation to succeed Max Planck, the inventor of the quantum hypothesis, at the University in Berlin, and he joined an extremely distinguished faculty that included Einstein. There he remained until 1933 when, although of Catholic background, he decided that he could no longer live in a country in which the persecution of Jews had become a

Early work in Vienna

Schrödinger.

national policy. He then began a seven-year odyssey that took him to Austria, Great Britain, the Pontifical Academy of Science in Rome, and—finally in 1940—to the Dublin Institute for Advanced Studies, founded under the influence of Premier Eamon de Valera, who had been a mathematician before turning to politics. Schrödinger remained in Ireland for the next 15 years, doing both research in physics and in the philosophy and history of science. During this period he wrote *What Is Life?*, an attempt to show how quantum physics can be used to explain the stability of genetic structure. Although much of what Schrödinger had to say in this book has been modified and amplified by later developments in molecular biology, his book remains one of the most useful and profound introductions to the subject. In 1956 Schrödinger retired and returned to Vienna as professor emeritus at the University. He died on January 4, 1961.

Of all of the physicists of his generation, Schrödinger stands out because of his extraordinary intellectual versatility. He was at home in the philosophy and literature of all of the Western languages, and his popular scientific writing in English, which he had learned as a child, is among the best of its kind. His study of ancient Greek science and philosophy, summarized in his *Nature and the Greeks* (1954), gave him both an admiration for the Greek invention of the scientific view of the world and a skepticism toward the relevance of science as a unique tool with which to unravel the ultimate mysteries of human existence. Schrödinger's own metaphysical outlook, as expressed in his last book, *Meine Weltansicht* (1961; *My View of the World*, 1964), closely paralleled the mysticism of the Vedānta.

Because of his exceptional gifts, Schrödinger was able in the course of his life to make significant contributions to nearly all branches of science and philosophy, an almost unique accomplishment at a time when the trend was toward increasing technical specialization in these disciplines.

BIBLIOGRAPHY. WILLIAM T. SCoTT, *Erwin Schrödinger: An Introduction to His Writings* (1967), is a good critical study of Schrödinger and his works.

(J.Be)

Schubert, Franz

One of the principal Austrian composers of the early 19th century, Franz Peter Schubert stands between the worlds of Classical and Romantic music and is noted particularly for the extraordinary melodic and harmonic gifts he displayed in his numerous songs and chamber works.

Early life and career. Schubert was born on January 31, 1797, in Himmelfortgrund (modern Alsergrund), then a suburb of Vienna. His father, Franz Theodor Schubert, was a schoolmaster; his mother, Elisabeth,

whose maiden name was Vietz, was in domestic service at the time of her marriage. Franz was their fourth surviving son. His elder brothers were Ignaz, Karl, and Ferdinand, and there was a younger sister, Maria Theresa. The elder Franz Schubert was a man of character who had established a flourishing school. The family was musical and cultivated string quartet playing in the home, the boy Franz playing the viola. He received the foundations of his musical education from his father and his brother Ignaz, continuing later with organ playing and musical theory under the instruction of the parish church organist. In 1808 he won a scholarship that earned him a place in the imperial court chapel choir and an education at the Stadtkonvikt, the principal boarding school for commoners in Vienna, where his tutors were Wenzel Ruzicka, the imperial court organist, and, later, the composer Antonio Salieri, then at the height of his fame. Schubert played the violin in the students' orchestra, was quickly promoted to leader, and in Ruzicka's absence conducted. He also attended choir practice and, with his fellow pupils, cultivated chamber music and piano playing.

From the evidence of his school friends, Schubert was inclined to be shy and was reluctant to show his first compositions. His earliest works included a long *Fantasia for Piano Duet*, written in 1811–12, D. 1 (i.e., no. 1 in Otto Erich Deutsch's *Schubert: Thematic Catalogue of All His Works in Chronological Order*, 1951); his first song (1811); several orchestral overtures; various pieces of chamber music; and, in 1811, three string quartets. An unfinished operetta on a text by August von Kotzebue, *Der Spiegelritter* (*The Looking-glass Knight*), also belongs to those years. The interest and encouragement of his friends overcame his shyness and eventually brought his work to the notice of Salieri.

In 1812 Schubert's voice broke; he left the college but continued his studies privately with Salieri for at least another three years. During this time he entered a teachers' training college in Vienna and in the autumn of 1814 became assistant in his father's school. Rejected for military service because of his short stature, he continued as a schoolmaster until 1818.

The numerous compositions written between 1813 and 1815 are remarkable for their variety and intrinsic worth. They are the products of young genius, still short of maturity but displaying style, originality, and imagination. Besides five string quartets, including those in E flat major and G minor, there were three full-scale masses and three symphonies. The third of these symphonies, in D major, a charming example of Schubert's youthful lyricism and high spirits, was finished in 1815. His first full-length opera, *Des Teufels Lustschloss* (*The Devil's Palace of Desire*), was finished in 1814 while he was at the training college. But at this period song composition was his chief, all-absorbing interest. On October 19, 1814, he first set to music a poem by Goethe, "Gretchen am Spinnrade" ("Gretchen at the Spinning

Creation
of the lied

Wheel"), from *Faust*; it was his 30th song and in this masterpiece he created at one stroke the German lied (art song). The following year, **1815**, brought the composition of more than **140** songs.

The many unfinished fragments and sketches of songs left by Schubert provide some insight into the working of his creative mind. Clearly, the primary stimulus was melodic. The words of a poem engendered a tune. Harmony (chordal structure of a composition) and modulation (change of key) were then suggested by the contours of the melody. But the external details of the poet's scene—natural, domestic, or mythical—prompted such wonderfully graphic images in the accompaniments as the spinning wheel, the ripple of water, or the "shimmering robe" of spring. These features were fully present in the songs of **1815**. The years that followed deepened and enriched but did not revolutionize these novel departures in song. During **1815** Schubert also continued to be preoccupied with his ill-fated operas: between May and December he wrote *Der vierjährige Posten* (*A Sentry for Four Years*), *Fernando*, *Claudine von Villa Bella*, and *Die Freunde von Salamanka* (*The Friends of Salamanca*).

At this time Schubert's outward life was uneventful. Friends of his college days were faithful, particularly Josef von Spaun, who in **1814** introduced him to the poet Johann Mayrhofer. He also induced the young and brilliant Franz von Schober to visit Schubert. Late in **1815** Schober went to the schoolhouse in the Saulengasse, found Schubert in front of a class with his manuscripts piled about him, and inflamed the young composer, a willing listener, with a desire to break free from his duties. In the spring of **1816** Schubert applied for the post of music director in a college at Laibach (now Ljubljana, Yugoslavia) but was unsuccessful. His friends tried to interest Goethe in the songs and in April **1816** sent a volume of **16** settings to the poet at Weimar. It produced no result. At length, in December **1816**, Schober persuaded Schubert to apply for leave of absence. Despite his father's reluctance, he obtained the leave of absence and subsequently spent eight months with Schober, living in the home of his friend's widowed mother and paying for his keep whenever he could.

Early in **1817** Schober brought the baritone Johann Michael Vogl to his home to meet Schubert. As a result of this meeting, Vogl's singing of Schubert's songs became the rage of the Viennese drawing rooms. His friendships with the Huttenbrenner brothers, Anselm, a composer, and Josef, an amateur musician, and with Josef von Gahy, a pianist with whom he played duets, date from these days. But this period of freedom did not last, and in the autumn of **1817** Schubert returned to his teaching duties. He wrote to his friends of himself as a *verdorbener* ("frustrated") musician. The two earlier years had been particularly fruitful. Songs of this period include "Ganymed" (the song which had captivated Vogl at their first meeting), "Der Wanderer," and the *Harper's Songs* from Goethe's novel *Wilhelm Meister*. Smaller but equally remarkable songs are "An die Musik" ("To Music"), "Der Tod und das Mädchen" ("Death and the Maiden"), and "Die Forelle" ("The Trout"). There were two more symphonies: *No. 4 in C Minor*, which Schubert himself named the *Tragic* (**1816**), and the popular *No. 5 in B Flat Major* (**1816**). A fourth mass, in *C* major, was composed in **1816**. The year **1817** is notable for the beginning of his masterly series of piano sonatas. Six were composed at Schober's home, the finest being *No. 7 in E Flat Major* and *No. 11 in B Major*; both were published posthumously.

Schubert's years of uncongenial schoolmastering ended in the summer of **1818**. His frustrated period in the spring had produced only one substantial work, the *Symphony No. 6 in C Major*. But in the meantime his reputation was growing, and the first public performance of one of his works, the *Italian Overture in C Major*, took place on March **1**, **1818**, in Vienna. In June he left the city to take up the post of music master to the two daughters, Marie and Karoline, of Johann, Count Esterházy, in the family's summer residence at Zseliz, Hungary. Letters to his friends show him in exuberant spirits, and the summer

months were marked by a fresh creative outburst. The piano duets *Variations on a French Song* in *E* minor and the *Sonata in B Flat Major*, sets of dances, songs, and the *Deutsche Trauermesse* (*German Requiem*) were all composed at Zseliz.

Maturity. On his return to Vienna he shared lodgings with Mayrhofer and during the winter months composed the operetta *Die Zwillingsbrüder* (*The Twin Brothers*). Although sponsored by Vogl, the production of the work was postponed, and in June **1819** Schubert and Vogl set off for a protracted holiday in the singer's native district of upper Austria. The composer delighted in the beauty of the countryside and was touched by the enthusiastic reception given everywhere to his music. At Steyr he composed the first of his widely known instrumental compositions, the *Piano Sonata in A Major*, D. **664**, and the celebrated *Trout Quintet* for piano and strings. The close of **1819** saw him engrossed in songs to poems by his friend Mayrhofer and by Goethe, who inspired the masterly *Prometheus*. A fifth mass, in *A* flat major, was started but laid aside. Another sacred work, begun in **1820** but left unfinished, was the cantata *Lazarus*, anticipating, by its fusion of lyrical and declamatory styles, the style of Richard Wagner.

In June **1820** *Die Zwillingsbrüder* was performed with moderate success in Vienna, Vogl doubling in the parts of the twin brothers. It was followed by the performance of incidental music for the play *Die Zauberharfe* (*The Magic Harp*), given in August of the same year. The lovely, melodious overture became famous as the *Rosamunde* overture. Schubert was achieving renown in wider social circles than the restricted spheres of friend and patron. The wealthy and influential Sonnleithner family was interested in his development; their son Leopold became a great friend and supporter. At the close of the year **1820**, Schubert composed the *Quartettssatz* (*Quartet-Movement*) in *C* minor, heralding the great string quartets of the middle **1820s**, and another popular piece, the motet for female voices on the text of Psalm XXIII. In December **1820** he began the choral setting of Goethe's *Gesang der Geister über den Wassern* (*Song of the Spirits over the Water*) for male-voice octet with accompaniment for bass strings, D. **714**, completed in February **1821**.

All of Schubert's efforts to publish his own work were fruitless. Early in **1821**, however, a few friends offered his song "Erlkönig" ("Erl King") on a subscription basis. The response was so successful that enough money was raised for the printing of "Gretchen am Spinnrade" also. "Erlkönig" appeared as Schubert's opus **1** on April **2**, **1821**, and "Gretchen" as opus **2** on April **30**, **1821**. From then on songs, part-songs, dances, and pianoforte duets were published. Eighteen months later, opus **12** had been reached.

In Vienna the popularity of Schubert's songs and dance music became so great that concert parties were entirely devoted to them. These parties, called *Schubertiaden*, were frequently given in the homes of wealthy merchants and civil servants. But the wider worlds of opera and public concerts still eluded him. He worked during August **1821** on a seventh symphony in *E* minor and major, but this, too, was put aside, along with many other unfinished works of the period. His determination to establish himself in opera led him in September and October to spend a short holiday with Schober at St. Pölten, west of Vienna, where the friends devoted their energies to the production of a three-act opera, *Alfonso und Estrella*. It was completed in February **1822** but was never performed. While spending a few days at Atzenbrugg in July **1822**, with Schober and other friends, he produced the document called *Mein Traum* ("My Dream"), describing a quarrel between a music-loving youth and his father. Fanciful biographical interpretations of this document have little, if any, factual foundation. The autumn of **1822** saw the beginning of yet another unfinished composition—not, this time, destined to obscurity: the *Symphony in B Minor* (*Unfinished*), which speaks from Schubert's very heart. Two movements were completed in October and November **1822**, the abandoned work including also a half-finished scherzo. In November of the same

year Schubert composed a piano fantasia in which the variations are on a theme from his song "Der Wanderer." The Mass in A Flat Major was also completed in this month.

At the close of 1822 Schubert contracted a venereal disease, probably syphilis, and the following year was one of illness and retirement. He continued to write almost incessantly. In February 1823, he wrote the Piano Sonata in A Minor, and in April he made another attempt to gain success in Viennese theatres with the one-act operetta *Die Verschworenen* (The Conspirators), the title being changed later (because of political censorship) to *Der häusliche Krieg* (Domestic Warfare). The famous work of the year, however, was the song cycle *Die schöne Müllerin* (The Miller's Beautiful Daughter), representing the epitome of Schubert's lyrical art. Other songs of this period are "Auf dem Wasser zu singen" ("Singing on the Water") and "Du bist die Ruh" ("You are Peace"). Schubert spent part of the summer in the hospital and probably started work—while still a patient—on his most ambitious opera, *Fierrabras*. The work was rejected by the directorate of the prestigious Kärntnerthor Theatre in Vienna. The year 1823 closed with Schubert's composition of the music for the play *Rosamunde*, performed at Vienna in December. This production failed. The text of the play is lost, and the music was subsequently heard only in the concert hall.

The early months of 1824 were again unhappy. Schubert was ill, penniless, and plagued by a sense of failure. Yet during these months he composed three masterly chamber works: The String Quartet in A Minor, a second string quartet in D minor containing variations on his song "Der Tod und das Mädchen," and the Octet in F Major for strings and wind instruments. His dejection is manifest in a letter of March 31, 1824, to his friend Leopold Kupelwieser, the painter, in which he speaks of himself as "the most unfortunate, the most miserable being in the world." In desperate need of money, he returned in the summer to his teaching post with the Esterházy family and in May 1824 went again to Zseliz. Once more his health and spirits revived. The period was marked by some magnificent piano duets, the Piano Sonata in C Major (Grand Duo), the Variations on an Original Theme in A Flat Major, and the Divertissement à la hongroise (Hungarian Divertissement). The first work was published posthumously, the other two in Schubert's lifetime, in 1825 and 1826.

Although his operas remained unperformed, there were frequent public performances of his songs and part-songs in Vienna during these and the following years. Publication proceeded rapidly, and his financial position, though still strained, was at any rate eased. In 1825 he spent another holiday in upper Austria, with Vogl, visiting Linz, Gmunden, and Badgastein and finding a warm welcome for himself and his music wherever he went. This is the period of the Lady of the Lake songs (to words of Sir Walter Scott, translated by P.A. Storck), including the once popular but later neglected "Ave Maria." Instrumental compositions are the piano sonatas in A minor and in D major, the latter composed at Badgastein. He sketched a symphony during the summer holiday (in all probability the beginnings of the Symphony in C Major [Great], completed in 1828). The spring of 1825 had seen the composition of two well-known songs, "Im Abendrot" ("At Sunset") and "Die junge Nonne" ("The Young Nun"); they were followed in the late summer by "Die Allmacht" ("The Almighty") and "Das Heimweh" ("Homesickness"), two of his greatest songs inspired by nature. New friends, Moritz von Schwind, a young painter, and Eduard Bauernfeld, a dramatist, were almost continuously in his company during this period. Schwind left pictorial records of Schubert; Bauernfeld, reminiscences.

Last years. The resignation of Salieri as imperial Kapellmeister (musical director) in 1824 had led to the promotion of his deputy, Josef Eybler. In 1826 Schubert applied for the vacant post of deputy Kapellmeister, but in spite of strong support by several influential people he was unsuccessful. From then until his death two years later he seems to have let matters drift. Neither by appli-

cation for professional posts nor submission of operatic work did he seek to establish himself. It can hardly be believed that Schubert was unaware of his exceptional powers; yet, together with an awareness of genius and the realization that it opened doors into cultivated society went the knowledge of his humble birth and upbringing and also of his somewhat uncouth bearing. This self-consciousness made him diffident, reserved, and hesitant. His life was almost entirely devoted to composition, and he derived his livelihood from publishers' fees and occasional teaching. The songs of 1826 include the settings of Shakespeare's "Hark! Hark! the lark!" and "Who is Silvia?" written during a brief stay in the village of Währing. Three fine instrumental works of this summer and autumn are the last String Quartet in G Major, the Piano Sonata in G Major, and the beginning of the Piano Trio in B Flat Major.

In 1827 he composed the first 12 songs of the cycle *Winterreise* (Winter Journey), a return to the poems of Wilhelm Müller, author of *Die schöne Müllerin* (The Miller's Beautiful Daughter). Beethoven's death in 1827 undoubtedly had a profound effect on Schubert, for there is no denying that a more profound, more intellectual quality appears in his last instrumental works. Some of them, especially the Piano Trio in E Flat Major (1827) and the Piano Sonata in C Minor (1828), suggest the authority of Beethoven, yet his own strong individuality is never submerged.

In September 1827 Schubert spent a short holiday in Graz. On his return he composed the Piano Trio in E Flat Major and resumed work on Part II of the *Winterreise*: the 13th song, "Die Post," was written in October 1827. This is the period of his piano solos, the Impromptus and Moments musicaux.

A succession of masterpieces marks the last year of his life. Early in the year he composed the greatest of his piano duets, the Fantasy in F Minor. The Great Symphony was concluded in March, as was also the cantata *Miriam's Siegesgesang* (Miriam's Victory Song). In June he worked at his sixth mass—in E flat major. A return to songwriting in August produced the series published together as the *Schwanertgesang* (Swan Song). In September and early October the succession was concluded by the last three piano sonatas, in C minor, A major, and B flat major, and the great String Quintet in C Major—the swan song of the Classical era in music.

The only public concert Schubert gave took place on March 26, 1828. It was both artistically and financially a success, and the impecunious composer, it is recorded, was at last able to buy himself a piano. At the end of August he moved into lodgings with his brother Ferdinand, then living in a suburb of Vienna. Schubert's health, broken by the illness of 1823, had deteriorated, and his ceaseless work had exhausted him. In October he developed typhoid fever as a result of drinking tainted water. His last days were spent in the company of his brother and several close friends. He died in Vienna on November 19, 1828. On his tomb in the Währingerstrasse Cemetery was engraved the epitaph of the Austrian dramatist Franz Grillparzer: "The Art of Music has here entombed a rich treasure, but yet far fairer hopes."

Although it has been said that Schubert's place in the history of music is equivocal, he is, however, the last of the great Classical composers. His music, subjectively emotional in the Romantic manner, poetically conceived, and revolutionary in language, is nevertheless cast in the formal molds of the Classical school—with the result that in the 20th century it has become increasingly apparent that Schubert more truly belongs to the age of Haydn, Beethoven, and Mozart than to that of Schumann, Chopin, and Wagner.

MAJOR WORKS

OPERAS AND OPERETTAS (dates given are years of writing): Nine completed and existing, which include *Des Teufels Lustschloss* (1813–14), *Claudine von Villa Bella* (1815), *Die Zwillingbrüder* (1818–19), *Alfonso und Estrella* (1821–22), *Fierrabras* (1823), *Die Verschworenen*, later changed to *Der häusliche Krieg* (1823).

CHORAL MUSIC: Seven masses, including Mass in A Flat

poverty,
and
depression

Final
composi-
tions

Major (1819–22) and *Mass in E Flat Major* (1828); various other settings of religious texts; 3 cantatas; *Gesang der Geister über den Wassern* (*Song of the Spirits over the Water*) for male voices and strings (1820–21); various songs with piano, including "Gott im Ungewitter" ("God in the Storms," c. 1815), "Hymne an den Unendlichen" ("Hymn to Infinity," 1815), "Gott in der Natur" ("God in Nature," 1822), "Gebet" ("Prayer," 1824), "Der Gondelfahrer" ("The Gondolier," 1824), "Nachthelle" ("Night's Brightness," 1826), "Miriams Siegesgesang" ("Miriam's Victory Song," 1828); various unaccompanied songs.

ORCHESTRAL WORKS: Nine symphonies, including *No. 4 in C Minor* (*Tragic*, 1816), *No. 5 in B flat Major* (1816), *Symphony in B Minor* (*Unfinished*, 1822), *Symphony in C Major* (*The Great*, 1828).

CHAMBER MUSIC: Two string trios; 4 piano trios for strings and piano, including *Trio in B Flat Major* (1827) and *Trio in E Flat Major* (1827); 22 string quartets, including quartets in B flat major, D. 112 (1814), in A minor, D. 804 (1824), in D minor, D. 810 ("Death and the Maiden"; 1824), in G major, D. 887 (1826); *String Quintet in C Major* (1828); *Piano Quintet in A Major* (*Trout*, 1819); *Octet in F Major* for wind and strings (1824); 3 sonatas for violin and piano; *Sonata in A Minor* for arpeggione (now played on cello, 1824).

PIANO WORKS: 21 sonatas; two sets of impromptus; 6 *Moments musicaux*; various waltzes and marches; *Fantasy in C Major* (*Wanderer*, 1822); *Fantasy in F Minor* for piano duet.

SONGS: More than 500, including the song cycles *Die schöne Müllerin* (*The Miller's Beautiful Daughter*, 1823), *Winterreise* (*Winter Journey*, 1827), *Schwanengesang* (*Swan Song*, 1828), and many well-known individual songs.

BIBLIOGRAPHY. OTTO E. DEUTSCH, *Franz Schubert: Die Dokumente seines Lebens und Schaffens*, 2 vol. (1913–14; Eng. trans., *Schubert: A Documentary Biography*, 1946, reprinted 1965; U.S. title, *The Schubert Reader*, 1947); *Schubert: Thematic Catalogue of All His Works in Chronological Order* (1951), the universal source of the D. numbers for Schubert's works, particularly useful in identifying works with similar titles; and *Schubert: Die Erinnerungen seiner Freunde* (1957; Eng. trans., *Schubert: Memoirs by His Friends*, 1958), a collection of obituaries and reminiscences of people who knew Schubert that were published in various journals at odd times during the 19th century—care should be exercised in the use since these reminiscences often contain romantic—i.e., fictional—anecdotes; ALFRED EISTEIN, *Schubert* (1951), a lively appreciation by a scholar who was not primarily a Schubert specialist; RICHARD CAPELL, *Schubert's Songs*, 2nd ed. (1957), a beautifully written and penetrating study of the songs; MAURICE J.E. BROWN, *Schubert: A Critical Biography* (1958), a standard life, with a study of Schubert as artist; and *Essays on Schubert* (1966), essays on manuscripts and editions, with a study of the sources for a complete edition of the sonatas; HEINRICH KREISLE VON HELLBORN, *Franz Schubert: Eine biografische Skizze* (1861; Eng. trans., *Franz Schubert*, 1865), the first biography of the composer, by now unreliable factually but still invaluable as giving a picture of the attitude of the mid-19th century to Schubert; SIR DONALD F. TOVEY, "Franz Schubert, 1797–1828," in HUBERT J. FOSS (ed.), *Heritage of Music*, vol. 1 (1927), an important essay that marks the start of the 20th century's realization of Schubert's greatness.

(M.J.E.B.)

Schumann, Robert

One of the leading German composers of the early 19th century, Robert Schumann was first and foremost a miniaturist, known particularly for his short piano pieces and songs, two genres in his case so closely connected as to be hardly more than two facets of the same thing. In larger fields, his touch was less certain, although some of his orchestral works, such as the *Symphony No. 4 in D Minor*, the *Piano Concerto in A Minor*, and the *Manfred* overture, show him successfully overcoming his difficulties with more ambitious composition. In his day he was rightly considered a very advanced composer, and his influence on his contemporaries and successors was considerable.

Schumann was born at Zwickau, Saxony, on June 8, 1810. His father was a bookseller and publisher. After four years at a private school, the boy entered the Zwickau *Gymnasium* (high school) in 1820 and remained there for eight years. He began his musical education at the age of six and in 1822 produced his earliest known composition, a setting of Psalm 150. At the same time he began to show at least equal literary ability, embarking

Robert and Clara Schumann, lithograph by J. Hofelich. The Bettmann Archive

on plays (a comedy and two "horror dramas") and poems, including some translations of Horatian odes, which have been preserved. In 1827 he came under the musical influence of the Austrian composer Franz Schubert and the literary influence of the German poet Jean Paul Richter, both of which proved deep and enduring; in the same year he composed some songs (all of which have since been published).

In 1828 Schumann left school and, under pressure from his mother and his guardian (his father having died), entered the University of Leipzig as a law student. At Leipzig his time was devoted not to the law but to song composition, improvisation at the piano, and attempts to write autobiographical novels in the manner of Richter. For a few months he studied the piano seriously with a celebrated teacher, Friedrich Wieck, and thus got to know Wieck's nine-year-old daughter Clara, a brilliant pianist who was just then beginning a successful concert career.

In the summer of 1829 he left Leipzig for Heidelberg where one of the law professors, Anton Friedrich Justus Thibaut, was known as a writer on musical aesthetics, and under Thibaut's influence Schumann made the acquaintance of a great deal of early choral music. He composed waltzes in the style of Franz Schubert, afterward used in his piano cycle *Papillons* (1832), and practiced industriously with a view to abandoning law and becoming a virtuoso pianist—with the result that his mother agreed to allow him to return to Leipzig in October 1830 to study for a trial period with Wieck, who thought highly of his talent but doubted his stability and capacity for hard work.

His Opus 1, also a set of variations, was published in 1831. An accident to one of the fingers of his right hand, which put an end to his hopes of a career as a virtuoso, was perhaps not an unmitigated misfortune, since it confined him to composition. For Schumann, this was a period prolific in piano pieces, which were published either at once or, in revised forms, later.

Two important piano works arose from a love affair with another of Wieck's pupils, Ernestine von Fricken: first, the cycle *Carnaval* (1835), based on the letters (and notes) A, S (Es, i.e., E♭), C, H (B♭ in German), which spelled the town, Asch, where she lived and also were contained in his own name; and, second, the *Études symphoniques* (*Symphonic Studies*, 1834), variations on a theme by her father. The affair lasted for more than a year, but long before the engagement was formally broken off (January 1, 1836) Schumann had fallen in love with the then 16-year-old Clara Wieck. Clara returned his kisses but obeyed her father when he ordered her to break off the relationship. Schumann found himself aban-

Wieck

doned for 16 months, during which he expressed his alternate despair and resignation in the great *Fantasy in C Major* for piano, drank wildly, sought consolation with other girls, and even published a bitter, veiled lampoon on Clara in the *Neue Zeitschrift für Musik* (*New Journal for Music*, a periodical that he had helped to found in 1834 and of which he had been editor and principal proprietor since the beginning of 1835). Clara herself made the first move toward a reconciliation, and on September 13, 1837—her 18th birthday—Schumann formally asked her father's permission to marry her; the request was at first evaded rather than refused.

Schumann now entered upon one of his most fertile creative periods, producing a series of imaginative works for piano. Even this was not a time of unalloyed happiness, for Clara refused to marry without financial security, and her father still withheld his consent. A formal statement by Clara on June 15, 1839, initiated legal proceedings for the setting aside of that condition. The affair dragged on for more than a year; it was taken to a court of appeal, which still upheld one of Wieck's objections, that Schumann was a heavy drinker, and then to a yet higher court, which ruled that Wieck must produce proof of habitual drunkenness. This he failed to do, and on September 12, 1840, the marriage took place. Early that year Schumann returned to a field he had neglected for nearly 12 years, that of the solo song; in the space of 11 months (February–December 1840) he composed nearly all the songs on which so much of his reputation rests: the cycles *Myrthen* (*Myrtle*), the two *Liederkreise* (*Song-Cycles*) on texts by Heinrich Heine and Joseph Eichendorff, *Dichterliebe* (*Poet's Love*), *Frauenliebe und Leben* (*Woman's Love and Life*), and many separate songs.

Clara had been pressing him to widen his scope, to launch out in other media—above all, the orchestra. He had in earlier days made at least five unsuccessful attempts at works for piano and orchestra; even the *Symphony in G Minor* was never finished. Now in January–February 1841 he composed the *Symphony No. 1 in B Flat Major*, which was at once (March 31) performed under the German composer Felix Mendelssohn at Leipzig; an *Overture*, *Scherzo*, and *Finale* (April–May); a *Phantasie* for piano and orchestra (May) which was expanded into the famous *Piano Concerto in A Minor* by the addition of two more movements in 1845; another symphony, in D minor (June–September); and the sketches for yet a third symphony, in C minor, of which only one movement, the scherzo, survives as a piano piece, in *Bunte Blätter*, Opus 99, No. 13. The orchestral impulse was temporarily spent.

Between June 1842 and January 1843 he wrote several chamber works, a new departure for him. The year 1843 was marked by Schumann's most ambitious work so far, a "secular oratorio" (originally conceived as an opera), *Das Paradies und die Peri* (*Paradise and the Peri*), on Thomas Moore's *Lalla Rookh*. He made his debut as a conductor—a role in which he was invariably ineffective—with its first performance (December 4).

During his work on *The Peri* the Staatliche Hochschule für Musik, Leipzig, had been opened with Mendelssohn as director and Schumann as professor of "piano playing, composition, and playing from score"; again he had embarked on activities for which he was unsuited. The first few months of 1844 were spent on a concert tour of Russia with Clara, which depressed Schumann by making him conscious of his inferior role. On returning to Leipzig he resigned the editorship of the *Neue Zeitschrift*. In August he composed some numbers for an opera on Goethe's *Faust*, but work was interrupted by a serious nervous collapse, which led to the Schumanns' leaving Leipzig. From December 1844 to September 1850 he and Clara lived in Dresden, where his health was gradually restored. In December 1845 he began another symphony, *No. 2 in C Major*; but because of aural nerve trouble nearly ten months passed before the score was finished.

Attempts to get posts in Leipzig and Vienna had also been abortive. In the end, for want of anything better, Schumann accepted the appointment of municipal direc-

tor of music at Düsseldorf. At first things went tolerably well; in 1850–51 he composed the *Cello Concerto in A Minor* and the *Symphony No. 3 in E Flat Major* (the *Rhenish*) and drastically rewrote the ten-year-old *Symphony in D Minor*, ultimately published as *No. 4*. He also conducted eight subscription concerts, but temperamental differences soon showed themselves, and Schumann's shortcomings as a conductor became obvious. There were a number of painful scenes and chaotic rehearsals; in December 1852 he was asked to resign but declined, and in October 1853 the choir's refusal to sing Mendelssohn's *Die erste Walpurgisnacht* under him brought the final break.

On February 10, 1854, Schumann complained of a "very strong and painful" attack of the ear malady that had troubled him before; this was followed by aural illusions, such as the dictation by angels of a theme (actually a reminiscence of his violin concerto) on which he proceeded to write some variations for piano. On February 26 he asked to be taken to a lunatic asylum and the next day attempted suicide by drowning. (He had contemplated suicide on at least three occasions during the 1830s.) On March 4 he was removed to a private asylum at Endenich, near Bonn, where he lived for nearly two and a half years, able to correspond for a time with Clara and his friends. One or two visits by Brahms or the young violinist Joseph Joachim agitated him terribly, and Clara was kept from him until July 27, 1856, when it was realized that the end was near. He seemed to recognize her but was unable to speak intelligibly. On July 29, 1856, he died.

MAJOR WORKS

Orchestral works

SYMPHONIES: Four complete symphonies, *No. 1 in B Flat Major*, op. 38 (*Spring Symphony*; 1841); *No. 2 in C Major*, op. 61 (1846); *No. 3 in E Flat Major*, op. 97 (*Rhenish Symphony*; 1850); *No. 4 in D Minor*, op. 120 (1841; rewritten 1851).

OVERTURES: Overture to Byron's *Manfred*, op. 115 (1848–49).

CONCERTOS: *Piano Concerto in A Minor*, op. 54 (1841–45); *Cello Concerto in A Minor*, op. 129 (1850).

Chamber music

Three string quartets; three piano trios; three violin sonatas; *Piano Quintet in E Flat Major*, op. 44 (1842); *Piano Quartet in E Flat Major*, op. 47 (1842).

Vocal music

SONGS: Numerous sets of solo songs with piano, including the song-cycles *Liederkreis* (on a text by Heine), op. 24 (1840); *Liederkreis* (on a text by Eichendorff), op. 39 (1840); *Frauenliebe und Leben*, op. 42 (1840); *Dichterliebe*, op. 48 (1840).

OPERA: *Genoveva*, op. 81 (1847–50).

CHORAL WORKS WITH ORCHESTRA: *Das Paradies und die Peri*, op. 50 (1841–43).

Piano music

Theme and Variations on the Name of Abegg, op. 1 (1830); *Papillons*, op. 2 (1832); *Etudes symphoniques*, op. 13 (1834); *Carnaval*, op. 9 (1834–35); *David'sbündlertänze*, op. 6 (1837); *Fantasiestücke*, op. 12 (1837); *Kinderszenen*, op. 15 (1838); *Kreisleriana*, op. 16 (1838); *Fantasy in C Major*, op. 17 (1836); three piano sonatas.

BIBLIOGRAPHY. GERALD ABRAHAM (ed.), *Schumann: A Symposium* (1952), authoritative essays on all the works; WOLFGANG BOETTCHER, *Robert Schumann: Einführung in Persönlichkeit und Werk* (1941), a monumental study of various aspects of the personality and works, based on fresh sources; JOAN CHISSELL, *Schumann*, rev. ed. (1967), a succinct general biography and study of the works; *Schumann's Keyboard Works* (1972), an introduction to the piano music; HENRY PLEASANTS (ed. and trans.), *The Musical World of Robert Schumann: A Selection from His Own Writings* (1965), a recent translation of Schumann's letters; LEON PLANTINGA, *Schumann as Critic* (1967), a valuable study of the prose writings; ERIC SAMS, *The Songs of Robert Schumann* (1969), an exhaustive study of the songs; STEPHEN WALSH, *The Lieder of Robert Schumann* (1971), a shorter, more general, and very perceptive study of the songs; GEORG EISMANN (ed.), *Robert Schumann: Tagebücher*, vol. 1, 1827–1838 (1972), the private diaries published in full for the first time.

Science, History of

Until recently, the history of science was a story of success. The triumphs of science represented a cumulative process of increasing knowledge and a sequence of victories over ignorance and superstition; and from science flowed a stream of inventions for the improvement of human life. The recent realization of deep moral problems within science, of external forces and constraints on its development, and of dangers in uncontrolled technological change has challenged historians to a critical reassessment of this earlier simple faith.

The historian soon recognizes that the idea of science that he acquired during his education is only one of many and that it is a product of temporary circumstances. The latter include the presence of nearly autonomous centres of research in universities; large-scale application of scientific results by technologists; and the independence of scientific research from politics and religion. In the 19th century there was a blurring of these present distinctions between science, industry, and philosophy, and three or four centuries earlier, the historian finds that the study of nature was conducted within a framework of assumptions about the world that are now rejected as magical or superstitious. Also, the deeper that historians penetrate to the roots of modern European science, the more difficult it is to separate the "scientific" attitudes, and the "factual" results, from those that appear to be their opposites. Earlier historians treated these mixtures as anomalies; they are now used as clues to reveal conceptions of the natural world, and man's way of knowing it, that had vitality and meaning in their own time. Thus the history of science demands and fosters an enhanced imagination: the ability to see oneself and one's science as one phase in a continuing evolution. In a period when relevance is demanded of scholarly studies, the history of science provides this just as much in its exploration of the distant and strange structures of inquiry into the natural world as in its critical analysis of the immediate sources of contemporary conceptions and practices.

This account will be organized around the natural science created by modern European civilization, for this is the form of science that has brought the world to its present condition and that, it seems, must be understood and controlled if mankind is to survive. The roots of this science lie deep in the human past and in many civilizations. Here, they can be mentioned only in passing, but at the outset it must be pointed out that the present way of comprehending the natural world is a very recent development. It was possible for great civilizations of the past to achieve highly developed technologies and religious and legal systems in the complete absence of a conception of science as it is now understood. Such were the civilizations of ancient Egypt, Mesopotamia, India, and the Western Hemisphere. Even the Hebrews, people whose religion forms a large part of the basis of European civilization, were indifferent to science. Although some two and a half millennia ago the Greeks created a system of thought that was similar to the scientific, in succeeding centuries there was little progress beyond their achievement and little comprehension of it. In Europe, science has enjoyed continuous progress for some 500 years, even though for most of that period it was of minor interest among a cultural elite. The lives of ordinary people were affected only in the most indirect ways by the thoughts of scientists and the application of their results. The great power of science and its pervasive influence on all aspects of life are thus very recent developments. Although knowledge of the world is independent of the particular circumstances of its first discovery and can be transmitted between nations and cultures, the human endeavour whereby that knowledge is achieved is a product of its everchanging human environment.

In this article, only a broad and general survey can be made. For details in the history of any particular subject, see the historical section in the article on that subject.

SCIENCE IN ANCIENT AND MEDIEVAL WESTERN CIVILIZATION

Science in Greek civilization. The dawn of European science has traditionally been located among the philoso-

phers of the Greek city-states on the coast and islands of the eastern Mediterranean, in the later 6th and 5th centuries BC. Their work is known only through fragments, references, and brief quotations made by authors who came later, perhaps by hundreds of years. By selection of fragments they can be made to appear more rational and scientific than is justified. For example, the famous saying of the earliest known philosopher, Thales, "All is water," is in its fragment actually followed by "and the world is full of gods." It does appear likely, however, that the early Greek philosophers were concerned with explaining the phenomena of the perceptual world rather than offering recipes for practice and that they did so by invoking causes rather than personal agents, even if these causes were themselves derived by analogy with handicraft experience and human behaviour (thus the cosmic principles of "love and strife" of Empedocles). In this break from the mythological explanations of their own culture and of the ancient civilizations from which they probably borrowed much of their detailed knowledge, the Greeks are precursors of the modern European scientific attitude. One very important tradition, that of the Pythagoreans, was explicitly religious. Their founder attempted to find the key to universal harmony, both natural and social, and the personality of numbers, which were seen as shaped arrays of dots, was an important clue. Somewhat later appeared the Eleatics, Zeno and Parmenides, using a sophisticated conceptual analysis to support the philosophical position that asserted the unchanging unity of existence. Zeno's paradoxes of aggregation and motion presented a challenge that is still alive.

Although by the later 5th century this inquiry became quite sophisticated, it was still speculative explanation of commonsense phenomena rather than highly technical argument about controlled artificial experiences; the latter emerges only with Aristotle. Also, although this philosophy flourished among the elite in the so-called golden age when Pericles ruled Athens, the common sense of the time was still mythical and magical, as can be seen from the list of crafts in Aeschylus' *Prometheus Bound*. In the troubled times of the later 5th century, the suspicion of irreligion among the philosophers became strong and is implicit in the condemnation of Anaxagoras and in the attacks on Socrates in *The Clouds* of Aristophanes.

The two learned arts in which there was an approach to maturity by this time were, first, medicine, the practice of which was at least attempting to apply disciplined method in observation and inference, and, second, geometry, which was accumulating a body of results about relations between particular constructed figures and was approaching the problems of logical structure (in successive editions of *Elements*, precursors of Euclid) and of definition (as with the irrational ratios, as $\sqrt{2}$).

Plato, early 4th century BC, is the earliest philosopher whose writings are extant. He was a powerful propagandist for mathematics. In the *Republic* he argued that geometry prepares the mind for the discourse of dialectic about the real ideas, of which perceptible things are but images, and thence to wisdom and illumination. His *Timaeus* was in earlier times a more influential work; in this he sketches a cosmogony along Pythagorean lines, including a theory of music in terms of simple ratios and a survey of accepted theories of physics and physiology. He befriended geometers, including Eudoxus, who probably founded the mathematical cartography of the spherical Earth, and also gave a profound treatment of irrational quantities.

Aristotle, also in the 4th century BC, was one of the world's first, and greatest, scholars. His interests ranged over the entire natural and human world, including ethics and metaphysics. Through accurate observations and disciplined theorizing, he created a biological science and a taxonomy much like those in use today. Later scholars have identified mistakes in his descriptions, but there are classic cases where his apparently false reports were checked and confirmed (on rare, local species) less than a century ago. He also organized cooperative research for large-scale studies, as in the comparative study of the constitutions of the Greek city-states. He was a master of

Basic principles of the Greek view

Aims of the history of science

scholarly method; in each study he would define the area and its problems, dialogue critically with his predecessors (usually showing they were naïve in some important respect), and then proceed by experience and reason to develop his argument. To him are owed most of the basic divisions of learning and also the articulation of the principles of method and of the different sorts of knowledge attainable by the use of reason.

Aristotle started his career as a disciple of Plato but eventually came to disagree with him on fundamentals. In particular, he considered mathematics as an abstraction from natural reality, which for him was a complex, self-regulating living system. Indeed, all subsequent philosophy of nature is a dialogue between Plato and Aristotle, for whom the deepest philosophical problems were related to life. His biological studies culminated in the problem of generation, the transmission of form between separate bodies. He tried also to explain the workings of the first cause of all physical phenomena, through the realization of its purposes in the celestial cycles. He had little sympathy with enchantments; for him, dreams were a result of subconscious thoughts and bodily discomfort rather than messages from a spirit. His principles of explanation were in terms of perceptible qualities (e.g., hot or cold, wet or dry) and a series of causes (matter, agent, plan, and purpose, in ascending order) on the analogy of craftwork by the principle "art imitates nature."

For some years he was tutor to the prince who later became Alexander the Great, and, though later this caused him difficulties at Athens, his influence passed on to the Museum of Alexandria. His writings were the basis of natural philosophy wherever it was practiced up to the 17th century, but he was inevitably misunderstood, and his writings were used for the framing of sterile dogmas. Aristotle was centuries ahead of his times and is still a source of insight and instruction today.

In the empire created by Alexander the Great (late 4th century BC) Greek culture flourished. The great cities competed for famous scholars and classical texts, and some of them established centres of learning such as the Museum at the planned city of Alexandria. Independent of the religious temples, these had large libraries, provided employment for scientists and scholars, and by preserving records and instruments lent continuity to research work. Although this Hellenistic Age (roughly 323 to 30 BC) did not reach the heights of genius of the earlier one, it produced some great mathematicians (Euclid, Archimedes, and Apollonius) and astronomers (Hipparchus). Studies in medicine and physiology also advanced, and, during this period, the origins of European alchemy were developed by Egyptian chemists attempting to rationalize chemical change by Aristotelian theories.

Science in Rome. Toward the close of the pre-Christian period, the Roman Empire achieved dominance over the entire Mediterranean world. Rome presents a paradox to historians of science. This civilization, so sophisticated and apparently modern in its politics and personalities, very strong in the learned discipline of the law, very progressive in the state technologies of warfare and public hygiene, with direct access to the corpus of Greek science, nonetheless failed to produce a single scientist. Two very great scientists lived during the reign of Marcus Aurelius in the 2nd century AD, but they were both Greek: Galen of Pergamon, who synthesized and advanced the study of medicine, anatomy, and physiology; and Ptolemy of Alexandria, who brought mathematical astronomy near to a classic perfection and also tried to bring the mathematical, scientific approach to the earliest empirical social science, astrological prediction. The Romans themselves considered science as fit only for casual speculation, on the one hand, and practical techniques, on the other. Their encyclopaedia literature is a cautionary tale of the corruptions of knowledge in the absence of critical standards. Scientific matters were discussed seriously among the Romans only in connection with basically ethical philosophies. The two leading schools were the Stoics and Epicureans, and the messages offered by them to the wise man were, respectively, dignified resignation

and the pursuit of happiness. The latter school, however, produced a masterpiece of speculative science, *De rerum natura* (On the Nature of Things), by Lucretius (1st century BC). The message of his atomistic explanations of phenomena was that immaterial spirits are only fictions whose function is to instill fear and obedience among the superstitious masses.

To explain the Romans' utter failing in science, historians have speculated on whether slavery, by stifling the drive for industrial innovation, was the cause; but this seems too simple. Perhaps the social structure of Rome, combined with its long adherence to gross forms of magic, left no place for an appreciation of that peculiar commitment to the hard and hazardous road to knowledge and wisdom that lies through disciplined inquiry into isolated aspects of the natural world. Indeed, when one considers how few have been the cultures in which science has flourished, one may reverse the question and consider Rome as the normal and classical Greece as the surprising phenomenon to be explained.

Medieval science. The Greco-Roman civilization went through its full cycle in about 1,000 years. The next half millennium in Europe, up to the year 1000, is often called the Dark Ages. Literate culture in western Europe, ruled by Rome, was barely kept alive in the monasteries, with occasional attempts at revival by great kings such as Alfred and Charlemagne. By contrast, in the Eastern Empire ruled by Constantinople a civilized society continued, although in all its own 1,000-year history Byzantium produced little new science of note. As a new, ruder form of society took shape in the West, there was great pioneering work in the clearing of forests and swamps for settlement, and some crucial inventions (horse collar, stirrup, heavy plow, windwheels, and waterwheels) were either invented or borrowed. In the early 11th century, most learned men knew and understood only a few tattered fragments of ancient science, but thereafter progress was rapid. The 12th century enjoyed a renaissance brought about partly by contact with the superior Islamic civilization in Spain and Palestine, partly by the development of towns with literate upper classes. From this period come the first speculative treatises on natural philosophy. The 13th century saw the founding of the universities and the great age of scholastic learning. To this age belong the great theologian St. Thomas Aquinas and the experimentally minded Roger Bacon. In the 1350s, however, Europe was struck by economic and social disaster in the form of a general financial collapse and the Black Death (the bubonic plague). Although philosophical debate, including interesting mathematical speculation, still took place, scientifically this later period was sterile.

Opinions on medieval science have oscillated wildly. Earlier historians saw it as unrelieved dogmatism and superstition, while others have tried to show that many essential facts and principles of modern science were discovered then. The problem becomes clearer when it is realized that learned men were not at all trying to do scientific research as it is understood now. Natural philosophy and particular facts were studied mainly in connection with problems relating to religion, either for the elucidation of biblical texts (literally and figuratively) or for debate with adherents of pagan philosophies (notably Aristotle as interpreted by the Muslim philosopher Averroes) or in the development of a mystical Neoplatonic cosmology in which light was studied as the clue to reality that can be grasped by the senses and described geometrically. The distinction between technique, theoretical magic, and folk magic was not at all clear to anyone. Hence in modern terms, even Roger Bacon was the gullible victim of superstition. Thus in Europe in a formative period of the present civilization, there is something that could be called science but that requires anthropological imagination to understand.

SCIENCE IN OTHER CIVILIZATIONS

Description of the scientific achievements of the other great civilizations of the world is brief in this article because of the considerably lesser contributions they made to science as it is presently understood.

Causes of
Roman
failure in
science

The root
of the
philosophy
of nature

Islām. Islāmic culture is the most relevant to European science. Not only is the religion itself closely related to Judaism and Christianity, but there was active cultural contact between Arabic-speaking lands and Latin Europe at crucial periods. Ironically, the great age of Islām coincided with the low point of culture in western Europe. Conquests by the Prophet's followers began in the 7th century, and, by the 10th, Arabic was the literate language of nations stretching from Persia to Spain. Arabic conquerors generally brought peace and prosperity to the countries they settled. For example, the library of Córdoba in Spain apparently had more than 500,000 books at a time when scarcely 5,000 survived north of the Pyrenees. Also, the Muslims were tolerant of the other monotheistic faiths, so that Jews rose to high position in Islāmic lands at a time when they were scarcely permitted survival in Europe. Drawing on the traditions of Greek science through Christian scholars of Syria, the early Arabic rulers of Baghdad in the 9th century had the bulk of the corpus of Greek science translated, and, soon after, their own scholars advanced further, particularly in mathematics, astronomy, optics, chemistry, and medicine. The social base of science, however, was thin. In a theocratic society, medicine alone among the pagan sciences was considered acceptable. Hence no single centre of scientific culture flourished for much more than a century, and, although materials were transmitted between them, the loss of continuity prevented a sustained development. Also, the style of scholarship was for a single man to try to encompass the whole world of learning for the achievement of secular wisdom, perhaps as a way toward illumination. The very greatest men could make creative advances, but cooperative scholarship, necessary for making lesser men effective, was rare.

Islāmic
Spain

Contact between Islām and Latin Europe came mainly through Spain, where Christians and Jews could act as intermediaries and translators. The 12th century saw a heroic program of translation of works from Arabic to Latin, at first in astrology and magic, then in medicine, and finally in philosophy and science. A lesser route was through southern Italy, where commercial contacts existed with Tunisia. It is significant that the earliest medical school in Europe was at Salerno and that it was later rivalled by Montpellier, also close to Arabic and Jewish sources. Despite its leadership, however, even by the time of the translations, the Islāmic civilization was under pressure from barbarians all along its periphery, and it soon went into decline. In addition to its enormous service to Western civilization in preserving and then transmitting the Greek heritage, Arabic has also contributed to modern science a number of words, mainly of plants and foods, but also such words as alcohol and algebra.

India. The Indian civilization is about the oldest still alive, and it achieved a high level of technology at an early stage. European contacts with it come mainly through Arabic sources, and historical research is not yet sufficiently advanced to distinguish priorities and lines of transmission. It does appear that Indian mathematics, with a highly developed system of numeration and reckoning, influenced Arabic algebra; it also provided the principal arabic numerals (*i.e.*, the nine digits and a zero in a place-value system). But the characteristic science of this civilization is that of the higher consciousness, and, in this, European thought has been so deficient that it becomes aware of its lack only occasionally. Hence the achievements of Europe and India cannot be compared strictly but must be recognized as being complementary.

China and Japan. China presents more of a challenge to the historian of European science. Its basic common sense is this-worldly, although it is based on interpersonal harmonies rather than abstract regularities. In spite of the distances between them and their totally different languages, there has been more or less continuous contact between Europe and China since classical Greek times. Usually the connection was indirect and restricted to trade in luxury goods, but even in classical times there were curious synchronisms in philosophical movements in Europe and China, and in the 13th century there was considerable personal contact, of which that of Marco

Polo is but the most famous instance. Also, Chinese technology until the Renaissance was consistently more advanced than European, and, in his monumental work, the British historian of science Joseph Needham has shown the patterns of transmission of a series of important inventions from China westward. Indeed, the three great inventions that 16th-century writers and, later, Francis Bacon saw as crucial for the transformation of European society all came from China: the magnetic compass, gunpowder, and the printing press. Yet Europe never recognized its debt to China, while, more important, the Chinese never achieved the breakthrough to modern science of the European sort.

China's
crucial
inventions

The ignorance of the debt of the West to China is easily explained. In the period when technical devices were imported or copied, they were of little concern to the learned, and so their ultimate origins were never questioned. When the Jesuit missionaries arrived in China in the late 16th century, bringing the fruits of Western science and technology as proofs of the superiority of Christianity, it was at a time when these pursuits were at a low ebb in China, so that many native achievements had been forgotten. The failure of China to make the breakthrough may be considered in relation to the two phases of the creation of European science discussed below. Chinese society was always stable, ruled by a nonhereditary civil service with a governing philosophy that was one of practical accommodation rather than of abstract principles. Merchants were a distrusted class, and technical innovation had to be accomplished within the bureaucracy. Thus, the features of European Renaissance society that impelled the practical arts forward at a rapid pace were never present in China. Moreover, the Chinese philosophy of nature was also based on organic analogies and relations of harmony. It never could have accommodated the picture of dead matter moving in accordance with mathematical laws, on which Galilean science was based. Related to this is the technical fact that only the Greeks had produced an abstract, logical mathematics that could function as the language of science. Chinese mathematics consisted of reckoning rules, and, in spite of their great sophistication, these could be applied only to the detailed calculations for which they had been designed. Thus, China failed to become Europe. It is likely, however, that with the new appreciation in the West of the need for the establishment of a subtle harmony between the individual self and nature, scientific society may yet have something to learn from the ancient Chinese way.

Finally, there is the fascinating case of Japan. For centuries a cultural colony of China, it had a brief exposure to Western science and religion before its rulers decided early in the 17th century to close the door on such dangerous influences. In the latter part of the 19th century, the Japanese decided to assimilate with the rest of the world and then did so with a vengeance. Their own native religion was sufficiently vague to accommodate any assertions of Western science, and the Japanese scientists, technologists, and ordinary folk now manage to live partly in a hyper-modern world and partly still in one of ancient, rigid social tradition.

CREATION OF EUROPEAN SCIENCE

The "science" of which histories are written is European. Although other civilizations made essential contributions toward it, and though now all nations participate in research, natural science is a distinctive creation of Europe and its cultural colonies. Its roots in thought and society are the same as those of European technology and of its acquisitive spirit; hence science is an important part of the process that achieved domination for this small and, until recently, barbarous corner of the world. The creation of European science has two phases, one of technical development in the 16th century, the other of philosophical revolution in the 17th century. Out of these came the idea of science that is current to this day.

Rebirth of science in the Renaissance. The word science and its ancestors in Greek and Latin is an old one, with continuously changing meanings. In the period now

Liberal
and
mechanical
arts

being considered, it was restricted to the fields providing knowledge: theology and philosophy. For the rest, the term was art or technique. Some arts were called liberal and were taught in Latin at schools and universities. They were language, logic, rhetoric, mathematics, and the learned, or professional, arts of medicine and law. The other arts were mechanical and generally involved unpleasant work for low pay. The ruling conception of knowledge was still radically different from that of the present day. It was universally accepted that there had been a golden age when all things were known (in the Garden of Eden and perhaps again in some age of sages or in classical times). The rediscovery of these truths was not merely a matter of gathering facts; for their first provision and subsequent loss had been events with religious significance. As the perceptible world was strongly influenced by divine, demonic, and magical agencies, so too the penetration of its secrets was more than a secular task. Since the modern conception of science has some of its roots in the conflict against this world view, it is difficult to imagine how a scientific point of view could have existed within it. Until the historian comes to terms with it, however, he remains imprisoned in his own temporary categories, unable to understand the larger world outside.

A convenient starting date for the period of European expansion is 1413, the year of the first raid by Europeans on the African coast, just a half millennium before World War I began the breakup of the European empires. In the early 15th century the cultural scene in Europe was generally bleak: the universities were in decay, the church was disintegrating, and the economy still suffered from effects of the Black Death; the subjects now called science barely existed except when studied in connection with some practical art; even then, materials were scarce, competence low, and social organization rudimentary.

Roots of
the rebirth

The roots of the rebirth of science can be located in three main centres. The first and most famous root is something that can be called the discovery of man and nature, a product of the artistic Renaissance of 15th-century Italy. The inspiration for this was the discovery of classical antiquity and the fact that the Humanist scholars edited and published Latin and Greek texts and translations in all fields, including science. The visual arts, loosely grouped as architecture, were raised in social esteem and given a classical pedigree in a book by the Roman author Vitruvius. The great artists became men of wide interests and culture, whom the nobility sought to patronize; the career of Leonardo da Vinci in the later 15th century exemplifies this exalted position and many-sided activity.

At the same time, the mountainous region in southern Germany, with end points at Nuremberg and Cracow, enjoyed a rapid growth in mining, metallurgy, and trade. Practical mathematics and the theory and practice of metalworking were developed there. The Rhine linked this region with the prosperous weaving centres of Flanders, and it was on this trade route that printing was invented by Gutenberg. This was a highly sophisticated and expensive venture in what might be called research and development, the problem being to find alloy metals of the correct properties for molds in which to cast replaceable bits of type. Once invented, the process spread rapidly. By the end of the century every major city had its press, and the availability of cheap books worked its transformation on learning and culture.

During the century, the Spanish and Portuguese began their explorations. The Portuguese worked down and around the coast of Africa, perhaps using Brazil for a landfall, looking for gold and for the legendary Prester John in Ethiopia. Instead, they found the sea route to India, thus bypassing the Middle East route for spices (then defined as anything purchased from the technically superior Eastern nations, including flavourings, condiments, and drugs). Joining the search late, the Spanish financed Columbus, and their conquistadores then opened up the New World. Transoceanic navigation created new demands on astronomy and on mathematical techniques and instruments, and the earliest research establishments were those of Spain and Portugal, specific-

ly for hydrographic techniques. The New World introduced new plants, animals, diseases, and civilizations to Europe; the excitement and unsettling effects of its discovery lasted for generations.

The printed books of the 16th century provide (in their modern reproductions) a convenient source of evidence for the state of science. At the beginning of the century, knowledge was still rudimentary and largely dependent on confused digests of ancient and Arabic sources. By midcentury there appeared works that surpassed the best of their predecessors. In astronomy, there was the *De revolutionibus* (1543) of the Polish Nicolaus Copernicus, a technical masterpiece as well as a revolutionary treatise on cosmology. In anatomy, the Belgian Andreas Vesalius created a new approach to anatomical research and teaching in his *De fabrica* (1543). In mathematics, the Italian Gerolamo Cardano advanced algebra (providing the general solution of the cubic equation) in his *Ars magna* (1545).

During this century the Protestant Reformation touched off a series of wars for which gentlemen officers needed certain new mathematical skills associated with fortification and gunnery, which also called for new classes of practitioners, such as military surgeons and engineers. Although some of the theoretical fields tended to be speculative, there was in general an enormous improvement in all these arts. By the end of the century, the applied mathematical arts were a standard part of the education of a gentleman on the Continent. The French mathematician-philosopher René Descartes learned them at his Jesuit school and the Italian Galileo taught them at the University of Padua. In this way there came a temporary lowering of the barriers of class snobbery against such arts. This was crucial for the formation of the new philosophy and its acceptance by the liberally educated audience to which it was directed.

The new philosophy, however, was not a prerequisite for successful science. Around the turn of the century, and later, there appeared great works of science containing particular discoveries that are still accepted as facts to this day, but the scientists who achieved them were still working within the world view that was shortly to be rejected by the new philosophy. Thus William Gilbert (1600) in England explained the compass needle in terms of the Earth's being a giant, very weak magnet, but he did this in the course of proving that the world soul is embodied in the magnet. In Prague, Johannes Kepler shortly afterward (1609) discovered the true orbits of the planets as ellipses around the sun, and he never ceased his search for the harmonies of the cosmos. Later (1628), William Harvey in England established the circulation of the blood, but for him it was more a microcosmic image of the circulations of the world than it was a purely mechanical system. The strangest mixture, by modern standards, is to be found in the chemistry of Paracelsus and his followers of the 16th and 17th centuries. They combined elements of metallurgical crafts, folk medicine, alchemy, mystical religion, and social reform, and yet they were successful as chemists.

Revolution in natural philosophy. In the 17th century, there occurred a radical recasting of the objects, methods, and functions of natural knowledge. The new objects were regular phenomena in a world devoid of human and spiritual properties; the methods were of disciplined, co-operative research; and the functions were the combination of scholarly knowledge and industrial power. Although this is frequently called the scientific revolution, it was a revolution about science rather than in it. In most fields of inquiry, progress was continuous through both centuries, nor did the external social environment of science change drastically. For a leading cause of the inception and rapid diffusion of this philosophy, the radical change in educated common sense about the world must be examined; briefly stated, the change was from the notion of a living cosmos of earlier times to that of a dead universe.

The main target of attack by the revolutionaries was the traditional higher education that was called Scholastic. Scholasticism assumed a living world, created and guided

The new
philosophy
of the
late 16th
century

by God quite simply for man's benefit, and its study was largely accomplished by citing authorities, either philosophical or scriptural. The function of this knowledge was to rationalize sense experience in harmony with revealed religion. By contrast, the ancient and honourable sciences of astrology and alchemy, and their relations, were usually dismissed by the new philosophers with a passing sneer because, in their common sense, these were so ridiculous as to require no refutation. Thus, in 1600 an educated man knew that the Earth was in the centre of the cosmos, the seat of change, decay, and Christian redemption, while above it circled the planets and stars, themselves pure and unchanging but moved by some sort of intelligent or divine spirits and also signalling and influencing human events by their locations and aspects. One hundred years later, his equally Christian descendant knew (unless he lived in a church-controlled Catholic country) that the Earth was but one of the planets moving through unimaginable distances in empty space and that God could still operate. Similarly, the earlier man, as a reasonable person, would accept the overwhelming evidence for the working of enchantments and the prevalence of witches; while the later one, with equal certainty, would dismiss all those stories as the effects of charlatanism, in the one case, and torture, in the other.

The prophets of revolution in the 17th century

The prophets of this 17th-century revolution were Francis Bacon in England, born 1561, Rene Descartes in France, born 1596, and Galileo Galilei in Italy, born 1564. Each of them was committed to a great mission, over and above particular facts and theories, and each in his way tasted tragic defeat. Bacon, professionally in the law and politics, borrowed themes from earlier pietistic philosophers and saw himself as inaugurating a reform of knowledge, so that the material redemption of mankind could go with spiritual salvation in preparation for the millennium. He hoped to effect this program through royal patronage and was shattered when his public career came to an end suddenly in an unjust disgrace. Descartes believed that he had rescued truth and religion from the corrosive criticism of the skeptics, by a method based on the example of geometry. By its means he would be the new Aristotle, constructing a complete philosophy, starting with mechanics and reaching medicine. Thus he would inaugurate a new epoch of longevity and wisdom, realizing the program of the Rosicrucian mystical fraternity with whose ideals he had become identified. But his work became bogged down in complexities of every sort, and, by the end of his short life, he knew that he was only a great metaphysician and mathematician. Galileo was less exalted in his ideals and more thorough in practice. He only wanted to destroy the Scholastic conception of philosophy and substitute his own, one of free exploration of an impersonal mathematical universe. For him, the Copernican system was a very beautiful fact in its own right and also a weapon against the professorial simpletons. He was insufficiently sensitive to the religious and ideological consequences of what he thought was his little revolution in its time and place, and so he blundered disastrously into a conflict with his former friend and protector Pope Urban VIII. Although under house arrest, ill, and going blind, he maintained an invigorating hate for his enemies and, at the age of 74, published his masterpiece on mechanics, the *Two New Sciences*. Bacon's contribution to science was nil, but he provided an inspiring ideal and also shrewd judgments on the social activity of science. Descartes created a new metaphysics, a radically improved algebra and geometry, and some viable results in physics (explanation of the rainbow). Galileo's vast labours for Copernicus had only an indirect effect, and that a mixed one; but by his mechanics he brought relative clarity to the science of motion and laid firm foundations for future work.

In spite of their differences in style and contribution, these three prophets shared a common commitment about the natural world and its study. Nature itself was seen by them as devoid of spiritual and human properties. There could be no dialogue with it, whether using mystical illumination or inspired authority. Rather, it had to be investigated soberly and impersonally, using sense experi-

ence and reason. Strange and prodigious phenomena, such as earthquakes, wonder cures, and monstrous births, which had been important subjects of speculation over the ages, were seen to be of less significance than regular, repeatable observations. Care and self-discipline were necessary in observation as well as theorizing, and cooperative work was important for the steady accumulation and testing of results.

The goals of inquiry still retained an influence from magic in that the traditional philosopher's ideal of contemplative wisdom was replaced by that of domination over nature for human benefit. But the loss of belief in magical powers entailed changes in methods and also in responsibilities. In the absence of potent enchantments and elixirs, knowledge of nature was either beneficial when applied to marginal improvements of industry and medicine or was innocent. The moral optimism of modern European science was thus built into its foundations and became unquestioned common sense, until the hour when atomic bombs were dropped on the civilians of Hiroshima and Nagasaki.

The establishment of scientific societies was a direct result of the new conception of natural knowledge and the methods of its pursuit. From the outset it was recognized that such societies, and their journals, must achieve a harmony between the needs of the community for rapid diffusion of results and the needs of scientists for the protection of their private property in their hard-won results. The Royal Society in London, proclaiming its adherence to the ideals of Francis Bacon and suppressing its connections with reformers on the parliamentary side, was chartered in 1662 by the newly restored king, Charles II. The French followed suit in a few years' time, and somewhat later other continental monarchs did the same. National styles asserted themselves even this early. The Royal Society, for example, was a private club with little more than moral support from the crown, while the continental academies were established by the state and the members gained an income though they lost their independence.

The scientific societies

As regards the constitution and workings of the natural world, the new philosophers (with the exception of Bacon) assumed that all visible phenomena are the result of interactions of invisibly small particles of matter. These have neither intelligence nor purpose, and thus the paradigm reaction is the collision of balls. Hence the perceptible qualities of things (on which Aristotelian science was based) are only secondary, mere effects in our minds. The primary qualities are those capable of mathematical description. Although this view had many disputed variations (Newton in particular adding force as a real agent), there was an unusually sharp demarcation between its adherents and those of its rival views, Aristotelianism and alchemy.

In some fields the new philosophy was appropriate for progress at that stage, and the fields were transformed. Such were cosmology, mechanics, and pneumatics. Elsewhere in science its distinctive achievements were modest. Optics had received its modern start from Kepler and electricity and magnetism from Gilbert. Chemical theory was not significantly advanced; the corpuscular explanations of Robert Boyle in England (middle 17th century) only rationalized existing ideas. In biology and medicine, although there was a premature attempt at reduction to a physical model, this did not show results for another two centuries. The direct impact on technology was restricted to the rationalization of simple machines and the development of vacuum techniques. Thus the new philosophy was not a generalization from the success of a new science. Rather, it was a prior metaphysical commitment that, eventually, over later generations, proved its fruitfulness in all fields.

Under these circumstances, it is not surprising that many scientists, particularly those in chemistry and medicine, rejected the corpuscular philosophy as a useless revival of an ancient atheistic system, since, if the corpuscles had no intelligence or purpose, their collisions were random, accidental, and the whole universe was without purpose. Chemistry was not yet a study of controlled

processes involving pure reagents but was still tied to craft-industrial practice and to Paracelsian medicine. In England during the Civil War, there occurred a debate on the nature and social functions of science and education, in which the mathematically oriented scholars found themselves on the conservative side. The issue, raised in 1654 by a chemist, John Webster, was whether or not the universities should replace their antiquated, sterile curriculum by studies of honest, hardworking, practical crafts based on Paracelsian chemistry. The defenders of the status quo (including the future founders of the Royal Society) argued that genuine scientific teaching was available to those who wanted it; but at last they had to admit that they accepted the universities' role as finishing schools for the elite and for that reason would not trouble the students with compulsory new subjects.

Achievements of
Sir Isaac
Newton

The career of Sir Isaac Newton at the end of the 17th century illustrates the complexities that persisted even when the revolution had been successful. One of the greatest scientists and mathematicians of all time, he brought the heavens and Earth together in one impersonal law of attraction, the law of gravity, and also brought a new rigour to methods of quantitative experimental investigation. Although he advocated the utmost caution in theorizing, he still believed it possible and proper to induce from the phenomena of nature to a discussion of the deity. When he came to the foundations of his physics and discussed space, time, gravity, and force, he found theology of direct relevance. He also used astronomical methods for an improvement of ancient and biblical chronology and firmly believed that a study of the Old Testament prophecies would produce a true interpretation, thus providing guidance in the politico-religious affairs of the time. His masterpiece, the *Principia* (1687), was in many ways the culmination of the scientific revolution. By the time it appeared, however, the impetus had slackened, and no new recruits of the same calibre were coming forward. Indeed, by the end of the 17th century, interest in natural philosophy had ebbed so much that the Royal Society was nearly defunct. It was revived by Newton himself from 1704, to become a club for gentlemen who enjoyed hearing about experiments and collections. Nevertheless, the main work of the revolution in philosophy had been accomplished, and European literate culture, including science, was firmly set on the path to complete secularization.

The image of Newton dominated science in the 18th century, just as that of his friend John Locke dominated philosophy. The early 18th century was a complacent age. Europe was recovering from two centuries of turmoil. Outside the sphere of the Enlightenment, there were no great philosophical struggles, and the science that was practiced was mainly consolidation. A handful of great mathematicians (the Bernoulli family and Leonhard Euler, all of Switzerland) developed the differential and integral calculus invented by the German philosopher Gottfried Leibniz to the form in which it is now taught. Natural history developed steadily, receiving social organization and an intellectual synthesis from the Swedish botanist Carolus Linnaeus. "Experimental philosophy" was cultivated by gentlemen, and a successful theory of static electricity was established by the American scientist and diplomat Benjamin Franklin. Although these achievements did not comprise a great advance, they firmly established a certain style of science—that advocated by the prophets of the new philosophy, although, of course, without their revolutionary inspiration.

Nature of European science. The special character of European science can be explained by the circumstances in which scientists in these two successive phases worked on their inherited materials. These included the basic principle of knowing the natural world through demonstrative argument, a principle first achieved in Greek culture, then picked up by Islamic civilization but not by any other. Although, at the beginning of the Renaissance, European science and technology were derived from older traditions and were generally inferior, certain features of European society of the time enabled it to make exceptionally rapid progress. Even though society was still

largely agrarian, undemocratic, and stratified by inherited social position, there were several areas in which the style of social life was more fluid and individualistic than anywhere else. There was a freedom to invent and to exploit one's inventions for private gain unhindered by state suppression. In other civilizations (the Far East and medieval Europe), technical innovation was monitored and suppressed if it threatened political or social stability. In the relatively fluid society of Europe, individuals had a motive for innovation in that they could advance themselves thereby. Also, the barriers between different fields of activity appropriate to different classes were relaxed, permitting the educated man to dabble in invention, using his knowledge and literate skills. Invention could be in devices or in knowledge; men could move freely from one to another and back again. The context in which this destabilizing activity was fostered was one of aggressive commercial and political expansion, of states pitted against each other, and of Europe against the world. This society has been called early capitalism, and, although its political structures tended to the principle of the absolute state, even these were liberal in comparison with the totalitarian societies of earlier and more recent times. And it was in the focal points of commercial and manufacturing development (Italy, south Germany) that the technical arts first made their most rapid progress.

Although, by the end of the 16th century, European science surpassed that of its sources and rivals, its products were still not qualitatively different from theirs. Then there came the revolution in philosophy that transformed European science into something unique. There had been earlier periods when an atomistic philosophy of matter had been advocated, but it had always been a philosophical speculation. This time it was injected into a flourishing scientific endeavour. Slowly at first, but at an accelerating pace, the synthesis created a new sort of science. Most important was the new style of the social activity of research, in which the secrecy and ruthless competition characteristic of private inventors were tempered and disciplined by the commitment to cooperative work for the common good. The roots of this lie partly in the loss of belief in magical powers, so that none could hope to unlock the secrets of the universe by solitary endeavour. Also, the idealism of the prophets of the new philosophy called for a new cooperative ethic of research, and, even as this inspiration waned, its effects were maintained by an adaptation of the code of honour of gentlemen scholars. Thus the mutual stimulus of theory and practice, maintained from the earlier period, was channelled into a cumulative and self-correcting process of winning reliable facts about the natural world. The successes of the new philosophy and its methods were patent by the end of the 17th century, and, even though the pace of advance slackened during the next century, the earlier achievements in knowledge and in methods were never lost. Hence a maturing European science was available for its next phase of interaction with practice, in the Industrial Revolution and beyond, and from this came the matured science of the epoch immediately preceding the present one. Also, the philosophy of dead matter turned out in the long run to be a fruitful strategy for scientific advance in that, although it suffered from many false starts, the sciences of chemical combination and of life could make their eventual triumphs in the 19th century only on the basis of this reductionist conception of the natural world.

In summary, therefore, European science owes its past successes and its special character to its sharing, in its metaphysics and methods, the basic features of European society: aggressive individualism tempered by a principle of cooperation for a common good.

SCIENCE IN THE AGE OF MODERN REVOLUTIONS

Toward the end of the 18th century, there began an industrial revolution that transformed Europe from an agrarian to an urban society; at the end of the century occurred the French Revolution, in which modern political ideas were first realized in practice. The activity of science experienced analogous changes. It was in this time

The
urbanization of
Europe

that social and institutional foundations were laid for the maturing of science in the 19th century. Simultaneously there occurred a romantic reaction in literature and the arts that had important repercussions in science itself.

At the beginning of this period, science was a very small-scale activity, mainly pursued by gentlemen of means or by trained professionals, such as physicians and engineers, in their spare time.

Only a very few universities (for example, Edinburgh and Leiden) provided effective instruction in science. The mathematical sciences (mathematics, astronomy, mechanics, optics) were well developed, but physics was still a scattering of experiments with qualitative and mainly speculative theories, chemistry was nearly entirely empirical, and the life sciences were concerned mainly with collectors' activities. By the end of the period there were successful examples of organized scientific work, and the foundations had been laid for coherent and effective theories in most areas of science.

Science during the Industrial Revolution. In the gradual but deep transformation of European industry, the direct contribution of science was at first small. Most of the early progress came through the rationalization of craft techniques and the invention of simple machines to replace manual operations. Even there, elementary materials and an experimental approach, derived from the study of popular textbooks, were of great importance. Power technology was the first to be influenced by the applications of advanced science. The English Newcomen steam-vacuum engine (1711) came from 17th-century pneumatics, and the improvements made by the English engineer James Watt from 1763 onward were intimately related to developments in the theory of heat. Industrial chemistry was similarly assisted through the organization of chemical knowledge achieved by the great Dutch medical teacher Hermann Boerhaave and his followers.

The contribution of the Industrial Revolution to science was at first similarly indirect. In the industrializing regions of Britain (Lowlands Scotland, the Midlands, and Cornwall), there developed an audience for scientific results. Philosopher-manufacturers such as Josiah Wedgwood, the potter and social reformer, combined with physicians to pursue research, to form local societies, and to patronize scientists. By the end of the century, not only free-lance lecturing but also the publication of journals for the specialist became economically feasible. On the Continent, the more progressive monarchs established specialized colleges of engineering, either industrial, civil, or military; these provided a training for potential recruits and also jobs. In Britain, in spite of its early start and broad interest, advanced training remained rudimentary, and locally sponsored institutions for artisans' education were the rule through this period and the following. Although most of the problems that emerged in industrial practice and in medicine were beyond the reach of the existing scientific theories of the time, there is no doubt that engagement in solving them provided a stimulus and audience for research and so led indirectly to scientific progress.

Intellectual origins of revolution. Starting somewhat earlier than the Industrial Revolution was a movement centred in France that first brought science into the realm of politics. Called the Enlightenment, it had as its program the struggle against church dogma and popular superstition, and it used the facts of science and its rational methods as the main weapon. It was started in the 1730s by Voltaire in a wave of anglophilia, who used the image of Newton to ridicule the officially imposed orthodoxy of Descartes's cosmology and physics. The Philosophes operated in the sophisticated environment of Paris salons and encouraged a growing readership for popular science books; for example, *Newtonianism for the Ladies* was a best seller. By midcentury the movement had matured. The Encyclopédiste Denis Diderot and the mathematician Jean d'Alembert edited the huge *Encyclopédie*, in which the democracy of knowledge was displayed by the alphabetical ordering of articles, and craft techniques were given equal dignity with metaphysical and scientific discussions. Aided by a hatred of a stupid and eventually

demoralized censorship, the Philosophes soon recruited all the best minds of France. They consciously considered themselves as carrying on the work of Bacon in advancing practical knowledge, but they did so in the style of Descartes, subjecting all things, social as well as philosophical, to the criticism of reason. The movement soon split into factions: the mathematician-rationalists, d'Alembert and his disciple Marie-Jean-Antoine Condorcet (who was a victim of the Terror during the Revolution); the romantics, Denis Diderot and Jean-Jacques Rousseau; and the atheist materialists, led by Paul-Henri Holbach. Nevertheless, they all agreed that their main enemy was the church. For all of them, natural science was philosophically committed, which was the opposite of being neutral and positive. From the ideas of these men came the slogans of the French Revolution, and their conflicts were eventually fought out in the realm of power politics.

The organization of science in the French Revolution. Natural science was deeply involved in the French Revolution. From the Enlightenment the revolutionaries inherited a faith in science and its methods that permitted the greatest scientists to devote themselves to the organization of war industry for the defense of the republic in its hour of need. During and after the Revolution, there appeared a state-supported system of education, with scholarships for talented boys, jobs in teaching and examining, subsidies for research, and rewards for inventions. The centre of the system was the École Polytechnique of Paris, mainly serving to train army engineers, but the greatest scientists taught there, and there they found their most promising students.

The dominant style of this Revolutionary science was mathematical. In applications, its method was rationalization, one lasting product of which is the metric system, which was intended to produce a coherent system of measures based on natural units and the decimal. At the time of the Revolution, France already had distinguished mathematicians (Pierre-Simon Laplace, Joseph-Louis Lagrange, and Gaspard Monge); and their pupils and successors (Jean-Baptiste-Joseph Fourier, Siméon-Denis Poisson, and Augustin-Louis Cauchy) maintained their excellence. Even in chemistry, the reform of nomenclature achieved by Antoine Lavoisier and his colleagues was mathematical and abstract in style. Chemical compounds were to be described by a regular scheme of combination of the names of their constituent elements, and all traditional names were to be discarded.

At the height of the Revolution there emerged a countermovement in science that condemned the mathematical approach as sterile and elitist. Drawing inspiration from the democratic and romantic ideas of Rousseau and led by the former physician and journalist, the Revolutionary Jean-Paul Marat, this movement called for "science for the people," open to the self-educated artisans and based on practical chemistry and natural history. They achieved the dissolution of the Academy of Sciences, while promoting the more popular Museum of Natural History. The ideological struggle over the nature of chemistry was probably a factor in the execution of Lavoisier (1794) during the Terror, but, with the collapse and destruction in late 1794 of the Jacobins (a political club that was extremely effective in supporting the democratic radical movements within the Revolution and of which Marat was the leader for a while), the populist conception of chemistry was suppressed and the rationalistic, meritocratic style of French science was established in force.

Under Napoleon, the surviving grand old men and their first generation of disciples enjoyed patronage and prestige, but the "school of Laplace" went into eclipse after the restoration of the monarchy in 1815. A new group of distinguished scientists took over, but somehow the impetus was soon lost. Although Paris was the mecca of the scientific world in the 1820s, stagnation was setting in. One clue to this is the exclusion, almost certainly for political grounds in both cases, of two young men of outstanding genius: Sadi Carnot, who established the basic principles of thermodynamics, and Évariste Galois,

The role of mathematics in France

Effects of the Industrial Revolution

the creator of group theory in abstract algebra. After 1830, the scientific scene in Paris, which had always drained talent from the provinces, was dominated by careerism, and the great achievements of 19th-century science were made elsewhere. Historians of science now appreciate that this decline was not an accident but a significant problem requiring explanation.

Romantic reaction and science. At the same time as the Revolution in France, *Naturphilosophie* flourished in Germany. Its devotees, led by the poet Goethe and the philosopher Schelling, denounced the dry, soulless mathematical and experimental science of the Newtonian tradition. Instead, they proposed a philosophy of nature in which hand and eye, mind and spirit would all be united. Goethe unsuccessfully attacked Newton's theory of colours, but he gave inspiration to biological speculation on the organizing and unifying principles behind the structure of vertebrate animals. His followers, like other German thinkers of the time, attempted grand speculative physical and spiritual syntheses of all the world.

In England, the effects of *Naturphilosophie* are seen most clearly in the Romantic poets. Samuel Taylor Coleridge had studied it and shared his vision with William Wordsworth. Independently William Blake had drawn on the same mystical sources as *Naturphilosophie*, and he denounced "The Atoms of Democritus and Newton's Particles of Light" as part of the blind and dehumanized culture of his age.

The lasting scientific achievements of the adherents of *Naturphilosophie* are few, although many more may be recognized when more sympathetic historical research is done. For example, the discovery of electromagnetism (1820) by the Danish physicist Hans Christian Ørsted is now known to be the outcome of a search, conducted over many years, for effects to display the unity and polarity of the forces of nature. Similarly, the earliest announcement of the notion of conservation of energy was made in 1841 by a physician, Julius Robert von Mayer, who had the same sort of program. The common pattern was for a young man to be captured by the vision of such a unified wisdom while at a university and then to spend his life trying to rescue as much of it as possible by dedicated research. This sort of career is well illustrated by that of Hermann Ludwig Helmholtz, a German physiologist and physicist.

Eventually *Naturphilosophie* became an orthodoxy taught by university professors. The founders of experimental science in Germany in the 1830s and 1840s found their way blocked by them, and bitter struggles ensued. Though the scientists won, they were haunted for generations by the ghost of *Naturphilosophie*, and they reacted by curbing all speculative tendencies most severely, reinforcing the dry, inhuman style of science that the poets had found abhorrent.

AGE OF MATURE SCIENCE

During the 19th century, the industrially advanced nations of Europe assimilated the consequences of the Industrial and French revolutions. Modern urban society developed in one nation after another with a constantly improving industrial base, elaborated state bureaucracies for regulation of trade and welfare, and increasing participation of the mass of people in social and political life. In one scientific discipline after another, there was a similar steady progress in the achievement of coherent systems and in the creation of institutions for the development of scientific activity. Science as a whole shared the general optimism of the age, receiving credit for its supposed contribution to industrial progress.

Science in the 19th century. In retrospect, the 19th century appears as a golden age. Science expanded successfully into new fields of inquiry, including a combination of mathematics and experiment in physics, the application of theory to experiment in chemistry, and controlled experimentation in biology. This was greatly aided by the establishment of new and reformed universities in which research was fostered, as well as teaching, and of communication through specialist journals and societies. National and international meetings, for both general

science and specialists, became common by the end of the century. The principle of socially organized research, rather than inquiries by isolated individuals, became effective. In all fields of learning there was increased rigour of methods and depth of scholarship. The end-of-century editions of the *Encyclopædia Britannica* with their long historical accounts of each science are a monument to this period and remain a valuable source of information for the student.

Differences in styles of research. There were still striking differences among the leading nations regarding the circumstances and styles of research. In Britain, there was a marked absence of institutions providing jobs for researchers, and so the tradition of the gentleman-amateur lasted longer than elsewhere (for example, Charles Babbage the mathematician, James Joule, the physicist, and the biologist Charles Darwin). This made British science thin in comparison with German, especially in applied fields such as chemistry; but the scope for individual style and eccentricity compensated for the quantitative deficiencies. In Germany, the natural sciences shared in the rise in size and prestige of the university system. There, research and teaching were joined, and genuine laboratory research training was established for the first time, notably by the German chemist Justus von Liebig and his school. With this institutional base and a highly developed scholarly apparatus of handbooks and journals, German science rose in the half century from 1830 to a position of leadership in most fields. During this same period, French science declined from what had previously been its commanding position during the Revolutionary and Napoleonic periods. On the edge of Europe, Russia had a strong Academy and several progressive universities amid generally backward conditions, and a tradition of scientific excellence (set by men like Nikolay Lobachevsky and Dmitry Mendeleyev) was available for helping the rapid modernization that followed the Revolution of 1917. Through the 19th century the United States remained a cultural colony of Europe, except to some extent in the field sciences. Its larger universities were oriented toward utility, giving little social support to pure research. Around the end of the century, American scientists went to Germany in large numbers and on returning established strong traditions, but the attainment of qualitative leadership by the U.S. required the influx of refugee scholars from Nazi Germany in the 1930s.

The commitment to so-called pure science could flourish best within the German university system. In Britain, men of science freely engaged in both philosophical debates and in industrial application, a notable instance being Lord Kelvin in physics; the issue was not the scholar's remoteness from the world but the gentleman's independence of action. Also, the dominance of mathematical and experimental sciences over field sciences grew very slowly through the period. Early in the century, geology was the leading science. It had both a philosophical side in its speculations on the history of the Earth and a practical side in the utilization of resources. Natural history, inherited from the 18th century, served the squire and also the free-lance explorer and collector, such as Thomas Henry Huxley in biology. Only in the latter part of the century was there a marked trend toward dominance of the specialized professional research man, with the abstract experimental scientists as the leaders. An indication of the gradualness of this change in England can be seen in the resistance to the two terms scientist and physicist. Although suggested for general use in the 1830s, they were condemned by men of science as well as by natural philosophers until the beginning of the 20th century.

The relationship of science to its applications had an equally gradual change; in spite of claims to the contrary, the direct transition of processes from laboratory to factory became effective only toward the end of the century. At the beginning of the period, the most successfully applied sciences were those traditional ones that were descriptive techniques of interest to the state. These were either the abstract disciplines of mathematical cartogra-

The rise of organized research

Triumph of *Naturphilosophie*

Slow growth of relationship between science and industry

phy and fortification or the very detailed natural-history studies. Later physics was directly involved in qualitatively new processes, such as improved steam-power generation and electrical telecommunications. Chemistry contributed at first to the rationalization of industrial processes and also to effective theories of agriculture and nutrition. The invasion of medicine by applied science came very late, with the germ theory of disease; and it is worth remembering that the improvement in life and longevity owed more through the century to soap and sewers—that is, to sanitary reform and economic improvement—than to medical science. Synthetic dyestuffs were the first example of a laboratory discovery turned directly to profit, and this was a German achievement. Actually, the invention was made in 1856 by an Englishman, William Henry Perkin; but he was a pupil of the German chemist August Wilhelm von Hofman, and the Germans soon took a commanding lead in this industry thanks to their system of higher technical education for industrial scientists. By the end of the century they dominated all of industrial chemistry, as well as the heavy electrical equipment industry. Only the Americans, with their combination of a large market and independent inventors, could compete effectively. The French had long since lost the early lead they had gained with their rational approach to engineering, and the British rested on their early prestige as the workshop of the world. World War II found the Germans capable of synthesizing ammonia for nitrate explosives from the air (the Haber process), while the British depended for their explosives on nitrates from Chile.

Progress in physics. During the 19th century, each of the major branches of experimental science made such great progress that in retrospect its earlier state seemed to be rudimentary. Physics achieved that close union of precise experimentation with abstract mathematical theory that brought unprecedented depth of knowledge and power in application of that knowledge. Different fields were brought under control and then successively unified by the concept of energy. Thermodynamics united the sciences of heat and work and then enabled a theory of chemical change to develop. The roots of this lay in the work done by physicists in power engineering pioneered by Sadi Carnot of France and James Joule of England, in a variety of experimental fields pioneered by the German Herman Helmholtz, and in the speculative search for the single agency of physical change. Electricity and magnetism were united, first experimentally and then theoretically, by the Dane Hans Christian Ørsted and the Englishmen Michael Faraday and Kelvin; and a fundamental constant in the theory of electromagnetic measurement, determined by the German Wilhelm Weber, was observed to be equal to the astronomically determined velocity of light by the Englishman James Clerk Maxwell. Thus, the general properties of matter were successively mastered and made coherent. Later physicists justly called the century the classical age.

Progress in chemistry. Chemistry built on the theoretical foundations of Lavoisier's nomenclature and Dalton's atomic theory and spent decades on the heroic task of classifying substances into elements and compounds. The decade from 1858 saw three great victories. In Italy, Stanislao Cannizzaro solved the twin riddles of atomic weight and chemical composition by the synthesis of neglected earlier ideas (specifically Avogadro's hypothesis) and new experimental results and heuristic principles developed in teaching. At last the composition of water, as H_2O and not HO , was known. Shortly afterward, Friedrich Kekulé in Germany uncovered the true structure of organic compounds, with the alternate bonds of the benzene ring. Then Lothar Meyer in Germany and Dmitry Mendeleyev in Russia mastered the structure of the periodic table of the elements and could predict the properties of unknown elements. Thereafter chemistry could move toward a closer unity with physics and an increasing power in industrial application.

Progress in biology. In biology, the experimental approach was first successfully developed in physiology, mainly by the school of Johannes Miiller in Germany in a

complex reaction with *Naturphilosophie*. Philosophical considerations similarly conditioned the enunciation of the cell theory by Theodor Schwann. These Germans were generally reductionist. The French, who tended to believe in the special character of vital forces, advanced the more synthetic aspects of physiology (Claude Bernard) and medicine (Louis Pasteur). Through the field sciences came perhaps the most important conceptual achievement of the century: the time dimension in nature, both as one of very long duration and as the framework of qualitative change. The geological record showed evidence of such complex series of transformations of structure and so many successions of life-forms that the attempts to reconcile this history with that sketched in the Bible became increasingly implausible. The battle between those whose explanations were ruthlessly naturalistic and those who tried to reconcile Genesis and geology had started in the 18th century, and it continued into the 19th century on new issues. With a long time scale universally accepted, the appearance of human artifacts and remains in sealed old layers raised even more troubling problems, and the evidence was rather neglected for more than a quarter of a century. The crucial sector of advance turned out to be natural history, in the problem of the differentiation of natural varieties, a process whose results appeared quite similar to that of selective breeding of domesticated plants and animals. In England, disinterested in supernatural explanations and given insights by a political essay on population control by the political scientist Thomas Malthus, the naturalists Charles Darwin and Alfred Russell Wallace conceived of natural selection by the Victorian principle of survival of the fittest. The doctrine of evolution (1859) then unified all these historical disciplines and, through the extension of the principle to man himself, collided with religious orthodoxy. It also provided powerful explanatory principles for the nascent social sciences (supplementing the evolutionary principles of the English social philosopher Herbert Spencer); and naturally it was a source of slogans for political movements ranging from Marxist Socialism to "robber baron" capitalism. This Victorian episode shows that the neutrality of science with respect to politics and ideology, either in its inspiration or in its effects, is a very recent and probably temporary phenomenon.

The theme of this age was progress, and science received credit for much of the real progress that occurred and also shared in the general optimism of the times. Three factors were present in the general praise of science. First came the ancient tradition of respect for learning as a contribution to civilization, independently of its applications. A more popular appeal was based on the applications, first to industry and later to medicine. A third factor, intermittent in its appearance, was inherited from the Enlightenment: natural science as a weapon against religious dogma and popular superstition, both in its facts and in its methods. The memory of the trial of Galileo stayed fresh in the folklore of science, so that the debate over Darwinism in England gave new impetus to this ideological struggle, in which liberal Christians sided with agnostics against the orthodox. Taken together, these three beliefs performed many of the functions of a religion and remained a strong inspiration for science until very recently. Their discrediting in the present period presents serious problems for the future of science.

Early 20th century. Certain tendencies within 19th-century science became heightened during the succeeding period. At this time, science was professional in its social organization, reductionist in style, and positive in spirit.

Science was then conceived as essentially the work of pure research, with teaching as a lesser, ancillary activity and industrial application a task for other workers in other institutions. Almost all research was done by highly trained experts, employed wholly or mainly for this work within special institutions. Communities of scientists, organized by discipline and by nationality, enjoyed a high degree of autonomy in the setting of goals and standards of research and in the certification, employment, and rewarding of their members. Individual scientists tended

The effects of the geological record on the notion of time

The ideal of pure research

to be forced by competition to become very specialized research workers. Correspondingly, undergraduate teaching in science tended increasingly to become a specialized pregraduate program designed for the minority who would proceed to research. As the costs of research increased beyond the means of individuals, science depended on grants from large agencies, either charitable foundations (as the Rockefeller) or departments of national states. These also set up their own laboratories, usually for applied research, the best of which paralleled the university system. The tensions in this system of external support remained latent. Similarly, there was no systematic recognition that the majority of science graduates were employed outside professional science, either as teachers or as employees in technological establishments.

The dominant style of work in this period was reductionist: investigations were concentrated on the artificially pure, stable, and controllable processes achieved in the laboratory; and the favourite theories were those involving the simplest physical causes, using heavily mathematical arguments. Almost all the philosophy of science in this period assumed that a real science is one modelled on theoretical physics. The prestige of this style is shown by the many attempts to extend it to the human sciences. Its limitations, as now seen, were centred in a dangerous ignorance of the facts and principles of the behaviour of the natural environment.

The positive spirit of this science was shown by its increasing separation from philosophical reflection. Einstein's theories of relativity (1905 and 1916) and the German physicist Werner Heisenberg's "uncertainty principle" in quantum theory (1927) raised vigorous philosophical discussions among scientists and laymen alike. But these were exceptional; afterward, the only major instances of philosophical concerns, by a lay public, with scientific research were disastrous. The Nazis attacked both theories and scientists on racial grounds; the Soviet state attacked genetics and persecuted leading scientists, with the excuse of the Marxist pseudo-genetics of T.D. Lysenko. As a result, it seemed to many scientists that both the progress of science and the preservation of the values of a liberal society required an affirmation of the ideological neutrality of science and an insistence on the complete autonomy of research. For them, pure science was not a retreat but a positive commitment.

The scientific achievements of the earlier 20th century are too immense even to be cataloged. There is, however, a common pattern of advance. In each major field, progress was based on the successful descriptive work of the 19th century. It went first to a finer analysis of constituents and their mechanisms and then to syntheses that straddled the inherited names of disciplines, producing vigorous hybrids such as biochemistry and biophysics. In physics, the classical theories of the main physical forces (heat, electricity, magnetism) had been unified at their foundations by thermodynamics; and the early part of the century saw the discovery of totally new effects (X-rays, radioactivity), the penetration into the structure of matter (atomic theory, isotopes); these required a recasting of the fundamental laws of physics and some of their metaphysical presuppositions (relativity, quantum theory). Chemical methods of analysis were necessary for much of this work in physics. Conversely, the new physical theories were sufficiently powerful to provide effective explanations for a wide variety of chemical phenomena. On this basis, the chemical industry could produce an enormous range of totally synthetic substances (fibres, plastics). In the life sciences, chemical and physical methods brought discovery and explanation of subtle agencies (vitamins, hormones) and the reconstruction of the complex cycles of chemical transformations whereby matter lives. Medical science could build on bacteriology, and, through the discovery of specific and general drugs (first Salvarsan against syphilis, then sulfonamides and penicillin), it nearly eliminated both the classic epidemic diseases and also the cruel diseases of childhood. It is little wonder that the triumphs of science seemed to promise knowledge and power in superabundance. Few men could foresee the problems that these very successes

would bring to their social and natural environment on their being applied in an aggressive spirit unchanged over five centuries of European expansion.

Problems and prospects. In the perspective of this long history, it can be seen that the moral, political, and environmental difficulties facing science and technology today are not totally new. Rather, they are a return to problems that had been forgotten, first with the decline of belief in magic and then with the coming of matured science. From this were inherited an ideology of pure science, a technology in which all problems were successfully solved, and a sheltered community of scholars. But even then there could occur stagnation within a scientific community and conflict between science and society. At the present time, the intimate connection of science with industry, defense, and politics has rendered the ideal of pure science obsolete and has confronted society with the need for a working conception of the natural world different from the reductionist model of the physicist.

Yet, although historians cannot be content with the simple story of continuous success told by earlier generations, they see that modern European science is an integral part of civilization. Its faults as well as its virtues derive from aspects of Europe that are deep in the Western way of life. The survival of science and the survival of the civilization go together. To reject the intellectual and spiritual triumphs and the material benefits that European science and technology have achieved would involve a mutilation. What transformations the future will bring and whether civilization can manage to achieve the harmony with nature that is necessary for survival cannot be guaranteed. To define the problem is to go a long way toward its solution. The problem is only partly technical. It is, equally, one of the character of natural science in European civilization as it has developed over the centuries.

BIBLIOGRAPHY. For introductions to the general history of science, the following may be recommended. CHARLES SINGER, *A Short History of Scientific Ideas to 1900* (1959), is clear and comprehensible, but now somewhat obsolete. J.D. BERNAL, *Science in History*, 3rd ed., 4 vol. (1971), is well written and well illustrated but marred by the author's certainty that all important scientific discovery had a simple relation to economic and social forces of its time. S.F. MASON, *Main Currents of Scientific Thought: A History of the Sciences* (1953; British title, *A History of the Sciences: Main Currents of Scientific Thought*, 1953; rev. ed., 1962), is more of a speculative essay on science in society and has many valuable insights; RENE TATON (ed.), *Histoire générale des sciences*, 4 vol. (1957-64; 2nd ed., 1966-); Eng. trans., *A General History of the Sciences, 1966-* , is the best English-language collection of essays leading into more specialized studies. For ancient and medieval science, a scholarly introduction is E.J. DIJKSTERHUIS, *De mechanisering van het wereldbeeld* (1950; Eng. trans., *The Mechanization of the World Picture*, 1961). On China, the standard work is JOSEPH NEEDHAM, *Science and Civilization in China*, 7 vol. (1954-). For the creation of European science, a well-organized introduction is provided by HUGH F. KEARNEY, *Science and Change, 1500-1700* (1971). The social and institutional aspects of modern science are thoroughly explored in JOSEPH BEN-DAVID, *The Scientist's Role in Society: A Comparative Study* (1971). There is now in progress a multivolume *Dictionary of Scientific Biography*, ed. by C.C. GILLISPIE (1970-), which will provide reliable information on the lives and works of many scientists. For the parallel histories of medicine and technology, good introductions are RH. SHRYOCK, *The Development of Modern Medicine: An Interpretation of the Social and Scientific Factors Involved* (1936, reprinted 1969); and FREDRICK KLEMM, *Technik: Eine Geschichte ihrer Probleme* (1954; Eng. trans., *A History of Western Technology*, 1959).

(J.R.R.)

Science, Philosophy of

Taken in a broad sense—i.e., as the progressive improvement of man's understanding of nature—the intellectual enterprise of science originally formed an integral part of philosophy, and the two areas of inquiry have never finally separated. Little more than a hundred years ago, theoretical physics—concerned with the fundamental debate about physical nature—was still described as "natural

The universal advance in science in the 20th century

philosophy," as distinguished from the two other chief divisions of abstract discussion, viz., moral philosophy and metaphysical philosophy—the latter comprising the study of the deepest nature of reality or being, also called ontology. In fact it was only during the 20th century, following on the professionalization and specialization of the natural sciences themselves, that the philosophy of science has become recognized as a separate discipline.

Methodological and epistemological issues—*i.e.*, issues regarding the investigator's manner of approach to nature—are treated in the present article. On the other hand, issues regarding the substantive character of nature as so revealed—*i.e.*, as it is in and of itself—are treated in NATURE, PHILOSOPHY OF. The present article is arranged under the following headings:

- I. General approach to the philosophy of science
 - Nature, scope, and relations of the subject
 - Historical development of the subject
- II. Conceptualization and methodology of science
 - Elements of the scientific enterprise
 - Movements of scientific thought
- III. Deeper issues and broader involvements of science
 - Philosophical status of scientific theory
 - Interrelationships of science and culture

I. General approach to the philosophy of science

NATURE, SCOPE, AND RELATIONS OF THE SUBJECT

As a discipline, the philosophy of science attempts, first, to elucidate the elements involved in the process of scientific inquiry—observational procedures, patterns of argument, methods of representation and calculation, metaphysical presuppositions, and so on—and then to evaluate the grounds of their validity from the points of view of formal logic, practical methodology, and metaphysics. In its contemporary form, the philosophy of science is thus a topic for explicit analysis and discussion in the same sense as are other subdivisions of philosophy: ethics, logic, and epistemology (the theory of knowledge). At the same time, the boundaries between these subdivisions are, at certain points, still somewhat arbitrary; it is not easy, for example, to separate completely the philosophical validation of scientific hypotheses from the formal study of inductive logic (which reasons from facts to general principles), or the debate about theory and observation in philosophy of science from that in epistemology.

Throughout the development of philosophy, the preoccupations of those who, if living today, would be called philosophers of science have been of two main kinds: ontological, or ontal, and epistemological, or epistemic. This division reflects a long-standing distinction between object and subject; *i.e.*, between nature, regarded as that about which man sets out to acquire scientific knowledge, and man himself, regarded as the creator, and either discoverer or possessor of that knowledge. Since 1920 new directions within physics itself—particularly in quantum mechanics—have discredited any hard-and-fast distinction between the knower and the known or between the observer and his observation. Nevertheless, the distinction remains relevant on an everyday, or working, level and can be cautiously retained for the purposes of initial exposition.

The ontal preoccupations of philosophers of science (*i.e.*, their concerns with being) have frequently overlapped into the substantive areas of the sciences themselves. For they have been concerned with the general problem,

What kinds of entities and elements or theoretical terms can properly figure in man's scientific theories? And what sort of existence, or other objective status, do such things possess?

As applied to particular cases, this general problem has inevitably raised questions of substance as well as of intellectual method. An early 20th-century debate between two Austrian physicists, Ernst Mach and Ludwig Boltzmann, and a German physical chemist, Wilhelm Ostwald, about the existence and reality of atoms, for instance, involved both substantive issues of physics and chemistry and philosophical issues of a more strictly analytical kind. Similar overlaps have been unavoidable,

also, in the biological and social sciences; *e.g.*, over the existence and status of distinctively vital and social agencies or entities.

Until recently the epistemic concerns of the subject have been more purely philosophical in character, though this autonomy is now being challenged by developments in psychology that explore and experiment with cognitive processes and others in sociology that study the conditioning of cognition through interpersonal and group relationships. Epistemologically, philosophers of science have analyzed and evaluated the concepts and methods employed in studying natural phenomena and human behaviour, whether individual or collective; and this analysis has covered both the general concepts and methods characteristic of all scientific inquiries and also the more particular ones that distinguish the subject matters and problems of different special sciences. In treating the epistemic issues that arise about science and scientific procedures, the emphasis in this article is placed upon their consideration in general terms; the concepts and methods peculiar, say, to sociology, physiology, or quantum physics are discussed elsewhere.

Given the vast range of its concerns, the philosophy of science has attracted the attention of men with very different professional backgrounds and interests. At one extreme, as in the writings of Ernest Haeckel, the German Darwinian evolutionist, it has merged into a sweeping kind of popular science; at an opposite extreme, as in 20th-century Logical Positivism or Logical Empiricism (see below), a leading school that holds that knowledge is only what is scientifically verifiable, it has been treated as an extension of formal logic and conceptual analysis. And between these extremes it has drawn in such working scientists as the British astrophysicist Arthur Eddington and the German quantum physicist Werner Heisenberg, whose work has taken them to the frontiers of the subjects and confronted them directly with problems about the existence, status, and validity of the theoretical entities and concepts with which they were dealing.

Correspondingly, different men have approached the philosophy of science in very diverse spirits, ranging from the highly abstract and mathematical to the concrete and historical and from the severely positivistic to the frankly theological. From René Descartes, the first important modern philosopher in the 17th century, to the Logical Positivist Otto Neurath in the 20th, the success of pure mathematics and logic has inspired the mathematically minded to cast the whole of natural science into a single formal system after the pattern of geometry. From John Locke, an 18th-century British Empiricist, to N.R. Hanson, a recent U.S. philosopher of science, their opponents, on the other hand, have sought the proper basis of man's intellectual confidence within the nature of scientific investigation regarded as a human activity. Equally, Positivists such as Hans Reichenbach, a 20th-century German-American philosopher, have looked to philosophy for proof that scientific inquiries alone can provide knowledge worthy of the name; while theists such as Pierre Duhem, a French theoretical physicist, have appealed to it, rather, to demonstrate that the claims of science are inherently limited and so leave room for other, more embracing varieties of metaphysical and religious truth.

This diversity of concerns and approaches has affected the relations between the philosophy of science and other neighbouring disciplines. On a practical plane, for instance, different philosophical interpretations have implied different procedures for testing and assessing the strength of rival concepts and hypotheses. Thus, no clear dividing line can be drawn between the philosophical analysis of scientific theories and the statistical analysis of scientific procedures and experiments nor between the philosophy of science and the history of scientific ideas. Recent debates about the historiography of science—*i.e.*, about the problems and methods that throw light on its history—indicate that the particular questions that a historian of science brings to his analysis of scientific change inescapably depend on his philosophical attitudes and commitments.

Diverse approaches

Ontal versus epistemic concern

Relations with other disciplines

On a more general and abstract level, the philosophy of science has never been definitively separated from metaphysics and epistemology. There are, indeed, some 20th-century philosophers—for instance, the U.S. philosophical logician Willard V. Quine—who effectively restrict the legitimate areas of metaphysics and epistemology to what have here been called the ontal and epistemic aspects of the philosophy of science. In Quine's view, the traditional ontological problem of what there is in the world as man knows it must be attacked by a logical analysis of the claims about what kinds of things exist that are implicit in alternative theoretical systems. Meanwhile, the work of such cognitive psychologists as Switzerland's Jean Piaget, who explore the processes involved in the genesis of knowledge, is eroding the barriers between the logical analysis of conceptual systems, the psychological investigation of thought processes, and the epistemological validation of intellectual procedures. Piaget, for instance, bases his investigations into the acquisition of concepts on a philosophy akin to that of Kant, who held that all knowledge bears the imprint of the mind's own structure; and, though a psychologist himself, Piaget even refers to certain aspects of his work by the name of "genetic epistemology," a philosophical designation.

The present survey of the philosophy of science, therefore, contains no effort to prejudge the central question whether the methods of logical analysis alone are legitimate or whether at certain points the subject legitimately overlaps into such neighbouring subjects as cognitive psychology, the history of science, and epistemology. About this question philosophers of science themselves have been sharply divided, some rejecting any alliance except with logic, others cultivating its wider historical and behavioral connections; and both points of view must thus be taken into account.

HISTORICAL DEVELOPMENT OF THE SUBJECT

Classical and medieval periods: the beginnings of a **philosophy of nature**. At the outset the problems of science were as much those of method as of substance and were inseparable from those of what has long been called natural philosophy. The first attempts to move beyond traditional mythologies to a rational account of nature, beginning with the Ionian and south Italian philosophers around 600 BC, involved the sorts of elements or entities that any such account should comprise. Detailed empirical, or observational, considerations favouring one or another of the rival accounts were premature. Were, for example, the diverse phenomena of nature manifestations of one single enduring form of matter or of several elementary substances mixed together, and was the fundamental substance continuous and fluid-like, or discrete and atomic? Alternatively, others asked whether the observed forms of phenomena were evidence, rather, of some universal, underlying mind or of a variety of coexisting kinds of spirit responsible for phenomena having different orders of complexity.

The various Pre-Socratics based their answers at least as much on epistemic grounds—by considering what type of account would be genuinely intelligible—as on ontal or empirical ones by considering what sorts of enduring entities could possibly have, or be found in experience to have, the required kind of existence. Their answers ranged from one extreme, the ontal Realism of Parmenides, foremost philosopher of Eleaticism (*q.v.*), a school of southern Italy—according to which all changes are transitory appearances concealing the mutual relations of deeper, unchanging realities—to the critical skepticism of Heraclitus, the Ephesian philosopher of change, at the other extreme, according to which nothing in nature as man knows it can ever have this Parmenidean reality, and everything empirical is in flux.

Though Plato and Aristotle displayed more precise concern for actual cases, their philosophies of science still rested on the same mixture of ontological, epistemological, and empirical considerations. Questions about nature discussed in Plato's *Timaeus* and Aristotle's *Physics*, for instance, were neither purely metaphysical nor purely

empirical in character though they had a methodological aspect akin to that of modern philosophy of science. Moreover, Plato's construction of the fundamental theories of science around concepts and patterns borrowed from geometry have had a profound influence in the modern period—upon René Descartes, for example, in the 17th century and upon the founder of modern logic, the German mathematician Gottlob Frege, in the 1880s and after.

Mathematical entities alone, Plato argued, have the sort of enduring intelligibility that Parmenides had rightly demanded of the ultimate constituents in a rational science of nature. Thus, only a physical theory built on a numerical and geometrical framework will reveal the truly permanent structures and relationships behind the evident flux of phenomena. Within such a theory, all inferences will be self-evidently valid at all times and so exempt from the mutability of empirical events; and, correspondingly, the numbers and figures of formal mathematics will have an immutability denied to familiar physical objects. Planetary astronomy and the theory of matter were, in Plato's view, scientific fields within which this mathematical methodology showed immediate promise; the movements of the planets must be explained by constructions drawn from three-dimensional geometry, and the physics of matter seemingly involved atoms with shapes reflecting the geometry of the five regular solids (the tetrahedron, dodecahedron, etc.). In either case, however, the mathematical theories themselves would alone be fully exact and intelligible, whereas empirical objects and processes could be no more than transitory and approximate illustrations of the enduring entities and theoretical relations underlying them.

Given Aristotle's very different scientific preoccupations—which were centred on marine biology rather than planetary movements—he quite naturally developed a very different scientific methodology. In his view, mathematical entities and relations were too completely general and too remote from actual experience to explain the qualitative details of empirical entities. So the ultimate elements of nature must be not Plato's entirely general and abstract mathematical forms—which supposedly existed quite apart from actual phenomena—but rather certain more specific entities, recognizable within the familiar sequences of empirical experience. Instances of such basic essences could be discovered by studying the typical life cycles of different creatures; thus, the morphogenesis of a seed exemplifies the "coming into being" of the corresponding type of animal or plant, of which the mature specific form—as defined by its essence—is the natural destination of its development.

Having recognized the natural destinations toward which natural processes of different kinds were directed, it was then possible to construct a comprehensive classification of essences in terms of which the whole natural world would, in principle, be intelligible. Explanations within such an all-embracing natural history might not be self-evidently general and immutable, as were those of Plato's geometry; but the theoretical inferences involved would be no less deductive or necessary, and it would have the added merit of accounting directly for the specific qualitative characters of different observed objects and processes.

Throughout the subsequent philosophy of science, the themes stated by Plato and Aristotle have recurred repeatedly and are represented even today by two rival approaches to the subject—one (Platonic) based in logic, the other (Aristotelian) based in the history of science. Between them they dominated the subject during the later period of Greek antiquity, which was otherwise notable for only one further debate—that between the Atomist successors of Democritus and Epicurus and the Stoic philosophers, led by Zeno of Citium. This debate provided the first profound analysis of the strengths and weaknesses of atomistic explanation. Epicureans, on the one hand, argued for a purely corpuscular view in which the individual units of matter moved quite independently, except when they were in actual contact. For the Stoics, on the other hand, the empirical world was intelligible

Atomists
and
Stoics

The
Pre-
Socratics

Plato
and
Aristotle

only in terms of interactions and stable patterns maintained by harmonies operative at a distance.

These two debates—between Platonists and Aristotelians and between Stoics and Epicureans—presented clearly and for the first time the chief alternative modes of explanation available to science and analyzed their possibilities and limitations in general terms. More than 2,000 years before the rise of modern thermodynamics and field theory, for instance, Aristotle had already recognized the difficulties of explaining changes in physical state (e.g., melting and evaporation) within a purely atomistic theory of matter; whereas, even earlier, Plato had demonstrated the possibility of a unified mathematical explanation of the differences between different kinds of material substance. Indeed, the theoretical physicist Werner Heisenberg was quite ready in the 20th century to cite pre-Socratic arguments regarding the ultimate constitution of nature as relevant to contemporary problems.

By contrast with the period before Euclid the geometer (i.e., to 300 BC), the ensuing Hellenistic, Islāmic, and medieval periods added little to the understanding of scientific methodology and explanation. From the Alexandrian astronomer Ptolemy, who detailed the geocentric theory, most natural philosophers deliberately restricted their intellectual claims in an instrumentalist manner; i.e., by endeavouring merely to "save the phenomena" by devising successful mathematical procedures for predicting, for example, lunar eclipses and planetary motions. In this way they disregarded the mechanisms responsible for those phenomena, thus preserving the computational techniques of the sciences from the risk of conflict with theology for the following 1,250 years, until the time of Copernicus.

In the High Middle Ages, accordingly, the possibility that man could make himself the intellectual master of nature was largely neglected. Human understanding was dependent on God's illumination. The guarantees of scientific knowledge lay not in the merits of its methodology but in the divine grace, which assured its reliability. On this interpretation, man had no direct line of access to nature; the only road to knowledge was through the divine mind. Thus, all of the central questions in the philosophy of science were restated as theological issues, as questions about the relationship between God's omniscience and the more limited knowledge of man. In this context the metaphor of "illumination" was taken so seriously in the 13th century that the very subject of optics was cultivated by a distinguished Oxford scholar as much for its theological implications as for its physical content.

The 17th and 18th centuries: from manifesto to critique. Although the intellectual Renaissance of the 16th and 17th centuries was accompanied by a secularization of learning, which shifted the centre of philosophical and scientific debate from monasteries to universities—and even to salons—the link between philosophy and theology was not abruptly snapped. Descartes, Newton, and Leibniz, the leading scholars of the time, were all concerned to demonstrate that their positions were compatible with sound theology; and medieval controversies about human knowledge and divine grace found an echo in such arguments as Descartes's assertion that the rational methods of inquiry can be relied on only provided that God does not deliberately deceive us. Two new factors, however, combined to give the 17th-century debate about scientific methodology a new autonomy: in the first place, philosophy now posed the central questions in the philosophy of science—both those about the origins and functions of scientific concepts and those about the structure and validity of scientific arguments—and faced them directly, instead of only as refracted through a theological prism. And, in the second place, these questions were acquiring an immediate relevance and significance, simply because men were then launching new, empirically based theories of nature with a seriousness unknown for some 1,200 years.

Between 1600 and 1800 the debate in the philosophy of science was barely separable from that within science itself. From Bacon and Galileo by way of Descartes and Leibniz to Laplace and Kant, all of the major partici-

pants in the philosophical debate played significant roles on the scientific stage as well. Thus, Francis Bacon, author of the method of exhaustive induction (see below), and René Descartes both conceived the same intellectual goal, that of formulating explicitly a new method for the improvement of the intellect; i.e., codifying the rational procedures of science in a way that would free them from arbitrary and unfounded or superstitious assumptions (Bacon's idols) and ground them in a logically impregnable manner on the properties of "clear and distinct," or self-evidently valid, concepts (as distinguished by Descartes).

To be sure, the two men offered different recipes for a rational science and described the outcome of a properly conducted scientific inquiry in quite different terms. On the one hand, Bacon was preoccupied with empirically observed facts as the starting point for all science and relied on theories only insofar as they were derived from those facts. Ideally, he held that the scientist should provide an exhaustive enumeration of all examples of the empirical phenomenon under investigation as a preliminary to identifying the natural "form" of which they were the manifestation. Though Bacon remained unclear about the exact character of the abstraction involved, he is commonly assumed to have claimed that theoretical propositions in science are justified only if they have been deduced formally from such an enumeration.

In contrast to such so-called "Baconian induction," Descartes focussed upon the problem of constructing self-consistent and coherent deductive systems of theory, within which argument would proceed with the formal security familiar in Euclidean geometry. Whereas Bacon had reacted against the Scholastic reliance on Aristotle's authority by calling for a return to firsthand experience, Descartes reacted against the Skepticism of 16th-century humanists by pointing to mathematics as the pattern to which all genuinely-certain knowledge about nature could aspire. Inasmuch as Euclid's axioms, definitions, and postulates had captured the intrinsic characteristics of spatial relations and provided a theoretical starting point from which the whole of geometry could be deductively inferred, the task for 17th-century physics was to extend Euclid's intellectual structure by adding further, equally self-evident axioms, definitions, and postulates. Only in this way could the theories of motion, magnetism, and heat—eventually those of physiology and cosmology, too—achieve the same necessary deductive authority. Descartes set out to show, in the four volumes of his *Principia Philosophiae* ("Principles of Philosophy"), how all of the familiar phenomena of physics could be accounted for by a single, fully comprehensive system of mathematical theory, based on Euclidean foundations and conforming to his own deductivist principles. The very possibility of so interpreting nature was so impressive to Descartes that it lent a "moral certainty" to his conclusions.

The arguments of Bacon and Descartes were really manifestos; both offered intellectual programs for a natural science yet to be built, and, while it is true that during the next 150 years, Galileo, Newton, and many others actually constructed the new physical science for which the philosophers had been calling, it is also true that the form of the resulting theories was, nonetheless, not exactly what either man had foreseen. On the one hand, there was little Baconian induction in Newton's intellectual procedures. Those 17th-century scientists, such as Robert Boyle—one of the founders of modern chemistry—who seriously attempted to apply Bacon's maxims found his pedestrian advice to be more of a hindrance than a help in the formulation of illuminating theoretical concepts. (It was said, somewhat unkindly, that Bacon "philosophized like a Lord Chancellor.") On the other hand, though Newton was powerfully influenced by Descartes's mathematical example, he followed his methodological maxims only up to a point. Granted that the theory of motion and gravitation of Newton's *Principia* did indeed conform to Descartes's recipe—adding further dynamical axioms, definitions, and postulates to those of Euclid's geometry—Newton nonetheless made no pre-

thetico-
deductive
method

tense of proving, in advance of empirical evidence, that these additional assumptions were uniquely self-evident and valid. Instead, he treated them as **working** assumptions to be accepted hypothetically for just so long as their consequences threw light, in exact detail, on hitherto-unexplained phenomena. Inevitably, the epistemic claims to be made on behalf of such explanations fell short of Descartes's full "**deductivist**" ambitions. Newton knew of no phenomena, for instance, that evinced the mechanisms of gravitational attraction and saw no point in "feigning hypotheses" about them.

In this way, Newton devised in practice—almost inadvertently—what philosophers of science have since labelled the hypothetico-deductive method, in which, as theorized by Descartes, the proper form of a theory is seen as a mathematical system in which particular empirical phenomena are explained by relating them back deductively to a small number of general principles and definitions. The method, however, abandons the Cartesian claim that those principles and definitions can themselves be established, finally and conclusively, before inquiring what light their consequences throw on actual scientific problems and phenomena.

From 1700 on, the terrain of debate in the philosophy of science shifted. At first, attacks on Newton's methods and assumptions by Leibniz, Berkeley, and the remaining Cartesians continued, from different points of view. But by 1740 the time for both manifestos and objections was past; the basic scientific soundness of Newton's concepts was no longer in doubt, and the philosophical question thus became retrospective, viz., How had Newton done it? Over this new question, 18th-century philosophers were divided into three camps: Empiricism, Rationalism, and Kantianism (*qq.v.*). There were those who believed, like the Scottish Skeptic David Hume, that Newton's philosophy conformed to the Empiricist maxims of Francis Bacon and John Locke. Again, there were those—like the Swiss mathematician Leonhard Euler, one of the founders of modern analysis, and Immanuel Kant in his younger days—who assumed that Newton's physical principles would eventually be put on a fully demonstrative or self-evident basis as required by Cartesian Rationalism. Neither of these positions proved entirely successful, as Kant himself came to recognize: the Empiricists failed to do justice to the deductive **rigour** of Newton's theoretical arguments; and the **Rationalists** could not rigorously demonstrate the mathematical uniqueness of Newton's system. As was already known, **even Euclidean** geometry, which involves the axiom of parallels (according to which one, and only one, line can be drawn through a given point parallel to another line) could no longer claim a formal uniqueness. It has been shown, in 1733 and again in 1766, that alternative geometrical systems can consistently be developed in which the axiom of parallels is replaced by other mathematically acceptable alternatives. Clearly, the authority claimed for Newton's concepts and methodology could no longer be sustained in the old Rationalist way; thus a third alternative, that of Kantianism, arose.

One of the prime goals of Kant's so-called critical philosophy, with its famous so-called transcendental method, in which knowledge reflects the categorial structure of the mind, was to provide an alternative philosophical justification of Newton's results. The system of concepts used in Euclidean geometry and Newtonian physics is uniquely relevant to man's actual experience, Kant argued, not because the empirical applicability of their principles is self-evident—no such self-evidence can tell the inquirer anything about external nature. Still less is it because their inductive support is so strong—no Baconian argument can yield the required kind of certainty. Rather, it is because the scientist can arrive at a coherent, rational system of empirically applicable explanations only by constructing his theories around just those (Euclidean and Newtonian) concepts. He could, in fact, go even further. Euclidean axioms are required, Kant claimed, not merely for science alone; they specify explicitly cognitive structures (of the mind) that are implicitly involved also—as so-called forms of intuition (specifi-

cally of space and time)—in the prescientific rational organization of sensory experience into a coherent, intelligible world of substantial objects seen as interacting by causal processes. A grasp of Kant's transcendental method would then enable a thinker to recognize (or so Kant hoped) how and in what respects the use of his established system of rational forms and categories is indispensable alike for any coherent understanding or even for any experience.

Through World War I: philosophy of classical physics. Kant's ambitious philosophical enterprise took a long time to digest. A century later, in the 1880s, philosophers of science as different in other ways as the Austrian phenomenalist Ernst Mach and Heinrich Hertz, pioneer in electromagnetic wave theory, were both pursuing questions opened up by Kant; and some of their implications were still being explored in the 1970s, as, for example, in cognitive psychology. In general terms, Kant's central thesis—i.e., that man confers a structure on his knowledge through the concepts and categories that he brings to the formation and interpretation of experience—has proved extremely fertile: it has helped in the analysis of theory construction, and it has suggested in sensory psychology that man's very capacity for perception can yield effective knowledge only to the extent that his sensory inputs themselves have a cognitive or conceptual structure.

In one respect, to be sure, Kant seems in retrospect to have attempted too much. Including in man's framework of sensory and intellectual organization all of Euclidean geometry and of fundamental Newtonian physics and the prescientific notions of substance and cause, Kant set out to demonstrate a priori that man's actual current framework is the one and only effective framework—a proof which, as is known today, was misguided, for its thesis is simply not the case. This is so, not merely because alternative systems of geometry and dynamics can be developed consistently in mathematical terms (for Kant himself was aware of that fact); rather, it is so because 20th-century astrophysics and quantum mechanics have succeeded in giving non-Euclidean and post-Newtonian concepts an entirely coherent empirical application in the scientific explanation of natural phenomena—and this was something that Kant was not prepared to contemplate. Pure mathematics aside, indeed, Kant and most of his immediate successors were convinced that Euclid and Newton between them had somehow hit on a uniquely adequate system of geometry and physics—if not on the final mathematical truth about nature.

For about 100 years, then, the epistemic foundations and ontal commitments of this so-called classical science were largely taken for granted. The 19th-century debate in philosophy of science, accordingly, concentrated on peripheral topics and **skirted** all issues that might have called into question the ascendancy of Euclid and Newton. The validity of the classical system having been assumed, the questions remaining for debate involved only its interpretation and implications; and the resulting positions can be classified, with slight oversimplification, under the headings of mechanistic (or Materialist) and Idealist doctrines, respectively.

The Idealists took to heart Kant's thesis that the cognitive structure of experience is imposed upon nature rather than discovered in it and sought to explore its broader consequences. The psychology of sensory perception, for example, previously barred from direct scientific study by Descartes's absolute separation of mind from matter, was now opened up for exploration; thus, by the mid-19th century, Hermann von Helmholtz, pioneer in a broad range of scientific studies, embarked on the remarkable investigations into the production of man's sensory experiences or ideas set out in his monumental *Handbuch der physiologischen Optik* (1856–67; Eng. trans., *Physiological Optics*, 1921–25).

For most of Kant's successors, however, the Idealist road led away from philosophy of science into other areas—particularly, into political ideology, philosophy of history, and sociology. Thus, it was not until well into the 20th century that the distinguished joint relativity—

quantum theorist Sir Arthur Eddington, in his *Fundamental Theory* (1946), once again took up seriously the basic task of Kantian Idealism, viz., that of demonstrating, on a priori epistemological principles, that man's physical interpretation of nature embodies certain-necessary structures imposed on physics by the character of his theoretical procedures themselves.

Meanwhile, the 19th-century mechanistic Materialists were disregarding Kant's central insights and concentrating instead on the apparent implications of the Newtonian system for other branches of science. A vigorous philosophical debate resulted, particularly in those fields that were just developing effective explanatory methods and theoretical concepts of their own. One good example of such a field was physiology, in which the work of a pioneering experimental physiologist, Claude Bernard, with its striking theoretical analysis of the vasomotor system and other regulatory mechanisms in the body, which anticipated 20th-century ideas about feedback systems, finally broke a long-standing deadlock between two opposed groups of scientists—the extreme mechanists, who recognized no difference at all between organic or physiological processes and the physicochemical phenomena of the inorganic world, and the outright vitalists, who insisted that the two kinds of phenomena were absolutely different. The debate also encouraged an epiphenomenal view of experience—as a kind of subjective mental froth without causal influence on the underlying physical mechanisms—and so sharpened the apparent threat to all claims about human “free will.” Today it seems, indeed, that the sweeping conclusions of such scientific popularizers as the German evolutionist Ernst Haeckel, who wedded the ideas of classical physics with the new Darwinian history of nature to form a comprehensive Materialistic cosmology, or “anti-theology,” carried more weight at the time than they seem in retrospect to have deserved.

There was one promising exchange about the central epistemic issues in the philosophy of science in mid-century, that which took place between William Whewell, a British philosopher and historian of science noted for his work on the theory of induction, and the political essayist, John Stuart Mill; but this was abortive. The debate ended in cross-purposes, largely on account of differences in temperament and preoccupations. Whewell's knowledge—not merely of contemporary physical science but of its whole historical background—was both broad and detailed. The mathematical necessity of arguments such as those in Newtonian dynamics impressed him quite as much as it had impressed Kant; but he gave a less grandiose account of the reasons for this necessity. Whewell's philosophy, a Kantian variation on Newton's *hypothetico-deductive* method, was historicized: it was only by a progressive approach that physicists arrived at the most coherent and comprehensive systems of what Whewell called “consilient” hypotheses—or separately derived, yet concordant, sets of laws—that were compatible with the empirical knowledge then at their disposal. Mill, on the other hand, principally concerned with the methodology of the social sciences, concentrated on the observational basis of science to the neglect of its theoretical organization and so emphasized the contingent, or unnecessitated, nature of all genuine empirical knowledge. In due course, certain of his doctrines, such as his account of arithmetical formulas as being a variety of empirical generalization, exposed him to some ridicule; but, for the time being, while the sheer bulk and learning of Whewell's writings muffled the force of his arguments, Mill's more fluent and less technical style of exposition captured the popular attention.

In consequence, it was not until the 1890s and early 1900s that serious doubts grew up about the finality of the Newtonian synthesis; and the writings of Ernst Mach, Heinrich Hertz, the eminent German physicist Max Planck, Pierre Duhem, and others inaugurated the new phase of far-reaching critical reanalysis characteristic of 20th-century philosophy of science. In one way or another, all of these men stood back and looked at the Euclidean and Newtonian systems with fresh and less com-

mitted eyes. They had learned Kant's lesson about the constructive character of formal theories, without sharing his belief in the unique rationality of the classical synthesis; and, as a result, the central topics of their discussions turned on the best ways of restating the Kantian problem. Granting that the intellectual activity of theory construction has the effect of building a physical necessity into man's theoretical arguments, they asked, what then follows, ontologically, about the reality or conventionality of the resulting atoms, forces, electrons, etc., and what can be said, epistemologically, about the cognitive status and logical validity of its theoretical principles?

At one extreme, an Austrian physicist and philosopher Ernst Mach, and Richard Avenarius, the author of a philosophy known as empiriocriticism, expounded a sensationalist form of Empiricism reminiscent of David Hume, who had insisted that all ideas be traceable to “impressions” (sensations). On their view, theoretical concepts are intellectual fictions, introduced to achieve economy in the intellectual organization of sensory impressions, or observations, for which alone ontal primacy can be claimed. Correspondingly, all claims to scientific knowledge had epistemic validity for them only insofar as they could be grounded in such sense impressions. As against this instrumentalist or reductionist position, Max Planck, author of the quantum theory, defended a qualified Realism, which, at the least, expressed the ideal toward which all conceptual development in physics proceeds; for, without a belief in the enduring reality of external nature, he argued, all motive for theoretical improvement in science would vanish. Between these two extremes, Henri Poincaré, equally distinguished in mathematics and the philosophy of science, and Pierre Duhem, a French theoretical physicist, occupied a range of intermediate so-called conventionalist positions, which attempted to do justice to the arbitrary elements in theory construction while avoiding the sort of radical doubt about the ontal status of theoretical entities that led Mach into lifelong Skepticism about the reality of atoms.

The 20th-century debate: Positivists versus historians. In the mid-20th century, debate in the philosophy of science became notably detailed, elaborate, and critical; those 50 years, in fact, have seen the subject finally achieving the status of a well-established professional discipline. Not least among the causes of this development have been the profound changes that have taken place since 1900 within theoretical physics and other fundamental branches of natural science. So long as the classical synthesis of Euclid and Newton retained its unquestioned authority, there had been little occasion to probe its ontological and epistemological bases at all deeply; but relativity theory—which qualified earlier geometries and laws in terms of new insights into the tie-ins between space and time—and quantum mechanics—which qualified them in terms of a statistical and *indeterministic* formulation—posed a frontal challenge to that synthesis and inevitably provoked critical and philosophical questions about the validity of the methods and assumptions on which it had relied. Consequently, between 1920 and 1940 there arose a renewed interaction between theoretical physicists and philosophers of science—especially between the Viennese Positivists and the authors of the new quantum mechanics.

The main themes of the subsequent debate were largely those introduced into discussion in the period around 1900. Mach's critical reductionism, based on his *Beiträge zur Analyse der Empfindungen* (1886; Eng. trans., *The Analysis of Sensations . . .*, 1959), in which he tried to reduce all knowledge to statements about sensations, was a prime source both of the Positivism and Logical Empiricism (*q.v.*) of the Vienna Circle—a group of eminent philosophers and scientists that met regularly in Vienna during the 1920s and 1930s—and also of the epistemological theories about sense-data and logical constructions developed in Britain about the same time by Bertrand Russell, perhaps the foremost logician and philosopher then in England; by G.E. Moore, a meticulous pioneer in Linguistic Analysis; and by others. Meanwhile, the qualified Realism of Planck and Hertz was

carried further by such men as Norman Campbell, an English physicist known for his sharpening of the distinction between laws and theories, and Karl Popper, an Austro-English philosopher recognized for his theory of falsifiability, both of whose views reflect the explicit methodology of many working scientists today. A notable exception would be the Positivistic followers of Niels Bohr in the Copenhagen school of theoretical physics. Finally, there has continued to be substantial support for intermediate, conventionalist compromises, with Kantian overtones, along the general lines developed by Poincaré and Duhem.

From the rich complexity of recent philosophy of science, two main strands may be selected for special mention here. The first is the strand of neo-Humean Positivism, which first developed in the Vienna Circle and has flourished more recently in the United States and has been fundamentally preoccupied with epistemological issues. While largely abandoning Mach's belief that sensations are the sole ultimate ground of knowledge, its proponents have continued, with Mach, to regard theoretical entities as fictions or logical constructs, the validity of which depends entirely on the capacity to give them a basis in empirical observations. This neo-Humean position has derived much encouragement, if not formal confirmation, both from Einstein's emphasis on the essential role of the observer in relativity physics and from the attack from the side of quantum theory made by the German physicist Werner Heisenberg on any sharp distinction, at the subatomic level, between the observer, his observation, and the system observed (see NATURE, PHILOSOPHY OF).

The Logical Positivists and Empiricists harnessed to these epistemic arguments a formal apparatus taken over from the philosophy of mathematics—specifically, from Russell and Whitehead's *Principia Mathematica* (1910–13). In their view, the activity of theory construction is logically equivalent to the creation of propositional systems, in which groups of propositions are ideally set out in axiomatic form. So interpreted, the hypothetico-deductive method becomes a recipe for devising a succession of progressively more comprehensive axiom systems, based on alternative sets of general postulates (or primitive propositions) posited without proof, from which particular, empirical propositions can be inferred. As in the case of the special theory of relativity, these particular propositions—for instance, that the axis of Mercury's orbital ellipse will precess (or turn) at a certain rate—can then be used to validate the general postulates by comparing them with actual experience thus—directly or indirectly—substantiating the more general primitive propositions as well. The subsequent debate within the Viennese school has been concerned, very largely, with the exact character and force of this substantiation—whether it be verification, confirmation, or corroboration and/or falsification. At its most ambitious extreme, the Viennese school aimed at constructing a single system of unified science, by which the entire corpus of positive knowledge would be embraced in a single, all-embracing axiom system to be constructed around Russell's abstract symbolic logic. According to this program, all truly scientific knowledge must, first of all, be validated by appeal to neutral empirical observations, on pain of being dismissed as meaningless; and it must then be incorporated into the larger scheme of unified science.

The strongest opposition to this Empiricist or Positivist strand has come, correspondingly, from a Neo-Kantian school that has questioned the very possibility of identifying the pool of theoretically neutral observations necessary for substantiating or discrediting alternative theories in a strictly logical manner. This Neo-Kantian strand in 20th-century philosophy of science was inaugurated by the pioneering thinkers Heinrich Hertz (in electromagnetic wave theory) and Ludwig Wittgenstein (in philosophy of language). Rejecting Mach's central epistemological questions about sensations and ideas, these men have started instead from Kantian questions about the use of representations or models in the explanation of phenomena. Hertz's treatise on *The Principles of Mechanics*

(1894), for instance, expounded Newtonian dynamics as a formal representation that logically entailed empirical conclusions only insofar as the phenomena concerned were already describable in terms drawn from the theory itself; and Wittgenstein's *Tractatus Logico-Philosophicus* (1922) extended Hertz's analysis to provide a general philosophical theory of language as an instrument for the representation of facts. The implications of this approach for the philosophical analysis and methodology of science have been explored further by some of Wittgenstein's pupils and successors, who have shifted the focus of discussion away from the verification of scientific propositions to the establishment of scientific concepts and theories; by highlighting the problem of conceptual change, they have revived interest in the philosophical significance of the history of scientific ideas. For, from this point of view, logical questions about the structure of propositional systems must be joined by other, equally fundamental rational questions about the manner in which different theoretical systems come to succeed one another (see below: *Conceptual change and the development of science*).

During this same period, the remarkable changes taking place within such sciences as theoretical physics, biochemistry, and psychology have been provoking philosophical discussions among scientists themselves. For instance, the displacement of classical Newtonian physics by Heisenberg's quantum mechanics has stimulated a new round of arguments about causality and determinism, with some people hailing Heisenberg's Principle of Indeterminacy—which holds that the location of a particle is intrinsically imprecise in the measure that its momentum is precise (and vice versa)—as giving human free will the toe-hold that rigorous 19th-century determinism did not seem to allow. Progress in cellular and subcellular physiology, moreover, has given rise to further rounds of debate in the philosophy of biology. Claude Bernard, the foremost experimentalist of 19th-century medicine, had never managed to extend his analysis of regulatory mechanisms, such as those of the nerves that control the size of blood vessels, to cover the processes of embryology and morphogenesis (development of organic forms); and, on this finer level, there had been a renewed deadlock, around the years 1900–20, between the vitalism of Hans Driesch, which posited an almost "soul-like" reality that guides development, and the mechanism of Jacques Loeb, both experimental biologists with philosophical concerns. Once again, supporters of neither extreme position could make out their case entirely; instead, biologists have tended toward the mediating systemic conceptions first introduced by Paul A. Weiss, a distinguished developmental biologist, in the mid-1920s, and subsequently developed in detail as applications of the new theories of cybernetics and feedback, which conduct comparative studies of automatic control systems in the nervous system and in electromechanical engineering. More recently still, the development of molecular biology has compelled scientists to reformulate the problem of morphogenesis yet again—this time as the problem of seeing how the structural patterns of nucleic acid macromolecules in the hereditary genetical material find a structural expression in the developing body as a result of interacting with the environment. At present, this question is still very largely unanswered.

Methodologically, since 1940 one new centre of philosophical debate has developed, this time in the behavioral sciences. Ever since Descartes and Hobbes, there has been sharp disagreement about the legitimacy of extending the methods and categories of physical science to the sphere of the higher, distinctively human mental processes; and, even in the 1970s, theoretical psychologists were still far from agreed in their explanations of human behaviour. Some psychologists insist that human actions are subject to laws and mechanisms of the same kind as physical processes; others deny that any direct analogy exists between rules of conduct and laws of nature. Currently, this dispute is most lively in the psychology of language. Behaviorists follow B.F. Skinner, an American psychologist, in rejecting any distinctive class of mental

Kantian-
ism

laws and processes, whereas cognitive psychologists and generative grammarians, led by **Noam Chomsky**, argue that linguistic activities are creative and rule conforming in respects that no behaviorist can explain. In sociology and anthropology, equally, the 20th century has been a period of methodological controversy. Here the unresolved conflict has to do with the significance of history in the explanation of collective human behaviour. On one side, there is, in sociology, a school of so-called structuralists or functionalists that follows another American scholar, **Talcott Parsons**; or, in anthropology, there are the British ethnologist **Arnold Radcliff-Brown** and **Bronisław Malinowski**, a student of primitive mentality and behaviour, who regard all of the cultural practices and social institutions that function within a given community at any time as related together systematically within an overall structure: to explain any one of those practices or institutions, they hold, it is enough to show how it connects up with **all** of the other contemporaneous aspects of the culture. On the other side, a more historically minded school, notably the German "critical Marxists" (such as **Jürgen Habermas**), emphasizes the dynamic, developing character of social structures and relationships. Here again, the methodological debate is still in progress, and its eventual outcome cannot yet be clearly foreseen.

II. Conceptualization and methodology of science

It is appropriate at this point to define the recurrent problems that have played a central part in the philosophical debate about science and the crucial elements that any adequate philosophy of science must include in its account. From the beginning, scientists themselves have been interested not merely in cataloging and describing the world of nature as they find it but in making the workings of nature intelligible with the help of compact and organized theories. Correspondingly, philosophers of science are obliged to consider not merely nature in isolation—as a mere assemblage of empirical facts, mutely waiting to be discovered by man—but also the manner in which man himself perceives and interprets those facts when bringing them within the grasp of an intelligible theory and the respects in which the validity of the resulting theoretical ideas (or concepts) is affected by that processing of the empirical data.

Historically speaking, the problems posed by this interaction of man and nature have been complex and confused. Though philosophers of science face, even today, many of the same questions that were already being debated in classical Athens, the range and relevance of those questions has been greatly clarified in the meanwhile. For instance, when philosophers in the 17th century analyzed the nature and possible scope of a mathematical and experimental account of nature, they helped to clear the ground for Newton to develop the intellectual program and methodology of modern theoretical physics; while the subsequent philosophical debate about natural and artificial classification similarly cleared the ground for the scientific taxonomy of the Swedish systematist **Carolus Linnaeus** and the theory of natural selection of **Charles Darwin**. Methodological clarification in the philosophy of science has, in this way, repeatedly led to creative advance in science itself and so given rise, in turn, to new experience on which philosophers can draw in taking their methodological analyses further.

ELEMENTS OF THE SCIENTIFIC ENTERPRISE

It is easy enough to list the chief elements that must find a place in any philosophy of science, but problems arise in mapping the relations between them.

Empirical data and their theoretical interpretation.

First are the empirical elements. The task of science is to explain actual events, processes, or phenomena in nature; and no system of theoretical ideas, technical terms, and mathematical procedures—or mathematical procedures alone—qualifies as scientific unless it comes to grips with those empirical facts at some point and in some way and helps to make them more intelligible. On the one hand, the facts in question may be discovered by using observational **methods**—*i.e.*, by recording them as and when they

occur naturally, without employing any special contrivances affecting their occurrence. This situation is, of course, the normal case in astronomy, in which the objects of study cannot be influenced or controlled. Alternatively, they may be discovered by using experimental **methods**—*i.e.*, by devising special equipment or apparatus with the help of which those processes or phenomena are caused to occur on demand and under specially controlled conditions. In that case, the scientist can attack scientific problems—to use Kant's vivid metaphor—by "**putting** Nature to the question," as in much of physics and fundamental biology. Either way, a philosophical difficulty at once arises about the results of the scientist's empirical studies: for he must ask how such raw empirical facts can be sifted, stated, and described in a way that throws light on the scientist's own theoretical problems. Do all empirical facts whatever serve as raw material for science? Or is this true only of those that have been preselected for their theoretical relevance—or even, to some extent, reshaped to ensure it? Is a scientist concerned with every particular empirical event, as such, or only with general phenomena or regularities recognizable in those events? Different schools of philosophers treat this raw material in very different ways.

In the second place, there are conceptual elements. Every science employs its own characteristic abstractions, terminology, and techniques of interpretation and explanation, which can be of very different kinds. They may be ideal types, as in gas theory and parts of sociology; **conservation** principles, as in dynamics and energetics; taxa, as in biological systematics; particles or constituents, as in genetics and subatomic physics; models or flow diagrams, as in econometric analysis. Such conceptual elements are the intellectual keys by which phenomena are made intelligible, and a most active philosophical debate has turned around the part they play in the interpretation of phenomena. If, for instance, the idea of particles or ultimate constituents of matter is regarded as a concept created by scientists for the purpose of their own theoretical analysis, can an independent existence then be claimed for such theoretical entities in the world of nature itself? Or must all such ideas be regarded as fictions or constructs for which the claim to reality goes no further than the paper on which the scientific explanations are written? Similarly, if the theoretical descriptions of nature arrived at in science are unavoidably idealized and abstract, does this imply that the necessity attaching to arguments in, say, theoretical physics is itself only an artifact, or by-product, of scientists' own procedures for interpreting phenomena? Or can one, after all, speak of natural events themselves as happening "of necessity"?

Finally, every natural science includes also formal and mathematical elements or mathematical elements alone. These may be mathematical algorithms, or procedures of calculation, like those used in computational astronomy since Babylonian days, or like the computer programs that are their 20th-century counterparts; or geometrical constructions, as in certain branches of optics; or methods of graphical analysis, such as those used in handling statistical data; or the axiomatic systems by which, from classical times on, geometry and physics have been organized into formal schemata of propositions bound together by logical relations. Philosophers in the Platonic tradition give such formal elements special consideration, viewing as authentically intelligible only those theories the content of which can be presented explicitly in formal, and preferably in mathematical, systems of propositions. Theories of this kind alone are capable—as the seminal German logician **Gottlob Frege** expressed it—of employing "concepts in their pure form." Thus, 20th-century philosophers of science have devoted much time and effort to the question: How far, and on what conditions, can other branches of natural science (*e.g.*, quantum mechanics or genetics) be cast in the same definitive, axiomatic form as classical mechanics and electrical theory? Or is this formal construction itself merely a human convenience, adopted to simplify the handling of the empirical data, which reveals nothing more about the underlying structure of nature itself?

Conceptual and formal elements

Empirical elements

Relation of
theory to
observa-
tion

Each of these three groups of elements poses problems about which philosophers of science are still in deep disagreement; and these differences of view can usefully be illustrated by indicating the various approaches adopted by members of rival schools when discussing each of the groups. At one extreme can be cited philosophers of a radically Empiricist frame of mind, who regard it as important, above all, to emphasize the empirical foundations of scientific knowledge; for them, the raw facts of experience are primary and entitled to absolute respect. On this view, general theoretical principles have authentic scientific content only when interpreted as empirical generalizations about directly grasped empirical data; and, correspondingly, abstract theoretical entities must be understood as logical constructions from more fundamental elements that can be directly identified in empirical experience. (This belief, of course, was the basis of Mach's conclusion that submicroscopic atoms were merely intellectual fictions and derived their scientific meaning entirely from the macroscopic sense experiences that they were used to explain.)

At the other extreme, philosophers of a fully Rationalist, or Cartesian, bent can be cited who reject the idea that raw empirical facts, in and of themselves, display any intelligible or law-governed relationships whatsoever—and still less any necessary ones. For them, as for Plato, the scientist's bare experience of nature is a disorganized aggregate, or flux, unless and until he is able to discover some rational structure or principles relating these disconnected facts to a larger, more intelligible whole. Rather than allow equal significance and authority to every passing occurrence, the scientist, on this view, must be highly selective in the observations to which he pays attention; indeed, the very function of a well-designed experiment is now to create phenomena that can illustrate the intelligible relationships that are the true concern of science and so deserve the status of scientifically authenticated facts.

Both of these approaches, the Empiricist and the Rationalist, emphasize valid and important points; but, in their extreme forms, they give rise to difficulties that are probably insuperable. As to the Empiricist approach, the credentials of any scientific concept or theory certainly depend to a substantial extent on its basis in empirical experience. Indeed, much has been learned about statistics, the calculus of probabilities, and the design of scientific experiments from careful analysis of the procedures by which empirical data are actually handled, even before questions of theoretical interpretation were directly raised. Yet it is questionable whether sense impressions alone could ever serve as evidence for any scientific position, as Mach and the sense-data philosophers assumed. All genuine scientific observations, as Kant expressed it, have the form of judgments—*i.e.*, are expressed in statements answering questions formulated beforehand. It is probably an exaggeration to insist that all legitimate theoretical statements in science must be related in a strictly deductive manner to the everyday empirical observations that they are used to explain; and it is a caricature to treat the explanatory power of theoretical laws and principles, as for example in physics, as no different in kind from that of such an elementary generalization as "All robins' eggs are greenish blue."

As to the Rationalist approach, one of the chief tasks for philosophers of science is certainly to account for the rational interconnections that give scientific explanations their characteristic intelligibility. In this respect, such men as Descartes, Kant, and Hertz have deepened the philosopher's understanding of the scientific enterprise by obliging him to recognize the ways in which the intellectual organization of scientific theories rests on the scientist's own constructive activities, rather than on the specific facts. Yet, it would again be misleading to use this fact as an excuse for regarding physical theories—to echo a phrase of Einstein's—as entirely "free creations of the human mind." While the step from observations to theories does not rest on formal entailments alone, it would be an equally serious counter-exaggeration to suggest that theory construction is totally arbitrary or uncon-

strained by the imperative demands of the specific problems to be solved.

The outstanding task for most philosophers of science is, accordingly, to find an acceptable middle way between the Rationalist and Empiricist extremes and thus to do justice both to the empirical foundations of theories and to their internal organization. The different emphases of philosophers commonly reflect, at most, differences in their substantive preoccupations. Those who are interested (as was Mill) in possible methods for developing the human or social sciences naturally place most stress on the empirical basis of scientific knowledge. Those who are familiar (as was Whewell) with the actual outcome of theory construction in established sciences, such as physics, naturally underscore the systematic coherence and structure of scientific understanding. Those who are concerned with the nature and validity of historical understanding (as Giambattista Vico was) likewise end by giving a very different account of certainty and necessity from those (like Descartes) whose ideal of scientific knowledge is a formal, mathematical one.

If the philosopher comes to grips with the full complexity of the scientific enterprise, this approach can lead him to a more exact understanding of the varied intellectual problems of the natural and human sciences. Once it is recognized how different are the kinds of questions arising within such diverse fields as quantum electrodynamics and developmental biology, clinical neurology and historical sociology, the goal of formulating a single scientific method—with a universally applicable set of procedures and criteria for judging new theories or ideas in all fields of science—may come to appear a mirage. Yet the philosopher's legitimate insistence on generality has already helped to promote important extensions and integrations of man's scientific understanding. So again, he must now avoid taking too dogmatic a stand, either for or against complete generality, bearing in mind Kant's warning that the reason can hope to map its own proper boundaries only at the price of occasionally overstepping them.

The empirical procedures of science. Along with the three groups of elements already discussed, each phase in the scientific enterprise—empirical, formal, and conceptual, or interpretative—involves its own characteristic procedures. On the level of empirical observation and description, three topics may be briefly touched upon, all of which are discussed at greater length in other articles (see MEASUREMENT, THEORY OF; CLASSIFICATION THEORY; and articles on the basic sciences).

First, there are the procedures of measurement through which scientists arrive at quantitative estimates of the variables and magnitudes considered in their theories. By now, there is a well-developed body of knowledge upon which scholars are agreed about many of the techniques and precautions to be employed in practice in the measurement of empirical quantities, in the calculation of probable errors or significant deviations, and so on. About the deeper significance of measuring procedures and their outcomes, however, there are still unresolved philosophical disputes. These disagreements reflect the same differences of approach already noted. Thus, some philosophers regard any scientific theory concerned with measurable (or quantifiable) magnitudes as intrinsically superior to a qualitative (or, as they would say, an impressionistic) one, however rich and well organized the latter may be. Others, by contrast, would argue that any insistence on employing numerical measures at all costs, even in such a science as, for example, systematic biology, can only lead the investigator to misconceive the true nature of the problems involved. Again, philosophers of an extremely Empiricist or Positivist persuasion have sometimes interpreted the experimental procedures for measuring theoretical magnitudes in, for example, physics as providing implicit definitions of the associated technical terms—the so-called operational definitions—and have thus felt able to claim that the logical entailments that the scientist is seeking between observations and theories are established by linguistic fiat (see below Status of scientific propositions *and* concepts or entities).

Science
as a
multiform
enterprise

Measure-
ment
theory

Design of
experi-
ments

Secondly, there are statistical analytical procedures for the design of scientific experiments. The mathematical techniques employed for this purpose are, in fact, closely related to those involved in the theories of measurement, probable error, statistical significance, and others. In this area, the connection between philosophical discussions of inductive logic and the practical procedures of working scientists is at its closest. Whereas a religious scientist (Blaise Pascal), a Nonconformist minister (Thomas Bayes), and an astronomer (Pierre, marquis de Laplace), all mathematicians as well, analyzed the philosophical foundations of the modern calculus of probabilities in the 17th and 18th centuries, 20th-century mathematicians and inductive logicians have similarly explored the intellectual basis for the design and interpretation of significant experiments; and, by now, the relevant procedures form a full-fledged branch of mathematical statistics with many valuable applications, particularly in fields such as sociology and economics, in which large numbers of variables are involved.

Problems of experimental design, however, can be stated clearly and unambiguously only in situations in which questions of fundamental theoretical interpretations are not actively at issue; *e.g.*, in experiments to determine which of two antibiotics is the more effective against a given infection or to learn whether significant correlation exists between two known physical variables. As soon as more fundamental questions of theory arise, however, the problems of experimental design go beyond the scope of any purely statistical analysis. Moreover, the same is true of computer-programming procedures: the numerical data obtained from a straightforward scientific experiment can in many cases be fed into a computer programmed to select the graph or formula in best statistical accord with the data from among those hypotheses conforming to a predetermined set of conceptual or interpretative requirements; thus, in this sense, a computer can be used to perform inductive inferences. Devising brand-new styles of conceptual or theoretical interpretation, by contrast, involves extending or modifying present explanatory procedures to satisfy novel intellectual requirements; and these tasks call for something more than formal statistical or programming techniques.

Classifi-
cation
theory

Finally, the initial handling of the scientist's empirical data requires him to employ procedures of systematic classification. The nature and validity of scientific classification procedures and of the species, genera, families, and so on into which scientists divide their empirical subject matter have been the subject of a long and contentious debate, which is dealt with at greater length in the article CLASSIFICATION THEORY. A long-standing philosophical deadlock between supporters of natural and artificial classification systems was largely broken—in zoological taxonomy, at any rate—through the success of Darwin's theory of natural selection. As Darwin showed, the species to which organic evolution gives rise are neither eternally unchanging natural entities nor mere fictions of the zoologist's arbitrary creation; considered as coherent, self-isolating populations, they have a genuine though temporary reality that is preserved by the contrary processes of variation and selection perpetuation. In some other areas of thought, however, the preliminary identification and classification of the empirical material still raises contentious philosophical questions. When the sociologist theorizes about social groups or systems in the human sciences, for instance, he has to decide what collections of men and institutions do, or do not, fall under those general headings. Can objective tests be found for identifying natural units of sociological analysis? Or, is this choice of units merely set up for the sociologist's own convenience? This uncertainty about the very subject matter of sociology is itself an obstacle to the creation of an agreed-upon body of social theory; and comparable difficulties can arise in anthropology, linguistics, and psychology as well. It is, therefore, not surprising that some critics have even questioned whether these disciplines can truly be called sciences.

The character of these continuing difficulties underscores one point of general significance about the relation

of empirical evidence to scientific theories: though philosophers may find it necessary to distinguish the empirical phases, elements, and procedures of science from the theoretical ones analytically, it does not follow that they can be kept wholly separate in actual practice. Satisfactory measuring procedures, experimental designs, and systematic classification principles are, no doubt, necessary preconditions for effective theorizing; but they themselves are subject, in turn, to revision and refinement in the light of subsequent theoretical considerations. In arriving at his dynamical theories, for example, Newton had to begin by relying on older commonsensical notions of effort, weight, and amount of movement; but he soon replaced these by the more exact, theoretically defined concepts of force, mass, and momentum, and this change reacted back onto the empirical procedures of physics also. Likewise in other fields of science, the decision as to whether or not the outcome of any empirical procedure is scientifically relevant or significant soon ceases to be a purely empirical question, as theoretical changes react back onto those empirical procedures and compel the scientist to modify his manner of collecting and describing the supposedly raw data of science. In this way, the empirical evidence by which his scientific conclusions are justified rapidly loses its pure and theoretically neutral character.

The formal structures of science. In this section and the next, those aspects of the scientific enterprise will be considered that have dominated recent debate in the philosophy of science, *viz.*, the formal structures of scientific theory and the processes of conceptual change. It will soon be clear that the philosophical problems to which these two aspects, respectively, give rise are correlative and complementary—the one being static, the other being dynamic.

Since 1920, most analytical philosophers of science have explicitly based their program on a presupposition inherited from Descartes and Plato, *viz.*, that the intellectual content of any natural science can be expressed in a formal propositional system, having a definite, essential logical structure—what a leading American philosopher of science, Ernest Nagel, concisely called "the structure of science" in his book of that title (1961). One immediate inspiration of this program was the work of David Hilbert, a late-19th-century mathematician. To make the methods of mathematical proof more explicit and more perspicuous and thus more rigorous, Hilbert employed the techniques of formalization, a reduction to relations while disregarding the nature of the relata, and axiomatization, a tracing of entailments back to accepted axioms.

The same techniques were taken over into the philosophy of mathematics by a pioneer German logician, Gottlob Frege, and into symbolic logic by Bertrand Russell and his collaborator Alfred North Whitehead; and, from 1920 on, the Viennese Positivists and their successors attempted to employ them in the philosophy of science also, hoping to demonstrate the validity of formal patterns of scientific inference by the straightforward extension of methods already familiar in deductive logic.

According to the resulting program, the primary task for the philosophy of science was to repeat in quite general terms the kind of analysis by which, in the science of mechanics, Heinrich Hertz, the formulator of electromagnetic wave theory, had already sorted out the formal aspects of science from its empirical aspects. The program was founded on the expectation that it would be possible, first, to demonstrate the existence of formal structures that were essential to any science, properly so-called, and second, to identify the nature of scientific laws, principles, hypotheses, and observations by their characteristic logical functions. Once this had been done, rigorous formal definitions could then be given of validity, probability, degree of confirmation, and all of the other evidential relations involved in the judgment of scientific arguments.

The actual working out of this program has involved complex and highly technical investigations, in the course of which great ingenuity has been displayed—as, for instance, by an outstanding philosophical semanticist and analyst, Rudolf Carnap, in his system of inductive logic,

Ideal of a
formalized
science

Problem of
generaliza-
tions
versus
laws

for the criticism of arguments in support of empirical generalizations, and by Hans Reichenbach, an eminent German-American Positivist, in his analysis of probabilistic arguments. So far, however, the program has yielded substantial results only as applied to arguments expressed in an idealized formal symbolism modelled on the lower functional calculus of mathematical logic. By contrast, little has been done to show how one might extend the resulting formal procedures to arguments expressed in the practical terminologies of working science. That extension, in fact, raises difficulties and ambiguities that are so far unresolved and may prove unresolvable. The goal of a purely formal analysis of scientific inference has generated difficulties, for instance, by tempting logicians to play down important differences between mere descriptive generalizations about natural phenomena and the explanatory theories (laws, principles, etc.) that a scientist develops to make those phenomena intelligible; and succumbing to this temptation creates problems both within inductive logic and in its applications.

One distinguished supporter of this program, Carl Hempel, originally a member of the Berlin group (allied with the Vienna Circle), has discussed what he calls the theoretician's dilemma: if the task of explaining natural phenomena requires a proof that the character of those phenomena is formally entailed by the conditions of their occurrence, taken together with certain straightforward generalizations based on previous empirical experience, and if those empirical generalizations include references to hypothetical entities, then the theorist is faced with an invidious choice: for, in that case, either his generalizations (his laws) do in fact provide a logical link between the conditions of the phenomena and their actual occurrence and the assumption of hypothetical entities is formally superfluous; or else they do not succeed in doing so, and that assumption will not have strictly explained the phenomena. Clearly, this dilemma can be evaded only by challenging the identification of laws with generalizations and insisting that any appeal to laws of nature always involves the scientist in reinterpreting natural phenomena, not in merely generalizing about them.

Looking beyond the internal structure of inductive logic, the dubious equation of scientific laws with empirical generalizations has also been criticized on the ground that it treats the content of those laws as matters of happenstance, far more accidental or contingent than those expressed in any genuine law of nature. In the opposing view, the explanatory force of, say, the physicist's law of inertia is totally different from that of such a generalizing statement as "All swans are white"; and one can learn nothing about the validity of actual physical arguments unless his philosophical analysis respects that crucial difference. It has not proved easy, however, to analyze the formal structure of the sciences in any less abstract manner than that of the Viennese Positivists or to give a true representation of the working language and arguments of science. In his *Essay on Metaphysics* (1940), R.G. Collingwood, a British philosopher and historian, made one striking attempt, in which the formal structure of intellectual systems was explained in terms not of direct entailments between more or less universal propositions but rather of mutual presuppositions between more or less general concepts. In this account, the principle of inertia was not the most universally true assertion in dynamics but was, rather, the most generally applicable presupposition, or principle of interpretation. Such an account has the merit of explaining why, within a particular science, certain formal patterns of argument carry the apparent necessity that they do; but at the same time it lays itself open to the charge of yielding too much to relativism and so of destroying the objectivity of scientific knowledge by giving the impression that the conceptual structures of science are imposed on phenomena by the arbitrary choice of the scientific theorist himself.

Doubts
about
formaliza-
tion

The late 1960s, accordingly, saw a renewal of questioning about the original assumption, viz., that the entire intellectual content of a science can be captured in a propositional or presuppositional system. Certain of the doubts about this thesis revive criticisms put forward at

the turn of the century by a U.S. Pragmatist, Charles Sanders Peirce, who argued that the logical status of the theoretical terms and statements in a science is—in the nature of the case—subject to historical change as the conceptual organization of the science develops. (This same insight has been explored more recently by a U.S. logician, Willard Quine, who rejects any attempt to classify statements within scientific theories using the traditional hard-and-fast dichotomies—contingent—necessary and synthetic—analytic—as fallacious and dogmatic.) Other criticisms of the thesis go deeper. By focussing his philosophical attention exclusively on the static formal structure of propositional systems and, so, on the intellectual content of the sciences at particular temporal cross sections in their development—they point out—the philosopher is distracted from the complementary questions about the manner in which the conceptual organization of a science changes and, so, from the traditional claims of natural science to be a rational as well as a logical enterprise. At this point in the debate, therefore, the spotlight shifts away from the static problem of analyzing a science in static logical terms to the historical problem of analyzing the dynamic processes of intellectual and conceptual change.

Conceptual change and the development of science.

The problem of conceptual change has recently come back to the fore. The crucial question it poses is: "What is a concept?" In the heyday of Logical Empiricism, that question had largely been disregarded. Following the example of Frege, the Viennese Positivists had condemned any tendency to regard the philosophy of science as concerned with scientific thinking—which was in their view a matter for psychologists—and had restricted themselves to the formal analysis of scientific arguments. This preoccupation with logic was also reflected in their view of concepts. To interpret a concept such as force as referring either to a feeling of effort or to a mental image could lead, they argued, only to confusion. Instead, the philosopher must equate concepts with the terms and variables appearing in the propositional systems of science and define them, in part by reference to their roles in the formal structures of those propositional systems—thus fixing their systematic import—and in part by reference to the specific events and phenomena they are used to explain—thus fixing their empirical import. In the 1920s and 1930s, accordingly, all substantive philosophical questions about the concepts of science were dealt with summarily: they were simply translated into logical or linguistic questions about the formal roles and empirical references of technical terms and mathematical variables.

Once the philosophy of science is approached more historically, however, those substantive questions must be faced afresh in their own right. Rival scientific theories will now be distinguished not merely as so many alternative formal systems, based on different primitive terms and axioms, but also as alternative ways of organizing the knowledge of nature, based on different explanatory techniques and modes of representation. The distinctive features of different scientific concepts will lie, as a result, not in their respective formal roles and empirical references but in the styles of explanatory procedure involved in their application. Those procedures may be of many different kinds: e.g., physical conservation calculations, optical-ray diagrams, functional analyses, taxonomic classifications, historico-evolutionary reconstructions, or dynamical axiom systems. Correspondingly, they provide occasions for employing mathematical formulas, or intuitively intelligible models, or genealogical trees, or other styles of representation. In each case, however, the philosopher can describe the conceptual organization of the resulting explanations in terms neither of intuitive models nor of mathematical formulas and variables taken alone: what he must now consider is the entire pattern of theoretical interpretation—models, mathematics, and all.

Viewed from this alternative standpoint, the philosophy of science will begin by identifying the different styles of explanation characteristic of different sciences or of different stages in a given science and will recognize how

Styles of
explanatory
procedure

those differences in explanatory style reflect the characteristic problems of different scientific fields and periods. So considered, empirical generalizations and descriptive classifications will serve to organize the empirical data of science in a preliminary way; but serious theoretical interpretation can begin only after that point. The central philosophical task now is to analyze, clearly and explicitly, (1) the standards by appeal to which scientists have to decide whether or not some interpretation is legitimate, justified, and conclusively established and (2) the considerations that justify giving up one currently accepted interpretation in favour of an alternative, novel one.

The first of these questions is one that the Logical Empiricists set out to answer in their own manner. They treated the empirical data and the theoretical principles of science as being connected by purely logical relations and attempted to define the required standards in terms of a formal theory of confirmation, corroboration, or falsification. The second question is one that they never seriously tackled. Instead, they assumed that one could, first, work out a quantitative index of acceptability for individual theories taken separately and, afterward, use this as a scale for measuring and comparing the merits of rival theoretical interpretations. By now, however, it is evident that, when biophysicists, say, abandon one theoretical approach in favour of another—as being more fruitful from the standpoint of biophysics—the considerations that lead them to do so are by no means analyzable in formal terms alone. On the contrary, the ability of a biochemist, say, to judge whether or not such a change in approach will effectively help to solve his theoretical problems is one of the most severe assessments of his substantive grasp of what biochemistry is about.

In this way, the shift of attention from the propositions of science to its concepts is making philosophers more aware of the extent to which theoretical understanding involves the reinterpretation of empirical results, not merely their formal transformation. Similarly, the problem of conceptual change is raising questions about the processes by which theoretical interpretations succeed one another and about the procedures of conceptual judgment that are applied in the rational development of a science. These questions are currently under active discussion, and several lines of attack are being considered, none of which has finally established itself.

At one extreme, there are some who still regard theoretical concepts and principles as organized into compact, logical systems and who attempt to define the alternative standpoints of different sciences as the consequences of different basic premises or presuppositions. Having adopted this systematic approach, the investigator then discovers that conceptual change at a fundamental level finds adequate scope **only** through the replacement of one complete formal system by another, distinct and separate successor system. As a result, fundamental theoretical change is, in this view, intelligible only as the outcome of thoroughgoing intellectual revolutions, in which one entire theoretical system—axioms, principles, criteria of relevance, standards of judgment, and all—is swept aside in favour of another.

Alternatively, there are those who distinguish two different kinds of fundamental principles in a science—marking off the basic theoretical assertions such as "Matter consists of atoms combining into molecules" from its methodological maxims and standards of judgment, such as "All physical phenomena are to be explained in mechanical terms"—and who recognize fundamental conceptual changes in the science as legitimate, just so long as they respect the methodological maxims that are definitive of the science in question. In this second view, conceptual changes of any depth in the intellectual substance of a science will continue to be intelligible, provided only that the new views are still governed by the established program and framework concepts of the science in question. There will then be revolutions in science only when some entire intellectual approach is discredited—e.g., that of 16th- and 17th-century iatrochemistry, which studied chemistry as a means of treating disease—

or when some entirely new science is created, with its own complete system of **interpretation**—e.g., molecular biology.

At the other extreme, there are some who doubt whether any sharp distinction can be drawn between substantive theoretical assertions and maxims of methodological procedure and who argue that all aspects of a natural science are alike open to historical reconsideration and modification. The more specific the theoretical doctrines and concepts being considered, the more risky they will be, and the more readily they will be modified or abandoned or both. From this third point of view, however, it is questionable whether any change, however drastic—even the hybridization of crystallography, viral genetics, and biochemistry, which led to the inauguration of molecular biology—is ever as discontinuous or **revolutionary** as the two former views imply. Instead, the attempt may be made to account for the procedures and processes involved in the historical development of scientific concepts by using the same general form of theory on every level—explaining innovation as requiring a selective choice between intellectual variants of different kinds; and, in this way, the theory of conceptual development can be brought into line with other historically based theories of natural and cultural change.

Whichever alternative is adopted, one point must be kept in mind: the moment that problems about the changing theoretical organization of science begin to be treated in an authentically developmental manner, philosophical inquiries are given a quite new direction. This step compels one to view all questions about the logical structure and propositional systems of science against a broader historical background. In this new context the natural sciences are seen not as static formal structures but as rational enterprises characterized by certain typical intellectual procedures or movements. These basic procedures of intellectual development in science are the topic to which attention is directed in the next section.

MOVEMENTS OF SCIENTIFIC THOUGHT

Discovery and rationality. In analyzing the natural sciences for philosophical purposes as historically developing enterprises, the question "What is it that makes the sciences rational?" is raised in a new form: do the intellectual procedures that scientists actually employ to investigate and explain natural phenomena have definite and objective intellectual merits that make their adoption rationally prudent, wise, and obligatory? In answering this question, philosophical opinion has tended to polarize in recent years toward two extreme positions: on the one hand, a formalist or positivist extreme, on the other, a romantic or irrationalist one.

Given their mathematical inspiration and preoccupations, both the Viennese Empiricists and their successors in Britain and the United States have interpreted the rationality of scientific procedures as depending solely on the formal validity, or logicity, of scientific arguments. In their view, questions of rationality can be raised about the scientist's work only at the final stage in his inquiries—i.e., when he sets out, as the final outcome of his work, the explicit explanatory arguments in support of his novel theories or interpretations—only then, they declare, will there be anything about science that is capable of being criticized in logical or philosophical terms.

It is therefore a commonplace of recent Empiricist analysis in the philosophy of science that one must distinguish at the very outset between discovery and justification. The term discovery refers to all the stages in a scientific inquiry preceding the formulation of the new explanatory arguments that are its final outcome. The term justification refers, by contrast, to the demonstration that the formal validity or explanatory power of those arguments justifies the scientist in accepting their conclusions as scientifically validated or established. In this view, the rational concerns of the philosopher of science are restricted solely to this final phase of justification. All questions about the earlier stages—i.e., about discovery—are matters of mere psychology, not of serious philosophy. As one widely accepted epigram ex-

Develop-
mental
nature
of
science

Reinterpre-
tation of
concepts
and
principles

Formalist
versus
irrational-
ist

presses it, "There is no logic of discovery"; and this distinction—given the equation of rationality within logicity—seemingly invalidates all questions about the rationality of the preliminary steps by which a scientist arrives at a discovery.

At the opposite extreme, there are those, such as Michael Polanyi, a Hungarian-born scientist and philosopher, and Arthur Koestler, a novelist and journalist, who emphasize the parts played by intuition, guesswork, and chance in scientific investigation, citing these as evidence that theoretical achievement calls into play an intellectual creativity superior to mere rationality. According to this anti-Positivist argument, the modern scientist is a sleepwalker whose creative insight guides him to intellectual destinations that he could never clearly see or state beforehand: any excessive preoccupation with the rationality of scientific procedures, by contrast, springs from a pedestrian desire to clip the wings of imagination and to confine the scientist to stereotyped procedures, thus destroying the creative fertility of science. Rather than subjecting scientific intuition to the barren intellectual accountability of the Positivists, the conclusion runs, one should embrace a romantic anti-rationalism.

In each of these extreme cases, however, the initial equation of rationality with logicity demands closer examination. Certainly, the activity of investigation and discovery can be examined with advantage from a psychological point of view as it has been, in fact, by a French mathematician, Jacques Hadamard, as well as from a philosophical point of view. Yet the possibility of such psychological inquiries does not obviously prove, entirely by itself, that procedures of intellectual investigation in science and mathematics are essentially nonrational. Chance, for instance, may help to bring relevant material to a scientist's attention. But chance—as has often been remarked—favours the prepared mind, and it is fair to ask how far the scientist acted rationally, after all, in picking out the items he did as being relevant to his particular problems. Similarly, in the case of creative intuition and the rest: once again, the man with the best trained mind can afford to give the freest rein to his intellectual imagination because he will be best qualified to appraise the rational context of his current problems and to recognize significant clues, promising new lines of analysis, or possible answers to his questions, as they come to mind.

Neither denigrating the early phases of scientific inquiry as of merely psychological interest nor overpraising them as exercises of creative imagination disposes therefore of the philosophical problem that is here involved, viz., that of showing what makes certain procedures of investigation more rational than others. To find a middle way between formalism and irrationalism, it is necessary to look more closely at the nature of the problems of scientific inquiry. If the improvement of scientific concepts and theories depends on the development of more powerful explanatory procedures, the philosophical analysis of discovery then requires that one show what is essentially involved in devising such procedures, testing them out, and determining the range of their application. This problem must be dealt with, furthermore, not by a formal analysis of the resulting arguments alone but first and foremost by establishing what tasks any novel explanatory procedure in science can be required to perform, what demands its performance can properly be asked to satisfy, and so what intellectual goals a scientist is expected to be aiming at in all the phases of his investigations. Posed in these alternative terms, the problem of scientific rationality becomes a problem of showing how conceptual changes in science result in the introduction of novel ideas, which are—in a phrase coined by Mach as early as 1910—"better adapted, both to the facts and to one another." It is rational for older scientific theories to be displaced by newer ones that are functionally superior; and the task for philosophers of science is to demonstrate explicitly in what such functional adaptedness consists.

At the present time, many younger philosophers of science are actively analyzing the nature of the problems of science in these terms. Significantly, most of these men have had their own primary training within the natural

sciences proper rather than in formal logic or pure mathematics, for the task requires a much more detailed analysis of the processes of intellectual innovation than has been customary hitherto. In place of the simple dichotomy between discovery and justification, for instance, it calls for a subdivision of the innovation process into a more complex sequence of distinct stages; and at each stage both rational and causal considerations are relevant. Thus, at the initial stage in any inquiry, a scientist must decide which among all of the philosophically conceivable variants from the current repertoire of explanatory methods are to be taken seriously at all; which, that is, are genuine possibilities. This preliminary sorting of initially plausible from implausible innovations must be dealt with—and dealt with in the most rational manner possible—long before any question of justification arises.

This initial sorting procedure is one about which scientists themselves also speak cogently and eloquently. Far from deciding what novel suggestions are genuinely possible or plausible on a purely psychological basis or by the exercise of some mysterious, nonrational intuition, scientists will commonly explain their reasons for accepting one set of conceptual variants rather than another as deserving serious consideration. At the same time, such micro-analyses of scientific innovation must certainly leave room for causal as well as rational questions. During certain periods in the historical development of science, for instance, scientists have notoriously disregarded novel possibilities that later turned out to hold a key to the solution of crucial theoretical difficulties. Looking back at such periods, it is possible to reconstruct with care the rational considerations that might have been advanced at the time to explain this neglect; but even so, one is occasionally forced to conclude that the men involved were prejudiced against those possibilities by factors external to their sciences; e.g., by influences originating in the wider social, cultural, or political framework of their time. Thus, Newton was particularly afraid that his theory of material particles might be accused of supporting Epicureanism, whereas Darwin concealed his private speculations about the cerebral basis of mental activities because of public objections to Materialism.

In analyzing the microstructure of scientific problem solving, it is necessary, accordingly, to resist any temptation to generalize prematurely. Scientific investigators working in different fields, or at different times, apparently face theoretical difficulties of quite different kinds. One must therefore begin by studying the specific needs and tasks of each particular science, at one or another stage in its evolution, separately—seeking to recognize, in each individual case, the particular intellectual demands to be met by any new concept or theory if it is to be successful. Eventually, the accumulated results of specific micro-analyses may bring the investigator to a point at which he can again afford to generalize about all of the assorted theoretical problems confronting, say, physics and about the broader intellectual demands to be met by successful theoretical changes in a variety of scientific situations. At the present stage, however, though philosophers of science still cannot afford to beg these questions, they are compelled to conduct their analyses in a more piecemeal way—building up their picture of scientific innovation and discovery by considering a wide range of sample cases and working their way only gradually toward a more comprehensive account of the problematics of the scientific enterprise.

Validation and justification. If this situation is true of the earlier stages in discovery, it is no less true in the case of justification itself. Here again, from 1920 on, the debate in the philosophy of science focussed predominantly on two sharply opposed positions, both of which appear in retrospect to be excessively narrow. On the one hand, Empiricist philosophers argued for a view that made prediction the crucial test of scientific validity; on the other hand, philosophers of a more Rationalist temperament saw coherence and scope as the crucial requirements.

For Empiricists, the fundamental presupposition is that the facts justifying changes in scientific ideas are both intellectually prior to the theories that are, in due course,

Diverse approaches in different fields

Empiricist versus constructivist positions

Problematics of scientific inquiry

developed to explain them and also capable of being recognized independently and in advance of all theory construction. Given this presupposition, they regard prediction and validation as the crucial and distinctive steps in scientific procedure, arguing that, to establish the validity of any general scientific proposition, it is necessary to show that the theoretical generalization of which the validity is in question entails particular factual statements that are borne out by independent empirical observations. This validation process then involves two essential steps: (1) the formal step of inferring novel predictions from the theory and (2) the empirical step of comparing those predictions with the facts and so confirming the theory or proving it false.

On closer inspection, both steps in the received Empiricist procedure face serious difficulties, and these have lent strength—by reaction—to the alternative, constructivist position. As to step (1), there appears to be no objection to the idea of deducing particular factual predictions directly from theoretical hypotheses, so long as one accepts the Empiricist interpretation of laws of nature as universal empirical assertions on the same logical level as "All polar bears are white." Once that interpretation is questioned, however, it is less clear that direct deductive inferences from theory to fact are always practicable. On the contrary, if theoretical laws and purely empirical reports are, in the nature of the case, framed in terms of distinct and diverse sets of concepts, no general procedure can be available for passing deductively from one to the other. For the theory will then be a reinterpretation of the facts, not a mere generalization from them. Similarly, with step (2), an empirical confrontation of theories and facts gives rise to a more complex range of choices than those implied by the Empiricist account. When faced with discrepancies between prediction and observation, scientists certainly have to modify their theoretical explanations; but this modification can normally be made in any of several alternative ways. For instance, the theoretical relevance of a particular observation may be questioned; or some alternative theoretical interpretation may be put forward; or further refinements may be made within the structure of the theory concerned—and all of this can be done before any question arises of a direct and necessary conflict between the discordant observation and the general theoretical doctrine under investigation.

The rival, constructivist position derives its attractions from such objections as these. This position follows lines of thought already sketched by the French theoretical physicist Pierre Duhem at the turn of the century. On this account, the essential test of a science is that it should provide coherent, consistent, and wide-ranging theoretical organizations. Empirical facts will then be recognized as scientifically relevant only to the extent that they exemplify these interpretations and make them more discriminating. Thus, no single factual observation can ever serve as a logically crucial experiment and confirm or refute any one specific doctrine conclusively, taken apart from a whole complex of theory and interpretation. What is at risk in any experiment or observation, therefore, is the whole body of the theory, together with the current conventions governing its empirical application; and the more comprehensive a theory is, the more are scientists free to vary the details of their specific applications of it, rather than to accept any single counter-example as a challenge to its general validity.

If these two philosophical approaches are reconsidered today against a broader and more historical background, however, they no longer appear to be either as exhaustive or as contradictory as they did in the 1920s and 1930s. By choosing suitable illustrations, of course, one can make each position highly attractive and plausible since, in one situation or another, the rational considerations that carry genuine weight in the actual justification of novel scientific theories include both predictive success and conceptual coherence. But the "Book of Nature," as Galileo called it, is like Holy Scripture: it offers texts to suit all occasions and purposes. And, on second thought, it can be argued that both Empiricist and constructivist philosophers oversimplify the justification process in

science and the criteria by which scientists judge the validity of novel concepts and theories. Far from there being any single or simple test of validity, the question whether predictive success or coherence, simplicity, historical authenticity, or mechanical intelligibility is the key consideration—and in what sense of each ambiguous phrase—must be considered afresh from case to case, with an eye to the specific demands of each new scientific problem situation.

Within the historically developing enterprise of science, intellectual problems arise of many different types, depending both upon the kinds of subject matter under investigation and upon the stage of development of the science concerned. In one science and at one stage, particular weight may attach to a single unexpectedly successful prediction: as when the wave theory of light led to the totally unexpected discovery that a perfectly circular obstacle placed in front of a point source of light produces a circular shadow having a bright spot at its centre. In another science or at another time, however, it may be neither practicable nor relevant to infer such specific predictions, and new theories and concepts may be validated by considerations of quite other kinds. Even within a single science such as physics, indeed, scientists are not faced at every stage by problems and judgments of a single, uniform type. Instead, the historical evolution of physics—down the centuries from Nicole Oresme, Galileo, and Newton to Maxwell, Rutherford, and Heisenberg—has generated an entire genealogy of varied problems; and the considerations bearing on the theoretical difficulties facing physicists at different stages have themselves changed, quite legitimately, along with the substantive concepts and theories of the science. So, within the more complex framework of a developing rational enterprise, the philosopher's task is no longer to impose any single or simple criterion of intellectual choice upon scientific judgments of all kinds. Rather, his task is to recognize how the rational considerations and criteria of validity relevant to particular judgments vary with the theoretical problem situations that provide their historical contexts.

Unification, pluralism, and reductionism. As one notable illustration of the tug-of-war between logical and pragmatic issues in the philosophy of science, the Unity of Science movement may be cited. Under the vigorous leadership of Otto Neurath, a polymath sociologist and philosopher, this movement represented the high point in the ambitions of Viennese Positivism between World Wars I and II; for the general philosophical aims that motivated the search for a unified science are in striking contrast with the specific problem-solving considerations that lead working physicists to unify or integrate their theoretical concepts and explanatory procedures in actual scientific practice.

Aside from the primary test of predictive success, the Positivists of the Vienna Circle also did allow—on their own terms—for the further theoretical virtues of coherence and comprehensiveness. Their logico-mathematical approach to the propositional structure of scientific theories, however, led them to interpret this demand for coherent and comprehensive theories in a formal sense. On their interpretation, a totally unified body of scientific ideas would be a comprehensive, quasi-Euclidean system of scientific theorems, based on a single set of general axioms, postulates, and primitive propositions and applicable to natural phenomena of all kinds. Given sufficiently all-embracing empirical generalizations as the starting points of such a unified science, it would then be possible, in their view, to deduce particular statements about all the phenomena covered by the varied special sciences unified within its axiomatic scope. Taking the symbolic logic of Russell and Whitehead as their formal core, philosophical advocates of the unity of science then set out to construct, on a single axiomatic pattern, a fully comprehensive account of nature capable of explaining (i.e., entailing) all natural phenomena whatsoever.

At first glance, this ambition seemed laudable and legitimate, but once again the Empiricist program subsequently encountered unforeseen entanglements. The reasons for

The Unity of Science philosophy

Complementarity of the modes of justification

this situation were not merely the discovery that the theoretical ideas employed within different branches of a science (*e.g.*, of mathematical physics) are more resistant to conceptual integration than had originally been hoped (the task of constructing a self-consistent relativistic theory of quantum electrodynamics, for instance, is one that still defeats the physicists); but, what is worse, it has now become apparent that several well-founded and properly respected branches of scientific theory do not lend themselves to exposition in a formal mathematical manner at all. Any satisfactory theory of organic evolution, for instance, has an irreducibly historical dimension; and there is no possibility of putting historical zoology on the sort of predictive basis that Empiricists have demanded, still less of incorporating it into Neurath's larger unified axiom system. Faced with this particular example, indeed, one distinguished Empiricist philosopher, Carl Hempel, has drawn a somewhat extreme conclusion, *viz.*, that the theory of natural selection is not really an explanation of organic evolution at all—not even a bad one—but is merely an elaborate redescription of the historical episodes concerned. Yet this is simply a roundabout way of conceding that neither the historical problems nor the theoretical ambitions of evolutionary zoologists conform to the quasi-mathematical pattern that the Logical Empiricists have set out to impose on all of the natural sciences alike in the interests of a longer term axiomatic unification.

If, on the other hand, the demand for integration or unification is considered as a practical problem of methodology, it will then be found that the scientists are facing problems of a different and more pragmatic kind. The science of physiology poses an interesting example because, within this field, the problem of **reductionism**—*i.e.*, of whether all phenomena whatsoever can be reduced to physico-chemical terms alone—has repeatedly drawn active debate. Since the time of Antoine Lavoisier, who first explained correctly the process of **combustion**—*i.e.*, since the late 18th century and even before—there has been a methodological division of opinion, involving, on the one hand, those chemists and physiologists who dreamed of equating physiological functions with chemical reactions and planned their program for biochemistry around that ambition and, on the other hand, those clinical scientists and functionally minded physiologists who questioned the legitimacy of this so-called physicalist program and insisted that physiological phenomena displayed certain features or aspects inexplicable in physico-chemical terms alone. The scientific issues in debate in this case have never been concerned with formal matters of axiomatization and logical integration alone; once again, they have involved substantive questions of interpretation. Correspondingly, the provisional resolution of this dispute, accomplished by Claude Bernard in the mid-19th century, was not arrived at by constructing a single, unified axiom system of **biochemistry-cum-physiology**. Rather, Bernard distinguished the proper questions and concerns of the two sciences and demonstrated the substantive character—and limits—of their mutual relevance.

Regarded as specific, localizable processes within the main organs of the body, he argued, all physiological phenomena do, indeed, come within the scope of the same general physico-chemical laws and concepts as govern similar processes in inorganic systems. Within the special micro-environments of the body, however, those same general types of phenomena serve certain unique physiological functions, having no inorganic counterparts; and, to this extent, special problems and questions arise within physiology that cannot be exhaustively translated into the language of inorganic physics and chemistry. Though biochemistry and physiology in no sense conflict, there accordingly remains an essential plurality in the explanatory aims of the two sciences; and this plurality gives rise, in turn, to a corresponding plurality of methods and concepts.

Yet even this example does not yield conclusions from which one can safely generalize. Though in certain respects the explanatory aims of physiology and biochemis-

try will, most probably, always be distinct and separate, in other cases matters have gone the other way. When, in 1873, the Scottish physicist James Clerk Maxwell, for instance, integrated the previously independent sciences of electricity, magnetism, and optics into the unified physics of electromagnetism, there was no comparable division of opinion and no such methodological peace treaty was needed. In this case it remained possible, after Maxwell's work as before, to distinguish between straightforwardly electrical, magnetic, and optical phenomena on the empirical level; but on a more general, theoretical level such distinctions lost their earlier significance, and it ceased to be necessary to keep the problems, methods, and explanatory categories of the three earlier sciences separated.

To sum up: in the methodological drive toward the unification of the sciences, as in the earlier phases of discovery and validation, the intellectual temptation to generalize prematurely exposes the philosopher to certain real dangers. In practice, the case for unifying the theories and concepts of two or more sciences has to be considered afresh in every instance, and it can rarely be decided in advance whether or not such a unification will achieve anything useful for the sciences. Instead, one has to analyze the practical demands of the current problems in the different fields and see how far those requirements can be met by developing a unified explanatory treatment for all of the special sciences in question. The integration of theoretical concepts achieved in the process will not consist solely in the formal running together of different propositional systems: more typically, it will require the development of a whole new pattern of theoretical interpretation. And, though it may be possible, in certain cases, to expound the resulting theory in axiomatic form, it must be established, in each case separately, whether or not this can be done. In this sense, conceptual and methodological unification represents a genuine movement in the development of scientific thought; but the logical form of the unified science towards which the philosopher is working is not something that he can lay down definitively before the event.

III. Deeper issues and broader involvements of science PHILOSOPHICAL STATUS OF SCIENTIFIC THEORY

Status of scientific propositions and concepts or entities. The section of this article entitled Conceptualization and *methodology* of science examined, first, the raw material (or elements) with which scientists have to work in developing their theories about the operations of the natural world and, second, the intellectual steps (or movements) by which they arrive at a scientific understanding of nature. By way of summary, it is appropriate to consider finally the main points of view about the intellectual status of the scientific concepts and doctrines embodying the understanding of nature that have emerged from the philosophical debate about science. Beginning with the epistemic status of theoretical propositions in science, it is well to consider the different claims that are made about the objectivity of their applications or their truth or both. Then, turning to the ontal status of the scientific concepts or entities, it is likewise necessary to consider the claims that are made about the objectivity of their reference or of their meaning or both. In either case, the purpose of a philosophical critique of science is to establish just how far the content and reference of scientific knowledge can be regarded as a true report about the actual structure and operations of nature and just how far they represent, on the contrary, intellectual constructs or artifacts in terms of which men have chanced, chosen, or found it desirable to organize their thoughts about the structure and operations of nature.

Starting with the epistemic status of scientific theories, three main views can be distinguished: At one extreme is a strict Realist position, which underscores the factual basis of all scientific knowledge and emphasizes the logical contingency that this basis implies for all substantive propositions in science. In this view, all but the most purely formal statements in science make assertions

Limited
scope of
unification

Epistemic
aspects

Unifica-
tion in
scientific
praxis:
reduction-
ism

about how the **world** of nature is constituted and operates in fact—as contrasted with all of those alternative states of affairs that are clearly intelligible and so possible but which turn out not to be true of the actual world. Seen from this Realist standpoint, every proposition in science, from the most particular observational report to the most general theoretical principle, simply reports a more or less comprehensive empirical set of facts about nature and **aspires** to be an accurate, objective mirror of the more or less universal facts about which it speaks.

At the opposite extreme, there is a strict conventionalist position, which underscores the constructive role of the scientist's own theory articulation and emphasizes the logical necessity that is thereby built into the resulting conceptual structure. In this view, all but the most purely observational statements in science reflect the patterns by which the scientist shapes his conceptual picture of the world of nature—the patterns in terms of which all states of affairs clearly conceivable on the basis of current ideas have necessarily to be formulated. Seen from this conventionalist standpoint, theoretical thermodynamics, say, determines the character of all possible worlds consistent with the principles of energy conservation and entropy (or randomness) increase: a world to which thermodynamics is not applicable will then be not so much factually false as inconceivable in present terms.

Finally, a wide range of intermediate views seeks to evade the central opposition between Realists and conventionalists. One representative view of this kind, first made popular by Mach toward the end of the 19th century, invoked Kant's attack on things-in-themselves, viewing the attack as providing grounds for dismissing all debates about reality and objectivity as inescapably barren and empty. In its most developed form, this so-called operationalist position encourages the philosopher to regard theoretical propositions in science as meaningful only insofar as scientific practice includes specific **operations**—either manual measuring operations, or computational pencil-and-paper operations—in terms of which those propositions are given operational meaning. Nothing is then to be read into scientific knowledge beyond its operational meaning; in particular, scientists are not to be understood as claiming or disclaiming anything about the reality or conventionality of the states of affairs that they report. The idea of nature as a thing-in-itself is thus eliminated, as being an intellectual superstition and an obstacle to better scientific understanding, which survives from an earlier metaphysical era.

The primary discussions of the ontological implications of scientific theory are in the articles **METAPHYSICS** and **NATURE, PHILOSOPHY OF**. It is, nonetheless, appropriate here to distinguish the three main views. The central question is, now, whether the nouns and noun phrases used as technical terms in the theoretical propositions of science rely for meaning on any claim that they refer to objective, external entities; and current approaches to this question parallel existing views about the epistemological issues, viz., whether the propositions themselves rely for their truth on a claim to be mirroring or reporting objective, external facts. Here, too, the Realist interprets all of the chief technical terms of scientific theory as the names of objective entities existing in nature independently of all human theories and interpretations. In this view, entropy, say—a measure of the increase in randomness that every total system undergoes—is a genuine, objective magnitude that has, at all times, played a crucial part in the operations of nature even though physicists have only recently had the wit to discover it; and it just happens, correspondingly, to be the case—in those parts of the cosmos that can be observed—that the total entropy of an isolated system nowhere decreases.

The instrumentalist, for his part, regards all theoretical notions such as entropy as intellectual fictions or artifacts created by the scientist's own theory construction and quite distinct from the natural world of objects, systems, and phenomena that scientific theories have to explain. No doubt, **scientific** theory and the external reality of nature do come into contact on the everyday or empirical level of tables and chairs, rocks and flowers. Given the

intellectual tasks of scientific theorizing, however, the resulting concepts are essentially abstract; and any grasping after real entities, as the objective external reference of the theoretical terms, reflects a plain misunderstanding of this theoretical enterprise.

Meanwhile, the phenomenalist repeats, in the case of the technical terms of science, the same agnostic criticism as that offered by the operationalist in the case of its theoretical propositions. In this view, it is simply a meaningless waste of time for scientists to debate the existence of enduring theoretical entities, regarded as external, objective things-in-themselves; just as it is similarly wasteful for them to interpret scientific theories as making, or denying, similar claims about the existence of objective, external states of affairs. Instead, the terms and concepts of science are all to be understood as the product of so many logical, or semantic, operations or constructions, and questions about their real existence are to be swept aside as damaging metaphysical superstitions.

Philosophical analysis and scientific practice. The arguments about these rival ontological and epistemological views cannot be safely left or judged without first looking more closely at the complex relationship between the general analytical interests of philosophers and the more specific intellectual concerns of working scientists themselves. For the degree to which each view about the reality of scientific entities and facts can carry conviction depends substantially on what branches of science are at issue. As the focus of philosophical attention has shifted historically from one scientific terrain to another, so, too, have the relative degrees of plausibility of these rival positions varied.

Since the 1920s, for instance, there has been a marked revival of philosophical discussion among scientists working in several specialized fields—particularly, among physicists concerned with the structure and development of quantum mechanics. In epistemic terms, the statistical character of quantum-mechanical explanations has prompted some fundamental questions about the status and limitations of human knowledge. Clearly, the extent and accuracy of human knowledge about nature are limited by the modes of operation of scientific instruments. Is it not also possible, however, that the significance of this statistical character lies at a deeper level? Perhaps the relevant objective relationships and states of affairs in nature itself are governed intrinsically by a merely probabilistic causality and so are essentially indeterminate. Or is there a point to be reached on the **micro**-physical level at which any such distinction between subjective human knowledge and the objective state of **affairs** has finally broken down? The ontal implications of quantum mechanics have been as puzzling as the **epistemic**. Is an electron, say, a discrete particle that just happens to elude man's exact observation; is it an essentially blurred wave bundle having no precise dynamical characteristics; is it a concentration of probability, a mere theoretical symbol, or what? Or must one set all these ontological questions aside as lacking any significance for physics and as standing in the way of the physicist's proper task, that of extending the direct explanatory power of quantum-mechanical explanation itself? (See **NATURE, PHILOSOPHY OF**. Also because these questions have played a significant part not merely in the philosophy of science but also in theoretical physics itself, they **are** discussed from the scientific standpoint in such articles as **MECHANICS, QUANTUM**; **ELECTRON**; **CONSERVATION LAWS AND SYMMETRY**; and **RELATIVITY**.)

Elsewhere, the philosophical debate about science has taken on other specific forms. Just as in Aristotle's natural philosophy the metaphysical controversy about Ideas and essences was reflected in Aristotle's own methodological approach to biology and to the study of the natural relations and classification of organisms, so once again 20th-century reappraisals of traditional taxonomy—in the light of evolution theory, genetics, and population dynamics—have been an occasion for renewed philosophical debate. As a result, earlier disagreements about natural and artificial classifications have been reformulated and have generated a new dispute, about the possibility

Quantum mechanics; taxonomy; perception

Ontal aspects

of basing taxonomy on a mathematical science of **phenetics**—in which the defining properties of different species, genera, etc. are all given quantitative numbers or measures—and so harnessing the technical resources of modern computers to its purposes.

Similarly, in the psychology of perception and related fields, the extension of understanding in recent years at last has permitted the framing of authentically empirical questions about perception and cognition, which lend themselves to direct investigation instead of being restricted to general *a priori* speculations. The result has been a theoretical debate, the final outcome of which will have profound effects on both philosophical epistemology and natural science. In areas of this debate where even Mach was content to pose entirely general questions, in the philosophical tradition of David Hume, about the role of sense impressions as the raw material of all cognition and perception whatsoever, it is now clear that many preliminary differences and complexities must be unravelled before one can hope to recognize the truly operative questions in this field. Far from all modes of knowledge and perception conforming to a single common pattern, man's sensory and practical dealings with the world call into play a variety of perceptual systems of which the operations justify no simple epistemological formula about impressions and ideas, sense-data and logical constructions, or intuitions and schemata. Thus, at the present time, the investigations of some physiologists, psychologists, and cyberneticists are bringing man's sensory and cognitive activities within the scope of natural science while at the same time preserving a feeling for the more general philosophical problems and insights of such philosophers as Locke and Leibniz, Hume and Kant, Helmholtz and Mach.

At this point, the alliance between science and philosophy is simply carrying over into fields of science that are areas of methodological perplexity today the same interactions that were fruitful in earlier centuries within sciences having methods by now well understood. These interactions are unlikely to vindicate finally any one of the rival positions in the philosophy of science, whether ontological (Realist, instrumentalist, or phenomenalist) or epistemological (Realist, conventionalist, or operationalist). Probably such a vindication was, in any event, too much to expect. For in all the different special sciences—both natural and social—historical development eventually brings the investigator to a point at which he is ready to operate with a variety of technical terms or entities having very different logical characters and functions and at which his most general theoretical propositions or principles display corresponding differences in their logical status and implications.

So long as philosophical discussion is confined within the limits of an artificial, ideal language or propositional system, it is possible, perhaps, to continue posing purely abstract, general dilemmas about, say, theoretical entities or confirmation theory. But the bearing of such formal dilemmas on the actual content of contemporary scientific thought is becoming increasingly unclear. In debating the ontal status of theoretical entities, for instance, the question must at some stage be faced whether that phrase is intended to cover such notions as gene or pi-meson, species or cold front, momentum or superego, social class or economic market. (Certainly, not all of these terms have identical characters and functions.) In debating the epistemic status of scientific theories, likewise, it must be made clear whether one has in mind, say, the mathematical schema of quantum-mechanical field theory, the populational analysis of natural selection, the microstructures and mechanisms of molecular biology, the developmental sequences of cognitive psychology, the labour theory of economic value, the general regularities of terrestrial meteorology, or what. (Once again, not all of these theories have identical kinds of status or implications.)

Philosophical doctrines and approaches that carry great conviction when applied to the theories and ideas of one science may—not surprisingly—lose all of their plausibility when extended to other fields. Thus, an Empiricist

analysis may apply quite straightforwardly to meteorology, yet entirely misrepresent the structure and implications of electromagnetic theory; while, in return, a Neo-Kantian account of theoretical physics may lack any direct relevance, say, to ideas about animal behaviour. Today as in classical Athens, analytical clarification in the philosophy of science goes, in this respect, hand in hand with methodological refinements in the sciences themselves. In retrospect, the methodological insights of Aristotle the marine biologist and of Plato the theoretical astrophysicist can be seen to have been complementary, rather than incompatible. Similarly, today, the philosopher must look at rival positions in the philosophy of science not merely as contradictory answers to technical questions within philosophy itself but equally as complementary contributions to the methodological improvement of theoretical understanding over the whole varied range of different scientific fields.

INTERRELATIONSHIPS OF SCIENCE AND CULTURE

This survey has been concerned, almost exclusively, with philosophical problems and arguments about the sciences regarded as sources of theoretical knowledge. In pitting Realism against instrumentalism, mechanistic ideas against organicist ones, divine knowledge against human fallibility, or Platonic Ideas against Aristotelian essences, the philosopher is in each case concerned with the intellectual status, implications, and validity of certain general scientific concepts, methods, or entities. To confine oneself entirely to these intellectual aspects, however, would mean accepting a total abstraction of theory from practice and of scientific ideas from their behavioral expression. Thus, along with the present-day shift of emphasis from the physical to the human and social sciences, one finds that all such abstract approaches are coming once again under criticism, as over-intellectualizing the nature and implications of science.

Some of these attacks come from the neo-Marxist direction and reflect a traditional Marxian insistence on the unity of theory and action. (It was not for nothing that Lenin picked on Ernst Mach as a special target for scorn.) Analogous criticisms, however, are also coming from men with very different intellectual loyalties—e.g., from the urban sociologist Lewis Mumford and from many contemporary Existentialists. In conclusion, therefore, a concise discussion is here given of some of the views about the relations between science and the rest of culture; i.e., about the relevance of scientific knowledge to other spheres of experience and concern and, conversely, about the significance of broader, practical considerations for man's understanding of scientific theory itself.

The variety of these views has always been very great. Their exponents have ranged all the way from those who, like the energeticist Wilhelm Ostwald and the evolutionist Julian Huxley—both of whom rooted ethics in nature—present scientific ideas and procedures as rational panaceas for intellectual and practical problems of all kinds to those who, like Pierre Duhem and Carl von Weizsacker, physicist and philosopher of nature, both of whom are theists, deliberately limit the claims of science so as to preserve a freedom of manoeuvre for ethics, for example, or theology. At each stage, most advocates of extreme claims for science have been ontological Realists; and, in strengthening their ontal and epistemic claims, they have also staked a claim to overriding intellectual priority on behalf of scientific knowledge, in contrast to other forms of experience. Similarly, those who would restrict the broader cultural claims of science have tended to be phenomenalist; and, in weakening their philosophical claims, they have also attempted to limit the authority of science to its own intellectual concerns as narrowly defined.

Whatever one's general philosophical position with respect to the reality of scientific knowledge and entities may be, however, there are other more practical questions to be faced, questions about the specific implications of different scientific ideas and beliefs for parallel fields of human action and experience. On this point, one particular theme unites a wide range of radical critics of science,

Turn to
broader
human
concerns

Science,
tech-
nology,
and ethical
values

Pluralism
and
comple-
mentarity

including both Lewis Mumford, U.S. social critic, and the Existentialists. Just as the Christian Dane Søren Kierkegaard, an early and seminal figure of Existentialism, condemned Kant's universalized system of ethics for ignoring the individuality of actual ethical problems and decisions, so today there is a widespread reaction against any tendency to treat social or practical decisions as technical matters, which can be left to the judgment of scientific or technological experts. The general methods of technology may, indeed, represent practical applications of the theoretical understanding arrived at by science; but all individual decisions about putting those general techniques to use—e.g., in constructing an airport or power station—must be made not by appealing to any general formula or rule of thumb but by balancing a whole range of diverse considerations—economic and aesthetic, environmental and human, as well as merely technical.

According to another contemporary critique, the theoretical points of view adopted in natural science are general and abstract, but the practical demands of sociopolitical action and, a fortiori, of individual action, are concrete and particular; and, by itself, this contrast places an immediate restriction on the existential relevance of scientific ideas and engineering techniques. Such scholars as Thomas Huxley, a versatile scientist and defender of evolution, or Wilhelm Ostwald, a pioneer in electrochemistry, who viewed reality as essentially energy, might argue in general, abstract terms for interpreting ethical principles in evolutionary or thermodynamical terms if they pleased (so the critics continue); but such abstract speculative arguments have no bearing on the actual tasks of ethical decision and action. Here again, every ethical choice involves a unique constellation of considerations and demands; and this problem cannot be dealt with by appealing to any universal rule but must be appraised on an individual basis, as and when it arises.

Others take a more positive approach toward the contribution of science to an understanding of human values. Without necessarily claiming to transform ethics itself into a "science," they at any rate argue that the personal attitudes needed for effective work in science—adventurous skepticism and critical open-mindedness—have a wider relevance also to human conduct and social affairs. Supposing only that social and political discussion were conducted in this same tentative and critical spirit (they claim), its typical and deplorable passion and confusion could be replaced by the more rational consideration of the means required in order to achieve explicitly stated ends. While specific scientific ideas and doctrines may not be enough to direct social and political action by themselves, the scientific attitude may, nonetheless, have a profound significance for social policy and individual ethics alike.

This contrast, between existentially minded critics of the claim that science is all-embracing and socially minded believers in the scientific attitude, may be epitomized by referring to contemporary discussions about the social significance of science itself. On the one hand, there has recently been a revival of explicitly anti-scientific views, which had been more or less dormant since the time of Blake, Johann Wolfgang von Goethe, and their successors in the Romantic movement. Supporters of this anti-science position point to the central role of military technology in the financial support of 20th-century scientific research and dismiss the average scientist's plea that he is not responsible for the uses to which his ethically neutral discoveries are put, as pallid and insincere. On the contrary (they argue), there is a long-standing and unholy alliance linking the collective institutions of the scientific and technological professions to the economic, industrial, and political powers that be. Faced with the fruits of this historical union (they conclude), it is time that scientists acknowledged their social responsibilities; and, failing better institutional controls, the outcome of this moral self-scrutiny may well prove to be a moratorium on further scientific research. Perhaps man already knows too much for his own good and needs to digest the significance of his existing stock of knowledge

much further before adding to it and so widening yet again the gulf between theoretical knowledge and practical wisdom.

On the other hand, there are those who recognize science as playing a crucial role in modern society, but who go on to draw the opposite conclusion. Rather than putting a stop to science (these men would argue), its scope should be broadened; that is, scholars should be studying and understanding better the manner in which science serves as an element in the larger social order—perhaps by developing more adequate analyses of the social structure or perhaps by a large-scale extension of the methods of operations research. Aside from anything else (they point out), a moratorium on science is as impracticable as a moratorium on sin. It could be enforced only if political unanimity prevailed to an unimaginable degree among scientists. In the absence of such enforcement, liberal-minded countries will merely put themselves at a needless disadvantage—both economic and military—as compared with totalitarian states. Instead of pursuing this will-o'-the-wisp, scholars should put more effort into the task of understanding both the social preconditions of effective scientific development and the economic and political priorities involved in the practical application of scientific research.

As compared with the controversies of earlier centuries, the debate between science and religion is curiously muted today. There seems little room nowadays for the theological passions that engulfed the discussion of Copernicus' new planetary theory, James Hutton's history of the Earth, or Darwin's theory of natural selection; and one would hesitate to speak any longer, as so many of our forefathers did, of warfare between science and religion as unavoidable. It is true that a few partisan writers can still find it a perplexing problem to decide such issues as whether the existence of life on other worlds would require a re-enactment there of the Christian fall and redemption or can insist—conversely—that the results of astronomical exploration refute any religious belief that God is an Old Man up in the sky. For most people, however, such questions have so far lost their earlier bite that they appear, by now, quite naïve.

What is the reason for this change? In earlier times, the term cosmology embraced not only the structure of the astronomical cosmos and the origins of the human species but also the religious significance of man's place in nature. Contemporary theologians, by contrast, see physics and biology as having much less bearing on man's religious attitudes and preoccupations than their predecessors had supposed that they had. As a result, men's earlier ambition to construct a single, comprehensive world view, embracing the essential truths of both science and religion, no longer plays the active part in intellectual life that it formerly did. The only branches of science still capable of provoking vigorous theological debate, even now, are the human, rather than the natural sciences. The implications of Freudian psychology for the doctrine of grace and the use of psychedelic drugs for inducing quasi-mystical experiences are topics for live discussion today, in a way that evolution, astrophysics, and historical geology no longer are.

This change of focus has been accompanied by a change in ideas about the intrinsic limits of science. It was formerly assumed that the boundaries between science and other aspects of human experience could be defined by marking off certain types of subject matter as essentially closed to scientific investigation. To one generation, the heart of this forbidden territory was the mind; to another, it was life; to a third, the creation. In this view, something in the essential nature of mental or vital activities, or in the origins of the present order of nature, made it impossible to treat these as phenomena open to study and explanation by the rational methods and intellectual procedures available to science. In fact, this view always had defects, from both the scientific and the theological points of view. To scientists, it seemed to impose an arbitrary restriction on their sphere of operations and so acted as a standing challenge and irritation. For theologians, it had the disadvantage of placing the essential claims of reli-

Science
and
religion

Limitations
of
science

Social
signifi-
cance of
science

gion, so to speak, on a sandbank, where they risked being submerged in time by the rising tide of scientific knowledge. So, by tacit consent, the essential limits of science are now defined in quite different terms. These limits are now identified by recognizing that the character of scientific procedures themselves places restrictions on the relevance of their results. A scholar may choose to study whatever objects, systems, or processes he may please, but only certain of the questions that he asks about them will be answerable in the general, theoretical terms characteristic of science.

This change of approach may not have made the substantive problem—that of delimiting the frontiers of science exactly at all points—very much easier to deal with than it was before, but it has one genuine merit: it respects the crucial fact, to which attention has been drawn at several points in this present survey, that the distinctive features of science lie not in the types of object and event to which the scientist has access but in the intellectual procedures that his investigations employ and so in the kinds of problem that lend themselves to a scientific solution.

BIBLIOGRAPHY. ERNEST NAGEL, *The Structure of Science* (1961); and M.W. WARTOFSKY, *Conceptual Foundations of Scientific Thought* (1968), together cover the main approaches to the philosophy of science as a general field of study; whereas ARTHUR DANTO and SIDNEY MORGENSEN (eds.), *Philosophy of Science* (1962), provides a useful anthology of classic papers on the subject; and SAMUEL B. RAPPOPORT and HELEN WRIGHT (eds.), *Science: Method and Meaning* (1964), is a stimulating anthology of nontechnical papers.

The origins and development of natural science and the attitudes of philosophers toward scientific explanation in antiquity and the Middle Ages are well treated in SAMUEL SAMBORSKY, *The Physical World of the Greeks*, 2nd ed. (1962; orig. pub. in Hebrew, 1954); and *The Physical World of Late Antiquity* (1962); JOHN H. RANDALL, JR., *Aristotle* (1960); and in ALISTAIR C. CROMBIE, *Medieval and Early Modern Science*, 2nd ed., 2 vol. (1963). For the 17th and 18th centuries, see EDWIN A. BURTT, *The Metaphysical Foundations of Modern Physical Science*, 2nd ed. (1932); ALEXANDRE KOYRE, *Newtonian Studies* (1965); HERBERT BUTTERFIELD, *The Origins of Modern Science: 1300–1800*, rev. ed. (1965); I. BERNARD COHEN, *Franklin and Newton* (1956); and GOTTFRIED MARTIN, *Immanuel Kant: Ontologie und Wissenschaftstheorie* (1951; Eng. trans., *Kant's Metaphysics and Theory of Science*, 1955). For the 19th century, the most significant contributions have come from scientists writing as philosophers: CLAUDE BERNARD, *Introduction à l'étude de la médecine expérimentale* (1865; Eng. trans., *An Introduction to the Study of Experimental Medicine*, 1927, reprinted 1961); HERMANN VON HELMHOLTZ, *Popular Scientific Lectures* (1962; reprint of a selection of lectures from *Popular Lectures on Scientific Subjects*, 1st and 2nd series, 1881); T.H. HUXLEY, *Science and Culture, and Other Essays* (1882); and WILLIAM WHEWELL, *The Philosophy of the Inductive Sciences, Founded upon Their History*, 2nd ed. (1847, reprinted 1966).

The background to the 20th-century debate in the philosophy of science, as it developed between 1890 and 1920, can be reconstructed from ERNST MACH, *Die Mechanik in ihrer Entwicklung historisch-kritisch dargestellt*, 9th ed. (1933; Eng. trans., *The Science of Mechanics*, 1960); and *Die Analyse der Empfindungen und das Verhältnis des Physischen zum Psychischen*, 5th ed. (1906; Eng. trans., *The Analysis of Sensations and the Relation of the Physical to the Psychical*, 1959); KARL PEARSON, *The Grammar of Science*, 3rd ed. (1960); PIERRE DUHET, *La Théorie physique: son objet et sa structure* (1906; Eng. trans., *The Aim and Structure of Physical Theory*, 1954); HENRI POINCARÉ, *La Science et l'hypothèse* (1903; Eng. trans., *Science and Hypothesis*, 1905); and HEINRICH HERTZ, *Die Prinzipien der Mechanik* (1895; Eng. trans., *The Principles of Mechanics*, 1889, reprinted 1956), especially the Introduction. The subsequent course of the debate, between 1920 and 1960, is illustrated in CARL G. HEMPEL, *Aspects of Scientific Explanation, and Other Essays in the Philosophy of Science* (1965); RUDOLF CARNAP, *Logical Foundations of Probability*, 2nd ed. (1962); KARL R. POPPER, *Logik der Forschung* (1935; 2nd ed., 1966; Eng. trans., *The Logic of Scientific Discovery*, 1959); ROBIN G. COLLINGWOOD, *An Essay on Metaphysics* (1940); NORMAN R. CAMPBELL, *What Is Science?* (1921); and WILLIAM H. WATSON, *On Understanding Physics* (1959). Two significant side-views of the debate from very different formal standpoints may be found in WILLIAM V.

QUINE, *From a Logical Point of View*, 2nd ed. rev. (1961); and RONALD A. FISHER, *Statistical Methods for Research Workers*, 14th ed. (1970). PETER ACHINSTEIN and STEPHEN F. BARKER (eds.), *The Legacy of Logical Positivism* (1969), is a first attempt at an historical appraisal of the period.

The current debates about conceptual change and the rationale of discovery in science are central topics in KARL R. POPPER, *Conjectures and Refutations*, 2nd rev. ed. (1965); NORWOOD R. HANSON, *Patterns of Discovery* (1958); STEPHEN TOULMIN, *Human Understanding*, vol. 1 (1972); THOMAS S. KUHN, *The Structure of Scientific Revolutions*, 2nd ed. rev. (1970); IMRE LAKATOS and ALAN MUSGRAVE, *Criticism and the Growth of Knowledge* (1970); and MICHAEL POLANYI, *Personal Knowledge* (1958). For broader cultural aspects of the contemporary debate about science, see C.H. WADDINGTON, *The Scientific Attitude*, new ed. (1968); JACOB BRONOWSKI, *Science and Human Values*, rev. ed. (1965); THEODORE ROSZAK, *The Making of a Counter Culture* (1969); and LEWIS MUMFORD, *The Myth of the Machine* (1967).

(S.E.T.)

Scipio Aemilianus

Publius Cornelius Scipio Aemilianus—surnamed Africanus (the Younger) and Numantinus, by adoption the grandson of Scipio Africanus (q.v.) who ended the Second Punic War by his defeat of Hannibal—was famed for ending the Third Punic War (149–146 BC) by his destruction of Carthage and for his interest in the cultural developments of his day.

Background and early life. Scipio was born in 185 or 184 BC, the second son of Lucius Aemilius Paullus, son of the consul who fell at the Battle of Cannae in 216. Paullus himself was an outstanding Roman leader who combined traditional Roman virtues with a keen interest in Greek culture. Paullus was twice consul (182 and 168) and was censor in 164; he brought the Third Macedonian War to a conclusion by his victory at Pydna (168). Soon after Scipio's birth, Paullus divorced his wife Papiria and remarried (the name of the new wife is not known); he had two sons by the later marriage, but both these half brothers of Scipio died in 167. It was probably after the father's remarriage that Scipio and his elder brother, Quintus Fabius Maximus Aemilianus, were adopted into other families. While the elder brother was adopted by a grandson, or possibly a son, of Quintus Fabius Maximus Cunctator, the famous general of the Second Punic War, Scipio himself was adopted by Publius Scipio, the son of the elder Scipio Africanus, whose ill health prevented him from following a public career. Thus Scipio succeeded to the family tradition of two of Rome's greatest generals—the conqueror of Hannibal and the conqueror of Perseus of Macedonia.

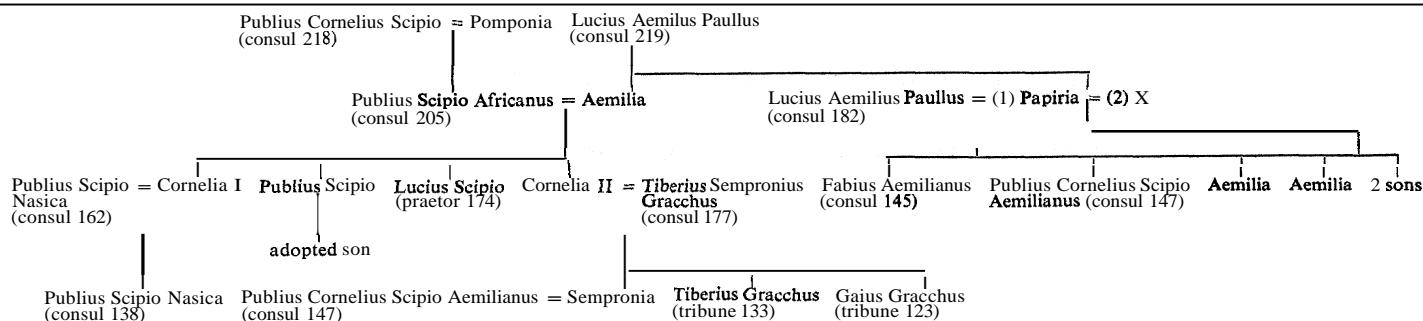

The ramifications of Scipio's family are somewhat complicated (see illustration) but important, since family ties were very strong in Roman society, while links with other families, by either marriage or adoption, provided a Roman noble with extended political influence. Scipio's adoptive father was, in fact, also his cousin by blood. This came about because Africanus' wife Aemilia was a sister of Aemilius Paullus' father; she was thus Scipio's aunt by blood (as well as being his grandmother by adoption). Africanus had two daughters (as well as his son Publius Scipio), who were also Scipio's blood cousins and adopted aunts; the elder of these Corneliae married Publius Cornelius Scipio Nasica Corculum (consul in 162 and 155); the younger married Tiberius Sempronius Gracchus (consul 177 and 163) and became the mother of the two Gracchi, Tiberius and Gaius (tribunes in 133 and 123, respectively), and of a Sempronia. This tightly knit group was linked still closer when Scipio himself married Sempronia. One final connection must be mentioned: Aemilius Paullus, Scipio's natural father, also had two daughters, one of whom married Cato the Censor's son, Marcus Porcius Cato; the other married Quintus Aelius Tubero. Thus Scipio's contacts were extremely wide.

Scipio's upbringing is described in a passage of Plutarch's biography of his father Aemilius Paullus, who

brought up his sons in accordance with the traditional native type of education, as he himself had been brought up, but also, and more keenly, on the Greek pattern. For

Family
connection

The Family of Scipio Aemilianus

the young men were surrounded not only by Greek teachers, scholars, and rhetoricians, but also by Greek sculptors, painters, overseers of horses and hounds, and instructors in hunting.

This education, based on a combination of Greek and Roman culture, set the direction of Scipio's further interests. He was introduced to military life in 168, when he and his brother served under their father Paullus in the Third Macedonian War. At the decisive Battle of Pydna he followed up the routed enemy with such dash that he was reported missing and was feared killed. After the battle, his father put him in charge of the Macedonian royal game preserves in order to develop his strength and courage. Scipio thus acquired a permanent taste for hunting, and after his return to Rome he spent much time in that pursuit when other young nobles were devoting themselves to legal and social business. Another legacy from Macedonia was the permission he received from his father to take what books he liked from the Macedonian royal library. He also went with his father on a tour of Greece and, on his return to Rome, took part in his father's triumph (November 167), a period that was overshadowed for Paullus by the death of his two younger sons.

Friendship
with
Polybius

The most significant influence on Scipio's development occurred when he became friendly with the Greek historian Polybius, one of the thousand Achaean leaders who had been deported and detained without trial in Italy. Polybius records that their acquaintance originated "in the loan of some books and conversation about them." Friendship quickly followed, and Scipio and his brother persuaded the authorities to allow Polybius to remain in Rome, where he became a close friend and mentor of the two young men. Polybius tells how one day Scipio asked him why he seemed to neglect him and to speak to his elder brother: was it because Polybius shared the common opinion of Scipio as "quiet and lazy, far removed from the character and ways of a Roman, because he did not care for pleading cases in the law-courts?" Polybius promptly reassured the young man and promised to help him "speak and act in a manner worthy of his ancestors." From that moment a relationship like that of a father and son developed, and Scipio found a counsellor to help him overcome his innate diffidence. No doubt he was oppressed by the thought of the responsibility that he would have on becoming the head of the great house of the Scipios (it is uncertain when his adoptive father Publius Scipio died) as well as in representing the Aemilii. He was now determined to prove a worthy representative and to pursue the normal aims of a Roman noble: honour, glory, and military success. The ambition of a naturally quiet man was now kindled.

Polybius emphasized two aspects of Scipio's character, his personal morality and his generosity. Of the former, he tells how Scipio sought to excel all his contemporaries in his reputation for temperance at a time when morals were generally declining and young men were becoming increasingly corrupt, partly because they had "caught the dissoluteness of Greek customs" and partly because of the great influx of public and private wealth as a result of the Macedonian War; "in about five years Scipio secured a general recognition of his character for goodness and

purity!" Of Scipio's generosity Polybius cites several examples: he gave great wealth from the estate of Africanus to his divorced mother **Papiria** and to his sisters, the Aemiliae; to the two **Corneliae**, daughters of Africanus; and over 45 talents in all to his own brother Fabius. Polybius' comment is illuminating:

this would be thought honourable anywhere, but at Rome it was quite astonishing; for there no one ever thinks of giving any of his private property to any one if he can help it.

Polybius, however, does not draw attention to an element of cruelty in Scipio's character that is noticeable in several episodes of his life; it may generally have had a deterrent purpose and not been an unusual trait in the Roman character, but not every Roman general celebrated a victory by throwing deserters to the wild beasts.

Military and political achievements. Scipio's early political apathy was soon cast aside; by 152 he had probably been elected quaestor, the first rung of an official career, and had entered the Senate. But at the same time he was pursuing his cultural interests: he was among the young nobles who were attracted by the lectures of three visiting Athenian philosophers whose views on political morality shocked more old-fashioned Romans, such as Cato. Scipio achieved public acclaim in 151. A series of disasters to Roman armies in Spain resulted in such reluctance to undertake military service in the peninsula that, in a dispute over the levy, the consuls who were responsible for it were even temporarily imprisoned by the tribunes who opposed the levy. In the crisis, Scipio, who had been assigned to Macedonia, inspired confidence by volunteering to serve in Spain instead: his example was at once followed by other officers and men. Sewing as military tribune to Lucius **Lucullus**, Scipio displayed great personal courage in the Spanish campaigns; in 151 he killed a **Spanish** chieftain who had challenged him to single combat, and at Intercatia he won the mural crown (*corona muralis*), which was awarded to the first man to mount the walls of an enemy town. In 150 he was sent by Lucullus to Africa to obtain some elephants from the **Numidian** king Masinissa, the friend of his grandfather Africanus. While there he witnessed a great but indecisive battle between Masinissa and the Carthaginians: the latter then asked him to arrange a settlement, but in the event negotiations broke down. Scipio then left Africa, but he was soon to return not as a peacemaker but as a conqueror. When back in Rome, at Polybius' request, he managed to gain the somewhat grudging support of old Cato (whose son had married Scipio's sister Aemilia) for a proposal to release the 300 Achaean internees who still survived without trial. Thus a great blot on Rome's good name was at length partially removed.

Expedition
to Spain

In 150, war with Carthage was in the air: it was passionately advocated by Cato and opposed by Scipio Nasica. With both these men Scipio had family links: his own attitude is unknown, but his policy is likely to have approximated closer to Cato's than to Nasica's, though, in fact, he was probably too young to have taken any effective part in the senatorial debates. At any rate, when war came in the following year, he returned to Africa with the Roman army, serving again as military tribune, and his

service was very effective. The two consuls besieged Carthage by land and sea, but later in the year, after one had returned to Rome, the Carthaginians launched a night attack upon the camp of the isolated Manilius, a situation that was retrieved only by the skill of Scipio. During the winter Scipio again displayed conspicuous ability when Manilius led two unsuccessful expeditions against the Carthaginian forces in the interior. Again he came into the limelight when the aged Masinissa, on the point of death, asked that the grandson of his friend Africanus should arrange the future of his kingdom. Scipio decided to divide Numidia between the King's three sons and thereby avoided any danger that a united Numidia might have presented. As the war against Carthage dragged on without decisive result, Scipio resolved to return to Rome in 148 to stand for the curule aedileship, but such was his military record and the general disappointment with the conduct of the war that the Roman people wanted to see him in command. Since he was at least five years under the legal minimum age for the consulship and had not been praetor, his election as consul for 147 was remarkable. When a tribune, voicing the popular enthusiasm, threatened to veto the consular elections unless Scipio was accepted as a candidate, the Senate gave way and allowed the tribunes to introduce a bill to exempt Scipio from the legal restrictions: he was thus elected consul and given the African command. Once back in Africa, he determined to starve out Carthage with a blockade by land and sea: gradually the cordon was drawn tighter around the beleaguered city, and in the spring of 146 it fell to his final assault: after six days of street fighting the citadel was captured and Carthage was destroyed. As Scipio surveyed the burning city and meditated on the fall of great nations, he wept and, grasping the hand of Polybius (the historian himself records the incident), said: "it is glorious, but I have a dread foreboding that some time the same doom will be pronounced upon my own country." After arranging for the organization of Carthaginian territory as the new Roman province of Africa, Scipio returned to Rome for a triumph and to be hailed as the second Africanus.

Thus before the age of 40, Scipio had gained Rome's final victory over Carthage and had become a popular hero, but he still had many opponents in the Senate. He soon reached the crown of a noble's career by his election to the censorship of 142, though the other censor Lucius Mummius, who had brought peace to Greece by his sack of Corinth, was not a welcome colleague. Scipio carried out his censorial duties with sternness, in the spirit of the censorship of Cato, who had lived just long enough to express approval of Scipio's African command. In general he aimed at a return to the *mos majorum*, the traditional habits of Roman life, in face of declining moral standards. In 140 he headed a tour of inspection to Egypt and the East, taking as a companion the philosopher Panaetius. During this period many of his political opponents (*inimici*) reached high office. In 137 he gained popularity, though not in the Senate, when he supported a measure to establish the secret ballot in most trials before the people (two years earlier the secret ballot had been introduced for elections).

The background of the next phase of Scipio's life was again Spain, where for years Rome had been engaged in war with the Celtiberians and had suffered a series of defeats and humiliating setbacks. One such scandal concerned the Senate's repudiation of a truce arranged by the commander Gaius Hostilius Mancinus and his young quaestor Tiberius Gracchus, which had saved a Roman army from destruction. The story cannot be repeated here, but, while Mancinus was shamefully condemned for his conduct, Gracchus was spared, thanks to his popularity at Rome for having rescued a trapped army. Scipio helped in Gracchus' escape, possibly because of their family relationship: Gracchus was his cousin and also his brother-in-law, though in fact Scipio's marriage to Sempronius had been a private failure. Scipio also urged the adoption of a more effective policy in Spain. This led to his own election to a second consulship for 134 and the command of the Celtiberian war; special legislation was

needed, because a second consulship was unconstitutional. Scipio took with him to Spain a number of volunteers and a corps of 500 friends and dependents as a kind of bodyguard (an embryonic praetorian cohort): these were perhaps all the more necessary because his first task was to rediscipline the Roman troops in Spain, who were in a shocking state. His main objective was to reduce the Celtiberian capital, the hill town of Numantia, which could not be stormed but had to be blockaded and starved out. Around the town he built seven camps, linked by a strong wall (traces of these works still survive), and, with overwhelming forces after an eight month siege, he finally forced the 4,000 besieged to capitulate (133). The town was burned. Thus Rome's dominion in Spain was established beyond question, and Scipio returned to Rome for a second triumph in 132.

In the meanwhile, Rome had been shaken by a constitutional crisis. The tribune Tiberius Gracchus introduced a bill for the distribution of public lands among the poor of the city. His disregard of constitutional procedure and custom in forcing his bill through had provoked the Senate to use force to crush him and his supporters and thus initiated a period of increasing political upheaval and revolution (133). Absent in Spain during the crisis, Scipio was spared the necessity for actively taking sides. In view of his friend Laelius' earlier attempted land law, it may be conjectured that he would not have opposed the bill as such. But surely he did not approve of Tiberius' methods; when forced to give a public opinion he quoted Homer's line, "So perish all who do the like again," and he admitted that Tiberius "had been killed justly." By his anti-Gracchan attitude Scipio lost much popularity, the more so when he helped to defeat a bill to legalize re-election to the tribunate. He then took up the cause of the Italian allies of Rome, who were discontented with the effects of Gracchus' land bill; he took some action to modify its working, at least as far as it concerned the allies. Then suddenly one morning, when he was due to make a speech on the Italian question, he was found dead in his bedroom (129 BC). His death remained an unsolved mystery. Various eminent people were suspected at the time or later (e.g., Gaius Gracchus or even Sempronius or Cornelia), but murder is not likely: suicide is possible, but a natural death is more probable.

Assessment. As a soldier Scipio contributed much to the maintenance and extension of Rome's power in the world. For some 20 years he was an outstanding figure, but he had many political enemies and his leadership was seldom unchallenged. His political aims and ideals have been variously assessed. Stern, upright, and conservative, he sought to maintain Rome's traditional virtues, which he felt were being undermined. But, though a traditionalist in regard to standards of public and private morality, he was a man of culture who gathered around himself a so-called Scipionic circle. This, though not a compact and permanent group, included friends such as Laelius and Polybius. They had close contacts in early days with the poet Terence and later with the satirist Lucilius and the Stoic philosopher Panaetius. Thus Scipio through his patronage exerted much influence on the development of Latin literature and also upon the blending of Greek and Roman thought, not least in the adapting of Stoic ideas to Roman needs. To many later Romans, especially to Cicero, he appeared as an ideal statesman, personifying the golden days of the republic provided by the balance of a mixed constitution and by aristocratic moderation.

BIBLIOGRAPHY. The main ancient sources for Scipio Aemilianus are POLYBIUS xxxi-xxxix, APPIAN, *Punica* 98ff., and *Hispanica* 84ff. For fragments of Scipio's speeches, see H. MALCOVATI, *Oratorum Romanorum Fragmenta*, 2nd ed. (1955). The standard work is A.E. ASTIN, *Scipio Aemilianus* (1967). See also for Scipio's politics, H.H. SCULLARD, "Scipio Aemilianus and Roman Politics," *Journal of Roman Studies*, 50:59-74 (1960).

(H.H.S.)

Scipio Africanus

Publius Cornelius Scipio, surnamed Africanus (the Elder), was one of the outstanding figures in the history of

Political crisis

Destruction of Carthage

the Roman Republic: his greatest achievement was the defeat of Hannibal, by which he brought the Second Punic War to a successful conclusion.

Silver coin from New Carthage, believed to be a portrait of Scipio. In the Royal Collection of Coins and Medals, National Museum, Copenhagen.

Family
back-
ground

Publius Scipio was born in 236 BC into one of the great patrician families in Rome; his father, grandfather, and great-grandfather had all been consuls in their day. In 218 BC Scipio's father, also named Publius, held the consulship in one of the most critical years of Rome's history: the city's very existence was threatened by Hannibal's coming invasion. The father was sent to southern Gaul to prevent Hannibal's advance into Italy but arrived too late; he then doubled back to Italy, sending his army on to Spain under his brother Gnaeus in order to cut off Hannibal from the Carthaginian forces that were still there. Back in northern Italy with a fresh army, he tried to hold up Hannibal by using the tributaries of the River Po to fight delaying actions. At the first of these, a cavalry engagement on the Ticinus, his son made his first appearance in history: young Scipio, seeing his father wounded and cut off by the enemy, charged forward and saved him. This anecdote is recorded by the historian Polybius on the authority of Scipio's friend Laelius, and it may well be true. Of Scipio's mother, Pomponia, little is known beyond a story that when Publius and his younger brother Lucius were standing for the aedileship (a city magistracy), she visited temples and sacrificed to the gods for their success; this may have been no more than normal practice (though if so, it would perhaps have been hardly worth recording), but it could suggest that she was an unusually pious woman from whom her son Publius inherited a religious outlook such as some ancient authorities attribute to him.

Of Scipio's birth something is said below, but of his boyhood or the date of his marriage to Aemilia, daughter of Aemilius Paullus, consul of 216 who fell at Cannae, nothing is known. He had two sons: Publius, who was debarred by ill health from a public career and who adopted Scipio Aemilianus; and Lucius, who became praetor in 174. More famous than the sons was one of the daughters, namely, Cornelia, who became a lady of great culture and the mother of the Gracchi. Scipio's physical appearance is shown on some coins minted at New Carthage—which almost certainly bear his portrait—and also probably on a signet ring found near Naples.

Military and political achievements. Such was the impact that Scipio made upon the Romans that even during his lifetime legends began to cluster around him: he was regarded as favoured by Fortune or even divinely inspired. Not only did many believe that he had received a promise of help from Neptune in a dream on the night before his assault on New Carthage (see below) but that he also had a close connection with Jupiter. He used to visit Jupiter's temple on the Capitol at night in order to commune with the god, while later the story circulated

that he was even a son of the god who had appeared in his mother's bed in the form of a snake. Although stories of the latter kind must be dismissed, his link with Jupiter seems authentic, and at some time (probably after his death) his portrait bust was placed in the Capitoline Temple (such *imagines* were usually kept by Roman nobles on display in their private houses). The historian Polybius thought that this popular view of Scipio was mistaken and argued that Scipio always acted only as the result of reasoned foresight and worked on men's superstitions in a calculating manner. But Polybius himself was a rationalist and has probably underestimated a streak of religious confidence, if not of mysticism, in Scipio's character that impressed so many of his contemporaries with its magnanimity and generosity. Thus, although Polybius had an intense admiration for Scipio, whom he called "almost the most famous man of all time," the existence of the legend, a unique phenomenon in Rome's history, indicates that Polybius' portrait is too one-sided.

Scipio served as a military tribune at the disastrous Battle of Cannae in 216. He escaped after the defeat to Canusium, where some 4,000 survivors rallied; there he boldly thwarted a plot of some fainthearts to desert Rome. Then in 213 he returned to a civilian career by winning the curule aedileship; the story is told that when the tribunes objected to his candidature because he was under the legal age he replied "If all the Roman people want to make me aedile, I am old enough." Soon family and national disaster followed: his father and uncle were defeated and killed in Spain, where the Carthaginians swept forward to the line of the Ebro (211). In 210 the Romans decided to send reinforcements to Spain, but it is said that no senior general would undertake the task and that young Scipio offered himself as a candidate; at any rate, the Roman people decided to invest him with a command there, although he was technically a *privatus* (not a magistrate). This grant by the people, to a man who had not been praetor or consul, of a military command outside Italy, created an important constitutional precedent. Thus Scipio was given the chance to avenge his father's death in Spain, where he hoped not merely to hold the Carthaginian armies at bay and prevent them sending reinforcements to Hannibal in Italy but to resume his father's offensive policy, to turn back the tide of war, and to drive the enemy out of the peninsula. Such a task must have seemed fantastic in 210, but Scipio had the confidence and ability: it was achieved in the next four years.

From his headquarters at Tarraco (Tarragona) in 209, Scipio suddenly launched a combined military and naval assault on the enemy's headquarters at New Carthage (Cartagena), knowing that all three enemy armies in Spain were at least ten days distant from the city. Helped by a lowering of the water in a lagoon, which exposed the northern wall, he successfully stormed the city. This tidal phenomenon, attributed to the help of Neptune, was perhaps caused by a sudden wind; at any rate it increased the troops' belief in their commander's divine support. In New Carthage he gained stores and supplies, Spanish hostages, the local silver mines, a splendid harbour, and a base for an advance farther south. After training his army in new tactics, he defeated the Carthaginian commander Hasdmbal Barca at Baecula (**Bailen**) in Baetica (208); whereas normally the two rear ranks of a Roman Army closely supported the front line, Scipio in this battle, under a screen of light troops, divided his main forces, which fell upon the enemy's flanks. When Hasdmbal broke away, ultimately to join his brother Hannibal in Italy, Scipio wisely declined the impossible task of trying to stop him and decided rather to accomplish his mission in Spain—the defeat of the other two Carthaginian armies still there. This he brilliantly achieved in 206 at the Battle of Ilipa (**Alcalá del Río**, near Seville), where he held the enemy's main forces while the wings outflanked them. He then secured Gades (**Cádiz**), thus making Roman control of Spain complete.

Elected consul for 205, Scipio boldly determined to disregard Hannibal in Italy and to strike at Africa. Having beaten down political opposition in the Senate, he crossed to Sicily with an army consisting partly of volunteers.

Victory
in Spain

Con-
nection
with
Jupiter

While preparing his troops, he boldly snatched Locri in the toe of Italy from Hannibal's grasp, though the subsequent misconduct of Pleminius, the man he left in command of the town, gave Scipio's political opponents cause to criticize him. In 204 he landed with perhaps 35,000 men in Africa, where he besieged Utica. Early in 203 he burned the camps of Hasdrubal (son of Gisco) and his Numidian ally Syphax. Then, sweeping down on the forces that the enemy was trying to muster at the Great Plains on the upper Bagradas (modern Sūq al Khamis, on the Majardah in Tunisia), he smashed that army by a double outflanking movement.

After his capture of Tunis, the Carthaginians sought peace terms, but Hannibal's subsequent return to Africa led to their renewing the war in 202. Scipio advanced southwestward to join the Numidian prince Masinissa, who was bringing his invaluable cavalry to his support. Then he turned eastward to face Hannibal at the Battle of Zama; his outflanking tactics failed against the master from whom he had learned them, but the issue was decided when the Roman and Numidian cavalry, having broken off their pursuit of the Punic horsemen, fell on the rear of Hannibal's army. Victory was complete, and the long war ended; Scipio granted comparatively lenient terms to Carthage. In honour of his victory he was named Africanus (see also PUNIC WARS).

In 199 Scipio was censor and became *princeps Senatus* (the titular head of the Senate). Though he vigorously supported a philhellenic policy, he argued during his second consulship (194) against a complete Roman evacuation of Greece after the ejection of Philip V of Macedonia, fearing that Antiochus III of Syria would invade it; his fear was premature but not unfounded. In 193 he served on an embassy to Africa and perhaps also to the East. After Antiochus had advanced into Greece and had been thrown out by a Roman army, Scipio's brother Lucius was given the command against him, Publius serving as his legate (190); together the brothers crossed to Asia, but Publius was too ill to take a personal part in Lucius' victory over Antiochus at Magnesia (for which Lucius took the name Asiagenus).

Meantime, in Rome, Scipio's political opponents, led by the elder Cato, launched a series of attacks on the Scipios and their friends. Lucius' command was not prolonged; the generous peace terms that Africanus proposed for Antiochus were harshly modified; the "trials of the Scipios" followed. On the trials the ancient evidence is confusing: in 187 an attack on Lucius for refusing to account for 500 talents received from Antiochus (as war indemnity or personal booty?) was parried; and Africanus himself may have been accused but not condemned in 184. In any case, his influence was shaken, and he withdrew from Rome to Liternum in Campania where he lived simply, cultivating the fields with his own hands and living on a country farm (*villa*) of modest size: Seneca later contrasted its small and cold bathroom with the luxurious baths of his own day. He had not long to live, however; embittered and ill he died in 184 or 183, a virtual exile from his country. He is said to have ordered his burial at Liternum and not in the ungrateful city of Rome, where his family tomb lay outside, on the Appian Way.

Significance and influence. A man of wide sympathies, cultured and magnanimous, Scipio easily won the friendship of such men as Philip, king of Macedonia, and the native princes of Spain and Africa, while he secured the devotion of his own troops. Though essentially a man of action, he may also have been something of a mystic in whom at any rate contemporary legend saw a favourite of Jupiter as well as a spiritual descendant of Alexander the Great. One of the greatest soldiers of the ancient world, by his tactical reforms and strategic insight he created an army that defeated even Hannibal and asserted Rome's supremacy in Spain, Africa, and the Hellenistic east. He had a great appreciation of Greek culture and enjoyed relaxing in the congenial atmosphere of the Greek cities of Sicily, conduct that provoked the anger of old-fashioned Romans such as Cato. Indeed, he was outstanding among those Roman nobles of the day who welcomed the civilizing influences of Greek culture that

were beginning to permeate Roman society. His Greek sympathies led him to champion Rome's mission in the world as protector of Greek culture; he preferred to establish Roman protection rather than direct conquest and annexation. For ten years (210–201) he commanded a devoted army at the people's wish. His position might seem almost kingly; he had been hailed as king by Spanish tribes, and he may have been the first Roman general to be acclaimed as emperor by his troops; but, though convinced of his own powers, he offered no challenge to the dominance of the Roman nobility ensconced in the Senate except by normal political methods (in which he showed no outstanding ability). Reaction against his generous foreign policy and against his encouragement of Greek culture in Roman life led to his downfall amid personal and political rivalries; but his career had shown that Rome's destiny was to be a Mediterranean, not merely an Italian, power.

Scipio's influence outlived the Roman world. Great interest was shown in his life during the early Renaissance, and it helped the early humanists to build a bridge between the classical world and Christendom. He became an idealized perfect hero who was seen to have served the ends of Providence. Petrarch glorified him in a Latin epic, the *Africa*, which secured his own coronation as poet laureate in 1341 on the Capitol where, some 1,500 years earlier, the historical Scipio used to commune in the temple of Jupiter.

BIBLIOGRAPHY. The chief ancient sources for Scipio are POLYBIUS and LIVY; the *Life of Scipio* by PLUTARCH does not survive. H.H. SCULLARD, *Scipio Africanus: Soldier and Politician* (1970), is a general study. For a more detailed review of Scipio's military career, see H.H. SCULLARD, *Scipio Africanus in the Second Punic War* (1930); and for details of his political activities, *Rotman Politics*, 220–150 B.C. (1951). See also R.M. HAYWOOD, *Studies on Scipio Africanus* (1933); and a more popular work, B.H. LIDDELL HART, *A Greater Than Napoleon: Scipio Africanus* (1926).

Scorpaeniformes

The scorpaeniform, or mail-cheeked fishes, are widespread throughout the oceans of the world. The group is believed to have originated in warm marine waters but has invaded temperate and even Arctic and Antarctic seas as well as freshwaters of the Northern Hemisphere. The mail-cheeked fishes are a highly successful biological group, occurring in the sea from the midlittoral (coastal) zone down to depths of at least 4,000 metres (about 13,000 feet). They inhabit some deep freshwater lakes but are more abundant in cold streams and rivers. The order is often divided into six suborders, only two of which have more than one family; these are the Scorpaenoidei (three families) and the Cottoidei (seven families). The best known groups are the scorpion fishes and rockfishes (family Scorpaenidae), gurnards or sea robins (Triglidae), flatheads (Platycephalidae), and sculpins (Cottidae). The flying gurnards (Dactylopteridae), considered by some authorities to belong in this order but more often separated in the order Dactylopteriformes, are treated here for convenience.

Many members are locally important commercial fish. Thus the redfishes of the genera *Sebastes* and *Sebastodes* of the North Atlantic and Pacific have considerable value to the fishing industries of Europe, the U.S.S.R., and North America; the flatheads are exploited in a wide area of the Indo-Pacific region, and greenlings (*Hexagrammidae*) are of commercial importance in the northwestern Pacific. In general, the fishery value of the group as a whole has a greater potential than is shown by the present actual utilization by man.

Members of the order Scorpaeniformes are not large fishes. Some of the deepwater species, such as the redfishes, grow to a length of 90 centimetres (three feet), but the majority attain a maximum length of around 30 centimetres (one foot). Externally, scorpaeniforms vary greatly; most are like the Perciformes in general appearance—i.e., they are typical, scaled, spiny-rayed fishes—but the lumpfishes (Cyclopteridae) among them are obese,

often jellylike, usually scaleless, and lack sharp fin spines. Body armour is often well developed, however, and most scorpaeniforms are well equipped with spines.

NATURAL HISTORY

Ecology. The greatest diversity of scorpaeniform fishes, especially among members of the family Scorpaenidae, is found in warm tropical seas. The order is particularly well represented in the shallow waters of the continental shelf. In the tropics many scorpaenids are found in association with coral; elsewhere most are found on rocky or rough bottoms. In both cases they are highly camouflaged to match their backgrounds. The sculpins, flatheads, and scorpaenids, although not fast or powerful swimmers, feed on many more active smaller fishes and crustaceans, usually capturing prey by a swift pounce using the large pectoral fins as auxiliary power units.

Cryptic (concealing) coloration is probably best exemplified by the stonefishes (*Synanceja*), inhabitants of shallow waters, including estuaries, mud flats, coral reefs, and coral sand pools of much of the tropical Indo-Pacific. Looking like a lump of eroded coral or rock, its body concealed by the cragginess of its outline and its coloration exactly matching the background, a stonefish is perfectly hidden and makes no movement until prodded with a stick or, more often, stepped on, at which time it erects its dorsal fin spines. Each spine has a pair of large gray-brown fusiform venom glands, one on each side. The spines inflict puncture wounds into which a considerable quantity of venom is injected through a channel on each side of the spine. Intense pain at the site of the puncture is instantaneous and radiates within minutes to involve

the whole of the affected limb. Death occasionally occurs, and secondary infections are common.

Many other scorpaeniforms can inflict severe wounds with their fin spines or head spines, but relatively few species are equipped with venom glands. One group of venomous species includes the turkey fishes (*Pterois* and related genera), also known as lion fishes or fire-fishes. Widespread in tropical Indo-Pacific waters, they are beautifully and boldly coloured, with patterns of contrasting stripes on the head and body that are specific for individual species and extremely long dorsal and pectoral fins. All of these fishes have long, needlelike dorsal spines with glandular venom-producing tissue and shallow channels capable of inflicting very painful but rarely fatal punctures. The bold and distinctive colouring of the turkey fish is clearly a warning, for, unlike most scorpaenids, it does not hide, but boldly swims in open water around the coral heads. If disturbed, the turkey fish displays by spreading its fins to their fullest extent, rotating until it assumes a position, often head down, with its dorsal spines pointing towards the intruder. If an attacker is not intimidated by this display, the turkey fish moves toward the attacker with its dorsal spines erect.

The flatheads (*Platycephalidae*) are found in the same oceans as the scorpaenids, but mainly in sandy, muddy or estuarine areas. Their greatly flattened bodies are clearly an adaptation to bottom life; indeed, they bury themselves on the bottom, leaving only the eyes exposed. Many species feed mainly on small fishes, but others, like the dusky flathead (*Platycephalus fuscus*), the largest and commercially most valuable of the Australian flatheads, have a varied diet of fishes, mollusks, crustaceans, and marine worms.

The sea robins (*Triglidae*) are bottom-living fishes of wide distribution. The lower two or three pectoral fin rays, which are long, thickened, and detached from the remainder of the fin, form organs of taste and touch and are used for locomotion. These rays are very mobile, and an active sea robin can move slowly along the bottom apparently supported on the rays, which continuously explore the ground ahead and on either side. The diet of most of these fish consists of crustaceans, mollusks, and other fishes, many of which burrow in the sea bed.

The most abundant littoral (shore) scorpaeniforms are the sculpins (*Cottidae*), significantly the only group found in freshwater, other than the closely related families Cottocomephoridae and Cornephoridae. Some members of the families Scorpaenidae and Cyclopteridae are also littoral fishes. The littoral sculpins are generally small, inhabiting densely weeded pools or crevices in rocks. Both the sculpins and cyclopterids found along the shore are strongly thigmotactic (attracted to surfaces), pressing as much of their bodies to the surface as possible. The cyclopterids have well-developed sucker disks, which are derived from the pelvic fin complex. The suck-

Adaptations for bottom living in sea robins

The dangerously venomous stonefishes

Figure 2: Basic types of venom apparatus of three scorpaeniform fishes.

From B.W. Halsted, Poisonous and Venomous Marine Animals of the World

ers, which are effective in resisting wave action, are capable of exerting considerable force; in one instance, a force of 13.3 kilograms (29.3 pounds) was required to break the hold of an adult lump sucker (*Cyclopterus lumpus*). The European littoral sea snail (*Liparis montagui*) can vary the suction exerted by its sucker as necessary to adjust for the speed of passing water currents.

The cyclopterids have adopted a wide variety of life styles in addition to the littoral habit. The genus *Nectoliparis* is pelagic (*i.e.*, inhabiting open water); members of the genera *Paraliparis* and *Rhodichthys*, of the North Pacific and Arctic Oceans, are bathypelagic (*i.e.*, in deep midwaters), at least for a large part of their lives. In fishes found at depths of 2,400 metres (7,900 feet), the pelvic sucker disk is completely absent. In the semitransparent but beautifully pink-tinged species of the genus *Careproctus*, found in deep, cold polar waters, the pelvic sucker is greatly reduced in size and presumably in efficiency.

In contrast to the cyclopterids, the greenlings are pelagic fishes that adopt a benthic (bottom) life only during the spawning season. One of the best known members, the Atka mackerel (*Pleurogrammus monopterygius*), which is common in the North Pacific and has considerable sporting and commercial fishing value, spends the major part of its life in the open sea. The related yellow-fish (*P. azonus*) has been observed in the upper layers of the ocean in calm weather and is usually captured in purse seines. At night it descends to the bottom.

The scorpaeniforms have adapted particularly well to freshwater. The members of the sculpin family (Cottidae) are widely distributed in the Northern Hemisphere, reaching their greatest diversity in North America and decreasing in numbers westwards through the Eurasian landmass. In extreme western Europe there is only one species, the miller's thumb (*Cottus gobio*). Two endemic forms, *C. kneri* and *C. kessleri*, both of some commercial importance, are found in Lake Baikal, U.S.S.R., and its tributary rivers. These species share Lake Baikal with a number of other species belonging to the related families Cottocomphoridae and Comephoridae. The sculpins in Lake Baikal have become adapted to exploit all of the living space offered by this inland sea. The family Cottocomphoridae is divided into eight genera and numerous species. Although many of the benthic species are restricted to a particular type of bottom and are found only within a certain depth range, most migrate into coastal waters in the spring and remain there during the warm season. Some species, however, remain in deep water all year; others, which are primarily pelagic fishes, use the bottom only to spawn.

The two members of the family Comephoridae, called Baikal cods (*Comephorus baicalensis* and *C. dybowskii*), are pelagic fishes, the latter living at depths to 1,000 metres (more than 3,000 feet). The feeding habits of these Baikal cottoid fishes all exploit potential food resources; the pelagic species feed mainly on various pelagic crustaceans and make daily vertical migrations accompanying their prey, and the benthic forms feed chiefly on certain species of benthic copepod crustaceans. The diet of one inshore species, *Batrachocottus nikolskii*, however, is mainly chironomid and caddisfly larvae.

Reproduction. The mail-cheeked fishes are highly variable in their mode of reproduction. Some of the methods used by them to reproduce are noted below. In the Comephoridae there is a remarkable imbalance between the numbers of each sex, the proportion of males in the total population being as low as 3 or 4 percent. The biological basis for this imbalance is unknown. Members of this family are viviparous (live-bearing). The females come near the surface to give birth to their young; the males remain at their normal depths. By contrast, the remaining cottoids are oviparous (egg laying), including the Cottocomphoridae of Lake Baikal. The females of most of the latter family deposit their eggs in shallow coastal water, then leave the males to guard them until they hatch. This is also the general rule among the sculpins, in which the males guard the eggs. In some species the eggs are shed loosely and adhere to the bottom, but

little reliable evidence is available concerning the breeding habits of most cottoid fishes. The northern Atlantic short-horned sculpin, or bullrout (*Myoxocephalus scorpius*), is known to build a rudimentary nest guarded by the male, as does the freshwater European miller's thumb. The males of these and other cottids have a well-developed structure called a urogenital papilla, which some authorities have suggested is used to introduce sperm into the female. Many cottoid species develop pronounced breeding coloration with sexual differences that apparently aid in recognition between the sexes and in territorial behaviour.

Some members of the family Cyclopteridae build nests that are guarded by the male. The familiar lump sucker, or sea hen (*Cyclopterus lumpus*), common on both sides of the North Atlantic, spawns along the coast in the winter. At least some of the inshore species, such as the striped sea snail (*Liparis liparis*), which has a distribution similar to that of the lump fish, deposit their spawn in clumps on hydroids (*e.g.*, anemones) and seaweeds, but there is no evidence of parental care. The females of some North Pacific cyclopterids (*e.g.*, *Careproctus sinensis*) have a long specialized structure (ovipositor) by which they lay their eggs under the shell of the Kamchatka crab. In general, however, little is known about the breeding biology of these fish.

In contrast to the rather specialized reproductive behaviour of the sculpins and the sea snails, the sea robins produce eggs that are simply shed in batches in the open sea. So far as is known, no special breeding behaviour accompanies spawning except that these noisy fishes become increasingly loquacious during the spawning season. The members of the family Hexagrammidae (the Atka mackerel, for example) deposit one clump of eggs, often on algae in shallow water on stony bottoms; some species, however, like the lingcod (*Ophiodon elongatus*) care for their egg masses during incubation. The sea poachers, or pogges (*Agonidae*), lay relatively few eggs, often hiding them away in crevices. The eggs are relatively large, 1.5–1.9 millimetres (0.06–0.07 inch) in diameter in *Agonus decagonus*, a species found in the extreme North Atlantic. The European hook-nose (*Agonus cataphractus*) lays up to 2,400 eggs inside the hollow rhizoid ("stalk") of the kelp *Laminaria* in a compact, membrane-covered mass. Incubation is prolonged, possibly as long as 12 months.

Scorpion fishes of the family Aploactinidae similarly shed their eggs in the open sea. Members of the scorpaenid subfamily Scorpaeninae extrude eggs in gelatinous balloon-shaped masses; those in the subfamily Sebastinae have internal fertilization and are viviparous. The three groups represent the principal evolutionary stem groups of the scorpion fishes. In the North Atlantic redfish (*Sebastes marinus*) fertilization is internal, and the eggs develop within the oviduct of the mother. Fertilization usually takes place during February, after which the females form shoals and migrate to spots where warm bottom currents pass. The female can be said to be a living incubator; in such fishes, which live in cold northern seas, it is clearly advantageous to carry the developing young to an area in which more favourable conditions prevail. The young at birth are very immature, nevertheless, and brood size in the redfish is relatively large (up to 360,000); the larvae must survive a lengthy planktonic life. A smaller, shallower water redfish, the Norway haddock (*Sebastes viviparus*) produces much smaller broods, with brood sizes ranging from 12,000 to 30,000 young. The scorpaeniforms are distinguishable among viviparous teleosts (advanced bony fishes) by their comparatively high fecundity; comparison with many other marine fishes, single individuals of which produce millions of freely shed eggs, however, illustrates the relative advantage, at least in numbers, of bearing living young over laying eggs.

The North Pacific redfishes or rockfishes (*e.g.*, *Sebastes*, *Sebastes*, and *Hosokius*) closely resemble the North Atlantic sebastine species in their reproductive biology; all species studied have been found to have relatively large brood sizes. The sebastine rosefishes (*Helico-*

lenus), found in both the northern Atlantic and Pacific Oceans, have morphological affinities with the subfamily Scorpaeninae. Studies of their reproductive biology have shown that the sebastine rosefishes have intra-ovarian embryos embedded in a gelatinous matrix, and they thus appear to combine sebastine viviparity with scorpaenine egg masses.

Sound production. Since the time of Aristotle, the sea robins have been known as sound-producing fishes, and their sonic performances and mechanisms are well-known. They have a large swim bladder loosely attached to the dorsal wall of the body cavity; the swim bladder is vibrated by lateral muscles in which the striated fibres run at right angles to the muscles' length. The sea robin of the North American Atlantic coast (*Prionotus carolinus*) produces single vibrant barks and growls, and series of rapid clucks with very little provocation. Some of the sculpins (Cottidae) produce dull groans and growls; it is believed that these sounds are mechanical in origin, arising from contractions of the muscles that produce periodic movements of the pectoral girdle. Flying gurnards (Dactylopteridae) are similar to the triglids in their sonic mechanism and sound production capacity.

FORM AND FUNCTION

General features. Many mail-cheeked fishes, such as the rockfishes, have simple fusiform (spindle-shaped) body plans, but others, such as some sea poachers, are extremely slender. Most scorpaenids, triglids, and cottids have two dorsal fins (sometimes joined), the forward one supported by stiff spines. In general, the dorsal, anal, and pectoral fins are large, sometimes strikingly so, but in some groups (e.g., cyclopterids) the spinous dorsal fin is reduced or absent.

The one feature diagnostic of the order is the presence of a bony bar, or stay, beneath the eye, an extension of the second infra-orbital bone. It is small and inconspicuous in some primitive scorpaeniforms and secondarily reduced in some specialized forms; in others, however, it is readily evident. Often it has become externally prominent, bearing protrusions or spines, or has expanded and fused other cranial bones to form a hard armour.

Camouflage and coloration. Many scorpaeniform fishes, such as scorpion fishes, rockfishes, and sculpins, which live on coral or rocky bottoms, possess a remarkable degree of cryptic (concealing) coloration and shape. Numerous fleshy lappets adorn the head, fin membranes, and body scales, rendering the fish virtually invisible against a background of rocks covered with marine organisms. The effectiveness of this camouflage cannot be appreciated unless the fish is viewed in its natural habitat.

Some members of the order, such as the sea robins, are notable for brilliant colours, especially reds. The large pectoral fins are often strikingly coloured; in the European tub gurnard (*Trigla lucerna*) they have spots of bright green and peacock blue. The spots on the pectorals of the flying gurnards resemble eyes, and apparently function to startle and frighten potential predators when the fins are suddenly spread. The brightly coloured fins of some sea robins may function in a similar manner.

CLASSIFICATION

Annotated classification. The following classification is modified from that suggested by British ichthyologist P.H. Greenwood and the Americans S.H. Weitzman, D.E. Rosen, and G.S. Myers.

ORDER SCORPAENIFORMES (mail-cheeked fishes)

Spiny-finned fishes generally with stout bodies. Second infra-orbital bone united with the preopercular to form a rigid stay across the cheek. Pelvic fins thoracic in location (sometimes modified into sucker disks), the bones directly attached to cleithra (bones like the collarbones of higher vertebrates).

Suborder Scorpaenoidei

Moderate-sized fishes with 24 to 40 vertebrae. Anterior ribs absent or sessile (rigidly attached). Numerous species.

Family Scorpaenidae (scorpion fishes and redfishes)

Paleocene to present. Marine fishes widely distributed in tropical, temperate, and northern seas. Perchlike appearance, dorsal fin spines long and numerous; head spiny, body scaly.

Locally important food fishes, some with venom glands on fin spines. Size to around 100 cm (39 in.).

Family Triglidae (gurnards and sea robins)

Upper Eocene to present. Marine fishes of warm and temperate seas. Characterized by rather slender form, body with small scales or bony plates; head heavily armoured. Lower pectoral fin rays separate, forming a tactile organ. Locally exploited by man as food. Size to around 70 cm (28 in.).

Family Synancejidae (stonefish)

Tropical Indo-Pacific. Scaleless, body covered with warty tubercles. Venom glands on fin spines; dangerously venomous. Size to around 60 cm (24 in.).

Families Aploactinidae, Pataecidae, and Caracanthidae

Tropical Pacific, often in coral. Small scaleless fishes (except Caracanthidae, which have dense dermal papillae). Size to about 25 cm (10 in.).

Suborder Hexagrammoidei

Moderate-sized, slender-bodied fishes. Vertebrae 42–64. Ribs attached to strong parapophyses (projections of vertebrae). Few species, midwater and benthic.

Families Hexagrammidae, Anoplopomatidae (skilfish), and Zaniolepididae (comb fishes)

Northern Pacific. Small scales, long dorsal fins, spines on the head few, powerful teeth in jaws. Locally important food fishes, some with sporting value. Size of most to about 45 cm (18 in.), some longer.

Suborder Platycephaloidei

Moderate-sized with head and anterior part of body strongly flattened. Vertebrae about 27. No air bladder.

Family Platycephalidae (flatheads)

Head and body flattened anteriorly. Marine; usually buried in soft bottom, some forms on coral; Indo-Pacific and tropical eastern Atlantic. Important commercial fishes in Southeast Asia, tropical Australia, and elsewhere. Size to 130 cm (52 in.) and 15 kilograms (33 pounds).

Suborder Hoplichthyoidei

Small fishes, with very depressed bodies. Scaleless, but body with bony plates. Head with heavy spiny ridges.

Family Hoplichthyidae

Found in moderately deep water in Indo-Pacific region. Size to 25 cm (10 in.).

Suborder Congiopodoidei

Moderate-sized fishes with angular bodies and well-developed dorsal fin spines. Scaleless, but sometimes rough skins.

Family Congiopodidae (horse fishes)

In moderately deep cold waters of Southern Hemisphere, off South America, Australia, and South Africa. Size to 75 cm (30 in.).

Suborder Cottoidei

Small to moderate fishes. Marine, from temperate to polar seas, and freshwater in Northern Hemisphere. Mostly scaleless; many with spiny skins, others with bony plates. Many species.

Family Cottidae (sculpins and bullheads)

Oligocene to present. Generally large headed, with well-developed head spines. Marine and freshwater of the Northern Hemisphere (one genus said to occur in the Tasman Sea). Mostly small, some up to 60 cm (24 in.).

Families Cottomephoridae and Comephoridae

Similar to cottids but post-cleithral bones absent or rudimentary. Freshwater, endemic to Lake Baikal, U.S.S.R. Size to about 16 cm (6 in.).

Family Icelidae (two-horn sculpins)

Head large, laterally compressed, and with small spines. Lateral line and dorsal fin base with scutes (plates). Small benthic fishes mainly of North Pacific, a few in the North Atlantic. Size to 25 cm (10 in.).

Family Normanichthyidae

Head and body with ctenoid (fringed) scales; head without spines. Two well-separated dorsal fins, soft fin rays branched. Marine waters off Chile. Size to 11 cm (4 in.). Probably does not belong in order Scorpaeniformes.

Family Cottunculidae

Body covered in loose skin covered with bony tubercles. Head large, lacking spines. Deep waters of the Arctic and North Atlantic oceans, Indian Ocean off South Africa, and Flores Sea, Indonesia. Size to 20 cm (8 in.).

Family Agonidae (poachers and pogges)

Eocene to present. Body covered in hard armour of large scutes. One or two dorsal fins. Teeth minute. Small, benthic,

The uniting feature of the order

coastal fishes of northern Pacific, Atlantic, Arctic oceans, and Antarctic waters. Size to 30 cm (12 in.).

Family Cyclopteridae (lumpfishes and sea snails)

Body short, thick, tadpole-shaped. Skin thick, naked or with bony tubercles or small thorns. Two dorsal fins, the first often minute or modified. Pelvic fins forming a sucker disk or absent. Marine, from littoral to abyssal depths (4,000 metres) in northern Atlantic and Pacific oceans, Arctic and Antarctic waters. Size to 60 cm (24 in.); 5.5 kg (12 lb).

ORDER DACTYLOPTERIFORMES

Resemble Triglidae. Head covered by bony plates expanded into huge shields. First infra-orbital bone connected to preoperculum. Pectoral rays long numerous, and brightly coloured.

Family Dactylopteridae (flying gurnards)

Tropical and warm-temperate regions of Atlantic and Indo-Pacific oceans. Few species. Size to 50 cm (20 in.).

Critical appraisal. The classification of the scorpaeniforms cannot be said to have approached a final synthesis. It has been suggested that they are an aggregation of three distinct evolutionary lines, the two dominant elements being the scorpaenid and cottid-hexammatid lines, the third, and minor group being the anoplopomatids. On the other hand, British ichthyologist P.H. Greenwood and colleagues have pointed out that all members of the order, as recognized here, share a distinctive type of caudal (tail) skeleton. The order Scorpaeniformes is clearly related to Perciformes within a superorder Acanthopterygii.

The systematic positions of some groups remain open to doubt. The flying gurnards have been placed by some workers in the Scorpaeniformes, and, indeed, the morphological and biological resemblance of the flying gurnards to members of the Triglidae suggests that such placement best expresses their phyletic affinities.

BIBLIOGRAPHY. Most of the information on the scorpaeniform fishes is found in short technical articles in scientific journals. The following works are broad in nature but contain substantial information on members of this order. E.S. HERALD, *Living Fishes of the World* (1961), is a well-illustrated book for the general reader; N.B. MARSHALL, *The Life of Fishes* (1965), contains some sections on the biology of scorpaeniforms; G.V. NIKOLSKII, *Special Ichthyology*, 2nd rev. ed. (1961; trans. of the 2nd Russian ed. of 1954), deals especially with species commercially important in the Soviet Union; B.W. HALSTEAD, *Poisonous and Venomous Marine Animals of the World*, vol. 3 (1970), provides information on the venom of these fishes and its effects. P.H. GREENWOOD *et al.*, "Phyletic Studies of Teleostean Fishes, with a Provisional Classification of Living Forms," *Bull. Am. Mus. Nat. Hist.*, 131: 339-455 (1966); and C.T. REGAN, "The Osteology and Classification of the Teleostean Fishes of the Order Scleroparei," *Ann. Mag. Nat. Hist.*, Series 8, 11:169-184 (1913), are rather technical, but important, contributions to the study of the scorpaeniforms.

(A.Wh.)

Scorpionida

Scorpions (order Scorpionida or Scorpiones), feared by man since ancient times, often play the role of evil-doers in fables and legends; Greek respect for scorpions prompted the naming of the constellation Scorpio, a sign of the zodiac. A long, curved tail tipped with venomous stinger in back, and grasping fingerlike appendages in front, are typical scorpion features; in some areas of the world (e.g., Mexico), venomous scorpions cause serious medical problems. Predators that have little in common with such other arthropods as insects and crustaceans, scorpions are arachnids and thus are closely related to spiders, harvestmen, and mites.

General features. The order Scorpionida comprises about 800 species, which are limited largely to tropical, subtropical, and warm temperate parts of the world. Although often thought of as desert animals, scorpions also are represented by a rich and varied fauna both in forests and in tropical jungles. Most species from deserts and other arid regions are yellowish or light brown in colour; those from moist or higher mountain habitats, however, are brown or black. Scorpions live at altitudes that range from sea level to 2,000 metres (6,000 feet) in the Alps,

3,000 metres (10,000 feet) in the mountains of southwestern North America, and 4,000 to 5,000 metres (13,000 to 16,000 feet) in the Andes. One species is known as far north as southern Germany, but none is found in Scandinavia or the British Isles. In North America, *Vejovis boreus* is found in regions of climatic extremes as far as the western provinces of Canada.

Scorpions are relatively large arachnids with an average size of about six centimetres (about 2½ inches). Giants among scorpions are the black species from tropical Africa—*Pandinus imperator* of Guinea attains a body length of 20 centimetres (eight inches). The length of one of the smallest scorpions, *Microbuthus pusillus*, is about 1.3 centimetres (about ½ inch). Although many were of average size, a few precursors of modern scorpions were comparative giants; *Gigantoscorpion* measured about 40 centimetres, and a still undescribed species is estimated to have had a length of about 90 centimetres (almost 36 inches).

Scorpions, often called living fossils because they are the most primitive of all land arachnids, have changed little in external appearance since Silurian times (about 400,000,000 years ago). Scorpions are believed to have become truly terrestrial in the Upper Devonian Period (about 345,000,000 years ago).

Natural history. **Reproduction and life cycle.** Scorpions exhibit few sexual differences, although males usually are more slender and have longer tails than females. In both sexes the genital opening is found between genital coverings, or opercula, located at the base of the abdomen. In order to survive on land, scorpions evolved a structure and mating procedures that prevent eggs and spermatozoa from drying out. The structure, called a spermatophore, is a hard ball of spermatozoa held together by a supporting structure and transferred to the female during mating by an injecting mechanism.

Mating in scorpions, a remarkable process paralleled in only a few other groups, is preceded by a complicated, and often extended, courtship; it is initiated by the male, who faces and grasps the female by appendages called pedipalps. Abdomens pressed to the ground and tails held high and continually entwined and disengaged in a manoeuvre commonly known as an *abre droit*, the pair, directed by the male, moves sideways and backward in a dancelike motion called *promenade à deux*. Many of these actions actually result from the efforts of the pair to find a smooth surface on which the male can extrude and attach the spermatophore by its stalk; his manoeuvres also serve to bring the spermatophore near the open genital opercula of the female. After contact has been made, spermatozoa are ejected into the genital opening (gonopore) of the female. Males that remain near females after mating sometimes are killed and eaten by them.

Once fertilized, eggs are retained in the female's body for periods varying from several months to a year before the young are born alive (viviparity). A young scorpion, white in colour, is still enveloped in a membrane, or chorion, at birth; after freeing itself, the immature scorpion crawls onto the mother's back, rests for several days, and sheds its cuticle (molts) for the first time. During this period, young scorpions utilize food reserves in their bodies; after they leave the female's back, however, the young must find their own food. Scorpions undergo seven or eight molts before they attain sexual maturity. Although development is slow, they may live several years.

Behaviour. Scorpions, exclusively carnivorous, eat living insects and small invertebrates; occasionally they also feed on mice and other small vertebrates. Capable of enduring long periods without food, some scorpions apparently do not drink water. Their methods for capturing and feeding on prey, generally common among arachnids, are necessitated by limited capabilities. Scorpions wait patiently to detect prey but lack pursuit ability if a potential victim escapes the first attack. Prey is perceived by receptors on sensory hairs and comblike projections (pectines) on the appendages that together provide a kind of combined sense of touch and smell; it is then captured and firmly held by pinching fingers on appendages near the front of the body (pedipalps). At the same

Feeding

time, the long tail, swung over the back, is positioned to sting and paralyze the victim if necessary (see figure 1).

Scorpions lack conventional jaws, and their feeding hab-

After M. Vachon, "Quelques aspects de la biologie des Scorpions," *Endeavour* 12:46 (April 1953) in A. Kaestner, *Invertebrate Zoology*, vol. 2 (1970); John Wiley & Sons, Inc.

Scorpion *Androctonus australis* killing prey.

its are unusual; a pair of toothed pincerlike appendages (chelicerae) and sharp edges of adjacent jawlike structures (maxillae and coxae) macerate the prey, as quantities of digestive fluids secreted from the small intestine pour over it. The victim's soft parts are broken down, liquefied, and sucked into the scorpion's stomach by a pumping action. The victim is gradually reduced to a ball of indigestible material, which is cast aside. Eating is a slow process, often taking many hours; after a large meal, a scorpion can live for long periods without food.

Respiration is accomplished by means of four pairs of book lungs (or book tracheae), so-called because they are arranged like the pages of a book, enclosed in body segments of the preabdominal region (mesosoma); each opens through a hole, or spiracle. Air enters the small spiracles and is expelled by slight movements of their covers. This is an adequate system, for these animals need little air and are only slightly affected even if most of their spiracles are artificially sealed.

Although powerfully armed for defense, scorpions are attacked by a variety of animals; vertebrates (e.g., birds, lizards, monkeys, and other mammals), predatory insects (e.g., ants, ground beetles, and mantids), and some of the larger spiders eat them, sometimes first tearing off the stinger. The cannibalistic habits of scorpions are well known, and they kill many of their own kind; scorpions do not commit suicide by stinging themselves, however, even though under certain circumstances, a scorpion may accidentally strike its own body. Some African and Oriental species produce buzzing and clicking sounds, which may be intended to frighten predators.

Ecology. Scorpions are solitary nocturnal animals that live together in loosely knit colonies only during times of mating or when climatic extremes are best met by communal protection.

Scorpions usually live under rocks or other ground debris, crawling into soil crevices or beneath bark. A few live close to man and invade his buildings; a dangerous Mexican species, *Centruroides limpidus*, migrates into trees and infests native huts at the beginning of the summer rainy season. Others actually burrow into the soil; vejovid scorpions, for example, may create special retreats by digging: in the Colorado River desert, *Paruroctonus mesaensis* digs into the loose sand and buries itself during the day; in Arizona, species of *Hadrurus* dig deep into gravel banks or under imbedded rocks and remain for long periods; in California, *Anuroctonus phaeodactylus*

lus digs deep burrows in the banks of arroyos and stands at the entrance awaiting prey. Some desert scorpions have adaptations for **flinging sand**—e.g., widened distal leg segments (tarsi), combs of stiff hairs. A thick, relatively waterproof covering, or integument, enhances their ability to retain body fluids during prolonged periods of drought. Although nocturnal and burrowing habits largely insulate them from climatic extremes, they cannot tolerate high temperatures, even for a short time.

Most scorpions shun water, but a few species live among plants near the sea, move about in the intertidal area, and are able to remain submerged under tidal waters for short periods. Although scorpions readily enter caves, few of them have adapted completely to this habitat; Mexican species of *Typhlochactas*, however, which lack both eyes and dark pigmentation, are obligate cave dwellers. One slender, spotted species, *Isometrus maculatus*, has been transported by commerce into new regions and is now widespread in tropical and subtropical climates.

Form and functions. The scorpion body is divided into two principal parts, the cephalothorax (head plus thorax) and abdomen, to which a variety of names have been applied. The cephalothorax is covered with a hardened structure (carapace) bearing a pair of median eyes and usually a cluster of two to five small lateral eyes on each side. Eyes play a small role in the lives of scorpions, probably only enabling them to distinguish night from day. The cephalothorax bears several pairs of appendages, including chelicerae, pedipalps, and four pairs of walking legs (figure 1). Chelicerae, small, pincerlike appendages in front of the mouth, are used during feeding; immediately behind the chelicerae are large pedipalps, which have the last two segments enlarged to form strong pincers for capturing prey. The walking legs are provided with tarsal claws.

The abdomen, which is broadly joined to the cephalothorax (also called prosoma), consists of 12 distinct segments, seven of which comprise a broad, flattened region (preabdomen); the remaining five narrow rings form a flexible postabdomen, or tail. Hard plates, or tergites, beneath the preabdomen have several specialized structures; the genital opercula lie just behind the ventral surface, or sternum, of the first abdominal segment; a pair of sensory appendages (pectines) on the second segment, found only in scorpions, react to tactile and vibratory stimuli; paired holes (spiracles) that open into book lungs are found on the third to the sixth segments. The postabdomen, often keel-shaped and ornamented, bears at its distal end the stinger.

The venom apparatus of the scorpion consists of a bulbous vesicle drawn out to a sharp, curved stinger. The venom, produced by a pair of glands and ejected by strong muscular contractions through an opening near the tip of the stinger, contains various proteins (including enzymes) and other elements. Some proteins carry nerve toxins capable of producing severe symptoms in warm-blooded animals, including man. Although the stings of common chactid and vejovid scorpions of southern Europe and the United States cause only trivial and transitory pain, some **buthid** scorpions of the Mediterranean region and the **Sonoran Zone** of Mexico inflict painful stings, which are followed by temporary local paralysis, fever, and general systemic effects that last a day or two. Certain dangerous buthids found in the Middle East, Brazil, western Mexico, and Arizona in the U.S. are capable of causing death within a few hours; their venom paralyzes the respiratory muscles and causes cardiac failure. Antiscorpionic serums are effective if administered in time.

Evolution and paleontology. That scorpions evolved from a now extinct group, the eurypterids, or giant water scorpions, is well established. Silurian scorpions lived in water 400,000,000 years ago, as did eurypterids, and the two groups had several common features—e.g., external gill books, large compound eyes, and similar chewing structures on the first segments (coxae) of the first pair of appendages. Evolution of external gills into enclosed book lungs made possible the migration of scorpions from water to land. Until the Upper Devonian, 345,000,000 years ago, most scorpions were aquatic in habit. About 30

Enemies

Venom apparatus

fossil species are known, most of which have been found in Carboniferous rocks (about 325,000,000 years old) in Europe and North America; all these latter fossils found thus far were air-breathing land animals.

Classification. *Distinguishing taxonomic features.* Six families and about two dozen subfamilies are identified by a limited number of characters, including shape and subdivision of the sternum; presence of spurs on the legs; number of lateral eyes; size and modification of the comblike appendages (pectines); and details of the granular rows on the fingers of the pedipalps.

Annotated classification. The following classification was established in 1899, and there have been few challenges to its basic features.

ORDER SCORPIONIDA (SCORPIONES) (scorpions)

Chelicerate arachnids with single carapace over cephalothorax; 2 3-jointed chelicerae, large chelate pedipalps; 4 pairs of walking legs; comblike pectines; 4 pairs of book lungs; tropics to warm temperate zone; about 800 extant and fossil species.

Family Buthidae (buthids)

Extant except for 1 Baltic amber (38,000,000 to 54,000,000 years ago in the Oligocene and Eocene Epochs) species; in tropics to warm temperate zones; triangular sternum; often with spine under stinger; about 300 species, including those most dangerously venomous.

Family Scorpionidae (scorpionids)

Extant; 1 Miocene species (about 20,000,000 years old); mostly in tropics and subtropics of Eastern Hemisphere; pentagonal sternum; single spur at base of tarsus; about 150 species; *Pandinus* of Africa and *Heterometrus* of Asia have largest known species.

Family Diplocentridae (diplocentrids)

Extant; warm regions of Middle East, Mexico, and the Antilles; pentagonal sternum, single tarsal spur, and tubercular spine under stinger; about 30 species.

Family Chactidae (chactids)

Extant; tropical to warm temperate zones, mostly in South America; a few species in Australia, Mexico, and Mediterranean region; pentagonal sternum and 2 lateral eyes on each side; about 70 species.

Family Vejovidae (vejovids)

Extant; mostly in warm temperate region of western North and South America, Middle East to eastern Asia; sternum with nearly parallel sides; 3 lateral eyes; about 125 species.

Family Bothriuridae (bothriurids)

Extant; tropical and subtropical South America; 1 Australian genus; broad, inconspicuous sternum consists of 2 narrow, transverse plates; 3 lateral eyes on each side; about 70 species.

Scotia Sea

The Scotia Sea, a marine region about 350,000 square miles (over 900,000 square kilometres) in area, lies in a complex and tectonically active marine basin enclosed on the north, east, and south by the island-dotted Scotia Ridge. The ridge forms a west-opening submarine loop about 2,700 miles long, connecting the Tierra del Fuego of South America with northern Palmer Land of the Antarctic Peninsula. The western limit of the sea is formed by a discontinuous northwest-trending rise that separates the basin from the Drake Passage (*q.v.*). The Scotia Ridge, with an active volcanic arc-trench system at its eastern end, compares in form and geologic record to the similar Northern Antilles volcanic chain in the eastern Caribbean Sea. The Scotia Ridge region was thus given the name Southern Antilles by the early geologists Eduard Suess and Otto Nordenskjöld.

Exploration. Named after the Scottish National Antarctic Expedition (1902–1904) vessel "Scotia," under command of William S. Bruce, the Scotia Sea has a lengthy record of exploration dating back to the 17th century. Through the 18th and 19th centuries exploration was encouraged by a relentless search for new and ever richer whaling and sealing grounds. Semipermanent and permanent settlements were established, particularly on South Georgia and the Falkland Islands. By the mid-20th century, sealing and whaling declined, and further exploration was largely scientific. During and since the International Geophysical Year (1957–59), the Scotia Sea region has been extensively explored, mainly by Chilean, Argentine, British, and American scientific teams.

Geology and physiography. The Scotia Sea is separated into two smaller basins, West Scotia Basin (the larger) and East Scotia Basin, by a slight rise connecting South Georgia with the South Orkney Islands. Water depths generally range between 10,000 and 13,000 feet, but to the east, across the volcanic arc of the South Sandwich Islands, depths exceed 26,000 feet in Meteor Deep of the South Sandwich Trench. Water of the Southern Seas in its unimpeded clockwise race around the Antarctic continent, is funnelled through the 600-mile-wide Drake Passage and the Scotia Sea, pouring through several main passes of the Scotia Ridge. Most escapes through the broad saddle between Burdwood Bank and South Georgia, into the Argentine Basin, and the rest through saddles between the South Sandwich Islands and South Georgia to the north and the South Orkney Islands to the south.

Reconnaissance mapping of magnetic anomaly patterns in the Scotia Sea, and their comparison to dated patterns elsewhere, suggests that the crust in this region is geologically young, perhaps no more than about 40,000,000 years old. Preliminary studies also suggest that a new South Sandwich crustal plate, growing at a rate of about 1.1 inches per year, may be overriding a southern Atlantic crustal plate. Reconnaissance seismic studies indicate that the Scotia Sea crust is in places thicker than typical oceanic crust and is probably of structure intermediate between oceanic and continental. The **Eltanin** Fracture Zone, which offsets the East Pacific Rise (Albatross Cordillera) in the central southern Pacific, extends southeastward, possibly meeting the northern arm of the Scotia Ridge. It is doubtless somehow related to the opening of the Scotia Sea basins.

Coring and dredge sampling indicate that the sea floor is largely covered with clayey silt, and with carbonate ooze locally along the northern margin and siliceous ooze along the eastern. Ferromanganese concretionary nodules, though occurring widely, are concentrated particularly beneath the Antarctic Convergence (of cold Antarctic water and slightly warmer Atlantic water) in a belt passing along the northern Scotia Sea and through the saddle between Burdwood Bank and South Georgia. Most of the sediments are derived from nearby volcanic terranes, having been deposited on the ocean floor by ice movements and by ocean currents.

The origin of the Scotia Sea is intimately tied to that of the Scotia Ridge. Thick sequences of highly deformed, almost unfossiliferous graywacke and shale occur in most of the islands, including South Georgia, Livingston Island in the South Shetland Islands, and the South Orkney Islands. In South Georgia, the beds are overlain by tuffaceous (volcanic detritus) graywacke, at least in part of Cretaceous age (from 65,000,000 to 136,000,000 years old). These sequences are believed to partly correlate with earlier (late Paleozoic) sequences in South America and in the Antarctic Peninsula, but the correlation is highly uncertain in the absence of dateable fossils. It has been postulated that the Andean Scotia Ridge is the remnant of a former direct connection between South America and Antarctica, a connection that in the Tertiary (2,500,000 to 65,000,000 years ago) was disrupted and bent by the eastward protrusion of the Pacific crust into the Atlantic.

Animal life and vegetation. The northern arm of the Scotia Ridge, including South Georgia, lies in the sub-

The sea bottom

Antarctic climatic zone, and the southern arm, south of the Antarctic Convergence, lies in the cold Antarctic zone. The biota varies accordingly. South Georgia supports a rich tundra-like flora with at least 50 species of vascular plants, whereas islands in the Antarctic zone, including the South Orkneys and South Shetlands, can maintain only primitive communities of mainly seedless plants, such as lichens, mosses, and algae. Only a few species of grasses can grow in protected locales in this southern zone. Many species of birds, mostly sea and a few shore birds and land birds, including petrels, penguins, gulls, **terns**, **skuas**, and **sheathbills**, inhabit these regions. Other sea life south of the Convergence includes nearly 100 species of fish and several species of whale and seal. Sea lions are **unknown** south of the Falkland Islands. Man has seriously reduced the sea mammal population, some species almost to the point of extinction. Accidental introduction of cats, dogs, mice, and rats threatens bird nesting grounds on some islands, and the natural tundra ecosystem is severely threatened on a few sub-Antarctic islands that have been overgrazed by introduced sheep and rabbits. Articles of the Antarctic Treaty (1959) are aimed at protecting and restoring this valuable natural habitat (see ANTARCTICA).

Scotland

Scotland, the most northerly of the four parts of the United Kingdom—England, Scotland, Wales, and Northern Ireland—is a generally cool, hilly, and, in the west, wet country that occupies about one-third of the island of Great Britain (England, Scotland, and Wales). It is bounded by England in the south and on the other three sides by sea: by the Atlantic on the west and north and by the North Sea on the east. Its mainland area is 29,794 square miles (77,167 square kilometres); including inhabited islands, it has an area of 30,414 square miles. Scotland is fringed by numerous islands on the west coast, and the island clusters of the Orkneys and the Shetlands lie to the north; but the east coast has only a few islands, and those are insignificant. At its greatest length, from Cape Wrath to the Mull of Galloway, the mainland extends to 274 miles (441 kilometres), while the maximum breadth from Applecross, in western Highland region, to Buchan Ness, in eastern Grampian region, is 154 miles. But, owing to the deep penetration of the sea in the fjords, or narrow, deep inlets, of the west coast and in the estuaries of the Tay and Forth rivers in the east, most places are within 40–50 miles of the sea, and only 30 miles separate the Firth of Clyde and the Firth of Forth, the two great estuarine inlets on the west and east respectively.

The country was originally known as Caledonia. The name Scotland originated in the 11th century, when the name **Scotia** was given to the southwestern tract settled by the tribe of Scots who had migrated from Ireland. After being independent until 1707, Scotland became an integral part of the United Kingdom, though something of a political curiosity. It has no separate legislature, executive, or political power, and, constitutionally, it is less than a state or province in a federal union. Yet it retains vestiges of ancient sovereignty in its own legal and educational systems, a national church, and a separate administration. Its economy is integrated with that of Britain, and it has no diplomatic or consular representation in other countries, but it has managed, nevertheless, to preserve its identity in the international scene by export trade and by cultural exchanges. Some of its products, especially whisky, tartan, and tweeds, are internationally known, and generations of emigrant Scots have spread the awareness of a distinctively Scottish culture. The image cherished by foreigners is often odd, but even romantic notions of stem and wild Caledonia, of Mary, queen of Scots, and of

Bonnie Prince Charlie (Charles Edward Stuart) prevent Scotland from being eclipsed in the comity of nations. (For related information see BRITAIN AND IRELAND, HISTORY OF; UNITED KINGDOM; and EDINBURGH.)

THE LAND

Natural features. Scotland is traditionally divided into three geographical areas, the Highlands, the Lowlands, and the Southern Uplands. The coastal plain, stretching from eastern Grampian region round the Moray Firth to the flat expanse of northeastern Highland region, is distinctive enough, however, to constitute a separate Northeast area. The Highlands are bisected by the fault line of the Great Glen (Glen More nan Albin), which is occupied by a series of lochs (lakes), the largest of which is Loch Ness, famous for its probably mythical monster. North of the Great Glen is an ancient plateau, which, through long erosion, has been cut into a series of peaks of fairly uniform height separated by glens (valleys) carved out by glaciers. The northwestern fringe of the mainland is particularly barren, the granulated and layered rocks having been worn down by severe glaciation to produce a hummocky landscape, dotted by small lochs and rocks protruding from thin, acidic soil. Farther inland are spectacular sandstone mountains, weathered into sheer cliffs, rock terraces, and pinnacles. South of the Great Glen, the Grampian Mountains were also formed by continuous denudation and glaciation of metamorphic rocks, though there are intrusions of granitic masses in the Cairngorm Mountains. The Grampians are less rugged and rocky than the mountains of the northwest, being rounded and grassy, with more of the appearance of a plateau. There are large basins between mountain groups, the most striking being the moor of Rannoch, a bleak expanse of bogs and granitic rocks, with narrow, deep lochs, such as Loch Rannoch and Loch Erriicht. The boundary of the Highlands is clearly marked by a fault (the Caledonian trend) running southwest to northeast from Helensburgh, on the River Clyde, to Stonehaven, on the east coast. The southern boundary of the Lowlands is not such a continuous escarpment, but the fault beginning in the northeast with the Lammermuir and Moorfoot hills and extending to Glen App, in the southwest, is a distinct dividing line. In some ways the label Lowlands is a misnomer, for, although this part of Scotland is low by comparison with adjoining areas, it is by no means flat. The landscape is varied by series of hills such as the Sidlaws, the Ochils, the Campsies, and the Pentlands, composed of igneous rocks rising as high as 1,898 feet (579 metres) and following the Caledonian trend. Most of the area is above 400 feet, but the lowlands in Lothian and Fife regions in the east, the rich plain in Tayside region in the northeast, and the Clyde Valley in Strathclyde region in the west are Scotland's best areas for arable farming. The Southern Uplands are not so high and fractured as the Highlands. Glaciation has resulted in narrow, flat valleys separating table mountains. To the east of Nithsdale (Valley of Nith) in the Borders region, the hills are rounded, gently sloping, and grass covered, providing excellent grazing for sheep. To the west of the Nith the landscape is rougher, with granitic intrusions around Loch Doon, and the soil more peaty and wet. The high moorlands and hills, of which Merrick (2,764 feet) is the highest, are also suitable for sheep farming. Toward the southeast the uplands open out into the Tweed Valley, which broadens into rich farming land, and to the southwest they slope toward the Galloway Peninsula.

Soil and drainage. With Scotland's diversity in geological structure, relief, and weather, the character of the soil varies greatly. In the northwest, the Hebrides, and the Shetlands, where the geological substratum is ancient rock, resistant to weather, the soil is poor, and cultivation is possible only at river mouths, glens, and coastal strips. On the west coast of some Hebridean islands, however, there are plains of calcareous sand (the machair) suitable for farming. On moors and hills between 1,000 and 2,500 feet, a peat covering is widespread because of high rainfall and poor drainage. Peat is estimated to cover some 2,600 square miles. It occurs also on lower ground, and north-

The
Great
Glen

Peat

eastern Highland region has large peat deposits. Where there is good soil for arable farming, as in the Orkneys, the eastern Highland region, the northeastern coastal plain, and the Lowlands, it has been derived from old red sandstone and younger rocks. Though the sea lochs, or fiords, of the west are supposed to be remnants of a river system submerged by the Minch Channel, the present drainage system runs toward the east. In the northern Highlands the watershed runs from north to south, close to the west coast, so that rivers running to the west are very short and those to the east longer and less rapid. In the central Highlands the rivers meander more, but the longest, the Spey, Don, and Dee, drain the area toward the east, as do the Tay and the Forth in the Lowlands. The Clyde and the Tweed both rise in the Southern Uplands, the one flowing to the west and the other to the east coast, while the Nith and a few other small rivers run south into the Solway Firth. Lochs are useful for drainage, for reservoirs, and as sources of power. They are numerous in the Highlands, ranging from moraine-dammed lochans (pools) in mountain comes (hollows) to large and deep lochs filling rock basins. Many of the bigger lochs have been dammed and enlarged to provide a flow of water to generate electricity in stations at lower levels. In the Lowlands and Southern Uplands, lochs are shallower and less numerous, though some, notably Loch Lomond, are extensive.

Climate. Scotland has a temperate oceanic climate, milder than might be expected from its latitude. Despite its small area, there are considerable variations in climate. Rainfall is greatest in the mountainous areas of the west, as prevailing winds blow from the southwest and come laden with moisture from the Atlantic. East winds are common only in winter and spring, when cold, dry continental air masses envelop the east coast. Hence, the west tends to be milder in winter, with less frost and with snow seldom lying long, but it is damper and cloudier than the east in summer. Tyree (Tiree), in the Hebrides off the west coast, has a mean temperature in winter of 41° F (5° C) in the coldest month (as high as southeastern England), whereas Dundee, on the east coast, has 37° F (2.8° C). Dundee's mean temperature in the warmest month is 59° F (15° C) and Tyree's 57° F (13.9° C). There is a smaller range of temperatures over the year in Scotland than in southern England. Rainfall varies remarkably. In the flat Outer Hebrides it does not exceed 40 inches (1,000 millimetres) a year, the average rainfall in Britain. Some two-thirds of the surface of Scotland, however, has more than 40 inches. In the mountains of Highland region, rainfall exceeds 100 inches. Most of the east coast has below-average rainfall, less than 25 inches in the Moray Firth lowlands and 27 inches in Dundee. Sunshine averages 3½ hours per day over the year.

Vegetation. Lower ground, up to about 1,500 feet, was once covered with natural forests, which have been cleared in the course of centuries and replaced by introduced trees, plants, and crops. Survivals of the original forest are found in the pinewoods of Rothiemurchus, in Highland region. Grass and heather cover most of the Grampians and Southern Uplands, where the soil is not so wet and dank as in the northwestern Highlands. On boggy soil, shrubs such as bearberry, crowberry, and blueberry grow, as does bog cotton. Alpine and Arctic species flourish on the highest slopes and plateaus of the Grampians, including saxifrages, creeping azalea, and dwarf willows. Ben Lawers is noted for the wealth of its mountain flora.

Animal life. For its size, Scotland is rich in animal life. Herds of red deer graze in the corries and remote glens, and their population is estimated at nearly 500,000. Lower down in wooded country the more elusive roe deer are found. Foxes and badgers are widespread, and the number of wildcats is thought to be increasing. Rabbits were decimated but not eliminated by the disease of myxomatosis. Pine marten, otters, and mountain and brown hares are among other wild animals. A few ospreys nest in Scotland, and golden eagles, buzzards, and kestrels are the most notable of resident birds of prey. Capercaillie (a species of grouse) have been successfully reintroduced. Sea-

birds, such as gannets, fulmars, and guillemots, and various types of gull abound on cliffs and the isolated rocks known as stacks around the magnificent coasts. The largest mammal in Scottish waters is the Atlantic gray seal, which breeds on the island of North Rona, off the west coast; the common seal is also numerous.

The human imprint. In early times, mountains, rivers, and seas divided the people into self-sufficient communities, which developed a strong sense of identity. This sense has been eroded by social mobility and by modern transport, broadcasting, and other standardizing influences. Yet vestiges of regional consciousness linger. The Shetland islanders speak of Scotland with detachment. The Galloway area in the southwest, cut off by hills from the rest of the country, has a vigorous regional patriotism. The Gaelic-speaking people of the Hebrides and western Highlands find their language a bond of community. A distinct dialect may differentiate some communities from others, as in the case of the Aberdeen area. Borderers celebrate their local festivals with fervour. This feeling of community survives to a varying degree in many areas, but it has no economic basis now and tends, like clan loyalty, to be a sentimental bond rather than a force of social cohesion. The most thickly populated rural areas are those with the best farming land, such as in Lothian region and in the Northeast. The Highlands nourished a large population before sheep farming led to continuous emigration. Now settlements in the Highlands are mostly crofting townships; that is, small farms of a few acres grouped together in an irregular manner. The old pattern of crofting was one of communities practicing a kind of cooperative farming, with strips of common land allotted annually to individuals. Examples of the old system survive, but now crofters have their own arable land fenced in, while they share the common grazing land. In Lothian region and other areas of high farming, the communal farm has long been replaced by single farms with steadings (farmsteads) and workers' houses. Scotland is noticeably lacking in those old villages that evolved in England from medieval hamlets of joint tenants. Some planned villages were built by enterprising landowners in the 18th century. Burghs, often little bigger than villages, were mostly set up as trading centres, ports, or river crossings or to command entrances to mountain passes. Around the east and northeast coast, there are many surviving small towns that were once obliged to be self-contained in consumer industries and burghal institutions because of poor land transport. Some coastal towns have preserved a dual character, the fishing community being grouped around the harbour, while other inhabitants occupy the higher ground. Growth of industry and transport has produced urbanization. Edinburgh, Dundee, and Aberdeen are centres of administration, commerce, and industry for their areas, but only Central Clydeside, including Glasgow with its satellite burghs, is large enough to deserve the official title of conurbation, with a population of more than 1,700,000. Depopulation of city centres is occurring in Scotland, as elsewhere, while that of surrounding areas is rising. In Glasgow the reduction has been due to a planned overspill program, but elsewhere the trend has been due to the growth in commuting.

THE PEOPLE

Despite their diverse origins, including Celts, Angles, and Normans, the Scots in time have been fused into a fairly homogeneous population. In the 19th century there was heavy Irish immigration, which some feared would form an alien element, with different social and educational standards and religion. The Irish have settled, however, without provoking marked social conflict.

Religion. Scotland is remarkably free from racial and religious strife. The Church of Scotland is the established religion and largest communion, though membership has been steadily declining and fell below 1,000,000 during the late 1970s. It is presbyterian in structure and evangelical in doctrine. Its well-articulated organization begins with the parish church or congregation, governed by a kirk session composed of minister and elders. The kirk session sends representatives to the presbytery (a group of par-

Crofting

Rainfall

Church
of
Scotland

ishes), and the presbyteries in turn are represented in the synod, which has declined in status. At the apex is the General Assembly, to which presbyteries send clerical and lay commissioners in equal numbers and which is the supreme court and legislature of the church. It meets annually and reviews the reports of numerous committees. It is perhaps the most representative body in Scotland and makes its voice heard on current moral, social, and international issues. The Roman Catholic Church, organized into two archdioceses and six bishoprics, has a membership of more than 800,000. The Episcopal Church in Scotland has about 70,000 members, and there are congregations of other denominations, such as the Free Church of Scotland, Baptists, Congregationalists, Methodists, and Unitarians. The ecumenical spirit and perhaps growing indifference have taken bitterness out of religious differences, though little progress has been made with church unity. Roman Catholics have their own schools, built and staffed from public funds on the same terms as the state schools.

Demography. Scotland, according to the 1981 census, was the home of 5,117,146 people, 112,000 fewer than in 1971. Since 1801 the population has increased almost continuously, though there was a decrease of some 40,000 in the decade 1921-31. The long-term decline in the birth rate has continued. In 1921 the number of births was 123,201; by 1977 the total was 62,342, the lowest yet recorded. By contrast, the death rate has remained remarkably constant, at around 12 per 1,000; in 1921 the number of deaths was 66,210, and in 1980 it was 63,300. During the 1970s the natural increase, that is, the excess of births over deaths, was only 58,600, while there was actually a natural decrease in the years 1977 and 1978.

Natural increase would have resulted in a much larger population, however, were it not for considerable losses from emigration. In the period 1931-51, for example, the natural increase was more than 500,000, but the actual increase was only half this figure. The drain of emigration has continued for two centuries. In the first half of the 20th century the net loss was 1,158,000. From 1951 to 1981 it was 667,300. The flow of migration overseas and to the rest of the United Kingdom deprives Scotland of many of its young, skilled, and educated. Emigration rises and falls, and, though there was some decline in the 1970s, adverse trends inevitably recur when economic conditions deteriorate. Emigration from Scotland used to be offset by heavy immigration from Ireland, which reached a peak of 205,064 in the 1901 census. Since then it has fallen steadily and is now insignificant. The great majority of the Irish-born live in Glasgow and the surrounding area. The number of English-born living in Scotland has increased considerably during the 1900s and now totals more than 250,000. In Glasgow there are Pakistani and Indian communities, but immigration from Asian countries to Scotland generally has been small and without the social tension that has occurred in some English cities.

Physical and economic factors explain the concentration of three-quarters of the population in the central Lowlands, which occupy only one-seventh of the country's area. The average density of population is about 170 per square mile, but in the central areas it is more than 1,000. By contrast, the Highlands have had almost continuous depopulation—by 11 percent between 1851 and 1901, by 18.8 percent between 1901 and 1951, and by 3.6 percent between 1951 and 1961. But the decline seems to have been arrested. Between 1961 and 1981 there was an increase of more than 36,000 in the population of the northern areas, but this figure includes a number of temporary residents working in oil-related activities. The 1981 census also reflected a continuing feature of the postwar years, namely, a drift from the cities to surrounding areas. The drop in population was least in the case of Aberdeen (4 percent), which has benefitted from North Sea oil exploitation. Glasgow fared the worst, with a loss of 28 percent, or 290,000 people, between 1961 and 1981. Depopulation has also taken place in Borders region and in the southwest, though less markedly than in the Highlands.

THE SCOTTISH ECONOMY

Scotland's economy compares unfavourably with that of European countries of similar size except Ireland. Scotland's growth is slower, unemployment higher, and per capita gross domestic product (GDP) lower than other nations. Even in the context of the United Kingdom it is economically backward. Its GDP is about 9 percent of the U.K. total. Its unemployment rate in postwar years has been almost consistently twice that of Britain as a whole. Fewer people were employed in 1980 than in 1960, though the number of women at work has risen steadily. Male unemployment is one of the most disquieting features of the economy. Most parts of Scotland are scheduled as development areas, eligible for special state incentives to attract new enterprises.

Natural resources. *Mineral resources.* Coal is Scotland's chief mineral resource, but the Lanark coalfields are almost exhausted, and the main mining areas are now in Lothian and Fife regions and in western Strathclyde region. The industry reached its peak production of 43,000,000 tons in 1913 but has since declined to about one-fourth of that total. Many uneconomic collieries have been closed, and production has been concentrated on large, mechanized pits. Manpower has fallen from 82,000 in 1951 to two-fifths of that number. Though the industry has generally contracted, its productivity has risen. Other minerals that have been worked intermittently include gold, silver, lead, chromite, diatomite, and dolomite, but none has been successfully exploited. At Muirshields and Gass Water, both in Strathclyde region, some 30,000 tons of barite (barium sulfate, used in paint manufacture), one-third of the U.K. output, is produced each year. Though peat is available to a depth of two feet or more over some 1,700,000 acres, its economic value is limited. Some communities in the Highlands still burn it for fuel, but the time and labour involved in cutting and drying peat in an uncertain climate have led to decreasing use. Experiments in using peat as fuel for generating electricity proved it uneconomical.

During the 1970s a new Scottish resource, North Sea oil, was developed. The oil fields lie mostly in Scottish waters, but the British government holds their ownership and receives all the revenue yield. The oil has been located and extracted by large companies, most with the aid of U.S. technology. Aberdeen is the centre of the oil industry, and the Shetlands have also benefitted from discoveries in adjacent waters. About 75,000 jobs are estimated to have been created in Scotland by onshore oil-related enterprises, such as building oil production platforms and servicing North Sea operators. When production began in 1975, the output was about 1,200,000 tons, but it grew to 80 times that figure during the next five years. Natural gas from North Sea wells has replaced manufactured gas in Scotland.

Power resources. Water is a valuable resource, especially for generating electricity. The North of Scotland Hydro-Electric Board (NSHEB) was set up in 1943 to build dams and power stations. The NSHEB operates more than 50 hydroelectric stations, with a total capacity of more than 2,100 megawatts. The board also has pumped storage schemes by which electricity generated in off-peak periods may be used to pump water to a higher dam, from which it descends at peak periods to operate the turbo-generators. One such scheme, at Cruachan, in Strathclyde region, operates at a capacity of 400 megawatts, and there is another at Foyers, on Loch Ness. The NSHEB has also coal- and oil-fired stations. The board's obligation to provide power to consumers in remote areas entails a financial loss, but it was set up with a definite social responsibility. The South of Scotland Electricity Board relies mainly on coal-fired stations; those at Cockenzie, Kincardine, and Longannet are new and efficient. There are nuclear power stations at Chapelcross, in Dumfries and Galloway region, and at Hunterston, in Strathclyde region. A nuclear-research establishment, run by the U.K. Atomic Energy Authority, is located at Dounreay, in Highland region, where a prototype of a commercial fast-breeder reactor has been built. Work began in 1978 on a nuclear-power station at Torness, in Lothian region.

North
Sea

Depopulation
in the
Highlands

Agriculture, forestry, and fishing. As an economic resource wild animals, birds, and river fishes are of minor importance, though deer **stalking**, grouse shooting, and fishing provide employment in parts of the Highlands in which other activities are hardly possible. Venison is exported to the European mainland, and game birds, salmon, and trout are delicacies, as well as objects of sport.

Fishing. Sea fishing is still a major industry, though it has faced serious **difficulties** in recent years. The extension of fishery limits has excluded Scottish trawlers from traditional fishing grounds like those around Iceland and the Faeroe Islands. **Overfishing** has depleted stocks, and bans on herring fishing have been imposed at various periods. The fishing fleet is contracting in numbers, but it has become better equipped and more efficient. The inshore fleet has been modernized, and boats have been equipped for both netting herring and catching whitefish by seine nets. Aberdeen and Moray Firth ports are the busiest centres for landing and processing whitefish, but **Lerwick**, in the Shetland Islands, Ullapool and Mallaig, both on the west coast of the mainland, and Stornoway, on the island of Lewis, are also important. Catches naturally fluctuate from year to year, but Scottish vessels generally account for more than half of all U.K. landings by weight and by value. Twice the number of workers are employed in fish processing as in fishing.

Agriculture. In terms of productivity, no industry has made greater progress than agriculture in postwar years. Owing to mechanization, the labour force has fallen from about **88,000** in 1951 to barely a third of that number, though some casual and part-time workers are also employed. There are nearly **20,000** full-time farms in Scotland, of which roughly half are rented and half **owner-occupied**. In the Southern Uplands and the Highlands there are nearly 5,400 hill sheep farms, while in the Northeast livestock rearing combined with crops for animal feeding predominates. In the southwest, dairy farming suits the damp, mild climate, and the Central Clydeside conurbation is a convenient market. Wheat and barley are grown in **Lothian**, Fife, and Borders regions. Specialized **kinds** of farming flourish in certain areas, such as market gardens in eastern **Lothian** region, raspberry growing in Tayside region, and tomato growing under glass in the upper Clyde Valley. Early potatoes are a specialty of the southwest coast. Barley, used for distilling among other things, has become the principal crop; in 1951 the amount of barley produced was **192,000** tons, but in the following 25 years it increased to 10 times that amount. Wheat is grown only in the most fertile areas, but production is tending to rise, whereas the output of oats has markedly declined. While production of turnips and potatoes has fallen, that of hay and grass silage has substantially increased. In animal production the most striking feature has been the rise in the number of cattle, from **1,600,000** in 1951 to more than **2,400,000** by the early 1980s. Sheep and pigs have also tended to become more numerous over the long term. Crofting is a special section of the agricultural scene. It has to be supplemented by other work, such as forestry, road work, catering for tourists, and weaving. Though there are some **19,000** crofts in the northern areas, many of them are not cultivated. The Crofters Commission gives crofters advice, and it channels grants to them for the improvement of land and houses.

Forestry. Forestry is an expanding industry, which has helped retain the population in rural areas. It is managed by the Forestry Commission, a public body, and by private landowners. The commission has forests extending over about **1,230,000** acres, while privately owned forests cover two-thirds that area. Although the Forestry Commission plants throughout the country, it plays a particularly important role in Highland development. The trees it grows are conifers, including Scotch pine, Norway spruce, European larch, Sitka spruce, and Douglas fir.

Industry. In its industrial heyday Scotland's prosperity was based on such heavy industries as coal, steel, shipbuilding, and engineering. In more recent times these have been the industries most exposed to foreign competition and to changes of demand. The task of correcting Scot-

land's industrial balance by reducing dependence on heavy industries and replacing them with high-technology enterprises and those making consumer goods has been slow and laborious, but considerable progress has been made in diversifying the structure of industry and in modernizing it. As with wal, the history of steel and shipbuilding is one of a reduction in the number of plants and employees. Scottish steel plants now belong to the British Steel Corporation, and shipyards are under the control of another state industry, British Shipbuilders. Scotland has shared in the drastic reduction of British Steel's operations; obsolescent plants were closed, but the large strip mill at Ravenscraig, in Strathclyde region, was enlarged. An iron-ore terminal to import materials for Ravenscraig was built at Hunterston, where the water is deep enough to accommodate the largest vessels. Shipbuilding was subjected during the 1970s to a prolonged scrutiny in order to seek remedies for its failure to compete successfully with foreign yards like those in Japan; as the result of a government report, there were mergers among many shipyards. Most of the well-known names on Clydeside have vanished, and the remaining yards are **Govan** Shipbuilders, Yarrow, mostly engaged in naval shipbuilding, and the Swt Lithgow group on the lower reaches of the Clyde, which is capable of building anything from oil tankers to submarines. Small yards belonging to British Shipbuilders in Aberdeen, Leith, and Troon build trawlers and cargo vessels.

There is now a wide range of manufacturing industries in Scotland. The electronics and computer industries have expanded remarkably in recent years, especially in Fife and **Lothian** regions and in the Glasgow area. Most of the companies engaged in electronics and computers are branches of U.S. and English **undertakings** and include leading international firms like **IBM** and Hewlett-Packard. Manufacture of clocks, watches, cash registers, **earth-moving** machinery, precision instruments, and other modern products, introduced since World War II, has also helped to diversify the industrial structure. **Old-established** industries such as textiles in the Borders region towns of **Hawick**, Galashiels, **Selkirk**, and Peebles have retained their vitality. Carpet making flourishes in **Glasgow** and Ayr. Dundee's characteristic jute industry has been contracted and modernized and turned to the production of other fibres as well. Automobiles were made in Scotland in the pioneering days of motoring, but the industry faded away until it was revived on a considerable scale in the early 1960s through government encouragement. The industry failed to grow as much as had been expected, however, and makers of automobile components did not move to Scotland along with the car manufacturers. British Leyland has two plants, one in **Bathgate** and another in Glasgow, but the motor works at **Linwood**, near Glasgow, once owned by Chrysler, were closed in 1981 with the loss of **4,000** jobs, only one-half of the work force at its peak.

Printing and brewing are well-established industries in Edinburgh and Glasgow. The 120 distilleries in the Highlands and the Northeast produce the whisky for which Scotland is internationally famous. Despite crushing taxation on home consumption, whisky sales have continued to increase, and its appeal in foreign countries remains high. Separate records of Scotland's exports are not kept, but it is known that whisky's contribution to the U.K. overseas trade is substantial. Whisky is the chief earner of foreign currency, but the textile industries of the Borders region and the Harris tweed industry of the Hebrides also have a large export business. Mechanical- and **electrical-engineering** industries also export much of their output.

Finance. Scotland had eight joint-stock banks until the **1950s**, but, as a result of mergers, the number was reduced to three: the Bank of Scotland, the Royal Bank of Scotland, and the Clydesdale Bank. The Scottish banks have their own notes, they have introduced computers and new accounting methods, and they have moved into hire purchase (installment purchase), merchant **banking**, and insurance **broking**. Scotland formerly had been conspicuously **lacking** in merchant-bank facilities, but several native merchant banks have been established, in addition

Steel
and
ship-
building

Other
industries

Principal
crops

to branches of London banks. Investment trusts are among the most distinctive of Scottish financial institutions. One-third of Britain's investment trusts are managed in Edinburgh, Glasgow, and Dundee. They have large investments in North America and specialized knowledge of conditions there. Unit trusts are represented in Edinburgh, where some leading British insurance companies also have their headquarters.

Economic problems. Scotland's economic problems are serious. Unemployment, which by the 1980s had risen to a level that was appalling by postwar standards and was reminiscent of the depression of the 1930s, threatens to be an abiding problem. Manufacturing industries in Scotland show a fall in employment, offset to some extent by the greater number of jobs provided by services of various kinds in professional and administrative fields. Technological changes are diminishing the need for labour in manufacturing and threaten to do the same in commerce. Such changes, of course, affect the economies of every industrial country. The influx of foreign companies has helped to improve Scotland's ability to meet the challenge of new forces in markets and in technology. By the end of the 1970s upward of 300 manufacturing units in Scotland, accounting for more than 100,000 jobs, were owned by overseas companies; this has brought a notable accession of managerial and technical know-how.

It is a common complaint that Scotland's economic problems are aggravated by the policies of successive Westminster governments, framed to suit populous and prosperous regions in the Southeast and the Midlands of England. On the other hand, governments do try to compensate for the handicaps of distance and high transport costs by applying regional policies. Grants and loans for buildings and machinery are offered to industrialists willing to set up business in development areas, as those most afflicted with heavy unemployment are called. Especially attractive incentives are available in the most blighted areas like those devastated by the closings of mines or factories. The Scottish Development Agency attempts to attract foreign industrialists, to help native enterprises with financial and marketing problems, to manage industrial estates, and generally to stimulate growth.

TRANSPORTATION

Most public transport in Scotland is owned by state companies or local authorities. There is a certain amount of coordination; in 1968, for example, the Scottish Transport Group was created to bring under common control steamer services in the Clyde and the Western Isles and omnibus services throughout the country. Other forms of transport—rail, road haulage, and airlines—retain their own structure. Proliferation of automobiles has made it difficult for omnibus companies to maintain profitable services in rural areas, where they are being either subsidized by local authorities and the government or withdrawn. The pattern of steamship services has greatly altered. Services from mainland ports to island towns have been curtailed and replaced by car ferries using short crossings; such ferries operate from several west coast towns to the Hebrides and other islands and from north and east coast ports to the Orkneys and Shetlands.

Roads and railways. The road system extends to more than 30,500 miles. Despite improvement, much of it, especially single-track roads in the Highlands, is inadequate for rapidly growing traffic. Since 1964 the Forth Road Bridge, the Tay Road Bridge, and the Kingston and Erskine bridges over the Clyde have been opened. Main roads, such as Carlisle-Glasgow, Edinburgh-Glasgow, Glasgow-Stirling, and Edinburgh-Inverness, have been or are being reconstructed as motorways or dual carriage-ways. Road improvement has been speeded up by the traffic requirements of North Sea oil production.

Railway services have been severely reduced since 1948, when more than 3,000 miles of track were open to passenger and freight traffic. Many branch lines and stations have been closed, and the route mileage has shrunk to less than two-thirds of the former total. Diesel engines have replaced steam locomotives, and some lines have been electrified. Suburban lines from Glasgow on both

sides of the Clyde and to Airdrie in the east have been electrified, as has the main line from Crewe to Glasgow.

Shipping and air transport. Scottish ports handle many more imports than exports, a large proportion of which is sent abroad via English ports. Glasgow, the largest port, is under the administration of the Clyde Port Authority. The Forth ports, including Grangemouth and Leith, are grouped under the Forth Ports Authority, while Dundee and Aberdeen are independent. Greenock and Grangemouth are equipped for container traffic, and extensive improvement schemes have been carried out at Leith and other ports. Coastal trade has dwindled because of the competition of motor transport, and inland waterways have never been a commercial success. The Forth and Clyde Canal is closed, and the Caledonian Ship Canal is used only by small craft.

Air transport is growing steadily. The major airports are Glasgow, Edinburgh, and Prestwick, all operated by the British Airports Authority. Transatlantic services fly from Prestwick, on the west coast, which is remarkably fog-free, and Glasgow and Edinburgh are used for domestic services in the United Kingdom and to a lesser extent for flights to European cities. The Highlands and islands have several airfields, but the services to them from Edinburgh, Glasgow, and Aberdeen are unprofitable and are operated by British Airways for social reasons.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Scotland is represented in the United Kingdom Parliament by 71 members, and since the election of 1964 all Scottish peers have been entitled to sit in the House of Lords. The secretary of state for Scotland is responsible to Parliament for departments under his jurisdiction. These consist of the departments of Home and Health, Education, Agriculture and Fisheries, Economic Planning, and Development. In his multifarious functions the secretary of state is assisted by a minister of state and three parliamentary undersecretaries. In the House of Commons, bills relating solely to Scotland are referred to the Scottish Grand Committee, which consists of all Scottish MPs. The Grand Committee has a general debate on a bill and usually sends it for detailed examination to the Scottish Standing Committee, a smaller body of some 30 Scottish MPs. The Select Committee on Scottish Affairs, composed of Scottish MPs, investigates specific administrative or economic issues.

Political parties. The two major British parties, Labour and Conservative, have separate organizations in Scotland, hold annual conferences, and take notice of Scottish problems and grievances. They hardly have distinctive policies for Scotland but rather adapt general proposals to Scottish purposes. In the 1955 general election the Conservatives won 36 of the 71 Scottish seats and gained 50 percent of the vote cast. This was the high-water mark of the Conservatives in modern times, for the party's support has ebbed ever since. In 1966 the Conservatives held only 20 seats, and in 1970 won 23. In the 1979 election, which returned a Conservative government for the United Kingdom, the party managed to win only 22 seats in Scotland. Labour's position as the predominant party has been confirmed by all elections since 1955. In 1966 Labour gained 46 seats, and in 1970, 44; in 1979, although defeated in the United Kingdom, the party elected 44 MPs in Scotland. Labour's strength lies in industrial areas, chiefly Glasgow and Dundee, and in Fife region and parts of Central and Strathclyde regions. Conservatives are most successful in Edinburgh and in rural constituencies such as Dumfries and Galloway region and parts of the Northeast. The Scottish Liberal Party, which stands for a type of federal home rule for Scotland, also has a few rural seats.

Devolution, or self-government, became a lively issue during the 1970s, though the question had agitated the political scene in earlier years. The Scottish National Party (SNP), which advocates independence, including control of defense and foreign policy, had a sensational success at a by-election in 1967, winning the apparently impregnable Labour seat at Hamilton, near Glasgow. This was followed by a surge of nationalism, reinforced

ports

Incentives
for
develop-
ment

Move
for self-
govern-
ment

perhaps by the **SNP's** argument that the rich oil deposits in Scottish waters in the North Sea were being exploited for England's benefit. The **SNP** had some setbacks in local elections, but it fared well in the two general elections in 1974, winning seven seats in February and 11 in October. Labour, alarmed by this threat to their Scottish base, was reconverted to the cause of self-government. Their plan for an elected Scottish assembly was enacted after a long struggle, though it was opposed by the Conservatives and by a number of Labour's own **MP's**. It was submitted to a referendum of the Scottish people in 1979 and approved by a vote of 1,230,937 to 1,153,502, but it failed to secure the support of 40 percent of the registered electors (as opposed to those actually voting). The new Tory government repealed the act on that ground. The Labour plan was complicated and of doubtful practicability; it excited little enthusiasm, and the strength of support for devolution is undoubtedly greater, as opinion polls indicate, than the referendum result implied. After the referendum Scottish politics relapsed into their former condition of marginal interest in the eyes of the major parties; the **SNP** lost all but two of its seats in the 1979 election.

Local government. The local government structure of Scotland was reorganized in 1975. The number of local authorities was reduced and a two-tier system created. In place of the rather complex **pattern** of cities, burghs, and counties, the country was divided into nine regions: Borders, Central, **Dumfries** and Galloway, Fife, Grampian, Highland, **Lothian**, Strathclyde, and Tayside. Three island authorities—Orkney Islands, Shetland Islands, and Western Isles—have separate status. Power is distributed between the regions and the 53 districts into which they are divided. The regional authorities are responsible for planning, transport, education, police, and fire services, while the districts deal with such matters as housing, sanitation, libraries, and recreation facilities. Elections to these authorities are held every four years; most local contests are fought on party lines. Labour controls Strathclyde, the largest region, and is the **predominant** party in local as in parliamentary politics. Regional and district councils are financed partly by government grants and partly by the yield of rates, local taxes levied on householders, commercial properties, and industrial plants. Government grants normally cover two-thirds of the expenditure of local authorities, but they are the subject of annual negotiations. The reform of local government cannot be said to have satisfied its critics. It is felt by many of them to have become even more bureaucratic and more out of touch with local feelings. Persistent increases in the tax rates, mainly due to inflation, also fuel discontent with the system, while **conflict** between local authorities and the central government is apt to be keen when different parties are in power at Westminster and in the Scottish local councils.

Justice. In law Scotland has preserved its own system and courts. The lord advocate and the solicitor general for Scotland are the ministers responsible for justice; they advise the government on legal affairs and help to draft legislation. The country is divided into 12 sheriffdoms, each with a sheriff principal and a varying number of sheriffs substitute. Offenses triable by jury are reserved for the High Court of Justiciary, the supreme court for criminal cases. The judges are the same as those of the Court of Session, the supreme court for civil cases. An appeal may be directed to the House of Lords from the Court of Session, but not from the High Court of Justiciary. The Court of Session, consisting of the lord president, the lord justice clerk, and 19 other judges, sits in Edinburgh and is divided into Inner and Outer houses. The Outer House judges hear cases at first instance. The Inner House, of which there are two divisions, each of four judges, hears appeals from the Outer House and from inferior courts. The sheriff courts have a wide jurisdiction in civil cases, but certain actions, such as divorce, are reserved for the Court of Session. The police investigate cases of crime discovered by or made known to them, but the decision whether or not to prosecute is made by the lord advocate in the High Court and by procurator fiscals in the sheriff courts.

Military services. Scotsmen serve in the Royal Navy and the Royal Air Force (RAF). There are naval bases at Rosyth, in Fife region, which services nuclear submarines, and at Holy Loch, on the Clyde, for U.S. nuclear submarines. The North Atlantic Treaty Organization (NATO) has a network of **airfields**, storage facilities, and communications along the west coast. But Scotland's defense associations are primarily with the army. The infantry regiments, especially the Highland regiments, the Queen's Own Highlanders, the Black Watch, the Gordon Highlanders, and the Argyll and Sutherland Highlanders, with their **colourful** uniforms and pipe bands, embody the military traditions of the country. The Royal Scots are proud of being the oldest infantry regiment in the British Army.

The social milieu. Education. In Scotland, education is supervised by the Education Department and administered by the education committees of the regional authorities. Unlike the English system, fee-charging, independent "public schools" play only a minor role in Scottish education. Direct-grant schools, located mostly in Edinburgh and Glasgow, get a government grant to supplement the fees paid by pupils. Though education authorities were informed in 1971 that they were no longer required to organize secondary education on comprehensive lines (*i.e.*, in schools providing several types of secondary education—academic, vocational, technical—in one building), this system has been widely adopted, especially in urban areas. Teachers, many of them university graduates, get their professional training in colleges of education. A shortage of teachers was a constant problem in postwar years; but toward the end of the 1970s the situation began to change, and teachers found it **difficult** to get jobs. The number of entries to the colleges of education had to be reduced to bring supply into line with demand.

Health and welfare services. Health and welfare services and housing are the joint responsibility of government departments and local authorities. The National Health Service is administered in Scotland by 15 Health Boards and the Common Services Agency; local authorities provide for the welfare of mothers, children, and the aged. Standards of health are rising; tuberculosis has almost disappeared, and infant mortality has been reduced to 14 per 1,000, a notable improvement over former figures. Heart disease and cancer have become the major causes of mortality, together accounting for more than half of all deaths. Incomes rise continuously, more because of inflation than real increases, but they are lower in Scotland than in the United Kingdom as a whole. Average weekly earnings of manual workers have caught up with those of British workers in general. But incomes from profits and professional services are below the U.K. levels, and there are more people in the lower income groups and fewer in the higher ones than in the United Kingdom as a whole. Only in investment income is Scotland almost on equal terms.

Housing. No social problem causes more concern in Scotland than housing. Since 1919 well over 1,400,000 houses have been built, but that has not been enough to eradicate the legacy of substandard, overcrowded houses, lacking proper conveniences, bequeathed by the Industrial Revolution in the 19th century. Despite much demolition and rebuilding, nearly a quarter of Glasgow's houses are below statutory tolerable standards. Scotland used to differ from England in that far more houses were built by local authorities for renting than by private enterprise for sale. A striking change took place in housing supply during the 1970s, however, when local authorities were unable to keep up with the mounting costs of house building and there was a rise in private construction. Because most new houses have been owned by local authorities, the cost in subsidies from the exchequer and from taxes has been high; local authorities have commonly been criticized for charging unduly low rents. To lessen the demand on public funds, the government introduced a scheme for raising the rents of local-authority houses, with rebates for tenants unable to pay the higher charges.

Police forces. Since the secretary of state has a general responsibility for law and order, he shares control of the police forces with local authorities. The police committees

Income
differ-
entials

High
Court
of
Justiciary

provide the buildings and equipment needed by the forces. The secretary of state, assisted by the chief inspector of constabulary, is concerned with efficiency and discipline; he approves the appointment of chief constables and can make regulations on conditions of service.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. Scotland's culture is in an indeterminate state. It could be argued that there is not a national culture but only a regional variation of a wider British culture. Scotland's culture does have stirrings of independence. Although it is perhaps dominated by the intellectual and artistic influences of London, its cultural institutions and achievements transcend the provincial level. The Edinburgh International Festival of Music and Drama in scale and quality is an outstanding event in the cultural calendar. Scotland's own contribution to it is modest but creditable, and it has probably had a good effect in raising the standards of artistic performance. The Scottish National Orchestra, Scottish Opera, and Scottish Ballet have earned high reputations, though they rely much on imported talent. These and other enterprises are subsidized by the Scottish Arts Council, which supports theatres, concerts, and exhibitions, besides giving grants or scholarships to individual artists. Scottish writers have the choice of three languages: Gaelic, Lallans (or Scots vernacular), and English. Gaelic is understood by a small minority; there are only about 90,000 Gaelic speakers, mostly in western Highland region, the Hebrides, and Glasgow, but the Gaelic poets **Sorley Maclean** and **George Campbell Hay** are highly esteemed. **Hugh MacDiarmid**, the poet, nationalist, and Marxist, achieved an international reputation for his Scots poetry, and **Robert Garioch** wrote in Scots with humour and craftsmanship; but the Lallans revival has faded. English is the tongue of most poets, such as **Norman MacCaig**, and of popular novelists and dramatists. Scottish painting and sculpture are flourishing, as the annual exhibition of the Royal Scottish Academy proves. Folk songs and music are popular and are collected by the School of Scottish Studies, which is attached to the University of Edinburgh; it is also responsible for two great works of scholarship, *A Dictionary of the Older Scottish Tongue* and *The Scottish National Dictionary*, the latter of which has been completed. Edinburgh houses cultural institutions of notable prominence, such as the National Library of Scotland, which has a statutory right to receive copies of all books published in Britain. It has more than 2,000,000 printed books and a large collection of manuscripts. The National Gallery of Scotland has paintings by many famous European artists in addition to works by **Allan Ramsay**, **Sir Henry Raeburn**, and other Scottish painters. The National Portrait Gallery portrays the principal personages in Scotland's history, and the Scottish National Gallery of Modern Art has works by contemporary European painters and sculptors, as well as those of native artists. The National Museum of Antiquities contains archaeological and later evidence for the development of the material and domestic aspects of Scottish society. The Royal Scottish Museum, perhaps the most popular of all, has extensive collections in its departments of art and archaeology, natural history, technology, and geology. The galleries and museums are the responsibility of the secretary of state and are maintained by public funds.

Universities, too, may be included among Scotland's cultural institutions, though their main object is research and the training of students. They give increasing attention to the study of Scottish history, literature, and politics, though the extent varies from university to university. There are now eight universities; in 1960 there were only four. The University of **Strathclyde** in Glasgow and the **Heriot-Watt University** in Edinburgh, formerly technological colleges, were upgraded to universities, retaining their scientific and technological emphasis. The University of Dundee was separated from the University of St. Andrews, which had some departments in Dundee. The University of Stirling, the only completely new foundation, was opened in 1967. The new universities do not teach law and divinity but place most emphasis on science

and technology and have close links with science-based industries in their neighbourhoods. Edinburgh, famous for its medical school, is the largest of the universities, with a student population of more than 10,000. Though the constitutions of the universities vary, nearly all have rectors, elected by the students, and student representative councils.

The media. *The press.* The Scottish press has tended to shrink in size because of rising costs and competition, but newspapers survive in sufficient variety of quality and popular appeal. There are Scottish editions printed in Manchester of London's *Daily Express* and the *Sunday Express*, and northern editions of other London newspapers are imported. Among indigenous newspapers, *The Scotsman* and the *Glasgow Herald* rank highest in antiquity and influence, giving a sound coverage of Scottish and international news and well-informed explanations and comment. Glasgow also has the *Daily Record*, a Scottish version of the London *Daily Mirror*, while Dundee and Aberdeen have well-established morning papers. There are evening papers in Glasgow, Edinburgh, Dundee, and Aberdeen. The *Sunday Post*, read by more than 1,000,000, is something of an institution, owing to its individual features, especially cartoons, and its somewhat conservative views. The 150 weekly newspapers published in Scotland have a local range, but the venerable *People's Journal* has many local editions and circulates throughout the country. Among illustrated periodicals, two monthly magazines—*Scottish Field* and *Scots Magazine*—vividly display Scotland's scenic beauty and provide a wealth of interest for outdoor enthusiasts.

Television and radio. Television and radio are probably more influential media than the press. The British Broadcasting Corporation (BBC) broadcasts Gaelic news, music, and church services, perhaps more than the number of Gaelic speakers would warrant. There is a good deal of Scottish dance music, songs, gardening talks, sport, and religious services on the radio and Scottish news, sport, and occasional features on television. The BBC is well disposed toward Scottish culture, but its Scottish material hardly does more than flavour programs supplied for the greater part from London. Scottish Television Ltd., a commercial company, scarcely ventures beyond sport and discussions in its specifically Scottish program content, and its contribution to Scottish culture is insignificant.

Sport and recreation. Sport plays a large part in the life of Scotland. Though support is dwindling, association football (soccer) is still the national game. It is dominated by the Glasgow clubs, Celtic and Rangers; their rivalry is sharpened by religion, Roman Catholics supporting Celtic and Protestants supporting Rangers. Their encounters are sometimes marred by hooliganism, but the number of incidents in proportion to the size of the crowds is slight. Most spectators have no interest in the religious feud, which is largely a matter of tradition. Internationally, Scotland's football prestige is tested in the World Cup contests. Rugby Union football, still a pastime for amateurs, is played by former pupils of the Edinburgh and Glasgow private schools, but in towns of the Borders region it draws players and spectators from a wider social range. Rugby internationals played at **Murrayfield**, in Edinburgh, attract large crowds. Hockey, tennis, and swimming are common pastimes; and athletics are enjoyed at Edinburgh's splendid sports stadium. Golf, however, is a more popular game and is within the reach of all, not only the affluent, as in many other countries. There are many municipal courses, as well as private clubs, most of which have moderate subscriptions. The Old Course at St. Andrews, in Fife region, is the most famous of the excellent seaside courses that abound in Scotland; there are other especially well-known courses on the links on the west coast around Ayr. As a result, Scottish golfers play creditably in international competitions, though they seldom win the top awards. For hill walking, rock climbing, and sailing Scotland has natural advantages, as for golf. Skiing has been developed in the Cairngorms; the necessary accommodations and equipment are there, but snow conditions are not as dependable as they are in countries with higher altitudes. **Sum-**

The use of
Gaelic

The Highland Games

mer sports, many unique to Scotland, are provided by the Highland Games. Strong men toss the caber (a heavy pole) and perform other feats of strength; pipers play, and agile men and girls do Highland dances. The colour of the tartan and the panache of kilned pipe bands fascinate tourists, and the Braemar Gathering, in Grampian region, always attended by a royal party from Balmoral Castle, is the culmination of these displays. Many Scots find these games and other traditions, such as Burns suppers (after Robert Burns, the 18th-century national poet) and eating haggis (a delicacy consisting of offal boiled in a sheep's stomach), a self-conscious parade of legendary characteristics that have little to do with ordinary Scottish life—a show put on, like national costumes, to gratify the expectations of tourists. This objection can hardly be levelled against the National Mod, a musical festival run annually by An Comunn Gaidhealach, a society that hopes to keep Gaelic alive by competition among choirs and soloists in singing Gaelic songs and by bards in composing Gaelic verses.

BIBLIOGRAPHY. The *Reader's Guide to Scotland*, a bibliography published by the NATIONAL BOOK LEAGUE (1968), provides annotated lists of works on history, education, administration, law, the economy, sport, and other subjects. A similar bibliography for *The Highlands and Islands of Scotland* was produced by the NATIONAL BOOK LEAGUE in 1967. Excellent articles on the geography of Scottish regions appear in J.B. MITCHELL (ed.), *Great Britain: Geographical Essays* (1962). I.G. MCINTOSH and C.B. MARSHALL, *The Face of Scotland*, 3rd ed. (1977), is an introductory geography. Among innumerable books on topography, MORAY MCLAREN, *The Shell Guide to Scotland* (1977), an informative gazetteer; CALUM MACLEAN, *The Highlands* (1959), written by a Gaelic-speaking Highlander; and W.H. MURRAY, *The Hebrides* (1966), are notable for text and illustrations. F. FRASER DARLING and J. MORTON BOYD, *The Highlands and Islands* (1964); and J.B. WHITTOW, *Geology and Scenery in Scotland* (1977), are written with impressive authority. Political history since 1870 is surveyed in J.G. KELLAS, *Modern Scotland* (1968), and *The Scottish Political System*, 2nd ed. (1975). The self-government debate has inspired a prolific literature, including H.J. PATON, *The Claim of Scotland* (1968), which puts a philosopher's case for self-government. Other works on the same theme are H.J. HANHAM, *Scottish Nationalism* (1969); J.P. MACKINTOSH, *The Devolution of Power* (1968); C. HARVIE, *Scotland and Nationalism: Scottish Society and Politics 1707-1977* (1977); H.M. DRUCKER and G. BROWN, *The Politics of Nationalism and Devolution* (1980); and D.A. HEALD, *Financing Devolution Within the United Kingdom* (1980). The title of W.H. MARWICK, *A Short History of Labour in Scotland* (1967), is self-explanatory, as is that of J. BRAND, *Parties and Politics in Scotland* (1977). The *Scottish Government Yearbook*, edited by H.M. DRUCKER and published annually since 1977, provides surveys and analyses of Scottish politics. A study of the economy by T.L. JOHNSTON, N.K. BUXTON, and D. MAIR, *Structure and Growth of the Scottish Economy* (1971), is a useful textbook. G. MCCRONE, *Scotland's Economic Progress, 1951-1960* (1965), covers the 1950s; the same author's *Scotland's Future: The Economics of Nationalism* (1969), discusses the financial problems of devolution. The Scottish Office has issued booklets describing the work of its departments; the subject is treated more fully in SIR DAVID MILNE, *The Scottish Office and Other Scottish Government Departments* (1957), and more recently by M. MACDONALD and A. REDPATH, *The Scottish Office, 1954-79* (1980). The *Scottish Abstract of Statistics*, produced yearly by the Scottish Office, and its twice-yearly *Scottish Economic Bulletin* are mines of information on the economy. The Fraser of Allander Institute publishes research and quarterly projections in its *Economic Commentary*. Census reports and the annual reports of the Registrar General for Scotland, of the government departments, and of the boards of state industries are also useful sources. On family history, R.W. MUNRO, *Kinsmen and Clansmen* (1971), is a handy reference book; and ROBERT BAIN, *The Clans and Tartans of Scotland*, rev. ed. (1964), is a standard work, as is J. TELFER DUNBAR, *The History of Highland Dress* (1962). J.B. KIRKWOOD, *The Regiments of Scotland* (1949), is a general account, and there are histories of individual regiments. On the arts, IAN FINLAY, *Scottish Crafts* (1948); and S. CURSITER, *Scottish Art to the Close of the Nineteenth Century* (1949), are concise introductions. FRANCIS COLLINSON, *The Traditional and National Music of Scotland* (1966); MAURICE LINDSAY, *History of Scottish Literature* (1977); F.R. HART, *The Scottish Novel* (1978); and the publications of the Association of Scottish Literary Studies may be recommended.

(Ma.J.M.)

Scott, Sir Walter

The life and achievement of Sir Walter Scott, as well as his reputation, form a mass of contrasts and paradoxes. He was, at one and the same time, a sensible 18th-century Edinburgh intellectual and a pioneer of the Romantic movement; a conservative who celebrated the greatness of beggars, outcasts, and madmen; a rationalist constantly fascinated by superstitions, omens, and prophecies; an "incorrigible Jacobite" (a supporter of the House of Stuart's claim to the throne of England and Scotland against those of the ruling House of Hanover) who acted as master of ceremonies for George IV's Scottish coronation tour; an immensely successful writer, earning vast sums, who went bankrupt; a man of simple tastes and of reckless extravagances.

Scott, oil painting by Sir Edwin Henry Landseer, 1824. In the National Portrait Gallery, London.

Perhaps Scott's greatest achievement as a novelist and his most important contribution to the study of history lay in his idea of the clash of cultures. While the Augustan writers of 18th-century England tended to assume that human nature was everywhere the same and that there was only one kind of civilization, the Greco-Roman, to which the alternative was barbarism, Scott demonstrated in his novels that there are many different kinds of civilization, and his favourite device of plot is to place his hero between two cultures, feeling the pull of a double loyalty. For Scott this involved much more than a simple moral problem. It involved completely contrasted ways of living, thinking, and feeling. So it is that the dilemma of the hero of *Waverley*, between the Jacobite and the Hanoverian cause, or of the hero of *Old Mortality*, torn between loyalty to the rebels of the Scottish lowlands and loyalty to the English king, takes on a wide historical significance; as many later historians have testified, these personal dilemmas bring to life the essential history of the times with which they deal.

Scott was born in Edinburgh on August 15, 1771. His father was a lawyer, descended from a long line of country gentry, and his mother was the daughter of a physician. From his earliest years, Scott was fond of listening to his elderly relatives on both sides of the family, and he derived much historical material from these accounts and stories. Though bookish and in his way a distinguished scholar, Scott always preferred to rely for his historical impressions upon oral tradition. That is one reason why, though he wrote about many different centuries and often used a medieval setting, all his best books deal with Scotland and with times within a century and a half of his own.

Like many other famous Scots writers, he was educated at the high school at Edinburgh and also for a time at the grammar school at Kelso. He was then apprenticed to his father as writer to the signet, a Scots equivalent of the English solicitor (attorney). His study and practice of law were somewhat desultory, for his immense youthful energy was never really directed into a single channel. He

became a traveller, a volunteer cavalryman (the Napoleonic wars were fought during most of his youth and early middle age), an antiquary, and a voracious reader in several languages—Italian, Spanish, French, German, and Latin. After a very deeply felt early disappointment in love, he married on December 24, 1797, Charlotte Carpenter, of a French royalist family, with whom he lived happily until her death in 1826. His antiquarian studies bore fruit in 1802–03 with *Minstrelsy of the Scottish Border*. In this work, Scott was playing a part in a wider movement of recovery of ancient British poetry in which the 18th-century English scholar Bishop Thomas Percy and others had preceded him. He also began to develop his work as a journalist, contributing to the very influential *Edinburgh Review*, and as a poet, publishing in 1805 *The Lay of the Last Minstrel*. At this time he was the intimate friend of several eminent English writers, notably William Wordsworth and Robert Southey; and he was later to become the trusted friend of Lord Byron. To be liked by both Wordsworth and Byron and to admire the work of both was unusual but also characteristic. It was natural to Scott to like people and to relish the strangeness of eccentric characters. His hospitable nature and thorough enjoyment of many forms of society helped to make him one of the best loved men of his time.

In the next years his popularity as a poet continued to advance. He wrote in verse with great ease and fluency, and his work showed a power of lively description and honest pathos. Nevertheless, he is essentially a minor poet, a fact he knew very well. Scott even warned his daughter against reading his poetry because it was so bad. More significant in some ways than his verse was his 1808 edition of the poetic works of John Dryden. It was typical of his balance and independence that he never subscribed to the fashionable Romantic denigration of the great Augustans such as Dryden.

The turning point of his literary career came in the early summer of 1814, when, with extraordinary speed, he wrote almost the whole of his novel *Waverley*. It was one of the rare and happy cases in literary history when something original and powerful was immediately recognized and enjoyed by a large public. A story of the Jacobite rebellion of 1745, it reinterpreted and presented with living force the manners and loyalties of a lost Highland civilization. The book was published anonymously, as were all its many successors down to 1827. The reason for anonymity has been difficult to ascertain. Some knew and many guessed that Scott was the author, but he boldly denied it and seemed to enjoy the prolonged cat-and-mouse game with the public, which his position as the "Great Unknown" entailed. After *Waverley*, there followed a rapid series of distinguished books; and much of his best work—including *Guy Mannering*, *Old Mortality*, and *The Heart of Midlothian*—was published in the next four or five years. It was Scott's habit to do most of his writing very early in the morning while the rest of the household was asleep. So there is the odd paradox that, while he was writing with a speed and expense of energy that did permanent damage to his health, he always seemed to have most of the day to spare for his friends and for his personal interests.

Scott's immense earnings in those years contributed to his financial downfall. Eager to own an estate and to act the part of a bountiful laird (lord), he anticipated his income and involved himself in exceedingly complicated and ultimately disastrous financial agreements with publishers. The great financial collapse of 1826, one of the worst of the century, found him defenseless, and he spent the rest of his life under the stigma of bankruptcy. Everyone, including his creditors, paid tribute to the selfless honesty with which he set himself to work to pay all his huge debts. Unfortunately, though, the corollary was reckless haste in the production of all his later works. After the notable recreation of the end of the Jacobite era in *Redgauntlet* (1824), he produced nothing equal to his best early work, though his rapidity and ease of writing remained largely unimpaired, as did his popularity. In his later years he began writing a journal, and the picture it

gives of his life after 1825 is a sad one, in which bereavement, ill health, financial disgrace, and gloom about public affairs all combine to darken the picture. However, there were consolations. His creditors were not hard with him, everyone believed in his honesty, and he was generally revered as the grand old man of English letters. His courage, his humour, and his modesty show attractively in these last personal writings.

On February 23, 1827, the authorship of the "Waverley" novels was finally made public. Characteristically, Scott said that he had now ceased to be the "Great Unknown" and became the "Small Known." In 1831 his health deteriorated sharply, and he tried a Continental tour with a long stay at Naples to aid recovery. But, while abroad, he had a further attack of apoplexy. He was taken home and died on September 21, 1832. His biographer J.G. Lockhart records that "Almost every newspaper that announced this event in Scotland, and many in England, had the signs of mourning usual on the demise of a king."

MAJOR WORKS

POETRY: *The Lay of the Last Minstrel* (1805); *Ballads and Lyrical Pieces* (1806); *Marmion: A Tale of Flodden Field* (1808); *The Lady of the Lake* (1810); *The Vision of Don Roderick* (1811); *Rokeby* (1813); *The Bridal of Triermain* (1813); *The Lord of the Isles* (1815); *Harold the Dauntless* (1817).

NOVELS: *Waverley* (1814); *Guy Mannering* (1815); *The Antiquary* (1816); *The Black Dwarf and Old Mortality* (*Tales of My Landlord*, first series; 1816); *Rob Roy* (1818); *The Heart of Midlothian* (*Tales of My Landlord*, second series; 1818); *The Bride of Lammermoor* and *A Legend of Mortzrose* (*Tales of My Landlord*, third series; 1819); *Ivanhoe* (1819); *The Monastery* (1820); *The Abbot* (1820); *Kenilworth* (1821); *The Pirate* (1822); *The Fortunes of Nigel* (1822); *Pevelevil of the Peak* (1822); *Quentin Durward* (1823); *St. Ronan's Well* (1824); *Redgauntlet* (1824); *The Betrothed* and *The Talisman* (*Tales of the Crusaders*, 1825); *Woodstock* (1826); *The Highland Widow*, *The Two Drovers*, and *The Surgeon's Daughter* (*Chronicles of the Canongate*, first series; 1827); *St. Valentine's Day; or, The Fair Maid of Perth* (*Chronicles of the Canongate*, second series; 1828); *Anne of Geierstein* (1829); *Count Robert of Paris and Castle Dangerous* (*Tales of My Landlord*, fourth series; 1832).

PLAYS: *Halidon Hill* (1822); *Macduff's Cross* (1823); *The Doom of Devorgoil, a Melodrama* (1830); *Auchindrane; or, The Ayrshire Tragedy* (1830).

OTHER PROSE: Essays on "Chivalry" (1818), "The Drama" (1819), and "Romance" (1824), contributed to the *Encyclopædia Britannica*; *Paul's Letters to His Kinsfolk* (1816); *Description of the Regalia of Scotland* (1819); "Lives of the Novelists" in *Ballantyne's Novelists' Library* (1821–24); *Provincial Antiquities of Scotland* (1826); *The Life of Napoleon Buonaparte* (1827); *Tales of a Grandfather: Being Stories Taken from Scottish History*, 4 vol. (1828–30); *History of Scotland* (1829–30); *Letters on Demonology and Witchcraft* (1830); *Essays on Ballad Poetry* (1830).

BIBLIOGRAPHY

Editions: *The Waverley Novels*, 25 vol. (*Centenary Edition*, 1870–71); *The Letters of Sir Walter Scott*, ed. by H.J.C. GRIERSON (1932); *Miscellaneous Prose Works of Sir Walter Scott*, Bart., 28 vol. (1834–36); *The Journal of Sir Walter Scott*, 1825–32, ed. by J.G. TAIT, 3 vol. (1939–46; reprinted in one vol., 1950).

Biography and criticism: J.G. LOCKHART, *Memoirs of the Life of Sir Walter Scott*, 7 vol. (1837), is a full, intimate, and fascinating biography by Scott's son-in-law; H.J.C. GRIERSON, *Sir Walter Scott* (1932), criticizes and corrects Lockhart at various points. EDWIN MUIR, *Scott and Scotland* (1936), is a very acute analysis of Scott's relation to Scottish literature and of his use of the English and Scots languages. DONALD DAVIE, *The Heyday of Sir Walter Scott* (1961), analyzes Scott's debt to Maria Edgeworth and others and gives critical studies of some of the novels. See also EDGAR JOHNSON, *Sir Walter Scott: The Great Unknown*, 2 vol. (1970), a very full and detailed piece of research; and A.O.J. COCKSHUT, *The Achievement of Walter Scott* (1969).

(A.O.J.C.)

Scrophulariales

Economically, Scrophulariales, an order of flowering plants, is prominent for the many ornamentals it contains; for important food plants (e.g., potato, tomato); for well-known drugs (atropine, scopolamine, digitalis);

for certain agriculturally significant parasitic weeds (broomrapes, witchweeds); and for tobacco. The order contains 18 families, about 870 genera, and about 11,800 species. In variety of form and colour, some flowers of the order rival the orchids.

GENERAL FEATURES

Members of the order Scrophulariales occur on most of the landmasses of the Earth, with the exception of Antarctica. About two-thirds of the species are found in the tropics, one-third in temperate regions. About 50 species occur in the Arctic; of these, only a few species of lousewort (*Pedicularis*) reach the most northern lands.

In life-span, members of the order range from short-lived desert herbs to long-lived tropical trees. Many are annuals; *i.e.*, plants that complete a life cycle from seed to seed in a single growing season and withstand unfavourable seasons in seed form. A few are biennials, plants that produce flowers and fruit the second year and then die. Most, however, are perennials, plants that live several years and withstand adverse seasons by means of underground parts (*e.g.*, the herbaceous perennials) or by means of long-lived above ground parts (*e.g.*, woody perennials). Of the perennials, most are polycarpic (*i.e.*, they come into flower year after year). A few are monocarpic and live for several years—15 to 20 in certain cases (*e.g.*, *Boea*)—before flowering and then die after flowering once.

Life-span categories

Figure 1: Some representative members of the family Scrophulariaceae, the largest family in the order Scrophulariales.

Size range and diversity of structure. The plants range in size from the diminutive aquatic bladderwort, *Utricularia olivacea*, one of the smallest in bulk of all flowering plants, with threadlike stems to about four inches (ten centimetres) in length with a very few minute leaves, to large trees, of which the largest may be the guayacan

(*Tabebuia guayacan*), which reaches about 164 feet (50 metres) in height and 6.5 feet (two metres) in trunk diameter.

Flower size is also diverse. The smallest flowers are perhaps those of the aquatic *Micranthemum umbrosum*, about 0.06 inch (1.5 millimetres) in length. The largest are those of the tree daturas (*Datura*) and the related *Methysticodendron amesianum*, whose trumpet-shaped flowers grow to about 11 inches (28 centimetres) long and four to five (ten to 13 centimetres) wide.

Fruits of the order range from the minute globose capsules of *Micranthemum*, less than $\frac{1}{16}$ inch long (about one millimetre), to the elongated pods of the midnight horror, or Indian trumpet flower (*Oroxylum indicum*), two to four feet (60 to 120 centimetres) long but only about three inches (eight centimetres) wide, and the sausage-shaped fruits of the sausage tree (*Kigelia pinnata*), which attain three feet (90 centimetres) in length and sometimes exceed 15 pounds (seven kilograms) in weight.

About two-thirds of the species in the order are herbaceous—*i.e.*, nonwoody. Most of the woody species are shrubs. There are few woody vines except in the bignonia family (Bignoniaceae). Trees are few and most, except for some in the bignonia family, are small (40 feet or less in height).

Especially well known among the aquatic plants of the order are the bladderworts (*Utricularia*), which are among the few "carnivorous" plants and the only ones that capture their prey underwater. Most bladderworts produce, on their leaves, small, pear-shaped bladders provided with a trap door. These bladders trap micro-organisms, such as protozoans, crustaceans, worms, and even newly hatched fish. Within the bladders, the animals are digested, but whether this occurs by bacterial action or through the action of enzymes secreted by the plant is not certain. Nitrogenous end-products of the digestion are presumably absorbed by cells in the walls of the bladder and provide a nutritional supplement to the plant.

Parasitic species are known in 14 families of flowering plants. Two of these families, the broomrape family (Orobanchaceae) and the figwort family (Scrophulariaceae), are in the order Scrophulariales and contain all of the world's agriculturally important root parasites—*i.e.*, their roots are attached to the roots of their hosts by means of haustoria ("suckers"). Plants of the broomrape family are holoparasitic; *i.e.*, because they lack chlorophyll and are unable to carry on photosynthesis, they depend entirely upon their host for organic food materials. The broomrapes (Orobanchae) are serious pests on various crop plants—tobacco, tomato, eggplant, hemp, and sunflowers—and on various fodder plants. Aeginetia attacks sugarcane in Asia. In the Philippines, sugarcane is parasitized also by *Christisonia*.

Parasitic species

In the figwort family, parasitism is known in 26 genera. Among these, all degrees of parasitism exist, ranging from holoparasitism (*Harveya*, *Hyobanche*) to semiparasitism—in which the parasite, being green, can carry on photosynthesis but relies in greater or lesser degree upon the host for at least water and minerals. The most important of the parasites in the figwort family are the semiparasitic witchweeds (*Striga*, *Alectra*), which attack many grasses, including corn, sugarcane, rice, and sorghum, and certain broad-leaved plants, including peanuts, soybeans, and tobacco. An Old World native, the mealie witchweed (*Striga asiatica*) has appeared in the United States, where, starting in 1956, it was reported on corn in the Carolinas (see DISEASES OF PLANTS). Other well-known parasitic members of the figwort family are Indian paintbrushes (*Castilleja*), gerardias (*Agalinis*, *Aureolaria*), eyebrights (*Euphrasia*), bartsias (*Bartsia*), and yellow rattles (*Rhinanthus*), all semiparasitic.

All members of the broomrape family, so far as is known, and the witchweeds of the figwort family produce seeds that germinate only when close to a host root. They are stimulated to do so by substances secreted by the root. The emerging root of the parasite grows toward the host root and eventually may establish a haustorial union.

Epiphytes, plants that grow upon other plants for support, are infrequent in the order except in the family Gesneriaceae, which also includes species that grow on rocks. Many of these plants have tubers (thickened storage stems, such as potatoes) that function apparently as water-storage organs.

Drawing by M. Pahl

Figure 2: Representative plants from two of the large families of the order Scrophulariales.

Economic importance. Ornamentals. Ornamental herbaceous plants (annuals, biennials, and perennials), shrubs, trees, and vines are well represented in the order Scrophulariales. Among the best known herbaceous garden and greenhouse plants are flowering tobacco (*Nicotiana*), datura (*Datura*), butterfly flower (*Schizanthus*), petunia (*Petunia*), apple of Peru (*Nicandra*), salpiglossis (*Salpiglossis*), calceolaria (*Calceolaria*), veronica (*Veronica*), mullein (*Verbascum*), penstemon (*Penstemon*), foxglove (*Digitalis*), snapdragon (*Antirrhinum*), torenia (*Torenia*), monkey flower (*Mimulus*), nemesia (*Nemesia*), African violet (*Saintpaulia*), gloxinia (*Sinningia*), and bear's-breech (*Acanthus*).

Ornamental shrubs of the order include: matrimony vine (*Lycium*), *Cestrum*, angel's-trumpet (*Datura*), *Hebe*, *Leucophyllum*, Cape fuchsia (*Phygelius*), desert willow (*Chilopsis*), caricature plant (*Graptophyllum*), and shrimp plant (*Beleperone*).

Members of the Scrophulariales are among the showiest of tropical ornamental trees. Among them are the jacaranda (*Jacaranda mimosifolia*), widely used as a street tree for its blue flowers and lovely foliage; the white-flowered Indian cork tree (*Millingtonia hortensia*), once described as the handsomest of India's flowering trees; the African tulip tree (*Spathodea campanulata*), with scarlet flowers; and the New World trumpet trees (*Tabea*), with white, pink, lavender, purple, red, or yellow flowers. In temperate regions the catalpas (*Catalpa*),

with their white flowers and large leaves, and the princess tree (*Paulownia tomentosa*), with blue flowers, are well-known.

Both herbaceous and woody vines are frequent in the order. Some rank with the world's most beautiful flowering vines; including sky flower (*Thunbergia grandiflora*), with an abundance of sky-blue flowers; cat's-claw vine (*Doxantha unguis-cati*), golden yellow; flame vine (*Pyrostegia venusta*), orange; golden chalice (*Solandra maxima*), yellow; and Costa Rican nightshade (*Solanum wendlandii*), lilac blue and yellow. Woody vines are especially common in the bignonia family. Most of the vines in the order Scrophulariales are tropical but in the United States the native cross vine (*Bignonia capreolata*) and trumpet creeper (*Campsis radicans*) are well-known. Vines in the order support themselves by several means: by prickles on the stem (*Lycium*) or spines on the leaves (*Solanum*); by tendrils (*Bignonia*); by aerial clinging roots (*Campsis*); or simply by leaning on other plants.

Food plants. Food plants of the order include potato, tomato, eggplant, capsicum pepper, and sesame. The most important, and a basic food for millions of humans, is the potato (*Solanum tuberosum*). A potato is a **tuber**—i.e., a swollen portion of an underground stem. The potato was introduced into Europe from South America in the late 1500s and into the United States in the early 1620s. By the 19th century it had become a staple crop the world over, except in tropical lowlands.

The tomato (*Lycopersicon esculentum*), another New World contribution, was brought to southern Europe in the early 1500s and utilized there long before other Europeans accepted it. It was once even considered to be poisonous and was grown as a curiosity or an ornamental. By the end of the 19th century it had become a major vegetable crop.

The eggplant (*Solanum melongena*), native to India, is grown throughout warm regions for its purple, white, or yellow fruits, which are used as vegetables. The name eggplant refers to the **egglike** appearance of the fruits of certain white-fruited varieties, which were the first ones known to northern Europeans.

The only spice produced by a member of the order Scrophulariales is capsicum, or red **pepper**, derived from fruits of the genus *Capsicum*, native to tropical America. The many varieties differ in size, shape, colour, and pungency of the fruits. The fruits of some are used as a spice (e.g., tabasco and paprika); those of others, the sweet, or green, peppers, are used as food.

Cultivated for its edible, oil-rich seeds since antiquity, the sesame plant (*Sesamum orientale*), native to the Old World, is now grown in many warm regions. The oil is used largely in cooking; the seeds, in confections and as a garnish on baked goods.

Drug and narcotic plants. The order contains only a few drug plants, but they are important. In the potato family are the belladonna plant (*Atropa belladonna*), source of belladonna; henbane (*Hyoscyamus niger*), source of hyoscyamus; and jimsonweed (*Datura stramonium*), source of stramonium. Atropine, extracted from belladonna, and scopolamine, extracted from hyoscyamus, are much used in medicine. In the figwort family, the foxglove (*Digitalis purpurea*) is a source of digitalis.

Several members of the order have narcotic properties. These plants are members of the potato family. Best known are species of *Datura*, including jimsonweed and the tree daturas. Also narcotic is a relative of the tree daturas, *Methysticodendron amesianum*, unknown outside of one mountain valley in Colombia until the 1940s. The Aborigines of Australia utilized **pituri**, leaves of shrubs of the genus *Duboisia*, as a narcotic.

Tobacco, made from the cured leaves of *Nicotiana tabacum* (and to a much lesser extent, *N. rustica*), belongs to the potato family and is the world's most important material used for smoking. The tobacco plant, native to tropical America, is widely grown in temperate and tropical regions.

The order contains a number of poisonous plants.

Spice and oil species

Ornamental tree species

Among the best known are the jimsonweeds (*Datura*), belladonna (*Atropa*), henbane (*Hyoscyamus*), tobacco (*Nicotiana*), nightshades (*Solanum*), and foxglove (*Digitalis*). Even tomato and potato leaves are dangerous if fed to animals. Potato tubers that are turning green also contain poisons.

NATURAL HISTORY

Pollination. Pollination mechanisms in the order are varied. In addition to normally opening (chasmogamous) flowers, a few species regularly produce cleistogamous flowers; *i.e.*, flowers that never open but nonetheless develop viable seeds because they are self-pollinated in the bud. Such flowers characteristically are smaller and somewhat different in structure from chasmogamous flowers of the same species. In most members of the order Scrophulariales, the flowers open normally and then depend upon various agents for pollination. None is known to rely on water. A few species are wind-pollinated—*e.g.*, the plantains (*Plantago*), some of which are considered a cause of hayfever because they shed considerable pollen. Most members of the order rely on animals for pollination, especially insects, including bees, flies, moths, and butterflies. Some are pollinated by hummingbirds. A few are pollinated by bats; outstanding among these are the sausage tree (*Kigelia pinnata*) and the midnight horror (*Oroxylum indicum*).

Seed dispersal. The range of seed-dispersal mechanisms is great. In the family Acanthaceae seeds are thrown for short distances by the sudden—"explosive"—opening of the seed capsule. Most other plants of the order, however, rely upon external agents, such as wind, water, or animals, for dispersal. Those that are wind dispersed may have dustlike seeds or seeds with wings or netlike coats that increase their buoyancy. Those that are spread by water include some beach plants (*Nolana*), whose seeds owe their dispersal to sea drift. The seeds of animal-dispersed species are carried on or in animals. Small-seeded water plants are dispersed in the mud clinging to the feet of waterfowl. Fruits of species of the sesamum family (*Pedaliaceae*) and the family Martyniaceae may hook onto the feet and legs of grazing animals. Seeds of many species are eaten by birds and mammals and are voided undigested in the feces. Dispersal in this way is especially important for species that produce juicy, brightly coloured berries (*e.g.*, the nightshade, *Solanum dulcamara*). Seeds of a few members of the family Scrophulariaceae (*e.g.*, *Veronica*, *Melampyrum*, *Pedicularis*) are dispersed by ants, which seek the seeds for food. A portion of the seed, the "elaiosome," is white, oily, and edible. Such seeds are not only dispersed by the ants but can be planted by them as well—the ants carry them underground.

FORM AND FUNCTION

Vegetative characteristics. The leaves of most members of the order are simple. In few species—*e.g.*, in some louseworts (*Pedicularis*) and in tomato—they are pinnately compound (*i.e.*, each leaf has smaller leaflets arranged along both sides of a central axis). Leaf arrangement on the stem varies, being alternate, opposite, or, rarely, whorled or in rosettes. In certain members, the mature plant possesses but one leaf, up to 30 inches (76 centimetres) long and 22 inches (56 centimetres) wide, which has developed from growth of one of the two cotyledons, or "seed leaves"; the other cotyledon aborts early. This single-leaf condition is seen in several genera of the family Gesneriaceae (*e.g.*, *Streptocarpus*) in which the flowers develop on the leaf, at the base and on the midrib. Other, related species may produce a rosette of three or more leaves, the largest of which has developed from the one cotyledon.

The sesamum family and martynia family possess unique glandular ("mucilage") hairs, which secrete a mucilage responsible for the sticky feel of these plants.

Floral and fruiting characteristics. In arrangement of the flowers—*i.e.*, in the inflorescence type—the plants of the order are exceedingly diverse. The flowers of some are solitary and are borne in the axils of leaves, the upper

angles between the stem and the leafstalks, as in the monkey flowers (*Mimulus*). Other solitary flowers are borne on long leafless stalks (scapes) that arise from a rosette of leaves, as in African violets (*Saintpaulia*) and butterworts (*Pinguicula*). In the majority, however, the flowers are grouped into clusters of various kinds.

Flowers. The flowers are almost always complete; *i.e.*, they have sepals (leafy parts), petals, stamens (male reproductive structures), and carpels (simple ovaries or segments of a compound ovary—the ovary and its upper portions, the style and stigma, form the female reproductive unit called the pistil). Flowers of the family Hydrostachyaceae, however, have either only one stamen or one pistil. In most members of the order the flowers are perfect (bisexual); *i.e.*, they contain both stamens and carpels. Imperfect (unisexual) flowers occur in the family Hydrostachyaceae and in *Littorella* of the plantain family (*Plantaginaceae*). The plants with imperfect flowers may be monoecious (flowers of both sexes occur on each plant—*e.g.*, *Littorella*) or dioecious (flowers of one sex only occur on each plant—*e.g.*, *Hydrostachys*). Flowers of the order Scrophulariales are generally irregular in shape, sometimes strikingly so. In plantains (*Plantago*), in many members of the potato family (*Solanaceae*), and in some members of the family Gesneriaceae, however, regular, or radially symmetrical, flowers occur. Most members of the order are hypogynous; *i.e.*, the flowers have superior ovaries. In such flowers, the sepals, petals, and stamens originate at a position at the base of the ovary. The families Trapellaceae, Columelliaceae, and some members of the Gesneriaceae, however, are epigynous; *i.e.*, the flowers have inferior ovaries—the ovaries are enclosed within the basal portions of the other flower parts, which appear to arise at the upper end of the ovary. The calyx, or collection of sepals, is regular to highly irregular. Typically it is composed of five free to variously united sepals. In some species, suppression of one or more sepals may occur, as in many veronicas (*Veronica*), in which the upper sepal is absent. In bladderworts (*Utricularia*), the calyx is strongly two lipped, the upper lip being formed from the union of three sepals and the lower lip from the union of two sepals; the whole suggests a calyx of only two parts. In the plantain family there are only four sepals.

The corolla (the collection of petals) is regular in the plantain family, *Nolana* family (*Nolanaceae*), many species of the potato family, and in a few species of the gesneria family; in the rest of the order it is irregular, sometimes highly so. Typically it is composed of five united petals. The union ranges from little—only at the base, so that the five-petalled condition is evident—to complete—so that the five-petalled condition is obscure. The corolla, when composed of completely fused petals, is more or less trumpet- or funnel-shaped as in jimsonweed (*Datura*). In some of the highly irregular flowers of the order, the five-petalled condition is also obscure. The lowermost petals may, as in some linarias (*Linaria*) and in all bladderworts, bear a backwardly projecting spur. In many species the corolla is more or less two lipped; the upper lip is composed of two petals, the lower of three. The lips may be the same size, or one or the other may be larger, sometimes markedly so. An upward bulge, the palate, in the central portion of the lower lip may be pronounced in some species, such as the snapdragon (*Antirrhinum majus*), in which it closes the corolla throat. In some species (*e.g.*, *Veronica*) the corolla appears to be composed of four petals; in these, however, the upper "petal" is really two completely united petals. The plantains have only four petals.

In some members of the order, the full complement of five stamens is present, as in many species of the family Solanaceae. Typically, however, one or more stamens is missing. Species having four stamens (an upper pair and a lower pair) lack only the uppermost stamen. Other species lack the uppermost stamen and, in addition, either the upper or the lower pair; thus they have only two stamens. Any of the "lost" stamens may be represented by a staminode, or sterile stamen, borne in place of a normal stamen but not producing pollen. A staminode

Inflorescence types

Corolla structure and form

Insect pollination

may range, depending on the species, from a minute projection on the inner surface of the corolla to an elongated filament-like structure equal in size and conspicuousness to the normal stamens. Throughout the order the stamens are epipetalous; *i.e.*, their filaments are united with the petals. The union ranges from slight to considerably over one-half the length of the stamen. The stamens are alternate with the lobes of the corolla; *i.e.*, they are attached between the petals. In some highly irregular flowers, the alternate arrangement is difficult to see. The anthers (in which pollen develops) of all members of the order are tetrasporangiate; *i.e.*, they have four pollen sacs. Pollen grains are shed singly except in the family Hydrostachyaceae, in which they remain in groups of four. Pollen morphology (form and structure) is exceedingly diverse. One family of the order, the acanthus family is alleged to show a wider range of pollen morphological features than does any other plant family.

Female
flower
parts

The carpels of the order Scrophulariales are united into a compound gynoecium, or female structure. In the family Nolanaceae, there are five carpels. In other members of the order, almost without exception, there are two. The locule, or ovary chamber, number is usually two; the most notable exceptions are the one-locular broomrape family (Orobanchaceae) and gesneria family. In most species of the order, placentation, or ovule attachment, is axile—*i.e.*, along the central axis of the ovary. In some, however, notably the broomrape family and the gesneria family, it is parietal—to the ovary walls. The bladderwort family is characterized by free-central placentation, in which the ovules are borne on a central stalk that is attached only at one end of the ovary. In the family Globulariaceae, the solitary ovule is pendulous from the apex of the locule. In Littorella of the plantain family, the ovule arises from the base of the locule. In most members of the order, the septum partitioning the ovary into two chambers is horizontal. In the potato family, in contrast, the septum is oblique; its plane is about 45° from the horizontal.

Depending on the species, the ovule number may range from one to about 70,000 (in Aeginetia) per ovary. The ovules have one integument (covering) and are mostly anatropous (inverted and straight with the micropyle, or opening in the integument, next to the hilum, or point of attachment) or hemianatropous (similar to anatropous, but less pronounced). Less often the ovules are campylo-tropous (curved with the base and apex nearly together) or amphitropous (half-inverted and straight, the hilum lateral).

Fruits and seeds. Most Scrophulariales species are characterized by a capsular fruit. The capsule may open by splits or pores in its wall; in some species, the capsule top comes off like a lid. Another fruit type of the order is a berry, well illustrated by the tomato. Fruits of the nolana family typically consist of one ring of five sections or two or three such rings, one on top of another. Each section contains one to seven seeds and separates from the others at maturity.

Although most Scrophulariales species produce several to many seeds per fruit, a few produce only one (*Globularia*, *Littorella*). Perhaps the record for seed production in the order goes to *Boschniakia rossica* (broomrape family), an average plant of which is said to mature over 333,000 seeds. In size, the seeds of the order range from those of some members of the bignonia family, which may be several inches long, though thin and light, to the dustlike seeds of broomrapes (*Orobanche*), which are about 1/80 of an inch (about 0.3 millimetre) long.

EVOLUTION AND CLASSIFICATION

Evolution. Fossil record. Families of the order Scrophulariales are poorly represented in the fossil record and do not appear until the Tertiary Period (beginning about 65,000,000 years ago). These families, known from remains of leaves, pollen, fruits, and seeds, are the potato, figwort, bignonia, and acanthus families.

Relationships. The order Scrophulariales is closely related to the order Polemoniales and shares with it a common origin from the order Gentianales.

Within the order, the figwort, bignonia, sesamum, martynia, gesneria, broomrape, bladderwort, and acanthus families are clearly related to each other. The boundaries between some families are not clearly defined and thus are subject to individual interpretation.

The relationships of several families in the order are controversial; for example, the family Columelliaceae is variously considered to belong in the Scrophulariales or in the order Rosales. The family Buddlejaceae is sometimes placed in the order Gentianales. The families Solanaceae and Nolanaceae are thought by some to belong in the order Polemoniales. These differences of opinion have not yet been settled; the answers to them depend on individual—and varying—interpretations.

Classification. Distinguishing taxonomic features. The order Scrophulariales comprises somewhat more than 50 percent of the families included in the order Tubiflorae of older systems. Major characteristics helpful for delineating the families within the order include: symmetry of the flowers; carpel number; locule number; ovary position; placentation type; fruit type; presence or absence of endosperm; parasitic or nonparasitic habit; and collateral or bicollateral vascular bundles.

Annotated classification.

ORDER SCROPHULARIALES

Trees, shrubs, vines, or herbs, sometimes parasitic. Leaves simple or rarely compound, alternate or opposite, rarely whorled or rosulate. Inflorescence (arrangement of flowers) various, or the flowers solitary. Flowers complete (with sepals, petals, stamens, and pistil) or rarely incomplete, perfect (with both sexes) or rarely imperfect, actinomorphic (radially symmetrical) to zygomorphic (bilaterally symmetrical), hypogynous (superior ovary) or rarely epigynous (inferior ovary). Calyx usually of 4 to 6 sepals; corolla usually of 4 to 6 united petals. Androecium (male complex) usually of 5, 4, or 2 stamens that are joined to the inner side of the corolla tube (epipetalous) and are alternate in position with the corolla lobes. Gynoecium (female complex) of 2 or rarely 5 united carpels, with usually 1 or 2 locules (chambers); with ovule attachment usually axile, (along the central axis) or parietal (to the ovary wall). Ovules 1 to many, with a single integument (outer covering). Fruit usually a capsule or a berry, rarely a schizocarp (a fruit that splits into several 1-seeded pieces), nut, or drupe (stone-seeded fruit); seeds with or without endosperm (nutrient tissue for the developing embryo).

Family **Solanaceae** (potato family)

Herbs, shrubs, or trees, with bicollateral vascular bundles. Leaves alternate, fascicled (clustered), or some opposite; simple or rarely compound. Inflorescences cymose (in clusters that mature from the central flower or top downward) or of solitary flowers. Flowers complete, actinomorphic to zygomorphic, hypogynous; calyx of 4 to 6 united sepals; corolla of 4 to 6 united petals. Androecium of 5, 4, or 2 epipetalous alternate stamens, the stamens frequently unequal, staminodia (sterile stamens) sometimes present. Gynoecium of 2 united carpels; ovary superior, usually 2-locular, rarely 1-locular or, by false septation, 3- to 5-locular, the septum oblique; placentae axile, the ovules many, seldom few to 1. Fruit a berry or a capsule; seeds with endosperm. Eighty-five genera and about 2,300 species widely distributed in tropical, subtropical, and temperate regions, especially of the New World.

Family **Nolanaceae** (nolana family)

Herbs or small shrubs, with bicollateral vascular bundles. Leaves alternate, simple, usually fleshy. Inflorescences racemose (in clusters that mature from the bottom upward) or of solitary flowers. Flowers complete, actinomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 5 epipetalous alternate stamens. Gynoecium of 5 united carpels; ovary superior, divided longitudinally or transversely into 5 to 30 sections; placentae axile, the ovules 1 to 7 in each section of the ovary. Fruit of 5 to 30 mericarps (sections), these in 1 series or in 2 or 3 superposed series, each mericarp 1- to 7-seeded; seeds with endosperm. Two genera and 83 species distributed in western South America.

Family **Buddlejaceae** (buddleja family)

Trees or shrubs. Leaves opposite, alternate, or whorled; simple; with stipules (appendages at the base of the leafstalk). Inflorescence racemose, paniculate (many-branched), cymose, or capitate (headed). Flowers complete, actinomorphic to somewhat zygomorphic, hypogynous; calyx of 4 or 5 united sepals; corolla of 4 or 5 united petals. Androecium of 4 epipetalous alternate stamens, a staminodium sometimes also present. Gynoecium of 2 united carpels; ovary superior,

Contro-
versial
position
of some
families

2-locular, rarely 4-locular by false septation; placentae axile, the ovules many. Fruit a capsule or berrylike; seeds with endosperm. Nineteen genera and 160 species widely distributed in tropical and subtropical regions, especially in southern Africa and Madagascar.

Family Retziaceae (retzia family)

Shrubs. Leaves whorled, simple. Inflorescence cymose; flowers complete, actinomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 to 7 united petals. Androecium of 5 to 7 epipetalous alternate stamens. Gynoecium of 2 united carpels; ovary superior, incompletely 2-locular; placentae axile, the ovules 4 to 6. Fruit a capsule; seeds with endosperm. One genus and species (*Retzia*) distributed in southern Africa.

Family Scrophulariaceae (figwort family)

Herbs, shrubs, or trees, sometimes parasitic. Leaves alternate, opposite, whorled, or rosulate; simple or very rarely compound. Inflorescence racemose, spicate, paniculate, cymose, or of solitary flowers. Flowers complete, zygomorphic, hypogynous; calyx of 4 or 5 united sepals; corolla of 5 united petals. Androecium of 2, 4, or 5 epipetalous alternate stamens; staminodia sometimes present. Gynoecium of 2 united carpels; ovary superior, 2-locular or rarely 1-locular; placentae axile or rarely parietal (in 1-locular ovaries), the ovules 2 to many. Fruit a capsule or rarely a berry or a schizocarp; seeds with endosperm. About 200 genera and 3,000 species with worldwide distribution.

Family Bignoniaceae (bignonia family)

Trees, shrubs, vines, or rarely herbs. Leaves opposite or rarely alternate, simple or compound. Inflorescence racemose, paniculate, or cymose. Flowers complete, zygomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 5, 2, or 4 epipetalous alternate stamens; staminodia often present. Gynoecium of 2 united carpels; ovary superior, 1- or 2-locular; placentae axile or parietal, ovules many. Fruit a capsule or sometimes fleshy and indehiscent (not splitting open); seeds without endosperm. The family contains 120 genera and about 800 species, which are widely distributed in tropical and subtropical regions, especially in South America; only a few genera occur in temperate regions.

Family Pedaliaceae (sesamum family)

Herbs, or rarely shrubs, with characteristic glandular ("mucilage") hairs. Leaves opposite or alternate; simple. Inflorescence cymose or racemose or of solitary flowers. Flowers complete, zygomorphic, hypogynous; calyx of 4 or 5 united sepals; corolla of 5 united petals. Androecium of 4 or rarely 2 epipetalous alternate stamens; staminodia usually present. Gynoecium of 2 united carpels; ovary superior, 2- to 4-locular, the locules frequently divided by false septation; placentae axile, the ovules 2 to many. Fruit a capsule or a nut; seeds with scant endosperm. The family contains 16 genera and 55 species with distributions in tropical and subtropical regions of the Old World.

Family Trapellaceae (trapella family)

Herbs of aquatic habitats. Leaves opposite, simple. Inflorescence of solitary flowers. Flowers complete, zygomorphic, epigynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 2 epipetalous alternate stamens; 2 staminodia present. Gynoecium of 2 united carpels; ovary inferior, 2-locular, 1 locule reduced and sterile; placenta apical; ovules 2. Fruit 1-seeded, nutlike; seeds with thin endosperm. One genus (*Trapella*) with 2 species distributed in eastern Asia.

Family Martyniaceae (martynia family)

Herbs, with characteristic glandular ("mucilage") hairs. Leaves opposite or alternate; simple. Inflorescence racemose. Flowers complete, zygomorphic, hypogynous; calyx of 5 free or united sepals; corolla of 5 united petals. Androecium of 2 or 4 epipetalous alternate stamens; staminodia present. Gynoecium of 2 united carpels; ovary superior, 1-locular; placentae parietal, sometimes cohering to form false septa; ovules few to many. Fruit a capsule; seeds without endosperm. The family contains 5 genera and 16 species distributed in temperate to tropical regions of the New World.

Family Gesneriaceae (gesneria family)

Herbs, shrubs, vines, or trees. Leaves opposite, whorled, or rosulate; simple; 1 of a pair sometimes much reduced. Inflorescence cymose or of solitary flowers. Flowers complete, actinomorphic to zygomorphic, hypogynous or epigynous; calyx of 5 free or united sepals; corolla of 5 united petals. Androecium of 4, 2, or rarely 5 epipetalous alternate stamens; 1 to 3 staminodia sometimes present. Gynoecium of 2 united carpels; ovary superior or inferior, 1-locular; placentae parietal; ovules many. Fruit a capsule or a berry; seeds with or without endosperm. The family contains 140 genera and 1,800 species distributed mostly in tropical and subtropical regions of both hemispheres.

Family Columelliaceae (columellia family)

Shrubs or small trees. Leaves opposite, simple. Inflorescence

cymose. Flowers complete, slightly zygomorphic, epigynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 2 epipetalous alternate stamens. Gynoecium of 2 united carpels; ovary inferior, incompletely 2-locular; placentae parietal; ovules many. Fruit a capsule; seeds with endosperm. One genus (*Columellia*) with 4 species distributed in the Andes mountains of South America.

Family Orobanchaceae (broomrape family)

Root-parasitic herbs. Leaves reduced to scales, alternate. Inflorescence racemose or spicate or rarely of solitary flowers. Flowers complete, zygomorphic, hypogynous; calyx typically of 4 or 5 united sepals; corolla of 5 united petals. Androecium of 4 epipetalous alternate stamens. Gynoecium of 2 or 3 united carpels; ovary superior, usually 1-locular; placentae parietal; ovules many. Fruit a capsule; seeds with endosperm. The family contains 13 genera and 150 species widely distributed in temperate and warm regions, especially of the Old World and the Northern Hemisphere.

Family Lentibulariaceae (bladderwort family)

Herbs of aquatic and wet habitats. Leaves alternate or rosulate, modified for the capture of minute animals. Inflorescence racemose or of solitary flowers. Flowers complete, zygomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 2 epipetalous alternate stamens; 2 staminodia sometimes present. Gynoecium of 2 united carpels; ovary superior, 1-locular; placentae free-central; ovules 2 or many. Fruit a capsule; seeds without endosperm. The family contains 5 genera and 300 species with wide distribution throughout the world.

Family Myoporaceae (myoporium family)

Shrubs or small trees. Leaves alternate or opposite; simple. Inflorescence cymose or of solitary flowers. Flowers complete, actinomorphic to zygomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 or 6 united petals. Androecium of 4 or 5 epipetalous alternate stamens. Gynoecium of 2 united carpels; ovary superior, 2-locular, or 3- to 10-locular by false septation; placentae axile; ovules 4 to 14. Fruit a drupe; seeds with scant or no endosperm. The family contains 5 genera and 180 species distributed in tropical and subtropical regions mostly of the Old World, especially Australia.

Family Globulariaceae (globularia family)

Herbs or small shrubs. Leaves alternate, simple. Inflorescence capitate or spicate. Flowers complete, zygomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 4 epipetalous alternate stamens. Gynoecium of 2 united carpels, which have the appearance of a single carpel (*i.e.* they are pseudomonomerous); ovary superior, 1-locular; placenta apical; ovule solitary. Fruit nutlike; seeds with endosperm. There are 2 genera and 27 species distributed in the Old World, especially the Mediterranean area.

Family Acanthaceae (acanthus family)

Herbs, shrubs, vines, or trees. Leaves opposite, simple. Inflorescence cymose, racemose, or of solitary flowers. Flowers complete, zygomorphic, hypogynous; calyx of 5 united sepals; corolla of 5 united petals. Androecium of 4, 2, or rarely 5 epipetalous alternate stamens. Gynoecium of 2 united carpels; ovary superior, 2-locular; placentae axile; ovules 2 to many. Fruit a capsule or a drupe; seeds usually without endosperm, typically supported by an indurated (hardened) funiculus. There are 250 genera and 2,600 species widely distributed in the tropics and subtropics, with limited representation in temperate areas.

Family Plantaginaceae (plantain family)

Herbs or shrubs. Leaves alternate, rosulate, or rarely opposite; simple. Inflorescence spicate. Flowers complete or rarely incomplete, perfect or rarely imperfect, actinomorphic, hypogynous; calyx of 3 or 4 united sepals; corolla of 3 or 4 united petals. Androecium of 4 or rarely 3, 2, or 1 epipetalous alternate stamens. Gynoecium of 2 united carpels, sometimes pseudomonomerous; ovary superior, 2-locular or rarely 3- or 4-locular by false septation; placentae axile, rarely basal or free-central; ovules 1 to many. Fruit a capsule or a 1-seeded nut; seeds with endosperm. There are 3 genera and 265 species with worldwide distribution.

Family Hydrostachyaceae (hydrostachys family)

Herbs of aquatic habitats. Stems tuber-like. Leaves simple or 1 to 3 times pinnatisect (deeply divided). Inflorescence spicate. Flowers imperfect, the plants dioecious (separately sexed flowers are on separate plants) or rarely monoecious (both sexes on one plant); calyx lacking; corolla lacking; staminate (male) flowers consist of a single stamen; carpellate (female) flowers of a single pistil. Gynoecium of 2 united carpels; placentae parietal; ovules many. Fruit a capsule; seeds without endosperm. The family contains 1 genus (*Hydrostachys*) and 30 species distributed in Madagascar and tropical and southern Africa.

Differing
classifi-
cation
schemes

Critical appraisal. The families included in the order Tubiflorae of older taxonomic systems have been variously grouped, the groupings depending upon the characteristics emphasized. Some authorities recognize one large order. Others group the families of the Tubiflorae into three to seven smaller orders, of which the order Scrophulariales, as presented here, is one of three. The evidence is not overwhelmingly in favour of any of these views. It is largely a matter of personal preference how these families are divided into orders if the large group Tubiflorae is considered too unwieldy as a single order.

Because phylogenists subdivide the old group Tubiflorae differently, it is difficult to find the equivalent of the Scrophulariales, as presented here, among the orders recognized by other authorities. In older classification systems there is simply no order comparable to it. It is most closely equivalent to the suborder Solanineae of the order Tubiflorae, but it differs mainly by the inclusion of the plantain family and the myoporace family. A major distinctive feature of the order Scrophulariales, as presented here, is the inclusion of the potato family, which most other phylogenists place in an order separate from the figwort family and its allies. Thus the order Scrophulariales as defined here is not the same grouping of families as the order of that name as recognized by many other authorities. The classification presented here is, nevertheless, a recent one of wide acceptance with as much claim to authoritativeness as other widely known systems.

(J.W.Th.)

Scrublands

Scrublands are areas where low, evergreen, leathery leaved, and often aromatic shrubs (or scrubs) dominate the vegetation. Mostly they are confined to a Mediterranean type of climate—dry, hot summers and cool, wet winters—and therefore are often called the Mediterranean vegetation. This type of climate is found most often near seacoasts, and it commonly occurs in a latitudinal zone between 30 and 40 degrees both north and south of the Equator. Scrublands merge into monsoon forests and evergreen forests toward regions of wetter climate and into thorn-shrub vegetation and steppes (dry prairies) toward regions of decreasing precipitation.

Scrubland characteristics. During the dry summer months, the temperature differential between day and night in scrublands is much greater than during winter, and during the wet winter months the night temperatures are usually between 50° and 60° F, which is optimal for the growth of scrub vegetation. The night temperature is most important in the control of plant growth.

The high summer temperatures make the small amount of precipitation insufficient for growth of scrubland plants, and most of them become dormant. Scrub plants flower and produce fruit before the onset of the hot, dry summer, the scrublands bursting into colourful display during spring. In California, for example, sage (*Salvia*), mountain lilac (*Ceanothus*), tree poppy (*Dendrome-*

con), and *Fremontia* bloom at this time. In Australia *Grevillea*, *Acacia*, *Callistemon*, and *Dryandra* are the principal genera of spring flowering plants. In the Cape scrublands of South Africa various members of the family Proteaceae and heath (*Erica*) colour the hillsides with spectacular displays of flowers. This same feature of the climate also conditions the dominance in the scrubland vegetation of winter annuals; *i.e.*, plants that complete their life cycle in a single growing season, in this case during the wet winter months. The summer drought makes it impossible for shallow-rooted herbs to survive, leaving most of the space between shrubs bare. Thus, at the beginning of the autumn rains, the seeds of annual plants are able to germinate on the bare ground.

The shrubs of the scrublands are adapted to growing in winters that combine low temperatures with adequate moisture. Typical desert plants that grow only at high temperatures, such as the creosote bush or *jarillo* (*Larrea*), cannot live in the scrublands nor can shrubs native to areas with summer rains and winter drought (*e.g.*, in western Texas or the Transvaal).

The dry climate of the hot summer months predisposes scrublands to fires, and most of them can be described as being a fire-maintained vegetation. The shrubs are adapted to fires in being able to sprout from their root crown. Since most trees are unable to form new shoots from the base of their trunk, a scrubland vegetation is kept free from invading trees through frequent fires.

Many of the scrubland plants have seeds whose germination is stimulated by high temperature treatment. This is known, for example, for the chamise (*Adenostoma fasciculatum*), whose seeds do not germinate until very old unless they are subjected to dry heat near 200° F or else are treated by being placed near charcoal or by being leached for a long time in water.

Scrublands are not usually browsed by animals; although deer may live nearby, they normally do not eat the frequently aromatic or toxic shrubs. Another reason why the scrublands in general are not grazed or browsed by the larger mammals is their impassable, dense growth. Although not as forbidding as the thorn-shrub vegetation, scrublands are accessible to larger animals only with difficulty. In Australia, the wallabies and even the so-called scrub wallabies use the scrub vegetation only for resting during daytime, feeding in open grasslands during night. Scrublands also are impassable to the Australian flightless birds.

While not inhabited by larger mammals, scrublands are frequented by small seed eaters. Typical of these seed eaters are small rodents, such as pocket mice and kangaroo rats, and quail. None of these animals is restricted to scrublands, however, and most prefer a more open vegetation.

Insects and insect-eating birds and reptiles are common in scrublands but not more so than in other types of vegetation. Because it is impossible to characterize scrublands by any typical animals, botanical criteria are relied upon exclusively.

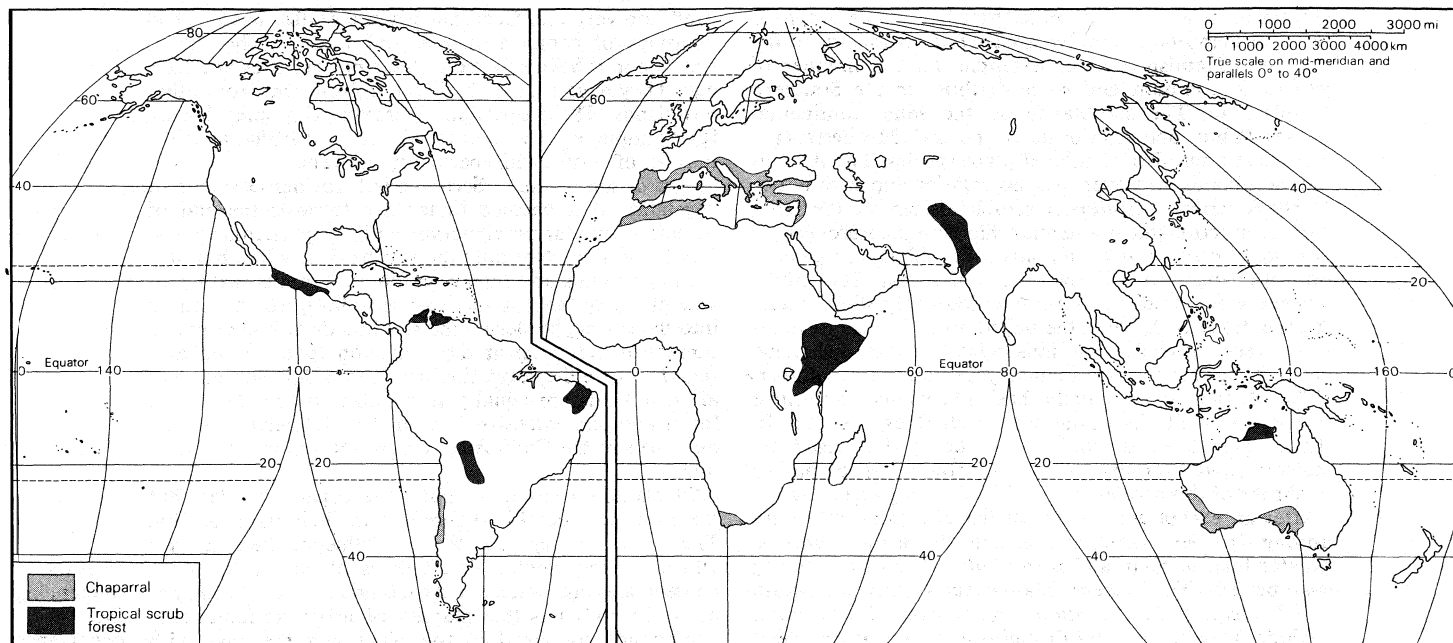

Scrubland distribution. The accompanying map shows the distribution of the most important scrublands over the world. A description of each of them follows.

The Californian chaparral. The scrubland vegetation of the Californian chaparral occurs everywhere on the lower slopes (generally below 1,000 metres or 3,000 feet) of the coastal and inland mountains of southwestern North America, wherever the yearly rainfall ranges from ten to 20 inches (about 200 to 500 millimetres) per year, with a pronounced dry summer. At higher altitudes with increasing precipitation, the vegetation gradually changes into fir and pine forests, and in the interior the scrubland flora is replaced by a steppe vegetation dominated by the sagebrush (*Artemisia tridentata*).

Along the coast and in the higher rainfall areas, the dominant shrubs of the chaparral are sages (*Salvia mellifera* and *S. apiana*), mountain-lilacs (*Ceanothus* species), *Rhus* species, *Eriogonum fasciculatum*, and the scrub oak (*Quercus dumosa*). In drier localities and on poorer soil, chamise (*Adenostoma fasciculatum*), or ribbon-wood (*Adenostoma sparsifolium*), becomes *domi-*

nant. If left undisturbed, live oaks (*Quercus agrifolia*) and big-cone fir (*Pseudotsuga macrocarpa*) invade the chaparral on the better sites of north slopes, gradually transforming them into forests. Only in exceptional localities does the chaparral remain undisturbed; normally it burns over once every ten to 40 years. After a fire the shrubs resprout from the root crown, and many germinate from seed, together with many herbaceous plants.

The Mediterranean *macchie* (*maquis*). Although human activities have removed much of the Mediterranean *macchie*, in Spain, southern France, Greece, Lebanon, coastal Israel, Tunisia, and Algeria a shrub vegetation still covers the lower slopes of the mountains bordering the Mediterranean Sea. This vegetation consists of many aromatic shrubs such as *Satureia* and other members of the mint family (*Lamiaceae*), *Cistus*, laurel, myrtle (*Myrtus*), and different brooms (*Genista*), with olives, *Ceratonia*, figs, and other semitrees transforming the scrublands into forests in the absence of human interference.

Where the soils are poorer and rockier, the *macchie* is more open, sometimes with shrub palms (*Chamaerops*); in the French Mediterranean this type of vegetation is called *garrigue*.

Many of the plants of these Mediterranean scrublands are well known, such as the laurel and the olive. The myrtle, and innumerable spices, such as rosemary, thyme, and marjoram, are also familiar members of this vegetation.

Northward, toward central Europe, summer rainfall increases, and a forest climate replaces the Mediterranean climate, whereas south and eastward the climate becomes drier and changes into a steppe and desert climate. This occurs along the Mediterranean shores in Libya and Egypt, where a semidesert vegetation replaces the *macchie* because of an absence of moisture.

A vegetation similar to the Mediterranean scrublands extends from Turkey along the lower mountain ranges of Asia Minor. This is a reflection of the climate, with the rainfall decreasing eastward but increasing at higher altitudes. It is at the borders of the Mediterranean scrubland climate where the first successful attempts at agriculture occurred in Asia Minor, about 10,000 years ago.

With the unprecedented increase in population since Roman times, most of the original *macchie* vegetation has been transformed by man into cultivated areas. River valleys are irrigated, and profitable crops now replace the *macchie*. On mountain slopes olive orchards now grow in areas formerly occupied by a varied *macchie* vegetation.

The Australian scrublands. Australia has probably the most extensive and richest scrubland vegetation. In Western Australia rainfall ranges from ten inches (about 250 millimetres) in the interior to 60 inches (about 1,500 mm) along the southwest coast. There are extensive Eucalyptus forests in the high rainfall area, but in areas having between 15 inches (about 380 mm) and 40 inches (about 1,000 mm) of precipitation, varied scrub vegetation covers the land except near the roads, where extensive clearings have removed the shrubs. There are about 1,000 shrub species living in southwestern Australia, many of them with spiny branches and leaves and with brightly coloured flowers ranging from deep blue, lilac, yellow, and brown to red. Most of these shrubs belong to a few families, such as the pea family (*Fabaceae*, especially the genus *Acacia*), the myrtle family (*Myrtaceae*), *Proteaceae*, and *Rutaceae*.

Eastward, past the desert of the Nullarbor Plain, another scrubland is found, commonly named **mallee**, where shrubby Eucalyptus, *Acacia*, *Banksia*, and other members of the *Proteaceae* family reign supreme in South Australia.

The Chilean scrublands. Also in the Southern Hemisphere are the scrublands of central Chile, where *Acacia cavenia*, *Baccharis*, and tall cacti grow on the Pacific slopes of the Andes. On the lower part of the eastern slope of the Andes in Argentina, desert shrubs are encountered, which are replaced further eastward by chaco, a thorn-shrub vegetation that merges into campos cerrados (scattered trees in dense grasslands) in central Brazil and into caatinga (stunted, sparse forests, leafless during the hot dry season) in eastern Brazil.

The Cape flora. The Cape flora is a very restricted shrub vegetation in South Africa, comprised chiefly of heath (*Erica*) and members of the *Proteaceae* family. This flora is remarkable in that it occupies an area of not more than 200 square miles, yet it is exceedingly rich in species, having more than are present on a several thousand times larger area of the central United States or of central Europe. It differs totally in its composition from the surrounding evergreen forest, karroo, veld, and desert vegetation, most of which occurs in a climate with winter drought and summer rains.

Scrubland growth and development. Floristic comparisons between scrublands. All of the scrubland floras have developed locally and are not related to each other, except for a few genera they have in common. In the five main regions with scrubland vegetation, all major floral constituents are unique for each of them, yet there are

The world's richest and most extensive scrublands

certain plant genera or families that have representatives in more than one of the five areas. The scrublands of the Northern Hemisphere, for example, have a number of genera in common and so have those in the Southern Hemisphere. The scrublands on the same continental masses (Chile and California, Cape and Mediterranean) also have a number of related plant species. The Australian scrubland, however, has no relationship with either North American or European scrublands, nor has the South American scrubland any relationship with the European.

Seasonal aspects of scrublands. Scrublands in general do not change much in the course of a year. The shrubs are evergreen, and they change colour only slightly during the dry season, when the bright green foliage turns an olive green. After the first rains in late autumn, lush, new, green foliage appears and remains green into early summer.

The Mediterranean climate has mild winters, and most of the scrubland species are only mildly frost resistant. In the chaparral, *Rhus laurina* is probably the least frost resistant, and after an exceptionally cold winter a number of shrubs of this species may be killed through freezing.

After an exceptional series of drought years, mortality among the less drought-resistant chaparral plants is greater than normal, and many *Salvia* shrubs die during such periods. The more resistant species, such as chamise and *Eriogonum fasciculatum*, survive even after drought periods. Thus these latter drought-resistant shrubs spread into the desert shrub vegetation. It is, therefore, not in the years with average winter temperature and average winter rainfall that selection in the chaparral occurs. It is in the exceptional years that the composition of the scrubland flora is determined.

The most pronounced seasonal changes in the flora of scrublands are provided by annual plants. Their seeds germinate within a few days after the first extensive autumn or winter rain, and the plants continue to grow slowly during winter. In spring, flowers are produced in response to the lengthening of the days. Fruit is set and ripens before the long summer drought. Many of these annual plants occur both in the chaparral and in the desert. The major difference between these two habitats is the frequency of winters having rainfall sufficient for germination of the annual plants. Since annual plants require one inch of rainfall to germinate, they develop only when enough water has fallen to complete their life cycles.

Annuals occurring both in chaparral and desert are goldfields (*Baeria chrysostoma*), which can produce spectacular displays in March and April, when whole acres become golden yellow with the flowers of this tiny composite, *Ernmenanthe penduliflora*, several poppy (*Eschscholzia*) species, fiddle necks (*Amsinckia*), and different kinds of forget-me-nots (*Cryptantha*).

In Western Australia the displays of annuals in the scrublands during September are just as spectacular, with the deep blue of *Leschenaultia* and *Dampiera* and the pinks of *Stylidium* and *sundew* (*Drosera*). Perennial herbs such as *Conostylis* and many orchids add to the flower displays in the underbrush. In the scrublands of the Mediterranean, the mustards of the Brassicaceae family, legumes, and bulbous plants such as grape hyacinths (*Muscari*) lend special colour to the spring annual flora.

Evolution of scrublands. The scrublands vegetation provides many interesting evolutionary problems. In the southwestern United States, all scrub areas are relatively young in an evolutionary sense. Until 10,000 years ago the area now occupied by chaparral in southern California had a much denser forest vegetation in which saber-tooth tigers, giant sloths, and camel-like animals lived. This oak woodland, which also occupied extensive areas in the Great Basin (now the semi-deserts of Nevada), gradually retreated against the onslaught of drought, which caused the disappearance of the great inland lakes—Bonneville and Lahontan—and which caused the extension of incipient deserts.

In the Mediterranean, the climate probably was drier to start with and the vegetation did not change as rapidly as it did in the southwestern United States.

And in Australia the flora and fauna, like the continent

itself, are very old. Consequently the mallee has not had invasions of exotic elements, and most of the shrubs growing in it have evolved in their present sites and long ago. They have evolved in directions different from other scrublands. The proportion of shrubs with spiny leaves, for example, is very great in Western Australia, as is the number of shrubs with spectacular flowers.

Fires in scrublands. Scrublands form dense stands of vegetation that become tinder dry towards the end of summers without precipitation and are particularly susceptible to fires. Not only the shrubs themselves but also the dry annuals and litter accumulation underneath provide plenty of fuel for very extensive fires, which bum up into the forests bordering the scrublands at higher elevations. But they stop at the transition to the more arid regions where the vegetation becomes widely spaced. Not all scrublands are equally susceptible to fire. There are fewer and less extensive fires in the Mediterranean maquis than in the Californian chaparral or the Australian mallee.

All plants consist of combustible organic matter, but there are considerable differences in their flammability. There are two major factors that influence the ease with which a plant catches fire. One is obviously its water content, and thus water-filled cacti and succulents will not burn. The other is the quantity of aromatic flammable compounds contained in the plant and the ease with which they are released. The aromatic sage (*Salvia*) plants burn easily, whereas the Mediterranean rock rose (*Cistus*) is definitely fire retardant.

Economically, scrublands are unimportant. Growth of the scrubs is rather slow, because their development is restricted to the rainy period, which occurs in winter when temperatures are too low for rapid growth. They occur predominantly on slopes, which are costly to cultivate. In central California it has been practical to replace the chaparral vegetation with a grass cover, allowing the slopes to be grazed. In the lower rainfall areas of southern California, however, a grass cover is hard to maintain, and the main effort is to maintain the shrub vegetation in its most vigorous form to counteract erosion. A shrub fire is usually followed the next winter by destructive floods. For this reason attempts are made to re-establish as quickly as possible burned-over scrub vegetation. This is done by seeding a burned area with fast growing annual plants. But since these plants—ryegrass and mustard—take some time before they produce a protective cover, and also because they need a good rain before they germinate, such seeding does not provide protection against the first rains after summer or autumn fire; moreover, a vegetation of annual plants needs to be renewed every year. The ideal solution, therefore, is to get as quickly as possible a renewal of the permanent perennial shrub vegetation. This is the natural sequence of events anyway. Whereas a climax forest vegetation usually does not directly regenerate itself and passes through one or several different successional stages before it becomes re-established after destruction by man or fire, chaparral regenerates rather easily. The old stumps of the burned shrubs often resprout and usually do so before advent of the first rains. Secondly, the seeds of many chaparral plants are stimulated to germinate by the fire. Unfortunately, there usually are not enough seeds of chaparral plants present to get a good stand in the first year after the fire. Therefore a compromise is reached: as soon as possible after the fire, the slopes are seeded thinly with some annual plant that does not interfere with the re-establishment of the natural vegetation. The second year after the fire, the natural vegetation may have grown sufficiently to provide a fairly effective protection against erosion, which it does by shielding the soil against falling raindrops with foliage and litter.

Sculpture, Art of

Sculpture is not a fixed term that applies to a permanently circumscribed category of objects or sets of activities. It is, rather, the name of an art that grows and changes and is continually extending the range of its activities and evolving new kinds of objects. The scope of the **term** is much wider in the second half of the 20th century than it was only two or three decades ago, and in the present fluid state of the visual arts nobody can predict what its future extensions are likely to be.

Certain features, which in previous centuries were considered essential to the art of sculpture, are not present in a great deal of modern sculpture and can no longer form part of its definition. One of the most important of these is representation. Before the 20th century, sculpture was considered a representational art; but its scope has now been extended to include nonrepresentational forms. It has long been accepted that the forms of such functional three-dimensional objects as furniture, pots, and buildings may be expressive and beautiful without being in any way representational; but it is only in the 20th century that nonfunctional, nonrepresentational, three-dimensional works of art have been produced.

Again, before the 20th century, sculpture was considered primarily an art of solid form, or mass. It is true that the negative elements of sculpture—the voids and hollows within and between its solid forms—have always been to some extent an integral part of its design, but their role has been a secondary one. In a great deal of modern sculpture, however, the focus of attention has shifted, and the spatial aspects have become dominant. Spatial sculpture is now a generally accepted branch of the art of sculpture.

It was also taken for granted in the sculpture of the past that its components were of a constant shape and size and did not move. With the recent development of kinetic sculpture, however, neither the immobility nor immutability of its form can any longer be considered essential to the art of sculpture.

Finally, 20th-century sculpture is not confined to the two traditional forming processes of carving and modelling or to such traditional natural materials as stone, metal, wood, ivory, bone, and clay. Because present-day sculptors use any materials and methods of manufacture that will serve their purposes, the art of sculpture can no longer be identified with any special materials or techniques.

Through all of these changes there is probably only one thing that has remained constant in the art of sculpture, and it is this that emerges as the central and abiding concern of sculptors: The art of sculpture is the branch of the visual arts that is especially concerned with the creation of **expressive** form in three dimensions.

Sculpture may be either in the round or in relief. A sculpture in the round is a separate, detached object in its own right, leading the same kind of independent existence in space as a human body or a chair. A relief does not have this kind of independence. It projects from and is attached to or is an integral part of something else that serves either as a background against which it is set or a matrix from which it emerges.

The actual three-dimensionality of sculpture in the round limits its scope in certain respects in comparison with the scope of painting. Sculpture cannot conjure up the illusion of space by purely optical means or invest its forms with atmosphere and light as painting can. It does

have a kind of reality, however, a vivid physical presence that is denied to the pictorial arts. The forms of sculpture are tangible as well as visible, and they can appeal strongly and directly to both tactual and visual sensibilities. Blind people, even those who are congenitally blind, can produce and appreciate certain kinds of sculpture. It has, in fact, been argued by the 20th-century art critic Sir Herbert Read that sculpture should be regarded as primarily an art of touch and that the roots of sculptural sensibility can be traced to the pleasure one experiences in fondling things.

All three-dimensional forms are perceived as having an expressive character as well as purely geometric properties. They strike the observer as delicate, aggressive, flowing, taut, relaxed, dynamic, soft, and so on. By exploiting the expressive qualities of form, a sculptor is able to create images in which subject matter and expressiveness of form are mutually reinforcing. Such images go beyond the mere presentation of fact and communicate a wide range of subtle and powerful feelings.

The aesthetic raw material of sculpture is, so to speak, the whole realm of expressive three-dimensional form. It may draw upon what already exists in the endless variety of natural and man-made form, or it may be an art of pure invention. It has been used to express a vast range of human emotions and feelings from the most tender and delicate to the most violent and ecstatic.

All human beings, intimately involved from birth with the world of three-dimensional form, learn something of its structural and expressive properties and develop emotional responses to them. This combination of understanding and sensitive response, which constitutes what is often called a sense of form, can be cultivated and refined. It is to this sense of form that the art of sculpture primarily appeals.

This article deals with the following aspects of sculpture: elements and principles of design; materials; methods and techniques; the forms of sculpture, including sculpture in the round and various types of relief; subject matter and imagery; symbolism; and uses.

ELEMENTS AND PRINCIPLES OF SCULPTURAL DESIGN

Elements of design. *Mass and space.* The two most important elements of sculpture—mass and space—are, of course, separable only in thought. All sculpture is made of a material substance that has mass and exists in three-dimensional space. The mass of sculpture is thus the solid, material, space-occupying bulk that is contained within its surfaces. Space enters into the design of sculpture in three main ways: the material components of the sculpture extend into or move through space; they may enclose or enfold space, thus creating hollows and voids within the sculpture; and they may relate one to another across space.

The amount of importance attached to either mass or space in the design of sculpture varies considerably. In Egyptian sculpture and in most of the sculpture of the 20th-century artist Constantin Brancusi, for example, mass is paramount, and most of the sculptor's thought has been devoted to shaping a lump of solid material. In 20th-century works by Antoine Pevsner or Naum Gabo, on the other hand, mass is reduced to a minimum, consisting only of transparent sheets of plastic or thin metal rods. The solid form of the components themselves is of little importance; their main function is to create movement through space and to enclose space. In works by such 20th-century sculptors as Henry Moore and Barbara Hepworth, the elements of space and mass are treated as more or less equal partners.

Volume. It is not possible to see the whole of a fully three-dimensional form at once. The observer can only see the whole of it if he turns it around or goes around it himself. For this reason it is sometimes mistakenly assumed that sculpture must be designed primarily to present a series of satisfactory projective views and that this multiplicity of views constitutes the main difference between sculpture and the pictorial arts, which present only one view of their subject. Such an attitude toward sculpture ignores the fact that it is possible to apprehend solid

Ways in which space enters into the design of sculpture

Definition of sculpture

Mass and space.

forms as volumes, to conceive an idea of them in the round from any one aspect. A great deal of sculpture is designed to be apprehended primarily as volume.

A single volume is the fundamental unit of three-dimensional solid form that can be conceived in the round. Some sculptures consist of only one volume, others are configurations of a number of volumes. The human figure is often treated by sculptors as a configuration of volumes each of which corresponds to a major part of the body, such as the head, neck, thorax, and thigh.

Holes and cavities in sculpture, which are as carefully shaped as the solid forms and are of equal importance to the overall design, are sometimes referred to as negative volumes.

Surfaces. The surfaces of sculpture are in fact all that one actually sees. It is from their inflections that one makes inferences about the internal structure of the sculpture. A surface has, so to speak, two aspects: it contains and defines the internal structure of the masses of the sculpture, and it is the part of the sculpture that enters into relations with external space.

The expressive character of different kinds of surfaces is of the utmost importance in sculpture. Double-curved convex surfaces suggest fullness, containment, enclosure, the outward pressure of internal forces. In the aesthetics of Indian sculpture such surfaces have a special metaphysical significance. Representing the encroachment of space into the mass of the sculpture, concave surfaces suggest the action of external forces and are often indicative of collapse or erosion. Flat surfaces tend to convey a feeling of material hardness and rigidity; they are unbending or unyielding, unaffected by either internal or external pressures. Surfaces that are convex in one curvature and concave in the other can suggest the operation of internal pressures and at the same time a receptivity to the influence of external forces. They are associated with growth, with expansion into space.

Light and shade. The sculptor cannot, like the painter, create his own lighting effects within the work itself. The distribution of light and shade over the forms of his work depends upon the direction and intensity of light from external sources. Nevertheless, to some extent he can determine the kinds of effect this external light will have. If he knows where the work is to be sited he can adapt it to the kind of light it is likely to receive. The brilliant overhead sunlight of Egypt and India demands a differ-

ent treatment from the dim interior light of a northern medieval cathedral. Then again, it is possible to create effects of light and shade, or *chiaroscuro*, by cutting or modelling deep, shadow-catching hollows and prominent, highlighted ridges. Many late Gothic sculptors used light and shade as a powerful expressive feature of their work, aiming at a mysterious obscurity, with forms broken by shadow emerging from a dark background. Greek, Indian, and most Italian Renaissance sculptors shaped the forms of their work to receive light in a way that makes the whole work radiantly clear.

Colour. The colouring of sculpture may be either natural or applied. In the recent past, sculptors became more aware than ever before of the inherent beauty of sculptural materials. Under the slogan of "truth to materials" many of them worked their materials in ways that exploited their natural properties, including colour and texture. More recently, however, there has been a growing tendency to use bright artificial colouring as an important element in the design of sculpture.

In the ancient world and during the Middle Ages almost all sculpture was artificially coloured, usually in a bold and decorative rather than a naturalistic manner. The sculptured portal of a cathedral, for example, would be coloured and gilded with all the brilliance of a contemporary illuminated manuscript.

Combinations of differently coloured materials, such as the ivory and gold of some Greek sculpture, were not unknown before the 17th century; but the early Baroque sculptor Gian Lorenzo Bernini greatly extended the practice by combining variously coloured marbles with white marble and gilt bronze.

Principles of design. It is doubtful whether any principles of design are universal in the art of sculpture; for the principles that govern the organization of the elements of sculpture into expressive compositions differ from style to style. In fact, distinctions made among the major styles of sculpture are largely based on a recognition of differences in the principles of design that underlie them. Thus, the art historian Erwin Panofsky was attempting to define a difference of principle in the design of Romanesque and Gothic sculpture when he stated that the forms of Romanesque were conceived as projections from a plane outside themselves, while those of Gothic were conceived as being centred on an axis within themselves. The "principle of axuality" was considered by

**Chiar-
oscuro
effects**

Panofsky to be "the essential principle of classical statuary," which Gothic had rediscovered.

The principles of sculptural design govern the approaches of sculptors to such fundamental matters as orientation, proportion, scale, articulation, and balance.

Orientation. For conceiving and describing the orientation of the forms of sculpture in relation to each other, to a spectator, and to their surroundings, some kind of spatial scheme of reference is required. This is provided by a system of axes and planes of reference.

An axis is an imaginary centre line through a symmetrical or near symmetrical volume or group of volumes. Thus, all the main components of the human body have axes of their own, while an upright figure has a single vertical axis running through its entire length. Volumes may rotate or tilt on their axes.

Planes of reference are imaginary planes to which the movements, positions, and directions of volumes, axes, and surfaces may be referred. The principal planes of reference are the frontal, the horizontal, and the two profile planes.

The principles that govern the characteristic poses and spatial compositions of upright figures in different styles of sculpture are formulated with reference to axes and the four cardinal planes: for example, the principle of axuality already referred to; the principle of frontality, which governs the design of Archaic sculpture; the characteristic contrapposto (pose in which parts of the body, such as upper and lower, are twisted in opposite directions) of Michelangelo's figures; and in standing Greek sculpture of the Classical period the frequently used balanced "chiastic" pose (stance in which the body weight is taken principally on one leg, thereby creating a contrast of tension and relaxation between the opposite sides of a figure).

Proportion. Proportional relations exist among linear dimensions, areas, and volumes and masses. All three types of proportion coexist and interact in sculpture, contributing to its expressiveness and beauty. Attitudes toward proportion differ considerably among sculptors. Some sculptors, both abstract and figurative, use mathematical systems of proportion; for example, the refinement and idealization of natural human proportions was a major preoccupation of Greek sculptors. Indian sculptors employed iconometric canons, or systems of carefully related proportions, that determined the proportions of all significant dimensions of the human figure. African and other tribal sculptors base the proportions of their figures on the subjective importance of the parts of the body. Unnatural proportions may be used for expressive purposes or to accommodate a sculpture to its surroundings. The elongation of the figures on the Portail Royal ("Royal Portal") of Chartres Cathedral does both: it enhances their otherworldliness and also integrates them with the columnar architecture.

Sometimes it is necessary to adapt the proportions of sculpture to suit its position in relation to a viewer. A figure sited high on a building, for example, is usually made larger in its upper parts in order to counteract the effects of foreshortening. This should be allowed for when a sculpture intended for such a position is exhibited on eye level in a museum.

Scale. The scale of sculpture must sometimes be considered in relation to the scale of its surroundings. When it is one element in a larger complex, such as the facade of a building, it must be in scale with the rest. Another important consideration that sculptors must take into account when designing outdoor sculpture is the tendency of sculpture in the open air—particularly when viewed against the sky—to appear less massive than it does in a studio.

Because one tends to relate the scale of sculpture to one's own human physical dimensions, the emotional impact of a colossal figure and a small figurine are quite different.

In ancient and medieval sculpture the relative scale of the figures in a composition is often determined by their importance; *e.g.*, slaves are much smaller than kings or nobles. This is sometimes known as hierarchic scale.

Proportion. Four figures possibly of the royal family of Judah, stone, 1145–50. Portail Royal of Chartres Cathedral, France. Height approximately 2.50 m.

Articulation. The joining of one form to another may be accomplished in a variety of ways. In much of the work of the 19th-century French sculptor Auguste Rodin, there are no clear boundaries, and one form is merged with another in an impressionistic manner to create a continuously flowing surface. In works by the Greek sculptor Praxiteles, the forms are softly and subtly blended by means of smooth, blurred transitions. The volumes of Indian sculpture and the surface anatomy of male figures in the style of the Greek sculptor Polyclitus are sharply defined and clearly articulated. One of the main distinctions between the work of Italian and northern Renaissance sculptors lies in the Italians' preference for compositions made up of clearly articulated, distinct units of form and the tendency of the northern Europeans to subordinate the individual parts to the all-over flow of the composition.

Balance. The balance, or equilibrium, of freestanding sculpture has three aspects. First, the sculpture must have

**Articulation.**

actual physical stability. This can be achieved by natural balance—that is, by making the sculpture stable enough in itself to stand firmly—which is easy enough to do with a four-legged animal or a reclining figure but not with a standing figure or a tall, thin sculpture, which must be secured to a base. The second aspect of balance is compositional. The interaction of forces and the distribution of weight within a composition may produce a state of either dynamic or static equilibrium. The third aspect of balance applies only to sculpture that represents a living figure. A live human figure balances on two feet by making constant movements and muscular adjustments. An effect of this "living balance" can be achieved in sculpture by subtle displacements of form and suggestions of tension and relaxation.

Design relationships between sculpture and the other visual arts. Sculpture has always been closely related to architecture through its role as architectural decoration and also at the level of design. Architecture, like sculpture, is concerned with three-dimensional form; and, although the central problem in the design of buildings is the organization of space rather than mass, there are styles of architecture that are effective largely through the quality and organization of their solid forms. Ancient styles of stone architecture, particularly Egyptian, Greek, and Mexican, tend to treat their components in a sculptural manner. Moreover, most buildings viewed from the outside are compositions of masses. The growth of spatial sculpture during the 20th century is so intimately related to the opening up and lightening of architecture, which the development of modern building technology has made possible, that many contemporary sculptors can be said to treat their work in an architectural manner.

Some forms of relief sculpture approach very closely the pictorial arts of painting, drawing, engraving, and so on. And sculptures in the round that make use of chiaroscuro and that are conceived primarily as pictorial views rather than as compositions in the round are said to be "painterly"; for example, Bernini's "Ecstasy of St. Teresa" (Sta. Maria della Vittoria, Rome).

The borderlines between sculpture and pottery and the

metalworking arts are not clear-cut, and many pottery and metal artifacts have every claim to be considered as sculpture. Today there is a growing affinity between the work of industrial designers and sculptors.

The close relationships that exist between sculpture and the other visual arts are attested by the number of artists who have readily turned from one art to another; for example, Michelangelo, Bernini, Antonio Pisanello, Edgar Degas, and Pablo Picasso.

MATERIALS

Any material that can be shaped in three dimensions can be used sculpturally. Certain materials, however, by virtue of their structural and aesthetic properties and their availability, have proved especially suitable. The most important of these are stone, wood, metal, clay, ivory, and plaster. There are also a number of materials of secondary importance and many that have only recently come into use.

Stone. Throughout history, stone has been the principal material of monumental sculpture. There are practical reasons for this: many types of stone are highly resistant to the weather and therefore suitable for external use; stone is available in all parts of the world and can be obtained in large blocks; many stones have a fairly homogeneous texture and a uniform hardness that make them suitable for carving; stone has been the chief material used for the monumental architecture with which so much sculpture has been associated.

Igneous, sedimentary, and metamorphic rocks. Stones belonging to all three main categories of rock formation have been used in sculpture. Igneous rocks, which are formed by the cooling of molten masses of mineral as they approach the Earth's surface, include granite, diorite, basalt, and obsidian. These are some of the hardest stones used for sculpture. Sedimentary rocks, which include sandstones and limestones, are formed from accumulated deposits of mineral and organic substances. Sandstones are agglomerations of particles of eroded stone held together by a cementing substance. Limestones are formed chiefly from the calcareous remains of organisms. Alabaster (gypsum), also a sedimentary rock, is a chemical deposit. Many varieties of sandstone and limestone, which vary greatly in quality and suitability for carving, are used for sculpture. Because of their method of formation, many sedimentary rocks have pronounced strata and are rich in fossils.

Metamorphic rocks result from changes brought about in the structure of sedimentary and igneous rocks by extreme pressure or heat. The most well-known metamorphic rocks used in sculpture are the marbles, which are re-crystallized limestones. Italian Carrara marble, the best known, was used by Roman and Renaissance sculptors, especially Michelangelo, and is still widely used. The best known varieties used by Greek sculptors, with whom marble was more popular than any other stone, are **Pentelic**—from which the Parthenon and its sculpture are made—and **Parian**.

Because stone is extremely heavy and lacks tensile strength, it is easily fractured if carved too thinly and not properly supported. A massive treatment without vulnerable projections, as in Egyptian and pre-Columbian American Indian sculpture, is therefore usually preferred. Some stones, however, can be treated more freely and openly; marble in particular has been treated by some European sculptors with almost the same freedom as bronze, but such displays of virtuosity are achieved by overcoming rather than submitting to the properties of the material itself.

The colours and textures of stone are among its most delightful properties. Some stones are fine-grained and can be carved with delicate detail and finished with a high polish; others are coarse-grained and demand a broader treatment. Pure white Carrara marble, which has a translucent quality, seems to glow and responds to light in a delicate, subtle manner. (These properties of marble were brilliantly exploited by 15th-century Italian sculptors such as Donatello and Desiderio da Settignano.) The colouring of granite is not uniform but has a salt-and-

Colours and textures of stone

pepper quality and may glint with mica and quartz crystals. It may be predominantly black or white or a variety of grays, pinks, and reds. Sandstones vary in texture and are often warmly coloured in a range of buffs, pinks, and reds. Limestones vary greatly in colour, and the presence of fossils may add to the interest of their surfaces. A number of stones are richly variegated in colour by the irregular veining that runs through them.

Hardstones. Hardstones, or semiprecious stones, constitute a special group, which includes some of the most beautiful and decorative of all substances. The working of these stones, along with the working of **more** precious gemstones, is usually considered as part of the **glyptic** (gem carving or engraving), or lapidary, arts, but many artifacts produced from them can be considered **small-scale sculpture**. They are often harder to work than steel. First among the hardstones used for sculpture is jade, which was venerated by the ancient Chinese, who worked it, together with other hardstones, with extreme skill. It was also used sculpturally by Mayan and Mexican artists. Other important hardstones are rock crystal, rose quartz, amethyst, agate, and jasper.

Wood. The principal material of tribal sculpture in Africa, Oceania, and North America, wood has also been used by every great civilization; it was used extensively during the Middle Ages, for example, especially in Germany and central Europe. Among modern sculptors who have used wood for important works are Ernst Barlach, Ossip Zadkine, and Henry Moore.

Both hardwoods and softwoods are used for sculpture. Some are close-grained, and they cut like cheese; others are open-grained and stringy. The fibrous structure of wood gives it considerable tensile strength, so that it may be carved thinly and with greater freedom than stone. For large or complex open compositions, a number of pieces of wood may be jointed. Wood is used mainly for indoor sculpture, for it is not as tough or durable as stone; changes of humidity and temperature may cause it to split, and it is subject to attack by insects and fungus. The grain of wood is one of its most attractive features, giving variety of pattern and texture to its surfaces. Its colours, too, are subtle and varied. In general, wood has a warmth that stone does not have, but it lacks the massive dignity and weight of stone.

The principal woods for sculpture are oak, mahogany, limewood, walnut, elm, pine, cedar, boxwood, pear, and ebony; but many others are also used. The sizes of wood available are limited by the sizes of trees; North American Indians, for example, could carve gigantic totem poles in pine, but boxwood is available only in small pieces.

In the 20th century, wood was being used by many sculptors as a medium for construction as well as for carving. Laminated timbers, chipboards, and timber in block and plank form can be glued, jointed, screwed, or bolted together, and given a variety of finishes.

Metal. Wherever metal technologies have been developed, metals have been used for sculpture. The amount of metal sculpture that has survived from the ancient world does not properly reflect the extent to which it was used, for vast quantities have been plundered and melted down. Countless Far Eastern and Greek metal sculptures have been lost in this way, as has almost all the goldwork of pre-Columbian American Indians.

The metal most used for sculpture is bronze, which is basically an alloy of copper and tin; but gold, silver, aluminum, copper, brass, lead, and iron have also been widely used. Most metals are extremely strong, hard, and durable, with a tensile strength that permits a much greater freedom of design than is possible in either stone or wood. A life-size bronze figure that is firmly attached to a base needs no support other than its own feet and may even be poised on one foot. Considerable attenuation of form is also possible without risk of fracture.

The colour, brilliant lustre, and reflectivity of metal surfaces have been highly valued and made full use of in sculpture although, since the Renaissance, artificial patinas have generally been preferred as finishes for bronze.

Metals can be worked in a variety of ways in order to

produce sculpture. They can be cast—that is, melted and poured into molds; squeezed under pressure into dies, as in coin making; or worked directly—for example, by hammering, bending, cutting, welding, and **repoussé** (hammered or pressed in relief). Each method produces a different effect.

Important traditions of bronze sculpture are Greek, Roman, Indian (especially Cōla), African (Bini and Yoruba), Italian Renaissance, and Chinese. Gold was used to great effect for small-scale works in pre-Columbian America and medieval Europe. A fairly recent discovery, aluminum has been used a great deal by modern sculptors. Iron has not been used much as a casting material, but in recent years it has become a popular material for direct working by techniques similar to those of the blacksmith. Sheet metal is one of the principal materials used nowadays for constructional sculpture. Stainless steel in sheet form has been used effectively by the American sculptor David Smith.

Clay. Clay is one of the most common and easily obtainable of all materials. Used for modelling animal and human figures long before men discovered how to fire pots, it has been one of the sculptor's chief materials ever since.

Clay has four properties that account for its widespread use: when moist, it is one of the most plastic of all substances, easily modelled and capable of registering the most detailed impressions; when partially dried out to a leather-hard state or completely dried, it can be carved and scraped; when mixed with enough water, it becomes a creamy liquid known as slip, which may be poured into molds and allowed to dry; when fired to temperatures of between 700°–1,400° C (1,300°–2,600° F), it undergoes irreversible structural changes that make it permanently hard and extremely durable.

Sculptors use clay as a material for working out ideas; for preliminary models that are subsequently cast in such materials as plaster, metal, and concrete or carved in stone; and for pottery sculpture.

Depending on the nature of the clay body itself and the temperature at which it is fired, a finished pottery product is said to be earthenware, which is opaque, relatively soft, and porous; stoneware, which is hard, nonporous, and more or less vitrified; or porcelain, which is fine-textured, vitrified, and translucent. All three types of pottery are used for sculpture. Sculpture made in low-fired clays, particularly buff and red clays, is known as *terra-cotta* (baked earth). This term is used inconsistently, however, and is often extended to cover all forms of pottery sculpture.

Unglazed clay bodies can be smooth or coarse in texture and may be coloured white, gray, buff, brown, pink, or red. Pottery sculpture can be decorated with any of the techniques invented by potters and coated with a variety of beautiful glazes.

Paleolithic sculptors produced relief and in-the-round work in unfired clay. The ancient Chinese, particularly during the T'ang (618–907) and Sung (960–1279) dynasties, made superb pottery sculpture, including large-scale human figures. The best known Greek works are the intimate small-scale figures and groups from Tanagra. Mexican and Mayan sculptor-potters produced vigorous, directly modelled figures. During the Renaissance, pottery was used in Italy for major sculptural projects, including the large-scale glazed and coloured sculptures of Luca Della Robbia and his family, which are among the finest works in the medium. One of the most popular uses of the pottery medium has been for the manufacture of figurines—at Staffordshire, Meissen, and Sèvres, for example.

Ivory. The main source of ivory is elephant tusks; but walrus, hippopotamus, narwhal (an Arctic aquatic animal), and, in Paleolithic times, mammoth tusks also were used for sculpture. Ivory is dense, hard, and difficult to work. Its colour is creamy white, which usually yellows with age; and it will take a high polish. A tusk may be sawed into panels for relief carving or into blocks for carving in the round; or the shape of the tusk itself may be used. The physical properties of the material invite the

most delicate, detailed carving, and displays of virtuosity are common.

Ivory was used extensively in antiquity in the Near and Far East and the Mediterranean. An almost unbroken Christian tradition of ivory carving reaches from Rome and Byzantium to the end of the Middle Ages. Throughout this time, ivory was used mainly in relief, often in conjunction with precious metals, enamels, and precious stones to produce the most splendid effects. Some of its main sculptural uses were for devotional diptychs, portable altars, book covers, retables (a raised shelf above the altar), caskets, and crucifixes. The Baroque period, too, is rich in ivories, especially in Germany. A fine tradition of ivory carving also existed in Benin, a former kingdom of West Africa.

Related to ivory, horn and bone have been used since Paleolithic times for small-scale sculpture. Reindeer horn and walrus tusks were two of the Eskimo carver's most important materials. One of the finest of all medieval "ivories" is a carving in whalebone of "The Adoration of the Magi" (Victoria and Albert Museum, London).

English, 11th–12th century. In the Victoria and
Albert Museum, London. Height 37 cm.

Plaster. Plaster of Paris (sulfate of lime) is especially useful for the production of molds, casts, and preliminary models. It was used by Egyptian and Greek sculptors as a casting medium and is today the most versatile material in the sculptor's workshop.

When mixed with water, plaster will in a short time recrystallize, or "set"—that is, become hard and inert—and its volume will increase slightly. When set, it is relatively fragile and lacking in character and is therefore of limited use for finished work. Plaster can be poured as a liquid, modelled directly when of a suitable consistency, or easily carved after it has set. Other materials can be added to it in order to retard its setting, to increase its hardness or resistance to heat, to change its colour, or to reinforce it.

The main sculptural use of plaster in the past was for molding and casting clay models as a stage in the production of cast metal sculpture. Many sculptors today omit the clay-modelling stage and model directly in plaster. As a mold material in the casting of concrete and fibre-glass sculpture, plaster is widely used. It has great value as a material for reproducing existing sculpture; many museums, for example, use plaster casts of distinguished works for study purposes.

Concrete. Basically, concrete is a mixture of an aggregate (usually sand and small pieces of stone) bound together by cement. A variety of stones, such as crushed marble, granite chips, and gravel, can be used, each giving a different effect of colour and texture. Commercial cement is gray, white, or black; but it can be coloured by additives. The cement most widely used by sculptors is *ciment fondu*, which is extremely hard and quick setting. A recent invention—at least, in appropriate forms for sculpture—concrete is rapidly replacing stone for certain types of work. Because it is cheap, hard, tough, and durable, it is particularly suitable for large outdoor projects, especially decorative wall surfaces. With proper reinforcement it permits great freedom of design. And by using techniques similar to those of the building industry, sculptors are able to create works in concrete on a gigantic scale.

Fibre glass. When synthetic resins, especially polyesters, are reinforced with laminations of glass fibre, the result is a lightweight shell that is extremely strong, hard, and durable. It is usually known simply as fibre glass. After having been successfully used for car bodies, boat hulls, and the like, it has developed recently into an important material for sculpture. Since the material is visually unattractive, it is usually coloured by means of fillers and pigments. It was first used in sculpture in conjunction with powdered metal fillers in order to produce cheap "cold-cast" substitutes for bronze and aluminum, but with the recent tendency to use bright colours in sculpture it is now often coloured either by pigmenting the material itself or by painting.

It is possible to model fibre glass, but more usually it is cast as a laminated shell. Its possibilities for sculpture have not yet been fully exploited.

Wax. Various formulas for modelling wax have been used in the past, but these have been generally replaced by synthetic waxes. The main uses of wax in sculpture have been as a preliminary modelling material for metal casting by the lost-wax, or *cire perdue*, process (see *Methods and techniques*, below), and for making sketches. It is not durable enough for use as a material in its own right, although it has been used for small works, such as wax fruit, that can be kept under a glass dome.

Paper. *Papier-mâché* (pulped paper bonded with glue) has been used for sculpture, especially in the Far East. Mainly used for decorative work, especially masks, it can have considerable strength; the Japanese, for example, made armour from it. Sculpture made of sheet paper is a limited art form used only for ephemeral and usually trivial work.

Other materials. Numerous other permanent materials, such as shells, amber, and brick, and ephemeral ones, such as feathers, baker's dough, ice and snow, and cake icing, have been used for fashioning three-dimensional images.

In view of recent trends in sculpture it is no longer possible to speak of "the materials of sculpture." Modern sculpture has no special materials. Any material, natural or man-made, is likely to be used, including inflated polythene, foam rubber, expanded polystyrene, fabrics, and neon tubes; the materials for a mid-20th century sculpture by Claes Oldenburg, for example, are listed as canvas, cloth, Dacron, metal, foam rubber, and Plexiglas. Real objects, too, may be incorporated in sculpture, as in the mixed-medium compositions of Edward Kienholz; even junk has its devotees, who fashion "junk" sculpture.

METHODS AND TECHNIQUES

Sculpture and the decorative arts. Although a sculptor may specialize in, say, stone carving or direct metalwork,

Advantages of concrete

Jade horse head, Chinese, Han dynasty (206 BC–AD 220). In the Victoria and Albert Museum, London. Height 19 cm.

Jaina pottery figurine, late classic Maya style, from the state of Campeche, Mexico. In the collection of Dumbarton Oaks, Washington, D.C. Height 15.5 cm.

Diverse materials and techniques

"Virgin and Child," polychromed oak statue of the school of Auvergne, France, 12th century. In the Metropolitan Museum of Art, New York. 78.7 × 32.4 cm.

"Isaac, Jacob, and Esau," gilded bronze relief panel from the east doors ("Gates of Paradise") of the baptistery in Florence, by Lorenzo Ghiberti, 1425–52. 79.4 cm square.

"The Ecstasy of St. Teresa," marble and gilded bronze niche sculpture by Gian Lorenzo Bernini, 1645–52. In the Coronaro Chapel, Sta. Maria della Vittoria, Rome. Lifesize.

Painted wood male figure standing on a fish, fantastic cult image from Northern New Ireland, Melanesia. In a private collection. Height 1.53 m.

Diverse kinds of representational and nonrepresentational sculpture

"Development of a Bottle in Space," nonrepresentational sculpture by Umberto Boccioni, silvered bronze, 1912. In the Museum of Modern Art, New York. 38.1 X 32.7 X 59.7 cm.

"Cubi XVII," non-objective sculpture by David Smith, stainless steel, 1963. In the Dallas Museum of Fine Arts, Texas. Height 2.74 m.

"The Diner," representational environmental sculpture by George Segal, mixed media (plaster, wood, chrome, masonite, and formica), 1964-66. In the Walker Art Center, Minneapolis. 2.59 X 2.74 X 2.13 m.

Unconventional materials of modern sculpture.

the art of sculpture is not identifiable with any particular craft or set of crafts. It presses into its service whatever crafts suit its purposes. Technologies developed for more utilitarian purposes are often easily adapted for sculpture; in fact, useful artifacts and sculptured images have often been produced in the same workshop, sometimes by the same craftsman. The methods and techniques employed in producing a pot, a bronze harness trapping, a decorative stone molding or column, a carved wooden newel post, or even a fibre-glass car body are essentially the same as those used in sculpture. For example, the techniques of *repoussé*, metal casting, blacksmithing, sheet-metal work, and welding, which are used for the production of functional artifacts and decorative metalwork, are also used in metal sculpture; and the preparation, forming, glazing, decoration, and firing of clay are basically the same in both utilitarian pottery and pottery sculpture. The new techniques used by sculptors today are closely related to new techniques applied in building and industrial manufacture.

The sculptor as designer and as craftsman. The conception of an artifact or a work of art—its form, imaginative content, and expressiveness—is the concern of a designer, and it should be distinguished from the execution of the work in a particular technique and material, which is the task of a craftsman. A sculptor usually functions as both designer and craftsman, but these two aspects of sculpture may be separated.

Certain types of sculpture depend considerably for their aesthetic effect on the way in which their material has been directly manipulated by the artist himself. The direct, expressive handling of clay in a model by Rodin, or the use of the chisel in the *stiacciato* (very low) reliefs of the 15th-century Florentine sculptor Donatello could no more have been delegated to a craftsman than could the brushwork of Rembrandt. The actual physical process of working materials is for many sculptors an integral part of the art of sculpture, and their response to the working qualities of the material—such as its plasticity, hardness, and texture—is evident in the finished work. Design and craftsmanship are intimately fused in such a work, which is a highly personal expression.

Even when the direct handling of material is not as vital as this to the expressiveness of the work, it still may be impossible to separate the roles of the artist as designer and craftsman. The qualities and interrelationships of forms may be so subtle and complex that they cannot be adequately specified and communicated to a craftsman. Moreover, many aspects of the design may actually be contributed during the process of working. Michelangelo's way of working, for example, enabled him to change his mind about important aspects of composition as the work proceeded.

A complete fusion of design and craftsmanship may not be possible if a project is a large one or if the sculptor is too old or too weak to do all of the work himself. The sheer physical labour of making a large sculpture can be

considerable, and sculptors from Phidias in the 5th century BC to Henry Moore in the 20th century have employed pupils and assistants to help with it. Usually the sculptor delegates the time-consuming first stages of the work or some of its less important parts to his assistants and executes the final stages or the most important parts himself.

On occasion, a sculptor may function like an architect or industrial designer. He may do no direct work at all on the finished sculpture, his contribution being to supply exhaustive specifications in the form of drawings and perhaps scale models for a work that is to be entirely fabricated by craftsmen. Obviously, such a procedure excludes the possibility of direct, personal expression through the handling of the materials; thus, works of this kind usually have the same anonymous, impersonal quality as architecture and industrial design. An impersonal approach to sculpture was favoured by many sculptors of the 1960s such as William Tucker, Donald Judd, and William Turnbull. They used the skilled anonymous workmanship of industrial fabrications to make their large scale, extremely precise, simple sculptural forms that are called "primary structures."

General methods. Broadly speaking, the stages in the production of a major work of sculpture conform to the following pattern: the commission; the preparation, submission, and acceptance of the design; the selection and preparation of materials; the forming of materials; surface finishing; installation or presentation.

Almost all of the sculpture of the past and some present-day sculpture originates in a demand made upon the sculptor from outside, usually in the form of a direct commission or through a competition. If the commission is for a portrait or a private sculpture, the client may only require to see examples of the artist's previous work; but if it is a public commission, the sculptor is usually expected to submit drawings and maquettes (small-scale, three-dimensional sketch models) that give an idea of the nature of the finished work and its relation to the site. He may be free to choose his own subject matter or theme, or it may be more or less strictly prescribed. A medieval master sculptor, for example, received the program for a complex scheme of church sculpture from theological advisers, and Renaissance contracts for sculpture were often extremely specified and detailed. Today a great deal of sculpture is not commissioned. It arises out of the sculptor's private concern with form and imagery, and he works primarily to satisfy himself. When the work is finished he may exhibit and attempt to sell it in an art gallery.

Most of the materials used by 20th-century sculptors are readily available in a usable form from builders' or sculptors' suppliers, but certain kinds of sculpture may involve a good deal of preparatory work on the materials. A sculptor may visit a stone quarry in order to select the material for a large project and to have it cut into blocks of the right size and shape. And since stone is costly to transport and best carved when freshly quarried, he may decide to do all of his work at the quarry. Because stone is extremely heavy, the sculptor must have the special equipment required for manoeuvring even small blocks into position for carving. A wood carver requires a supply of well-seasoned timber and may keep a quantity of logs and blocks in store. A modeller needs a good supply of clay of the right kind. For large *terra-cottas* he may require a specially made up clay body, or he may work at a brickworks, using the local clay and firing in the brick kilns.

The main part of the sculptor's work, the shaping of the material itself by modelling, carving, or constructional techniques, may be a long and arduous process, perhaps extending over a number of years and requiring assistants. Much of the work, especially architectural decoration, may be carried out at the site, or *in situ*.

To improve its weathering qualities, to bring out the characteristics of its material to the best advantage, or to make it more decorative or realistic, sculpture is usually given a special surface finish. It may be rubbed down and polished, patinated, metal plated, gilded, painted, inlaid with other materials, and so on.

Stages
in the
production
of a major
work

Finally, the installation of sculpture may be a complex and important part of the work. The positioning and fixing of large architectural sculpture may involve cooperation with builders and engineers; fountains may involve elaborate plumbing; the design and placing of outdoor bases, or plinths, in relation to the site and the spectator may require careful thought. The choice of the materials, shape, and proportions of the base even for a small work requires a considerable amount of care.

Carving. *Direct carving.* Whatever material is used, the essential features of the direct method of carving are the same; the sculptor starts with a solid mass of material and reduces it systematically to the desired form. After he has blocked out the main masses and planes that define the outer limits of the forms, he works progressively over the whole sculpture, first carving the larger containing forms and planes and then the smaller ones until eventually the surface details are reached. Then he gives the surface whatever finish is required. Even with a preliminary model as a guide, the sculptor's concept constantly evolves and clarifies as the work proceeds; thus, as he adapts his design to the nature of the carving process and the material, his work develops as an organic whole.

Direct carving.
(Top) "Reclining Figure" in progress, elmwood sculpture by Henry Moore, 1945–46. (Bottom) "Reclining Figure." Length 1.90 m.

The process of direct carving imposes a characteristic order on the forms of sculpture. The faces of the original block, slab, or cylinder of material can usually still be sensed, existing around the finished work as a kind of implied spatial envelope limiting the extension of the forms in space and connecting their highest points across space. In a similar way, throughout the whole carving, smaller forms and planes can be seen as contained within implied larger ones. Thus, an ordered sequence of containing forms and planes, from the largest to the smallest, gives unity to the work.

Indirect carving. All of the great sculptural traditions of the past used the direct method of carving, but in

Western civilization during the 19th and early 20th centuries it became customary for stone and, to a lesser extent, wood sculpture to be produced by the indirect method. This required the production of a finished clay model that was subsequently cast in plaster and then reproduced in stone or wood in a more or less mechanical way by means of a pointing machine (see *Reproduction techniques: pointing*, below). Usually, the carving was not done by the sculptor himself. At its worst, this procedure results in a carved copy of a design that was conceived in terms of clay modelling. Although indirect carving does not achieve aesthetic qualities that are typical of carved sculpture, it does not necessarily result in bad sculpture. Rodin's marble sculptures, for example, are generally considered great works of art even by those who object to the indirect methods by which they were produced. The indirect method has been steadily losing ground since the revival of direct carving in the early part of the 20th century, and today it is in general disrepute among carvers.

Carving tools and techniques. The tools used for carving differ with the material to be carved. Stone is carved mostly with steel tools that resemble cold chisels. To knock off the corners and angles of a block, a tool called a pitcher is driven into the surface with a heavy iron hammer. The pitcher is a thick, chisel-like tool with a wide bevelled edge that breaks rather than cuts the stone. The heavy point then does the main roughing out, followed by the fine point, which may be used to within a short distance of the final surface. These pointed tools are hammered into the surface at an angle that causes the stone to break off in chips of varying sizes. Claw chisels, which have toothed edges, may then be worked in all directions over the surface, removing the stone in granule form and thus refining the surface forms. Flat chisels are used for finishing the surface carving and for cutting sharp detail.

There are many other special tools, including stone gouges, drills, toothed hammers (known as *bushhammers* or *bouchardes*), and, often used today, *power-driven* pneumatic tools, for pounding away the surface of the stone.

Because medieval carvers worked mostly in softer stones and made great use of flat chisels, their work tends to have an edgy, cut quality and to be freely and deeply carved. In contrast is the work done in hard stones by people who lacked metal tools hard enough to cut the stone. Egyptian granite sculpture, for example, was produced mainly by abrasion; that is, by pounding the surface and rubbing it down with abrasive materials. The result is a compact sculpture, not deeply hollowed out, with softened edges and flowing surfaces. It usually has a high degree of tactile appeal.

Although the process of carving is fundamentally the same for wood or stone, the physical structure of wood demands tools of a different type. For the first blocking out of a wood carving a sculptor may use saws and axes, but his principal tools are a wide range of wood-carver's gouges. The sharp, curved edge of a gouge cuts easily through the bundles of fibre and when used properly will not split the wood. Flat chisels are also used, especially for carving sharp details. Wood rasps, or coarse files, and sandpaper can be used to give the surface a smooth finish, or, if preferred, it can be left with a faceted, chiselled appearance. Wood-carving tools have hardwood handles and are struck with round, wooden mallets. African wood sculptors use a variety of adzes rather than gouges and mallets.

Ivory is carved with an assortment of saws, knives, rasps, files, chisels, drills, and scrapers.

Modelling. In contrast to the reductive process of carving, modelling is essentially a building-up process in which the sculpture grows organically from the inside. Numerous plastic materials are used for modelling. The main ones are clay, plaster, and wax; but concrete, synthetic resins, plastic wood, stucco, and even molten metal can also be modelled. A design modelled in plastic materials may be intended for reproduction by casting in more permanent and rigid materials, such as metal, plaster,

Tools for
stone
carving

Clay models

concrete, and fibre glass, or it may itself be made rigid and more permanent through the self-setting properties of its materials (for example, plaster) or by firing.

Modelling for casting. The material most widely used for making positive models for casting is clay. A small, compact design or a low relief can be modelled solidly in clay without any internal support; but a large clay model must be formed over a strong armature made of wood and metal. Since the armature may be very elaborate and can only be altered slightly, if at all, once work has started, the modeller must have a fairly clear idea from his drawings and maquettes of the arrangement of the main shapes of the finished model. The underlying main masses of the sculpture are built up firmly over the armature and then the smaller forms, surface modelling, and details are modelled over them. The modeller's chief tools are his fingers, but for fine work he may use a variety of wooden modelling tools to apply the clay and wire loop tools to cut it away. Reliefs are modelled on a vertical or nearly vertical board. The clay is keyed, or secured, onto the board with galvanized nails or wood iaths. The amount of armature required depends on the height of the relief and the weight of clay involved.

To make a cast in metal, a foundry requires from the sculptor a model made of a rigid material, usually plaster. The sculptor can produce this either by modelling in clay and then casting in plaster from the clay model or by modelling directly in plaster. For direct plaster modelling, a strong armature is required because the material is brittle. The main forms may be built up roughly over the armature in expanded wire and then covered in plaster-soaked scrim (a loosely woven sacking). This provides a hollow base for the final modelling, which is done by applying plaster with metal spatulas and by scraping and cutting down with rasps and chisels.

Fibre-glass and concrete sculptures are cast in plaster molds taken from the sculptor's original model. The model is usually clay rather than plaster because if the forms of the sculpture are at all complex it is easier to remove a plaster mold from a soft clay model than from a model in a rigid material, such as plaster.

A great deal of the metal sculpture of the past, including Nigerian, Indian, and many Renaissance bronzes, was produced by the direct lost-wax process, which involves a special modelling technique (see *Reproduction techniques: casting and modelling*, below). The design is first

modelled in some refractory material to within a fraction of an inch of the final surface, and then the final modelling is done in a layer of wax, using the fingers and also metal tools, which can be heated to make the wax more pliable. Medallions are often produced from wax originals, but because of their small size they do not require a core.

Modelling for pottery sculpture. In order to withstand the stresses of firing, a large pottery sculpture must be hollow and of an even thickness. There are two main ways of achieving this. In the process of hollow modelling, which is typical of the potter's approach to form, the main forms of the clay model are built up directly as hollow forms with walls of a roughly even thickness. The methods of building are similar to those employed for making hand-built pottery—coiling, pinching, and slabbing. The smaller forms and details are then added, and the finished work is allowed to dry out slowly and thoroughly before firing. The process of solid modelling is more typical of the sculptor's traditional approach to form. The sculpture is modelled in solid clay, sometimes over a carefully considered armature, by the sculptor's usual methods of clay modelling. Then it is cut open and hollowed out, and the armature, if there is one, is removed. The pieces are then rejoined and the work is dried out and fired.

General characteristics of modelled sculpture. The process of modelling affects the design of sculpture in three important ways. First, the forms of the sculpture tend to be ordered from the inside. There are no external containing forms and planes, as in carved sculpture. The overall design of the work—its main volumes, proportions, and axial arrangement—is determined by the underlying forms; and the smaller forms, surface modelling, and decorative details are all formed around and sustained by this underlying structure. Second, because its extension into space is not limited by the dimensions of a block of material, modelled sculpture tends to be much freer and more expansive in its spatial design than carved sculpture. If the tensile strength of metal is to be exploited in the finished work, there is almost unlimited freedom; designs for brittle materials such as concrete or plaster, however, are more limited. Third, the plasticity of clay and wax encourages a fluent, immediate kind of manipulation, and many sculptors, such as Auguste Rodin, Giacomo Manzù, and Sir Jacob Epstein, like to preserve this record of their direct handling of the medium in their finished work. Their approach contrasts with that of the Benin and Indian bronze sculptors, who refined the surfaces of their work to remove all traces of personal "handwriting."

Constructing and assembling. A constructed or assembled sculpture is made by joining preformed pieces of material. It differs radically in principle from carved and modelled sculpture, both of which are fabricated out of a homogeneous mass of material. Constructed sculpture is made out of such basic preformed components as metal tubes, rods, plates, bars, and sheets; wooden laths, planks, dowels, and blocks; laminated timbers and chipboards; sheets of Perspex (used for acrylic plastic), Formica, and glass; fabrics; and wires and threads. These are cut to various sizes and may be either shaped before they are assembled or used as they are. The term assemblage is usually reserved for constructed sculpture that incorporates any of a vast array of ready-made, so-called found objects, such as old boilers, typewriters, engine components, mirrors, chairs, and table legs and other bits of old furniture.

Numerous techniques are employed for joining these components, most of them derived from crafts other than traditional sculptural ones; for example, metal welding and brazing, wood joinery, bolting, screwing, rivetting, nailing, and bonding with new powerful adhesives.

The use of constructional techniques for the production of sculpture is the major technical development of the art of sculpture in recent years. Among the reasons for its popularity are that it lends itself readily to an emphasis on the spatial aspects of sculpture that have preoccupied so many 20th-century artists; it is quicker than carving

and modelling; it is considered by many sculptors and critics to be especially appropriate to a technological civilization; it is opening up new fields of imagery and new types of symbolism and form.

For constructed "gallery" sculpture, almost any materials and techniques are likely to be used, and the products are often extremely ephemeral. But architectural sculpture, outdoor sculpture, and indeed any sculpture that is actually used must be constructed in a safe and at least reasonably permanent manner. The materials and techniques employed are therefore somewhat restricted. Metal sculpture constructed by rivetting, bolting, and, above all, welding and brazing is best for outdoor use.

Direct metal sculpture. The introduction of the oxy-acetylene welding torch as a sculptor's tool has revolutionized metal sculpture in recent years. A combination of welding and forging techniques was pioneered by the Spanish sculptor Julio González around 1930; and during the 1940s and 1950s it became a major sculptural technique, particularly in Britain and in the United States, where its greatest exponent was David Smith. In the 1960s and early 1970s, more sophisticated electric welding processes were replacing flame welding.

Welding equipment can be used for joining and cutting metal. A welded joint is made by melting and fusing together the surfaces of two pieces of metal, usually with the addition of a small quantity of the same metal as a filler. The metal most widely used for welded sculpture is mild steel, but other metals can be welded. In a brazed joint, the parent metals are not actually fused together but are joined by an alloy that melts at a lower temperature than the parent metals. Brazing is particularly useful for making joints between different kinds of metal, which cannot be done by welding, and for joining nonferrous metals. Forging is the direct shaping of metal by bending, hammering, and cutting.

Direct metalworking techniques have opened up whole new ranges of form to the sculptor—open skeletal structures, linear and highly extended forms, and complex, curved sheet forms. Constructed metal sculpture may be precise and clean, as that of Minimalist sculptors Donald Judd and Phillip King, or it may exploit the textural effects of molten metal in a free, "romantic" manner.

Reproduction techniques: casting and molding. Casting and molding processes are used in sculpture either for making copies of existing sculpture or as essential stages in the production of a finished work. Numerous materials are used for making molds and casts, and some of the methods are complex and highly skilled. Only a broad outline of the principal methods can be given here.

Plaster waste molds. These are used for producing a single cast from a soft, plastic original, usually clay. They are especially useful for producing master casts for subsequent reproduction in metal. The basic procedure is as follows. First, the mold is built up in liquid plaster over the original clay model; for casting reliefs, a one-piece mold may be sufficient, but for sculpture in the round a mold in at least two sections is required. Second, when the plaster is set, the mold is divided and removed from the clay model. Third, the mold is cleaned, reassembled, and filled with a self-setting material such as plaster, concrete, or fibre-glass-reinforced resin. Fourth, the mold is carefully chipped away from the cast. This involves the destruction of the mold—hence the term "waste" mold. The order of reassembling and filling the mold may be reversed; fibre glass and resin, for example, are "layered-up" in the mold pieces before they are reassembled.

Plaster piece molds. Plaster piece molds are used for producing more than one cast from a soft or rigid original and are especially good for reproducing existing sculpture and for slip casting (see below). Before the invention of flexible molds (see below), piece molds were used for producing wax casts for metal casting by the lost-wax process. A piece mold is built up in sections that can be withdrawn from the original model without damaging it. The number of sections depends on the complexity of the form and on the amount of undercutting; tens, or even hundreds, of pieces may be required for really large, complex works. The mold sections are carefully keyed together and supported by a plaster case. When the mold has been filled, it can be removed section by section from the cast and then reassembled and used again. Piece molding is a highly skilled and laborious process.

Flexible molds. Made of such materials as gelatin, vinyl, and rubber, flexible molds are used for producing more than one cast; they offer a much simpler alternative to piece molding when the original model is a rigid one with complex forms and undercuts. The material is melted and poured around the original positive in sections, if necessary. Being flexible, the mold easily pulls away from a rigid surface without causing damage. While it is being filled (with wax, plaster, concrete, and fibre-glass-reinforced resins), the mold must be surrounded by a plaster case to prevent distortion.

The lost-wax (cire perdue) process. The lost-wax process is the traditional method of casting metal sculpture. It requires a positive, which consists of a core made of a refractory material and an outer layer of wax. The positive can be produced either by direct modelling in wax over a prepared core, in which case the process is known as direct lost-wax casting, or by casting in a piece mold or flexible mold taken from a master cast. The wax positive is invested with a mold made of refractory materials and is then heated to a temperature that will drive off all moisture and melt out all the wax, leaving a narrow cavity between the core and the investment. Molten metal is then poured into this cavity. When the metal has cooled down and solidified, the investment is broken away, and the core is removed from inside the cast. The process is, of course, much more complex than this simple outline suggests. Care has to be taken to suspend the core within the mold by means of metal pins, and a structure of channels must be made in the mold that will enable the metal to reach all parts of the cavity and permit the mold gases to escape. A considerable amount of filing and chasing of the cast is usually required after casting is completed.

Sand casting. While the lost-wax process is used for producing complex, refined metal castings, sand molding is more suitable for simpler types of form and for sculpture in which a certain roughness of surface does not matter. Recent improvements in the quality of sand cast-

Welding
and
forging

The
traditional
method of
casting
metal
sculpture

ings and the invention of the "lost-pattern" process (see below) have resulted in a much wider use of sand casting as a means of producing sculpture. A sand mold, made of special sand held together by a binder, is built up around a rigid positive, usually in a number of sections held together in metal boxes. For a hollow casting, a core is required that will fit inside the negative mold, leaving a narrow cavity as in the lost-wax process. The molten metal is poured into this cavity.

The lost-pattern process. The lost-pattern process is used for the production by sand molding of single casts in metal. After a positive made of expanded polystyrene is firmly embedded in casting sand, molten metal is poured into the mold straight onto the expanded foam original. The heat of the metal causes the foam to pass off into vapour and disappear, leaving a negative mold to be filled by the metal. Channels for the metal to run in and for the gases to escape are made in the mold, as in the lost-wax process. The method is used mainly for producing solid castings in aluminum that can be welded or rivetted together to make the finished sculpture.

Slip casting. Slip casting is primarily a potter's technique that can be used for repetition casting of small pottery sculptures. Liquid clay, or slip, is poured into a plaster piece mold. Some of the water in the slip is absorbed by the plaster and a layer of stiffened clay collects on the surface of the mold. When this layer is thick enough to form a cast, the excess slip is poured off and the mold is removed. The hollow clay cast is then dried and fired.

Pressing. Simple casts for pottery sculpture—mainly tiles and low reliefs—can be prepared by pressing clay into a rigid mold. More complex forms can be built up from a number of separately press-cast pieces. Simple terra-cotta molds can be made by pressing clay around a rigid positive form. After firing, these press molds can be used for press casting.

Reproduction techniques: pointing. A sculpture can be reproduced by transposing measurements taken all over its surface to a copy. The process is made accurate and thorough by the use of a pointing machine, which is an arrangement of adjustable metal arms and pointers that are set to the position of any point on the surface of a three-dimensional form and then used to locate the corresponding point on the surface of a copy. If the copy is a stone one, the block is drilled to the depth measured by the pointing machine. When a number of points have been fixed by drilling, the stone is cut away to the required depth. For accurate pointing, a vast number of points have to be taken, and the final surface is approached gradually. The main use of pointing has been for the indirect method of carving.

Enlarged and reduced copies of sculpture can also be produced with the aid of mechanical devices. A sophisticated reducing machine that works on the principle of the pantograph (an instrument for copying on any predetermined scale, consisting of four light, rigid bars jointed in parallelogram form) is used in minting for scaling down the sculptor's original model to coin size.

Techniques of surface finishing. Surface finishes for sculpture can be either natural—bringing the material of the sculpture itself to a finish—or applied. Almost all applied surface finishes preserve as well as decorate.

Smoothing and polishing. Many sculptural materials have a natural beauty of colour and texture that can be brought out by smoothing and polishing. Stone carvings are smoothed by rubbing down with a graded series of coarse and fine abrasives, such as carborundum, sandstone, emery, pumice, and whiting, all used while the stone is wet. Some stones, such as marble and granite, will take a high gloss; others are too coarse-grained to be polished and can only be smoothed to a granular finish. Wax is sometimes used to give stone a final polish.

The natural beauty of wood is brought out by sandpapering or scraping and then waxing or oiling. Beeswax and linseed oil are the traditional materials, but a wide range of waxes and oils are currently available.

Ivory is polished with gentle abrasives such as pumice and whiting, applied with a damp cloth.

Concrete can be rubbed down, like stone, with water and abrasives, which both smooths the surface and exposes the aggregate. Some concretes can be polished.

Metals are rubbed down manually with steel wool and emery paper and polished with various metal polishes. A high-gloss polish can be given to metals by means of power driven buffing wheels used in conjunction with abrasives and polishes. Clear lacquers are applied to preserve the polish.

Painting. Stone, wood, terra-cotta, metal, fibre glass, and plaster can all be painted in a reasonably durable manner provided that the surfaces are properly prepared and suitable primings and paints are used. In the past, stone and wood carvings were often finished with a coating of gesso (plaster of Paris or gypsum prepared with glue) that served both as a final modelling material for delicate surface detail and as a priming for painting. Historically, the painting and gilding of sculpture were usually left to specialists. In Greek relief sculpture, actual details of the composition were often omitted at the carving stage and left for the painter to insert. In the 15th century, the great Flemish painter Rogier van der Weyden undertook the painting of sculpture as part of his work.

Modern paint technology has made an enormous range of materials available. Constructed sculptures are often finished with mechanical grinders and sanders and then sprayed with high-quality cellulose paints.

Gilding. The surfaces of wood, stone, and plaster sculpture can be decorated with gold, silver, and other metals that are applied in leaf or powder form over a suitable priming. Metals, especially bronze, were often fire-gilded; that is, treated with an amalgam of gold and mercury that was heated to drive off the mercury. The panels of the "Gates of Paradise" in Florence, by the 15th-century sculptor Lorenzo Ghiberti, are a well-known example of gilded bronze.

Patination. Patinas on metals are caused by the corrosive action of chemicals. Sculpture that is exposed to different kinds of atmosphere or buried in soil or immersed in seawater for some time acquires a patina that can be extremely attractive. Similar effects can be achieved artificially by applying various chemicals to the metal surface. This is a particularly effective treatment for bronze, which can be given a wide variety of attractive green, brown, blue, and black patinas. Iron is sometimes allowed to rust until it acquires a satisfactory colour, and then the process is arrested by lacquering.

Electroplating. The surfaces of metal sculpture or of specially prepared nonmetal sculpture can be coated with such metals as chrome, silver, gold, copper, and nickel by the familiar industrial process of electroplating. The related technique of anodizing can be used to prevent the corrosion of aluminum sculpture and to dye its surface.

Other finishes. The surfaces of metal sculpture can be decorated by means of numerous metalworking techniques—etching, engraving, metal inlaying, enamelling, and so on. Pottery sculpture can be decorated with coloured slips, oxides, and enamels; glazed with a variety of shiny or mat glazes; and brought to a dull polish by burnishing.

Other materials have often been added to the surface of sculpture. The eyes of ancient figure sculpture, for example, were sometimes inlaid with stones. Occasionally—as in Mexican mosaic work—the whole surface of a sculpture is inlaid with mother-of-pearl, turquoise, coral, and many other substances.

FORMS OF SCULPTURE

Sculpture in the round. *Freestanding sculpture.* A great deal of sculpture is designed to be placed in public squares, gardens, parks, and similar open places or in interior positions where it is isolated in space and can be viewed from all directions. The opportunities for free spatial design that such freestanding sculpture presents are not always fully exploited. The work may be designed, like many Archaic sculptures, to be viewed from only one or two fixed positions, or it may in effect be little more than a four-sided relief that hardly changes the

poly-
chrome
sculpture

Patinas
achieved
artificially

three-dimensional form of the block at all. Sixteenth-century Mannerist sculptors, on the other hand, made a special point of exploiting the all-around visibility of freestanding sculpture. Giambologna's "Rape of the Sabines," for example, compels the viewer to walk all

Alinari

Sculpture in the round.
The changing appearance of freestanding sculpture observed when walking around a statue is suggested by these two views of "Rape of the Sabines," marble sculpture by Giambologna, 1583. In the Loggia dei Lanzi, Florence. Height 411 cm.

around it in order to grasp its spatial design. It has no principal views; its forms move around the central axis of the composition, and their serpentine movement unfolds itself gradually as the spectator moves around to follow them. Much of the sculpture of Henry Moore and other 20th-century sculptors is not concerned with movement of this kind, nor is it designed to be viewed from any fixed positions. Rather, it is a freely designed structure of multidirectional forms that is opened up, pierced, and extended in space in such a way that the viewer is made aware of its all-around design largely by seeing through the sculpture. The majority of constructed sculptures are disposed in space with complete freedom and invite viewing from all directions. In many instances the spectator can actually walk under and through them.

The way in which a freestanding sculpture makes contact with the ground or with its base is a matter of considerable importance. A reclining figure, for example, may in effect be a horizontal relief. It may blend with the ground plane and appear to be rooted in the ground like an outcrop of rock. Other sculptures, including some reclining figures, may be designed in such a way that they seem to rest on the ground and to be independent of their base. Others are supported in space above the ground. The most completely freestanding sculptures are those that have no base and may be picked up, turned in the hands, and literally viewed all around like a netsuke (a small toggle of wood, ivory, or metal used to fasten a small pouch or purse to a kimono sash). Of course, a large sculpture cannot actually be picked up in this way,

but it can be designed so as to invite the viewer to think of it as a detached, independent object that has no fixed base and is designed all around.

Wall and niche sculpture. Sculpture designed to stand against a wall or similar background or in a niche may be in the round and freestanding in the sense that it is not attached to its background like a relief; but it does not have the spatial independence of completely freestanding sculpture, and it is not designed to be viewed all around. It must be designed so that its formal structure and the nature and meaning of its subject matter can be clearly apprehended from a limited range of frontal views. The forms of the sculpture, therefore, are usually spread out mainly in a lateral direction rather than in depth. Greek pedimental sculpture illustrates this approach superbly: the composition is spread out in a plane perpendicular to the viewer's line of sight and is made completely intelligible from the front. Seventeenth-century Baroque sculptors, especially Bernini, adopted a rather different approach. There may be considerable recession and foreshortening in their compositions, but the forms are carefully arranged so that they present a coherent and intelligible whole from one special frontal viewpoint.

The frontal composition of wall and niche sculpture does not necessarily imply any lack of three-dimensionality in the forms themselves; it is only the arrangement of the forms that is limited. Classical pedimental sculpture, Indian temple sculpture such as that at Khajurāho, Gothic niche sculpture, and Michelangelo's Medici tomb figures are all designed to be placed against a background, but their forms are conceived with a complete fullness of volume.

Relief sculpture. Relief is a complex art form that combines many features of the two-dimensional pictorial arts and the three-dimensional sculptural arts. On the one hand, a relief, like a picture, is dependent on a supporting surface, and its composition must be extended in a plane in order to be visible. On the other hand, its three-dimensional properties are not merely represented pictorially but are in some degree actual, like those of fully developed sculpture.

Among the various types of relief are some that approach very closely the condition of the pictorial arts. The reliefs of Donatello, Ghiberti, and other early Renaissance artists make full use of perspective, which is a pictorial method of representing three-dimensional spatial relationships realistically on a two-dimensional surface. Egyptian and most pre-Columbian American low reliefs are also extremely pictorial but in a different way. Using a system of graphic conventions, they translate the three-dimensional world into a two-dimensional one. The relief image is essentially one of plane surfaces and could not possibly exist in three dimensions. Its only sculptural aspects are its slight degree of actual projection from a surface and its frequently subtle surface modelling.

Other types of relief—for example, Classical Greek and most Indian—are conceived primarily in sculptural terms. The figures inhabit a space that is defined by the solid forms of the figures themselves and is limited by the background plane. This back plane is treated as a finite, impenetrable barrier in front of which the figures exist. It is not conceived as a receding perspective space or environment within which the figures are placed nor as a flat surface upon which they are placed. The reliefs, so to speak, are more like contracted sculpture than expanded pictures.

The central problem of relief sculpture is to contract or condense three-dimensional solid form and spatial relations into a limited depth space. The extent to which the forms actually project varies considerably, and reliefs are classified on this basis as low reliefs (bas-reliefs) or high reliefs. There are types of reliefs that form a continuous series from the almost completely pictorial to the almost fully in the round.

One of the relief sculptor's most difficult tasks is to represent the relations between forms in depth within the limited space available to him. He does this mainly by giving careful attention to the planes of the relief. In a carved relief the highest, or front, plane is defined by the

Difference between wall and niche and freestanding sculpture

Representation of forms in depth

surface of the slab of wood or stone in which the relief is carved; and the back plane is the surface from which the forms project. The space between these two planes can be thought of as divided into a series of planes, one behind the other. The relations of forms in depth can then be thought of as relations between forms lying in different planes.

Sunken relief. Sunken relief is also known as incised, coelanaglyphic, and intaglio relief. It is almost exclusively an ancient Egyptian art form, but some beautiful small-scale Indian examples in ivory have been found at Bagrām in Afghanistan. In a sunken relief, the outline of the design is first incised all around. The relief is then carved inside the incised outline, leaving the surrounding

originally from the tomb of Thetha at Thebes,
c. 2300 BC. In the British Museum. Figure
height 43 cm.

surface untouched. Thus, the finished relief is sunk below the level of the surrounding surface and is contained within a sharp, vertical-walled contour line. This approach to relief preserves the continuity of the original surface and creates no projection from it. The outline shows up as a powerful line of light and shade around the whole design.

Low relief. Figurative low relief is generally regarded by sculptors as an extremely difficult art form. To give a convincing impression of three-dimensional structure and surface modelling with only a minimal degree of projection demands a fusion of draftsmanship and carving or modelling skill of a high order. The sculptor has to proceed empirically, constantly changing the direction of his light and testing the optical effect of his work. He cannot follow any fixed rules or represent things in depth by simply scaling down measurements mathematically, so that, say, one inch of relief space represents one foot.

The forms of low relief usually make contact with the

background all around their contours. If there is a slight amount of undercutting, its purpose is to give emphasis, by means of cast shadow, to a contour rather than to give any impression that the forms are independent of their background. Low relief includes figures that project up to about half their natural circumference.

Technically, the simplest kind of low relief is the **two-plane relief**. For this, the sculptor draws an outline on a surface and then cuts away the surrounding surface, leaving the figure raised as a flat silhouette above the background plane. This procedure is often used for the first stages of a full relief carving, in which case the sculptor will proceed to carve into the raised silhouette, rounding the forms and giving an impression of three-dimensional structure. In a two-plane relief, however, the silhouette is left flat and substantially unaltered except for the addition of surface detail. Pre-Columbian sculptors used this method of relief carving to create bold figurative and abstract reliefs.

Stiacciato relief is an extremely subtle type of flat, low relief carving that is especially associated with the 15th-century sculptors Donatello and Desiderio da Settignano. The design is partly drawn with finely engraved chisel lines and partly carved in relief. The stiacciato technique depends largely for its effect on the way in which pale materials, such as white marble, respond to light and show up the most delicate lines and subtle changes of surface.

Stiacciato
relief

High relief. The forms of high relief project far enough to be in some degree independent of their background. As they approach the fullness of sculpture in the round, they become of necessity considerably undercut. In many high reliefs, where parts of the composition are completely detached from their background and fully in the round, it is often impossible to tell from the front whether or not a figure is actually attached to its background.

Many different degrees of projection are often combined in one relief composition. Figures in the foreground may be completely detached and fully in the round, while those in the middle distance are in about half relief and those in the background in low relief. Such effects are common in late Gothic, Renaissance, and Baroque sculpture.

Modern forms of sculpture. Since the 1950s, many new combined forms of art have been developed that do not fit readily into any of the traditional categories. Two of the most important of these, environments and kinetics, are closely enough connected with sculpture to be regarded by many artists and critics as branches or offshoots of sculpture. It is likely, however, that the persistence of the terms environmental sculpture and kinetic sculpture is a result of the failure of language to keep pace with events; for the practice is already growing of referring simply to environments and kinetics, as one might refer to painting, sculpture, and engraving, as art forms in their own right.

Kinetic sculpture. Traditional sculptures in relief and in the round are static, fixed objects or images. Their immobility and immutability are part of the permanence traditionally associated with the art of sculpture, especially monumental sculpture. What one refers to as movement in, say, a Baroque or Greek sculpture is not actual physical motion but a movement that is either directly represented in the subject matter (galloping horses) or expressed through the dynamic character of its form (spirals, undulating curves). In recent years, however, the use of actual movement, kineticism, has become an important aspect of sculpture. Naum Gabo, Marcel Duchamp, László Moholy-Nagy, and Alexander Calder were pioneers of kinetic sculpture in modern times, but many kinetic artists see a connection between their work and such forms as the moving toys, dolls, and clocks of previous ages.

There are now types of sculpture in which the components are moved by air currents, as in the well-known mobiles of Calder; by water; by magnetism, the speciality of Nicholas Takis; by a variety of electromechanical devices; or by the participation of the spectator himself. The

Kinetic sculpture.

"Homage to New York," a self-constructing and self-destructing work of art by Jean Tinguely, 1960. Small pieces now in the Museum of Modern Art, New York.

neo-Dada satire quality of the kinetic sculpture created during the 1960s is exemplified by the works of Jean Tinguely. His self-destructing "Homage to New York" perfected the concept of a sculpture being both an object and an event, or "happening."

The aim of most kinetic sculptors is to make movement itself an integral part of the design of the sculpture and not merely to impart movement to an already complete static object. Calder's mobiles, for example, depend for their aesthetic effect on constantly changing patterns of relationship taking place through space and time. When liquids and gases are used as components, the shapes and dimensions of the sculpture may undergo continual transformations. The movement of smoke: the diffusion and flow of coloured water, mercury, oil, and so on; pneumatic inflation and deflation; and the movement of masses of bubbles have all served as media for kinetic sculpture. In the complex, electronically controlled "spatio-dynamic" and "lumino-dynamic" constructions of Nicolas Schoffer, the projection of changing patterns of light into space is a major feature.

Environmental sculpture. The environmental sculptor creates new spatial contexts that differ from anything developed by traditional sculpture. The work no longer confronts the spectator as an object but surrounds him so that he moves within it as he might within a stage set, a garden, or an interior. The most common type of environment is the "room," which may have specially shaped and surfaced walls, special lighting effects, and many different kinds of contents. Kurt Schwitters' *Merzbau* (destroyed in 1943) was the first of these rooms, which now include the nightmare fantasy of Edward Kienholz's tableaux, such as "Roxys" (1961) or "The Illegal Operation"; (1962) George Segal's compositions, in which

casts of clothed human figures in frozen, casual attitudes are placed in interiors; and rooms built of mirrors, such as Kusama Yayoi's "Endless Love Room" and Lucas Samaras' "Mirrored Room," in both of which the spectator himself, endlessly reflected, becomes part of the total effect.

Environmental art, in common with collage and assemblage, has tended toward greater concreteness not by making a more realistic representation, as naturalistic art does, but by including more of reality itself in the work; for example, by using casts taken from the actual human body, real clothes, actual objects and casts of objects, actual lighting effects, and real items of furniture. Plastic elements may be combined with music and sound effects, dance, theatrical spectacles, and film to create so-called happenings, in which real figures are constituents of the "artwork" and operations are performed not on "artistic" materials but are performed on real objects and on the actual environment. Ideas such as these go far beyond anything that has ever before been associated with the term sculpture.

SUBJECT MATTER AND IMAGERY

Representational sculpture. Sculpture in the round is much more restricted than relief in the range of its subject matter. The representation of, say, a battle scene or a cavalcade in the round would require a space that corresponded in scale in every direction with that occupied by an actual battle or cavalcade. No such problems arise in relief because the treatment of scale and relations in depth is to some extent notional, or theoretical, like that of pictures. Then again, because a relief is attached to a background, problems of weight and physical balance and support do not arise. Figures can be represented as floating in space and can be arranged vertically as well as horizontally. Thus, in general, sculpture in the round is concerned with single figures and limited groups, while reliefs deal with more complex "pictorial" subjects in-

volving crowds, landscape, architectural backgrounds, and so on.

The human figure. The principal subject of sculpture has always been the human figure. Next in importance are animals and fantastic creatures based on human and animal forms. Other subjects—for example, landscape, plants, still life, and architecture—have served primarily as accessories to figure sculpture, not as subjects in their own light. The overwhelming predominance of the human figure is due: first, to its immense emotional importance as an object of desire, love, fear, respect, and, in the case of anthropomorphic gods, worship; and, second, to its inexhaustible subtlety and variety of form and expression. The nude or almost nude figure played a prominent role in Egyptian, Indian, Greek, and African sculpture, while in medieval European and ancient Chinese sculpture the figure is almost invariably clothed. The interplay of the linear and modelled forms of free draperies with the solid volumes of the human body was of great interest to Classical sculptors and later became one of the principal themes of Renaissance and post-Renaissance sculpture. The human figure continues to be of central importance in modern sculpture in spite of the growth of nonfigurative art; but the optimistic, idealized, or naturalistic images of man prevalent in previous ages have been largely replaced by images of despair, horror, deformation, and satire.

GEKS

Narrative sculpture.
Lower portion of Trajan's Column, marble, Rome, c. AD 106–113. Height of one relief band about 127 cm.

Devotional images and narrative sculpture. The production of devotional images has been one of the sculptor's main tasks, and many of the world's greatest sculptures are of this kind. They include images of Buddha and the Hindu gods; of Christ, the Virgin, and the Christian saints; of Athena, Aphrodite, Zeus, and other Greek gods; and of all the various gods, spirits, and mythical beings of Rome, the ancient Near East, pre-Columbian America, Black Africa, and the Pacific Islands.

Closely connected with devotional images are all of the narrative sculptures in which legends, heroic deeds, and religious stories are depicted for the delight and instruction of peoples who lived when books and literacy were rare. The Buddhist, Hindu, and Christian traditions are especially rich in narrative sculpture. Stories of the incarnations of Buddha—Jitaka—and of the Hindu gods abounded in the temple sculpture of India and Southeast

Asia; for example, at Sānchi, Amarāvati, Borobudur, and Angkor. Sculpture illustrating the stories of the Bible is so abundant in medieval churches that the churches have been called "Bibles in stone." Sculpture recounting the heroic deeds of kings and generals are common, especially in Assyria and Rome. The Romans made use of a form known as continuous narrative, the best known example of which is the spiral, or helical, band of relief sculpture that surrounds Trajan's Column (c. AD 106–113) and tells the story of the Emperor's Dacian Wars. The episodes in the narrative are not separated into a series of framed compositions but are linked to form a continuous band of unbroken relief.

Portraiture. Portraiture was practiced by the Egyptians but was comparatively rare in the ancient world until the Romans made portrait sculpture one of their major artistic achievements. The features of many famous people are known to modern man only through the work of Roman sculptors on coins and medals, portrait busts, and full-length portraits. Portraiture has been an important aspect of Western sculpture from the Renaissance to the present day. Some of the best known modern portrait sculptors are Rodin, Charles Despiau, Marino Marini, and Jacob Epstein.

Scenes of everyday life. Scenes of everyday life have been represented in sculpture mainly on a small scale in minor works. The sculptures that are closest in spirit to the quiet dignity of the great 17th- and 18th-century genre paintings of Jan Vermeer and Jean-Baptiste-Siméon Chardin are perhaps certain Greek tombstones, such as that of the Stele of Hegeso, which represents a quiet, absorbed moment when a seated young woman and her maidservant are looking at a necklace they have just removed from a casket. Intimate scenes of the people and their activities in everyday rural life are often portrayed in medieval and Egyptian reliefs as part of larger compositions.

Animals. Animals have always been important subjects for sculpture. Paleolithic man produced some extraordinarily sensitive animal sculptures both in relief and in the round. Representations of horses and lions are among the finest works of Assyrian sculpture. Egyptian sculptors produced sensitive naturalistic representations of cattle, donkeys, hippopotamuses, apes, and a wide variety of birds and fish. Ancient Chinese sculptors made superb small-scale animal sculptures in bronze and pottery. Animals were the main subject matter for the sculpture of the nomadic tribes of Eurasia and northern Europe, for whom they became the basis for elaborate zoomorphic fantasies. This animal art contributed to the rich tradition of animal sculpture in medieval art. Animals also served as a basis for semi-abstract fantasy in Mexican, Mayan, North American Indian, and Oceanic sculpture. The horse has always occupied an important place in Western sculpture, but other animals have also figured in the work of such sculptors as Giambologna, in the 16th century, and Antoine-Louis Barye, in the 19th, as well as numerous sculptors of garden and fountain pieces. Among modern sculptors who have made extensive use of animals or animal-like forms are Brancusi, Picasso, Gerhard Marcks, Germaine Richier, François Pompon, Pino Pascali, and François-Xavier-Maxime Lalanne.

Fantasy. In their attempts to imagine gods and mythical beings, sculptors have invented fantastic images based on the combination and metamorphosis of animal and human forms. A centaur, the Minotaur, and animal-headed gods of the ancient world are straightforward combinations. More imaginative fantasies were produced by Mexican and Mayan sculptors and by tribal sculptors in many parts of the world. Fantastic creatures abound in the sculpture produced in northern Europe during the early Middle Ages and the Romanesque period. Fantasy of a playful kind is often found in garden sculpture and fountains.

In the period following World War I, fantasy was a dominant element in representational sculpture. Among its many forms are images derived from dreams, the technological fantasy of science fiction, erotic fantasies,

Modern
portrait
sculptors

and a whole host of monsters and automata. The Surrealists have made a major contribution to this aspect of modern sculpture.

Other subjects. Architectural backgrounds in sculpture range from the simplified baldacchinos (ornamental structures resembling canopies used especially over altars) of early medieval reliefs to the 17th- and 18th-century virtuoso perspective townscapes of **Grinling Gibbons**. Architectural accessories such as plinths, **entablatures**, pilasters, columns, and moldings have played a prominent role both in Greek and Roman sarcophagi, in medieval altarpieces and screens, and in Renaissance wall tombs.

Outside the field of ornament, botanical forms have played only a minor role in sculpture. Trees and stylized lotuses are especially common in Indian sculpture because of their great symbolic significance. Trees are also present in many Renaissance reliefs and in some medieval reliefs.

Landscape, which was an important background feature in many Renaissance reliefs (notably those of **Ghiberti**) and, as sculptured rocks, appeared in a number of Baroque fountains, entered into sculpture in a new way when Henry Moore combined the forms of caves, rocks, hills, and cliffs with the human form in a series of large reclining figures.

There is nothing in sculpture comparable with the tradition of still-life painting. When objects are represented, it is almost always as part of a figure composition. A few modern sculptors, however, notably **Giacomo Manzù** and **Oldenburg**, have used still-life subjects.

Nonrepresentational sculpture. There are two main kinds of nonrepresentational sculpture. One kind uses nature not as subject matter to be represented but as a source of formal ideas. For sculptors who work in this way, the forms that are observed in nature serve as a starting point for a kind of creative play, the end products of which may bear little or no resemblance either to their original source or to any other natural object. Many works by **Brancusi**, **Raymond Duchamp-Villon**, **Jacques Lipchitz**, **Henri Laurens**, **Umberto Boccioni**, and other pioneer modern sculptors have this character. The transformation of natural forms to a point where they are no longer recognizable is also common in many styles of primitive and ornamental art.

The other main kind of nonrepresentational sculpture, often known as nonobjective sculpture, is a more completely nonrepresentational form that does not even have a starting point in nature. It arises from a constructive manipulation of the sculptor's generalized, abstract ideas of spatial relations, volume, line, colour, texture, and so on. The approach of the nonobjective sculptor has been likened to that of the composer of music, who manipulates the elements of his art in a similar manner. The inclusion of purely invented, three-dimensional artifacts under the heading of sculpture is a 20th-century innovation.

Some nonobjective sculptors prefer forms that have the complex curvilinearity of surface typical of living organisms; others prefer more regular, simple geometric forms. The whole realm of three-dimensional form is open to nonobjective sculptors, but these sculptors often restrict themselves to a narrow range of preferred types of form. A recent kind of nonobjective sculpture, for example, consists of extremely stark, so-called primary forms. These are highly finished, usually coloured constructions that are often large in scale and made up entirely of plane or single-curved surfaces. Prominent among the older nonobjective sculptors are **Jean Arp**, **Antoine Pevsner**, **Naum Gabo**, **Barbara Hepworth**, **Max Bill**, and **David Smith**. Younger artists who have worked in this particular manner include **Robert Morris**, **Donald Judd**, and **Phillip King**.

Decorative sculpture. The devices and motifs of ornamental sculpture fall into three main categories; abstract, zoomorphic, and botanical.

Abstract shapes, which can easily be made to fit into any framework, are a widespread form of decoration. Outstanding examples of abstract relief ornament are found

on Islāmic, Mexican, and Mayan buildings and on small Celtic metal artifacts. The character of the work varies from the large-scale rectilinear two-plane reliefs of the buildings of Mitla in Mexico, to the small-scale curvilinear plastic decoration of a Celtic shield or body ornament.

(Bottom) Norse wood carving, late 11th century, detail of doorway of Urnes stave church, Norway. Doorway 3.90 × 2.60 m.

Zoomorphic relief decoration, derived from a vast range of animal forms, is common on primitive artifacts and on Romanesque churches, especially the wooden stave churches of Scandinavia.

Botanical forms lend themselves readily to decorative purposes because their growth patterns are variable and their components—leaf, tendril, bud, flower, and fruit—are infinitely repeatable. The acanthus and anthemion motifs of Classical relief and the lotuses of Indian relief are splendid examples of stylized plant ornament. The naturalistic leaf ornament of Southwell Minster, Reims Cathedral, and other Gothic churches transcend the merely decorative and become superbly plastic sculptures in their own right.

SYMBOLISM

Sculptural images may be symbolic on a number of levels. Apart from conventional symbols, such as those of heraldry and other insignia, the simplest and most straightforward kind of sculptural symbol is that in which an abstract idea is represented by means of allegory and personification. A few common examples are figures that personify the cardinal virtues (prudence, justice, temperance, fortitude), the theological virtues (faith, hope, and charity), the arts, the church, victory, the seasons of the year, industry, and agriculture. These figures are often provided with symbolic objects that serve to identify them; for example, the hammer of industry, the sickle of agriculture, the hourglass of time, the scales of justice. Such personifications abound in medieval and Renaissance sculpture and were until recently the stock in trade of public sculpture the world over. Animals are also frequently used in the same way; for example, the owl

Kinds of
nonrepresentational
sculpture

Allegory
and
personification

(as the emblem of Athens and the symbol of wisdom), the British lion, and the American eagle.

Beyond this straightforward level of symbolism, the images of sculpture may serve as broader, more abstruse religious, mythical, and civic symbols expressing some of mankind's deepest spiritual insights, beliefs, and feelings. The great tympanums (the space above the lintel of a door that is enclosed by the doorway arch) of Autun, Moissac, and other medieval churches symbolize some of the most profound Christian doctrines concerning the ends of human life and man's relations with the divine. The Hindu image of the dance of Śiva is symbolic in every detail, and the whole image expresses in one concentrated symbol some of the complex cosmological ideas of the Hindu religion. The Buddhist temple of Borobudur, in Java, is one of the most complex and integrated of all religious symbols. It is designed as a holy mountain whose structure symbolizes the structure of the spiritual universe. Each of the nine levels of the temple has a different kind of sculptural symbolism, progressing from symbols of hell and the world of desire at the lowest level to austere symbols of the higher spiritual mysteries at its uppermost levels.

In more individualistic societies, works of sculpture may be symbolic on a personal, private level. Michelangelo's "Slaves" have been interpreted as allegories of the human soul struggling to free itself from the bondage of the body, its "earthly prison," or, more directly, as symbols of the struggle of intelligible form against mere matter. But there is no doubt that, in ways difficult to formulate precisely, they are also disturbing symbols of Michelangelo's personal attitudes, emotions, and psychological conflicts. If it is an expression of his unconscious mind, the sculptor himself may be unaware of this aspect of the design of his work.

Many modern sculptors disclaim any attempt at symbolism in their work. When symbolic images do play a part in modern sculpture, they are either derived from obsolete classical, medieval, and other historical sources or they are private. Because there has been little socially recognized symbolism for the modern sculptor to use in his work, symbols consciously invented by individual artists or deriving from the image-producing function of the individual unconscious mind have been paramount. Many of these are entirely personal symbols expressing the artist's private attitudes, beliefs, obsessions, and emotions. They are often more symptomatic than symbolic. Henry Moore is outstanding among modern sculptors for having created a world of personal symbols that also have a universal quality; and Naum Gabo has sought images that would symbolize in a general way modern man's attitudes to the world picture provided by science and technology.

Examples of sculpture of which the positioning, or siting, as well as the imagery is symbolic are the carved boundary stones of the ancient world; memorials sited on battlegrounds or at places where religious and political martyrs have been killed; the Statue of Liberty and similar civic symbols situated at harbours, town gates, bridges, and so on; and the scenes of the Last Judgment placed over the entrances to cathedrals, where they could serve as an admonition to the congregation.

The choice of symbolism suitable to the function of a sculpture is an important aspect of design. Fonts, pulpits, lecterns, triumphal arches, war memorials, tombstones, and the like all require a symbolism appropriate to their function. In a somewhat different way, the tomb sculptures of Egypt, intended to serve a magical function in the afterlife of the tomb's inhabitants, had to be images suitable for their purpose. These, however, are more in the nature of magical substitutes than symbols.

USES OF SCULPTURE

The vast majority of sculptures are not entirely autonomous but are integrated or linked in some way with other works of art in other mediums. Relief, in particular, has served as a form of decoration for an immense range of domestic, personal, civic, and sacred artifacts, from the spear throwers of Paleolithic man and the cosmetic palettes of earliest Egyptian civilization to the latest

mass-produced plastic reproduction of a Jacobean linen-fold panel (a carved or molded panel representing a fold, or scroll, of linen).

The main use of large-scale sculpture has been in conjunction with architecture. It has either formed part of the interior or exterior fabric of the building itself or has been placed against or near the building as an adjunct to it. The role of sculpture in relation to buildings as part of a townscape is also of considerable importance. Traditionally, it has been used to provide a focal point at the meeting of streets, and in marketplaces, town squares, and other open places—a tradition that many town planners today are continuing.

Sculpture has been widely used as part of the total decorative scheme for a garden or park. Garden sculpture is usually intended primarily for enjoyment, helping to create the right kind of environment for meditation, relaxation, and delight. Because the aim is to create a light-hearted arcadian or ideal paradisaal atmosphere, disturbing or serious subjects are usually avoided. The sculpture may be set among trees and foliage where it can surprise and delight the viewer or sited in the open to provide a focal point for a vista.

Fountains, too, are intended primarily to give enjoyment to the senses. There is nothing to compare with the interplay of light, movement, sound, and sculptural imagery in great fountains, which combine the movement and sound of sheets, jets, and cataracts of water with richly imaginative sculpture, water plants and foliage, darting fish, reflections, and changing lights. They are the prototypes of all 20th-century "mixed medium" kinetic sculptures.

The durability of sculpture makes it an ideal medium for commemorative purposes, and much of the world's greatest sculpture has been created in order to perpetuate the memory of persons and events. Commemorative sculpture includes tombs, tombstones, statues, plaques, sarcophagi, memorial columns, and triumphal arches. Portraiture, too, often serves a memorial function.

One of the most familiar and widespread uses of sculpture is for coins. Produced for more than 2,500 years, these miniature works of art contain a historically invaluable and often artistically excellent range of portrait heads and symbolic devices. Medals, too, in spite of their small scale, may be vehicles for plastic art of the highest quality. The 15th-century medals of the Italian artist Antonio Pisanello and the coins of ancient Greece are generally considered the supreme achievements in these miniature fields of sculpture.

Also on a small scale are the sculptural products of the glyptic arts—that is, the arts of carving gems and hardstones. Superb and varied work, often done in conjunction with precious metalwork, has been produced in many countries.

Finally, sculpture has been widely used for ceremonial and ritualistic objects such as bishop's croziers, censers, reliquaries, chalices, tabernacles, sacred book covers, ancient Chinese bronzes, the paraphernalia of primitive tribal rituals, the special equipment worn by participants in the sacred ball game of ancient Mexico, processional images, masks and headdresses, and modern trophies and awards.

Scythians

The Scythians were a people who during the 8th–7th centuries BC moved from Central Asia to southern Russia, where they founded an empire that survived until they were gradually overcome and supplanted by the Sarmatians during the 4th century BC–2nd century AD.

Until the 20th century most of the information concerning the Scythians, as the Greeks called them, or the Sakas, as the Persians termed them, was based on the knowledge that Herodotus acquired when he visited Olbia, a Greek city founded c. 645 BC at the confluence of the Bug and Ingul rivers. He incorporated all that he had learned about them into the fourth book of his history. In modern times the work carried out in Siberia by Soviet scholars and archaeologists produced so much new information that the word Scythian is often extended to include the nomadic kinsmen of the Scythians who remained in Central Asia when the latter moved into Europe.

In its exact context the term Scythian should, however, be applied only to the tribes that settled in what is now southern U.S.S.R. The excavations begun in 1929 at Pazyryk in the Altai by M.P. Gryaznov and resumed in 1947 by S.I. Rudenko proved that the culture, art, and way of life of the tribesmen who continued to live in western Siberia and the Altai when the bulk of the Scythians marched into Iran and southern Russia remained closely akin to that of the migrants, the entire community being of Iranian origin and sharing a common language. Herodotus attempted to distinguish between the various tribes that settled in what later became Russia; and he was able to name among others the Callipidae, the Alazonas, the Arotres, the Neuri, the Androphagi, and the Melanchlaeni, defining the areas that each inhabited. These western Scythians seem to have maintained contact with those who had remained in Central Asia.

History. In the 9th century BC the Scythian and kindred tribes were probably concentrated somewhat to the east of the Altai, but it was not until the Chinese ruler Hsüan Wang (827–781 BC) decided to send an armed force to curb the fierce Hsiung-nu, who had begun to make a practice of raiding China's western boundaries, that the Scythian nomads became restless. When the Hsiung-nu were forced back from the Chinese frontier and, in retreating, dislodged the Massagetae, who occupied the grazing grounds to the north of the Oxus (Amu Darya) River, and when the latter in their turn assaulted their immediate neighbours, the Scythians, a wide-scale nomadic migration was set in motion. There is reason for thinking that the struggle for grazing land was rendered more acute by a severe drought and that this factor may well have decided the Scythians to move westward instead of remaining to fight for their traditional rights.

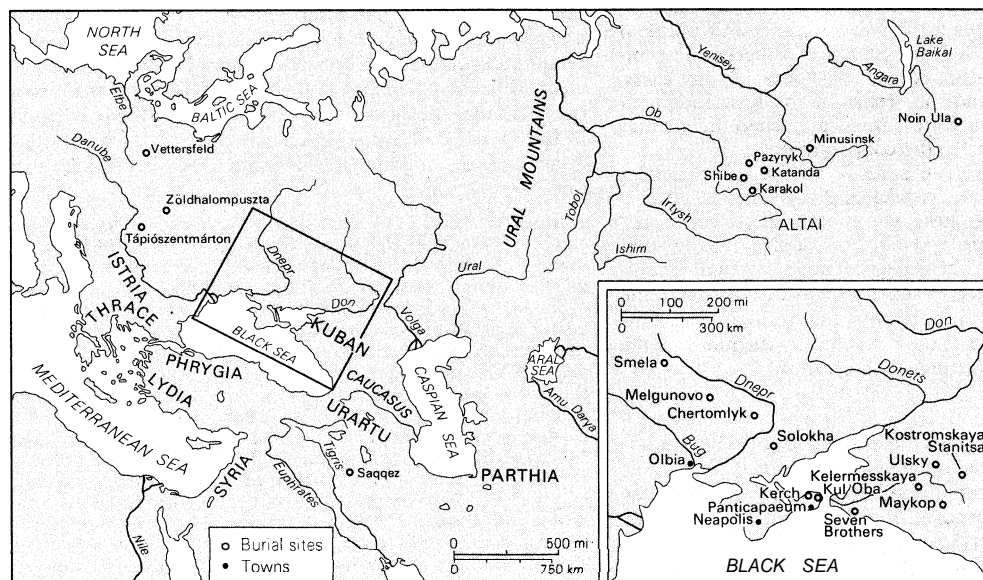

The Scythians were accomplished horsemen, among the earliest people to master the art of riding. Their mobility gave them a great advantage over their neighbours, so that when they eventually advanced westward across the Oxus they moved so fast that both Herodotus and contemporary Persian sources refer to the remarkable suddenness of their appearance on Iran's northeastern border. Their advance brought the Scythians into fierce conflict with the Cimmerians who had for centuries enjoyed possession of the Caucasus and the plain lying to the north of the Black Sea. But the Cimmerians still fought on foot and the Scythian cavalry quickly gained the upper hand. Some Cimmerians retreated through the Daryal (Dariel) Pass and were pursued across the Volga, where the Scythians were able to destroy and supplant them.

Meanwhile another Scythian force chased the rest of the Cimmerian Army across Urartu (Armenia), while a third entered the Derbent defile and reached Lake Urmia some time during the reign of King Sargon of Assyria (722–705 BC), linking up there with the second contingent to continue the fight against the Cimmerians. Thus strengthened, the Scythian troops were able to force the Cimmerians into a steady retreat that lasted for about 30 years, ending only when both combatants had reached the borders of Assyria. Then the Scythians formed an alliance with King Esarhaddon of Assyria (reigned 680–669 BC), but they soon abandoned this and concentrated on destroying the Cimmerians, giving the latter no respite until they had forced them back across Phrygia into Lydia, where they were finally wiped out.

This astonishing series of victories brought great fame to the Scythians. Their chieftain Partatua (Bartatua) and his son Madyes were quick to take advantage of it by setting themselves up as rulers of west Persian lands stretching to the Halys (Kizil Irmak) River, establishing their capital at Saqqez. They invaded Syria and Judaea c. 625 BC. Later they reached the borders of Egypt, but Psamtik I (663–610 BC) wisely decided to check any further advance by purchasing peace terms from them.

Meanwhile the Medes had become masters of Persia. They considered the Scythians' increasing might a real threat to their own security, and they decided to concentrate their efforts in launching a decisive attack against the tribesmen. Their better disciplined troops eventually contrived to push the Scythians northward, whence they had first appeared, some retreating through Urartu. Although the nomads thereby lost the control they had wielded during the previous 28 years over most of Anatolia, their lands still stretched from the Persian border through the Kuban into most of southern Russia. When forced by the Medes to retreat, some of them likewise settled between the Caspian and Aral seas, where they intermingled with their Dahae kinsmen to produce the

Destruction of the Cimmerians

Scythian settlements and burial grounds.

people who, some three centuries later, were to become known as the Parthians, while others penetrated into India and established kingdoms there.

The
Scythians
in southern
Russia

The Scythians who settled in the Kuban and southern Russia quickly attained a position of importance. Many of them became extremely prosperous. Graves of the 7th–6th centuries BC situated in the Kuban abound in objects of gold and other precious materials, and although a form of patriarchal rule remained in force, it is clear that a class of wealthy chieftains or nobles was beginning to come into being there. In the 6th–5th century BC the richest burials were in southern Russia and the Crimea. These are associated with a relatively small number of Scythians who, as the Royal Scyths, established themselves as rulers of the area. Isolated groups of their tribesmen penetrated as far as what became Hungary and East Prussia. The kingdom of the Royal Scyths developed into a community that was to enjoy considerable economic power until about the 1st century BC. Its political importance was established when it was able to resist Darius on his invasion of Scythian territory about 513 BC; the Scythians resorted to a scorched-earth policy, which enabled them to avoid a large-scale battle and obliged Darius to beat a hasty retreat in order to preserve his army. His consequent withdrawal from the plain lying to the northwest of the Black Sea left the Scythians in control of it; some of the Greek cities of the Pontus even had to pay the Scythians an annual tribute in order to preserve their security. Scythian power remained paramount there until the 4th century BC, when the Sarmatians appeared on the Don. Thenceforth the new invaders began steadily to increase their pressure on the Scythians until, in the 2nd century BC, they managed to confine them within the Crimean area, gradually supplanting them as rulers of the plain until, in the 2nd century AD, they finally succeeded in destroying the last remnants of this once powerful community.

The Royal Scyths. Though the patriarchal order and the nomadic way of life remained general, the Royal Scyths were ruled by a sovereign whose powers were transmitted to his son. He was surrounded by a group of wealthy nobles who were virtually his courtiers. The dynasty claimed descent from Targitaos, the founder of the house of Phalatae; but Targitaos was probably a legendary figure, and it is more likely that Colaxis was the first of the royal line. He was succeeded by Spargapeithes, who handed the crown to his son Lycus, who in turn passed it to his son Gnurus at about the time when Partautua and his son Madyes had established themselves as co-rulers in Transcaucasia (c. 630 BC). In 589 Saulius reigned over the Royal Scyths. His brother Anacharsis (whose existence is doubted by certain authorities) went to Greece as his ambassador and became so much respected there that the Greeks spoke of him as "the Scythian eloquence." The throne then passed to Idanthysus, who, with his brothers Taxacis and Scopasia, expelled Darius. Ariapeithes, the son of Idanthysus, came to the throne next, marrying in turn a Greek woman, a Scythian, and a daughter of a Thracian chieftain. He was succeeded by his son Scyles, who was murdered shortly before the time of Herodotus by his brother Ostomasades because of his fondness for Greek manners, dress, and religious observances. The murderer succeeded his victim on the throne. His successor, Arianthus, is remarkable for having organized a census of his people. The next known ruler, Aristagorus, reigned c. 495 BC. A descendant, Ateas, was killed in 339 BC at the age of 90 while fighting against Philip II of Macedonia. King Agarus' reign likewise ended with his death in battle (310 BC). Nothing is known of the kings who followed him until Scylurus established himself in 110 BC at Neapolis (in the Crimea) and struck Scythia's first coins at Olbia. He was succeeded by his son Palakus, the last Scythian sovereign whose name has been preserved in history.

Hippocrates described the Scythians as inclined to laziness, fatness, and gaiety, likening their appearance to that of eunuchs and commenting on their sexual impotence; but his statement is corroborated neither by the events in their history nor by the appearance of those Scythians

whose features have been preserved on contemporary Greek metalworks. Scythian women lived in subservience and semiseclusion.

Administration. For administrative purposes the Royal Scyths divided their kingdom into four districts, each of which was controlled by a governor provided with a paid military bodyguard. The governor dispensed justice and levied taxes from the settlers and tribute from certain of the Greek Pontic cities. The tribal way of life remained in force; communities were governed by their elders or chieftains, these dignitaries being periodically summoned to attend a general assembly held in the presence either of the governor or of the sovereign. These assemblies differed from the gatherings held by the sovereign in the spring of each year in order to inspect and feast his army. In times of war the country was divided for purposes of recruitment into three sections, the enrolled men being later grouped into units, each one of which was commanded by its own officer.

The army. The army consisted entirely of freemen; i.e., Scythian tribesmen; they were fed and clothed but paid no wage, though those of them who could produce the head of a soldier killed in battle were entitled to share in the day's booty. According to Herodotus, the Scythians scalped their victims, fashioning their skulls into cups that they wore attached to their belts, using them to pledge an oath in a mixture of blood and water. Such cups mounted in delicately worked gold have been found in several tombs.

Taking
of scalps

Many Royal Scyths wore bronze helmets and chain-mail jerkins of the Greek type lined with red felt. Their shields were generally round and made of leather, wood, or iron and were often decorated with a central gold ornament in the form of an animal, but other tribesmen carried square or rectangular ones. All used a double-curved bow, shooting over the horse's left shoulder; arrows had trefoil-shaped heads made, according to date, of bronze, iron, or bone. Arrows and bow were carried in a *gōrytos* (bow case) slung from the left side of the belt. Their swords were generally of the Persian type, with a heart-shaped or triangular crosspiece intricately ornamented. According to date, the blades were of bronze or iron; in southern Russia, the sheaths were often encased in gold worked into embossed designs and offset with paste or ivory inlay and gems. Their knives were of various shapes and lengths, some being curved in the Chinese manner. They wore the dagger attached to the left leg by straps, and many carried spears or standards surmounted by bronze terminals depicting real or imaginary beasts.

Horses. Every Scythian owned at least one gelding to serve as a riding horse, but the wealthy possessed a great many mounts; most Scythians also owned oxen or rough ponies, which served as beasts of burden. The finest riding horses were of the Fergana breed, but the majority were Mongolian ponies. The Scythians devoted much time and attention to their horses and ornamented all their trappings. Bridles were provided with metal cheekpieces in the shape of animals, and the leather straps were adorned with embossed, cutout, or *appliqué* designs, which also often represented animals. Saddles consisted of two felt cushions mounted on wooden frames bound with yellow or red and sometimes embellished with gold plaques; the felt saddle cloths were adorned, as were the seats of the saddles, with applique designs. Metal stirrups were not known to the Scythians, but there is reason to believe that they rested their feet in felt or leather supports. Women travelled with their children in covered wagons with solid wheels and a central shaft along which mules or oxen could be yoked in pairs.

Possessions. The frozen tombs of Pazyryk (see below *Tombs*) contained many well-preserved articles of clothing, all of which were profusely trimmed with complicated embroidered and applique designs; the clothes of the wealthy in southern Russia were covered with tiny gold-embossed plaques, sewn to the garments. At Pazyryk, felt applique wall hangings were found, some displaying religious scenes featuring the Great Goddess or anthropomorphic beasts, others with geometric or animal motifs. Even the embalmed body of a man was covered with

tattooed designs of real and mythical beasts executed with great spirit and delicacy. Felt rugs were found, as well as a knotted, woollen pile carpet of Persian origin, from the 5th century BC, displaying figures of riders, elks, and stars. Felt cushions and mattresses; wooden tables with carved or turned legs and detachable, slightly hollowed, traylike tops; and wooden blocks serving as stools or head rests were customary.

The tombs of the Eurasian plain as a whole produced a mass of tools and domestic utensils, many of them made of precious materials. Rich jewelry and arms of great value and beauty are frequently found in the burials belonging to the western section. In addition, each burial throughout the entire area contained a cast bronze caldron of the distinctive Scythian shape. These caldrons vary in size from quite small examples to others weighing as much as 75 pounds; an overwhelming majority have a solid base, shaped like a truncated cone, around which the fire was heaped. The upper section is a semispherical bowl provided not with a loop handle but with handles (shaped like animals) fixed to the rim opposite each other. The finest caldron, found at Chertomlyk in the Dnepr (Dnieper) district, has six handles. At Pazyryk, small caldrons filled with stones and hempseeds were found standing beneath leather or felt *tentlets* with three or six supports. Herodotus referred to what he termed a Scythian *purification* rite that, he noted, consisted in inhaling the fumes of hempseeds thrown onto hot stones; the passage was well-nigh incomprehensible until archaeologists discovered that a smoking outfit of this sort had been provided for each person buried at Pazyryk, making it clear that hemp fumes were inhaled for pleasure and not, as Herodotus assumed, as part of a religious observance.

Occupations and beliefs. The Scythians were keen huntsmen and fishermen; they were skilled at curing hides; they excelled at working metals; and the settlers were good agriculturalists. Though they had neither an alphabet nor, until later times, a coinage, they carried on a lively trade not only with the inhabitants of Central Asia but also with the Greeks of the Pontic cities, often exchanging surplus goods and furs for Greek luxuries such as fine ceramic wares.

The Scythians worshipped the elements but they were not a devout people and never felt the need for temples. Their deepest feelings were centred on the Great Goddess, Tabiti-Hestia, the patroness of the fire and beasts, and she alone of all their deities figures in art. They also wor-

shipped Papeus-Zeus, god of the air; Apia-Gaea, goddess of the earth; *Oetosyrus-Apollo*, god of the sun; *Artimpasa* (Aphrodite Urania), goddess of the moon; *Thagimadas* (Poseidon), god of water; and, in time of war, possibly also Ares and Heracles. They do not appear to have had any priests, but they had a class of magicians and soothsayers, the Enaries, who spoke in high-pitched voices and dressed as women. The Scythians believed that these feminine characteristics had been *inflicted* upon them by the Great Goddess as a punishment for desecrating her shrine at Ashkelon; they were probably eunuchs and may well have been the men Hippocrates had in mind when describing the appearance of the Scythians.

Burial customs. The Scythians venerated the graves of their ancestors, sparing neither wealth nor labour in providing vast tombs richly furnished and equipped. Their funerary rite was elaborate and as costly in lives as in material. In the Altai, interment took place only in the spring and autumn weeks, and embalming was therefore essential. The Scythians of southern Russia also resorted to it, adopting the process Herodotus ascribed to them. Once the corpse had been prepared, it was customarily placed on a cart. Then the mourners (in the case of a chieftain, the entire tribe; for a lesser person, the family and friends), having cropped their hair, wailing, and tearing their clothes, would conduct the dead man during 40 days through the lands that had once belonged to him or, if he had none, would escort him on visits to his relatives and friends.

On the 40th day the body was carried to the tomb and, while one of the dead man's wives, his principal servants such as his cupbearer and groom, and a substantial number of his riding horses were being put to death, his body was lowered into the main burial chamber; the dead man's newly killed companions and servants were then laid in the graves that had been prepared for them. The bodies of the horses were also placed within the mound, the tombs of the Scythian and kindred nomads all taking the form of horse burials.

All the dead wore their finest jewelry and clothes and the best of their arms and accoutrements, and they also took with them the objects considered necessary for their future life, only the best of their possessions being chosen for the tomb. The horses were harnessed in their finest trappings; at Pazyryk some were even provided with elaborate masks made of felt and leather touched up with gold, some in the shape of a stag's head, complete with

antlers, some surmounted with figures of birds. The number of horses varied with the period and the region, in some cases running into hundreds.

Finally, according to Herodotus, the Scythians marked the first anniversary of a chieftain's death by choosing 50 men from his bodyguard, all of them freeborn tribesmen, and putting them to death, together with their mounts; the men were then seated on their horses and the bodies impaled together on stakes set in a circle around the tomb so that the faithful dead might forevermore guard it from desecration. It is unfortunate that this method of protection, so costly to human and animal lives, failed to achieve its purpose; almost every Scythian grave opened by archaeologists has been found to have been rifled in antiquity.

Tombs. Tombs of the Scythian and kindred tribes are found from the Altai to eastern Europe. In the Altai the method of construction sometimes led to the formation of a layer of ice above the grave and to the preservation of the tomb contents as efficiently as in a modern deep freeze. As a result, many of the materials that perished in the western burials have been preserved in the Asiatic tombs. The frozen burials of Pazyryk date from the 5th to the 2nd century BC. There the size of the mounds is measured by their circumference rather than by their height, for all are low, being topped only with a covering of boulders. It was this boulder cover that caused the formation of a layer of ice when the rainwater that seeped through it to the earth filling beneath became frozen. The richest Scythian tombs are situated in the Soviet Union, primarily in the Kuban region and in the kingdom of the Royal Scyths (*i.e.*, on the Dnepr (Dnieper) and in the Panticapaeum region in the eastern Crimea), though poorer burials are found over a much larger area. The tombs of the chieftains are extremely elaborate, the larger having as many as five chambers, each measuring some 9 feet by 15 feet and 7 feet in height; they often lie as much as 40 feet below virgin soil, while the mounds erected on them vary from 400 to 1,200 feet in diameter.

In southern Russia, at a chieftain's death a sloping trench was first dug; at its further extremity a shaft was sunk into virgin soil to form the main burial chamber; subsidiary graves, as many as five in number, were prepared for the chieftain's companions. Next the trench had to be transformed into a corridor, and then the graves had to be made to resemble the rooms or tents in which the dead had spent their terrestrial existence. This was accomplished by smoothing the sides of the excavated areas and facing them, according to the region, with tree trunks, matting, birch bark, thatch, or even fabrics. In the Crimea painted decorations were often preferred, while at Pazyryk wall hangings were customary. Hooks were fixed into the walls and spare clothing hung on them; shelves were built around the sides to hold provisions. The ceilings of the subsidiary graves were treated in much the same manner as the walls, but four posts often were sunk into the main grave to support either a canopy placed above the corpse or a roof; floors often were covered with gravel or

rushes. The dead were oriented toward the east, laid on mattresses, often set on biers; in the Altai, however, the bodies were laid in coffins made of hollowed-out tree trunks.

In southern Russia the chieftain's body occupied the main chamber; his wife's was placed in the next best; and his retainers were laid in the others, the grooms always being given preferential treatment. No special graves were provided for the horses, their bodies being laid around the tomb in as orderly a manner as possible; but when a large number of horses were sacrificed the corpses were often piled one upon the other in a heap. At Pazyryk, on the other hand, the horses were ordinarily buried in a separate but adjoining chamber decorated in much the same manner as the section of the tomb reserved for the chieftain and his companions.

In Hungary the burials of Zöldhalompusztá and Tápíószentmárton are among the most important because of the magnificent gold plaques in the shape of stags found there; in eastern Germany the Vetersfeld find is of particular interest on account of the gold figure of a fish of remarkable design discovered in it, together with interesting items of military equipment.

Art. Nothing that has so far been found in the Altai has proved of the same intrinsic value as the objects discovered in the western burials; but they show that similar work was produced by the artists of the entire Eurasian area, whether they worked in wood, leather, bone, appliqué felts, and metals such as bronze and newly discovered iron, or whether they used more precious materials such as silver, gold, or electrum. The artists and craftsmen of the Scythian age were fascinated by the animals they saw or imagined, and though numerous objects were decorated with geometric forms, many of them symbolic or magical, the art of the period is essentially an animal art. Combat scenes between two or more animals are numerous, as are single animal figures. Many real or mythical beasts are represented, the majority of the types having roots in deep antiquity, but the Scythians fashioned them in a manner that was new and characteristically their own. As is to be expected with nomads who were constantly on the move, the objects they produced are generally small in size, but many are made of precious materials and practically all are of superb workmanship.

The gold figures of semirecumbent stags, measuring some 12 inches in length, are outstanding; they were probably used as the central ornaments for the round shields carried by many Royal Scythian fighters. In pre-Scythian times the stag was used as a totem by the tribesmen of Siberia, but in the Scythian period the emblem had lost much of its religious significance. Perhaps the loveliest of the gold stags is the 6th-century-BC example from the burial of Kostromskaya Stanitsa in the Kuban, but versions of the 5th century BC from Tápíószentmárton in Hungary and of the 4th century BC from Kul Oba in the Crimea are scarcely less beautiful. Certain scholars ascribe the former to Thracian and the latter to Ionian

Frozen
tombs

The golden
stags

craftsmen, yet all conform wholly to Eurasian traditions, and much more concrete evidence is necessary before the former of these attributions can be accepted as final. In the three the stag is shown in a recumbent position, with its legs tucked beneath its body, but with its head raised and its muscles taut so that it gives an impression of rapid motion. The stag also figures prominently in the art of the Pazyryk people, whether as leather or felt cutouts or as carved, wooden terminals.

The Scythians' artistic idiom is one of great compression as well as of synthesis; contrasting positions of the body are combined with astonishing skill to depict every possible aspect of the animal when visualized during all its diverse activities, zoomorphic junctures of astonishing intricacy helping to evoke the animal kingdom in its abundant multiformity. Thus, though the art is basically representational in character, it is at the same time impressionistic in spirit, while it also often verges on the abstract in conception; yet, however complex its elements, they are fused in the finished work into a single entity of compelling force and beauty.

Seaborg, Glenn Theodore

Glenn Theodore Seaborg, Nobel laureate in chemistry, is best known for his work on the discovery and detailed study of the synthetic elements that lie beyond uranium in the periodic chart of the elements. During World War II he played a key role in the preparation of plutonium for use in nuclear explosives. As chairman of the United States Atomic Energy Commission he encouraged the rapid growth of the nuclear-power industry.

Seaborg, 1968.

Seaborg was born of immigrant Swedish stock in Ishpeming, Michigan, on April 19, 1912, the son of a machinist. When he was ten, the family moved to the Los Angeles area, where he graduated from high school (1929) with a strongly developed interest in physics and chemistry. After undergraduate study in chemistry at the

University of California at Los Angeles (1934), Seaborg studied chemistry at the University of California at Berkeley under the direction of Gilbert N. Lewis, receiving his Ph.D. in 1937, and then spent two years as a research associate of Lewis. Appointed instructor at Berkeley in 1939 he worked on the radiochemical identification of radioactive isotopes produced by bombardment of common elements in Ernest Lawrence's cyclotron and discovered many important isotopes later widely used in medicine and industry.

In 1941 Seaborg and a group of collaborators first identified an isotope of plutonium (element 94) in uranium targets bombarded in the cyclotron and first demonstrated the high susceptibility of the plutonium-239 isotope to nuclear fission. These discoveries resulted in the secret Plutonium Project (organized 1942). At the age of 30, Seaborg organized a chemistry group at the University of Chicago, which he led in developing a chemical process for the extraction of plutonium from uranium, irradiated in nuclear reactors built at Hanford, Washington. The plutonium was used in the first test of a nuclear explosive device, code-named "Trinity," near Alamogordo, New Mexico, on July 16, 1945, and in the weapon exploded at Nagasaki, Japan, on August 9, 1945.

After World War II, Seaborg returned in 1946 to Berkeley as professor of chemistry to continue his pioneering development of nuclear transmutations. Of the 13 synthetic transuranium elements known in the early 1970s, Seaborg played an important role in the identification of the nine with atomic numbers 94 through 102, namely: plutonium, americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, and nobelium. The prediction of the chemical properties and placement of these and many heavier elements in the periodic table of the elements was helped greatly by an important organizing principle enunciated by Seaborg in 1944 and known as the actinide concept; according to this concept, the 14 elements heavier than actinium belong in a separate group in the periodic table. In 1951 he was awarded the Nobel Prize with Edwin M. McMillan for discoveries in the chemistry of the transuranium elements.

Seaborg served as Chancellor of the Berkeley campus from August 1958 until his appointment in January 1961 as chairman of the U.S. Atomic Energy Commission, a post he held for an unprecedented ten-year span during the administrations of Presidents Kennedy, Johnson, and Nixon. Rapid development of the nuclear-power industry occurred in this period, and plutonium emerged as the key nuclear fuel for breeder reactors, a virtually unlimited source of electrical energy. In 1971 he returned to Berkeley as university professor and as associate director of the Lawrence Berkeley Laboratory.

Seaborg is author of many scientific papers, co-author of many books on chemistry and the chemical elements, and editor of several comprehensive scientific treatises. During his period in government service Seaborg served each year as the United States Representative to the General Conference of the International Atomic Energy Agency.

BIBLIOGRAPHY. No full-scale biography exists, but data on his life and work are in the Nuclear Chemistry Division of the Lawrence Berkeley Laboratory, Berkeley, California. His work is also discussed by HERBERT CHILDS in *An American Genius: The Life of Ernest Orlando Lawrence* (1968). RICHARD G. HEWLETT and OSCAR E. ANDERSON, JR., *The New World, 1939-1946*, vol. 1 of *A History of the United States Atomic Energy Commission* (1962), is authoritative and readable on the World War II development of the atomic bomb. GLENN T. SEABORG and WILLIAM R. CORLISS, *Man and Atom* (1971), is a popular description of the use of plutonium for nuclear power.

Sea-Floor Spreading

The 1960s witnessed a revolution within the earth sciences as a result of rapid developments in the knowledge and understanding of the structure and age of the deep ocean basins. The concept of continental drift (*q.v.*) was formulated in considerable detail in 1912 by the German meteorologist Alfred Wegener, but most scientists rejected the

Earth's mantle and crust showing addition of crustal material at midoceanic ridge and destruction in trench systems (as at South American margin) due to system of convection currents at depths (see text).

By courtesy of Fortune Magazine. By Max Gschwind based on the work of Bruce C. Heezen and Marie Tharp

idea because there was insufficient evidence and no plausible mechanism to support it. In 1960, however, H.H. Hess, U.S. geologist, formulated a hypothesis now termed sea-floor spreading. Although unknown to Hess at that time, his ideas were very similar to a concept put forward 30 years earlier in a little-known paper by Arthur Holmes, the Scottish earth scientist.

Hess had been impressed by two fundamental discoveries about the deep ocean floor, which were made in the 1950s. A seismic refraction technique, involving the transmission of seismic waves through and along layered rocks in the Earth, was adapted for use at sea. It revealed that seismic velocities characteristic of the Earth's upper mantle are invariably encountered only 12 kilometres (7.4 miles) below sea level beneath the deep ocean basins. This implies that the crustal thickness is only 7 km in oceanic areas (because the water is about 5 km deep), which contrasts with a typical, although highly variable, thickness of 35 km of crust beneath the continents. The second discovery was that oceanic ridges (*q.v.*) are characteristic features of all the major ocean basins, with the exception of the northwest Pacific. The ridge crests can be traced on the basis of bathymetry (bottom topography) and earthquake data. In the Atlantic the ridge crest is also characterized by a median rift valley and active volcanism, both of which are developed subaerially (above water) on Iceland, which is situated astride the ridge crest.

Hess postulated that the continents have been drifted apart by convection currents in the Earth's mantle, the zone between the Earth's crust and core, and that the midocean ridges are situated over the rising parts of such currents. Thus, the oceanic crust was considered to be no more than a surface expression of the mantle, derived from it by simple chemical modification, and continuously created at ridge crests. From consideration of the earlier ideas on continental drift (with respect to the date of initiation of drift in the Atlantic area, for example), Hess suggested that currents in the mantle move at a rate of approximately one centimetre per year (1 inch equals

2.5 centimetres). This would mean that oceanic crust is formed at twice this rate because mantle-derived material spreads laterally away from ridge crests at this rate. Thus, the rate of opening for the Atlantic basin would be 2 cm/yr because material moves away from ridge crests on both flanks. A simple calculation shows that if spreading about ridge crests has gone on continuously at a rate of a few cm/yr in the past, then all of the present deep ocean floor would have been formed within the past 200 million years or so. The first implication of the sea-floor spreading hypothesis then is that two-thirds of the present surface of the Earth has been formed within the most recent 5 percent of geologic time. Having postulated the formation of so large a proportion of the Earth's crust within so short and recent a period of earth history, Hess was faced essentially with two alternatives: either the Earth's volume expanded during this time, with a resulting increase in its surface area, or pre-existing crust is destroyed at the same rate that new crust is generated at ridge crests. Finding the implications and possible causes of large-scale Earth expansion highly implausible, Hess suggested that the island arcs (*q.v.*) and trench systems of the Pacific hemisphere, arcuate zones in which earthquakes and volcanism are prevalent, are sites of downward moving mantle-wide convection currents, and that in these areas oceanic crust is destroyed, essentially by restoration into the mantle.

An integral part of the original hypothesis was that the oceanic crust formed at ridge crests is hydrated mantle material. It was thought that the required water is derived from the mantle itself, and that the hydration reaction is limited to shallow depths by the fact that it is only possible at temperatures below 500° C. With the reversion of the crust to mantle beneath the trench systems, water would find its way into the hydrosphere, principally the oceans, and oceanic sediments that accumulated on the crust during its passage from ridge crest to trench system would be accreted to the continents. Thus, bearing in mind that previous episodes of drift and spreading may have preceded that which has occurred within the past

Convection
currents
and rates
of
spreading

200 million years, this implies that at least part of the water of the oceans has been derived steadily from the mantle throughout geologic time. Hess maintained that the resulting increase in the depth of the oceans is matched by concomitant thickening of the continents by vertical accretion. In this way the continents will always have maintained essentially the same relation to sea level.

In summary, Hess postulated that despite their great age and apparent permanency continents have been passively drifted apart and together on the backs of mantle-wide convection cells. In contrast the ocean floors are young and ephemeral features, which are constantly being regenerated at ridge crests and destroyed in trench systems (see also OCEANS, DEVELOPMENT OF).

EVIDENCE OF SEA-FLOOR SPREADING

Heat-flow data

The flow of heat through the ocean floor from the Earth's interior was first determined in the 1950s by means of a thermal probe, which measured the temperature gradient (change with depth) in the bottom sediments. The preliminary results obtained revealed that the heat flow through the ocean floor is, in general, comparable to the heat flow through the continents, except over the midocean ridges, where in some localities it is three or four times the normal value (see EARTH, HEAT FLOW IN). Hess argued that these anomalously high values reflect the emplacement of hot mantle-derived material in the vicinity of ridge crests. Marine geophysicists also had discovered that ridge crests are characterized by anomalously low seismic-wave velocities in the crust and upper mantle. This was ascribed to thermal expansion and microfracturing associated with the upwelling mantle. Both would produce a reduction in the density and seismic velocities of the material beneath ridge crests. The concept of less dense material in the upper mantle as a result of enhanced geothermal gradients beneath midocean ridges was to prove an important one because no significant disturbance in the Earth's gravitational field is observed across a ridge. The mass excess of the ridge itself must, therefore, be compensated for by a corresponding mass deficiency at depth; that is, thermal expansion and probably a small degree of partial melting within the uppermost mantle give rise to the topographic expression of an oceanic ridge, and the whole system is in isostatic equilibrium or balance.

Magnetic data

Although there is no disturbance in the Earth's gravity field over ridges, by 1960 it was realized that there is, typically, a disturbance in the Earth's magnetic field. By that time magnetometers had been towed at sea by oceanographic research vessels and two surprising and enigmatic observations had been made. In the North Atlantic a pronounced enhancement of the magnetic field was observed over the median rift valley at the ridge crest. This is the reverse of what one would expect from a deficiency of magnetic material; that is, in the valley. In the northeast Pacific, and not obviously related to a ridge crest, remarkably linear disturbances were mapped; these trended approximately north-south and were bounded by steep magnetic gradients between highs and lows. The first detailed magnetic survey of an oceanic area therefore revealed anomalies unlike any known in continental areas. Moreover, the oceanic anomalies bore no obvious relation to the topography or structure of the underlying sea floor. F.J. Vine and D.H. Matthews, British geophysicists, discussed these magnetic anomalies with respect to sea-floor spreading in 1963 and substantially modified the hypothesis.

The Vine and Matthews hypothesis

Hess had considered the oceanic crust to be hydrated mantle, but an alternative hypothesis maintains that it is partly or entirely derived from the mantle by partial melting. The low-melting-point fraction of the mantle is thought to be basalt, and despite the fact that both basalt and serpentinite (hydrated mantle) are dredged from the ocean floor, Hess only considered partial fusion to be important in the construction of seamounts, atolls, and guyots (flat-topped volcanic peaks). Vine and Matthews accepted the concept of sea-floor spreading but maintained that at least the uppermost part, if not the entire oceanic crust, is derived by partial fusion of the mantle

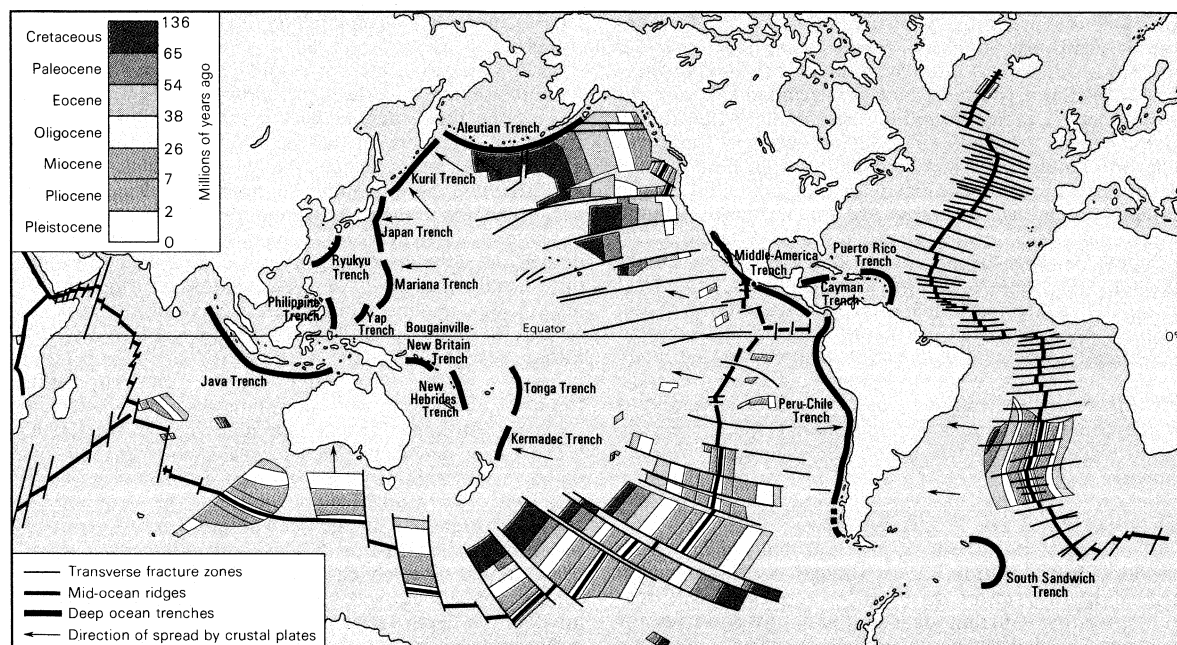

beneath ridge crests and thus consists of extrusive and intrusive rocks of basaltic composition. Basalt is capable of acquiring and retaining an appreciable intensity of permanent (fossil) magnetization; that is, a magnetization that is acquired on cooling soon after its solidification, and presumably reflecting the direction and intensity of the ambient magnetic field at that time. The intensity of this remanent (permanent) magnetization in basalts is invariably greater than that induced by the present earth's field (see ROCK MAGNETISM). Hence, the fossil magnetization might be all-important in considering disturbances in the Earth's magnetic field due to magnetization contrasts within the basalt layer of the ocean floor. To complete their idea, Vine and Matthews made one further assumption: that as new sea floor is formed and spreads laterally away from ridge crests, the Earth's magnetic field reverses its polarity (North and South magnetic poles) intermittently. This produces belts of material parallel to the ridge crests that are alternately magnetized in the normal and reverse directions. The contrasts produced between basaltic material with opposing directions of magnetization would be quite suitable to account for both the central magnetic anomaly observed over ridge crests and the linear anomalies of the northeast Pacific. The median rift valley in the North Atlantic, for example, is presumably floored by basalt extruded and intruded during the current (normal) polarity of the earth's field, but it will be flanked by material emplaced during the preceding, reversed, epoch. The great strength of this model is that it accounts for the magnetization contrasts implied by the magnetic anomalies without invoking improbable lateral variations in the chemical composition or physical structure of the oceanic crust or both.

Whether the Earth's magnetic field had in fact reversed was considered debatable in 1963, and even those who believed that it had could not suggest a detailed timetable for reversals. At about this time improvements in the potassium-argon radiometric dating technique made it possible to date with accuracy basaltic lava flows that had been extruded within the past few million years. Samples whose orientation within terrestrial flows were known were dated and their direction of magnetization measured. It was found that all flows of a particular age, irrespective of their geographic locations, indicate the same polarity for the Earth's magnetic field. By studying a great number of flows, from many parts of the world, it was possible in 1966 to suggest a geomagnetic reversal time scale for the past three and a half million years, during which time the Earth's magnetic field appears to have reversed its polarity at least nine times. Simultaneously, the fossil magnetization of deep-sea sediments also was studied. Where the top few metres of sediment recovered by corers consist of a complete record of pelagic (deep sea) sedimentation for the past few million years it was found that the same sequence of reversals was represented by the remanent magnetization of the sediments. These totally independent data provided striking confirmation of the reversal time scale that had been derived from the study of subaerial lava flows.

Armed with a magnetic reversal time scale and additional marine magnetic data it was possible to re-examine the Vine-Matthews hypothesis. Assuming that the reversal time scale, constant rates of spreading of a few centimetres per year, and the Vine-Matthews hypothesis were all applicable for the past few million years, the observed magnetic anomalies can be reproduced for almost all ridge crests for which magnetic data are available. Moreover, by obtaining a best fit between the observed and predicted anomalies, a precise rate of spreading can be deduced. Such rates vary from one centimetre per year per ridge flank in the vicinity of Iceland to more than 6 cm/yr/ridge flank in the equatorial Pacific. Two exceptions occur in the Eurasian basin of the Arctic and to the southeast of South Africa, where central anomalies are not recorded over the ridge crests. In these areas it is assumed that the ridges either are dormant or are spreading at a very slow rate. Additional profiles and surveys of the Earth's magnetic field over the oceans showed that the

Geomagnetic reversals

Rates of sea-floor spreading

Isochrons indicating ages deduced from magnetic time scale of belts of ocean floor (see text).

By courtesy of *Fortune Magazine*. By Max Gschwind based on the work of Bruce C. Heezen and Marie Tharp

anomalies about ridge crests do show a symmetry and correlation with the reversal time scale as the Vine-Matthews hypothesis predicted. This is more evident in the Pacific, however, where spreading rates are high (typically greater than 3 cm/yr/ridge flank), than in the North Atlantic and northwest Indian oceans, where most of the early work was done. The spreading rates are low in these areas, ranging from 1 to 2 cm/yr/ridge flank.

Unfortunately, the technicalities of both methods for determining the age of geomagnetic reversals are such that neither could extend the time scale back beyond 4,000,000 years very readily or precisely. Although it was possible to provide compelling evidence for spreading at ridge crests during the past few million years, the question of whether spreading had gone on for hundreds of millions of years, and formed the whole of the ridges and ocean basins, remained open. Fortunately, other tests of the hypothesis were possible. If the Earth's magnetic field has reversed its polarity throughout the past 200,000,000 years as it has recently, then spreading should be recorded in the form of linear magnetic anomalies paralleling ridge crests and symmetrically disposed about them. Moreover, if spreading has been continuous about all ridges, then the same sequence of anomalies should be reproduced across all ridge flanks. Since 1966 it has been possible to investigate this implication, and, indeed, the same sequence of anomalies is observed across ridge flanks in all the ocean basins. The distinctive linear anomalies of the northeast Pacific, which were first documented in the late 1950s, are the part of this sequence associated with the west flank of the East Pacific Rise, the crest of which has interacted with the west coast of North America since their formation. The same anomalies can be recognized on either side of the East Pacific Rise and Pacific-Antarctic Ridge in the South Pacific, to the south of Australia, and on both sides of the ridges in the South Atlantic and southeast Indian oceans. They can be recognized, to some extent, in the North Atlantic and northwest Indian oceans, but the slow spreading rates in these areas make correlations difficult without a detailed survey.

The worldwide correlation and symmetry of magnetic anomalies about ridge crests provide compelling evidence for sea-floor spreading and for reversals of the Earth's magnetic field throughout the time interval represented by these anomalies. The determination of this time interval is therefore of great interest. With the possible exception of the northwest Indian Ocean and the extreme North Atlantic, the anomaly sequence is complete in all areas. Thus, short of worldwide stoppages, spreading has

been continuous, but not necessarily at a constant rate. In fact, if one assumes a constant rate in any one area, one can deduce the implied variations in rate in all other areas. In order to provide a working hypothesis, ages were assigned to the anomalies, and hence to the oceanic crust and geomagnetic reversals, by assuming a constant rate of spreading in the South Atlantic, because this implied the least variation in rates elsewhere. The rate assumed was 2 centimetres per year per ridge flank, which was that deduced from the central anomalies. The results of this method suggested that the oldest correlative anomaly was approximately 75,000,000 years of age.

The vindication of the Vine-Matthews modification of Hess's sea-floor spreading hypothesis led to specific predictions about the age and history of the ocean basins (*q.v.*). In 1960 Hess claimed that no oceanic sediment or crust recovered by coring and dredging was more than 100,000,000 years in age. Many thought that it was possible to make this statement only because of the paucity of available data. Ten years later, however, after extensive coring, dredging, and, more recently, deep-sea drilling, the oldest material recovered still is only 160,000,000 years old. Hess had also maintained that the blanket of sediment in the ocean basins was 10 or 20 times thinner than one would predict if sedimentation rates in the past were similar to those of today and if the ocean basins were permanent and as old as the continents. Today, despite much more detailed and extensive determinations of the sediment thickness by seismic-reflection profiling, and more accurate determinations of sedimentation rates by use of magnetic reversal stratigraphy and new radiometric dating techniques, this conclusion remains valid.

The development of seismic-reflection profilers (low-frequency echo sounders) yielded details of the structures within the sediments and of the topography of the crust beneath them. Judicious use of profilers in conjunction with corers has facilitated sampling of deep reflecting horizons where they outcrop in erosional channels or on fault scarps. In this way, relatively old horizons have been dated and mapped. In all cases their distribution has been found to be consistent with predictions based on the distribution of the linear magnetic anomalies. Radiometric dating of basalt, serpentinite, and related rocks from the deep sea floor is fraught with difficulties, but the reliable dates obtained are consistent with the sea-floor spreading hypothesis. The results obtained from fission-track dating (which utilizes the amount of radiation damage from the fission of radioactive elements) thus far also have confirmed the ages assigned to the magnetic anomalies.

Age and distribution of marine sediments

Linear magnetic anomalies

In 1969 the preliminary results of the Joint Oceanographic Institutions Deep Earth Sampling Program (JOIDES) brought final and consummate proof of the sea-floor spreading hypothesis and the geomagnetic reversal time scale. At many sampling sites in the Atlantic and Pacific oceans the whole of the sedimentary column was penetrated and basalt was recovered. In no case did the age of the sediments conflict with that predicted by the sea-floor spreading hypothesis. In the southern Atlantic Ocean, holes were drilled across the Mid-Atlantic Ridge at 30° S, beneath the previously dated magnetic anomalies. The data obtained confirmed the geomagnetic reversal time scale in a remarkable way. The age of the oldest sediment encountered in each hole—that is, the sediment immediately overlying the basalt basement—was directly proportional to the distance of the hole from the ridge axis. Moreover, the implied rate of sea-floor spreading is two centimetres per year per ridge flank; this is precisely the rate assumed in calibrating the magnetic anomaly sequence.

THE CAUSE OF SEA-FLOOR SPREADING

The concept of giant belts of material that are driven by mantle-wide convection is now thought to be somewhat misleading, in terms of the mechanics and causes of sea-floor spreading. Current ideas on the nature and cause of the spreading process have been derived from more detailed consideration of the geometry of spreading and the seismicity (earthquake activity) of the Earth.

In 1965 J. Tuzo Wilson noted the occurrence of an entirely new class of fractures in the Earth's crust. He named these great fractures, whose active lengths terminate at oceanic ridge crests or trench systems, transform faults. Because ridge crests are considered to be the loci of the creation of oceanic crust, and trench systems the sites of its destruction, it is possible to predict the sense (directions) of movement on such faults. Terrestrial exposures of postulated transform faults in California and New Zealand were found to vindicate the implied sense of movement, but the many transform faults on the ocean floor required sophisticated analysis of earthquake activity along them before the sense of movement could be determined.

The simplest type of transform fault is that which traverses midocean ridges at right angles to the ridge crest. These faults offset the ridges by tens, or occasionally hundreds, of kilometres. The traditional explanation of such a geometry, assuming conservation of crust, was that the ridge crests on either side of the fracture originally matched and subsequently were offset by shearing; that is, that lateral translation occurred along the intervening fracture. Wilson pointed out that the nonconservative process of spreading implies that the offset might be original and unchanging with time. If this is the case the fault will be seismically active only between the offset points on the ridge crest, and the sense of movement along this active length of the fracture will be the opposite to that predicted by the classical analysis (see also ROCK DEFORMATION).

The establishment of the World-Wide Standardized Seismograph Network (WWSSN) in the 1960s enabled seismologists to determine the foci and epicentres (points on the Earth's surface above the foci) of earthquakes with great precision. In 1966, L.R. Sykes was able to show that the distribution of earthquake epicentres along midocean ridge crests and the focal mechanisms deduced for some of the larger earthquakes occurring on the transverse fractures confirm Wilson's predictions. Focal-mechanism solutions provide an indication of the sense of movement on faults and are obtained from the analysis of the first ground motion at many seismograph stations throughout the world.

The confirmation of transform faulting on the ocean floor provided further support for the concept of sea-floor spreading, but it also raised questions and sowed the seed for modification of the hypothesis. If sea-floor spreading and continental drift are caused by mantle convection, then how could both rising and descending limbs of convection cells be abruptly terminated and offset along

transform faults? Mechanically this seems quite unreasonable.

When earthquake epicentres obtained from the WWSSN were plotted on a world map it was seen that the seismicity of the Earth defines with great precision the three structural elements of the sea-floor spreading model, namely, ridge crests, trench systems, and transform faults. Furthermore, the maximum depths at which earthquakes occur beneath trench and mountain systems were very much greater than those beneath ridge crests. Earthquakes on ridge crests appear to be restricted to depths of less than 10 or 20 kilometres, whereas earthquakes beneath trench and mountain systems occur at all depths up to several hundred kilometres and, exceptionally, 700 kilometres. The seismicity of the Earth therefore is largely restricted to active ridge crests, transform faults, trenches, and young fold mountain systems. These narrow zones outline essentially aseismic areas of the Earth's crust that appear to behave as quasi-rigid plates, and the plates do not exhibit major internal deformation.

In 1967, W. Jason Morgan analyzed the geometry of sea-floor spreading in terms of relative movements between rigid crustal plates bounded by ridge crests, transform faults, and trench systems on the surface of a sphere. His success was remarkable, and it appears that much of the Earth's seismicity is clearly related to relative movements between quasi-rigid plates. Consequently, this new modification of sea-floor spreading is termed plate tectonics. The terms continental drift and sea-floor spreading are now deemed somewhat inappropriate because individual plates typically include both continental and oceanic crust. The Earth's outermost skin, or lithosphere, exhibits appreciable strength and rigidity and extends well beneath both continental and oceanic crusts to depths of 50 or even 100 kilometres. At ridge crests, the lithospheric plates are thinned by the elevation of the geotherms (temperature of the Earth's interior) due to mantle upwelling and emplacement. Beneath the trench systems the oceanic plate plunges downward, typically at an angle of about 45° to the adjacent plate as reflected in the deep focus seismicity. The processes of creation and destruction of oceanic plates display an intriguing symmetry and asymmetry, respectively.

It is clear that the most detailed and quantitative evidence for the sea-floor spreading hypotheses relates to the midocean ridges. The nature of the trench systems is an equally important aspect of the hypothesis but it is more equivocal. Many surficial structures in island arcs (*q.v.*) and trench systems suggest extension of the Earth's crust, as though the cold, descending lithosphere is pulling down the plates above; indeed this may be the case. Flat-lying sediments in some trenches, and the absence of buckled sediments in virtually all, have led some to doubt this aspect of the spreading hypothesis; however, the degree of buckling in sediment beneath the landward or inner wall of a trench and the extent of slumping of sediments off this wall are still unknown. The most compelling evidence for the underthrusting of island arcs and Andean-type continental margins by oceanic lithosphere comes from studies of deep-focus earthquakes.

Global analysis of the geometry of plate movements permits prediction of the direction and rate of underthrusting in trench systems because the direction and rate of spreading at ridge crests can be deduced from the transform faults and magnetic anomalies. The directions predicted in this way correspond to directions of underthrusting derived from focal-mechanism solutions for some of the larger shallow-focus earthquakes landward of trenches, and the rates deduced are directly proportional to the maximum depths at which earthquake foci occur. Presumably the latter reflect a thermal relaxation effect as the cold lithospheric slab is thrust down into the hotter upper mantle; in this case one would expect these maximum depths to depend on the rate of underthrusting. Studies of the variation in the velocity and attenuation of seismic shear waves for various ray paths beneath trench systems also confirm the picture of an underthrusting slab of cold lithosphere.

Hess's concept of convection to the surface was seen to

Plate
tectonics

Transform
faults

be improbable because of transform faults; his postulate of mantle-wide convection also seems improbable now for an equally simple geometric reason. A fixed geometry of mantle-wide convection cells, in which the rising limbs are correlated with ridge crests and descending limbs with trench systems, is incompatible with the concept of plate tectonics. The geometry of plate movements is such that only one plate, or one boundary between two plates, can be fixed with respect to some frame of reference such as the Earth's geographical coordinates. All other plates and boundaries then move with respect to each other and to the frame of reference. Consideration of the plates that incorporate Africa and Antarctica provides a simple example of this point. Both Africa and Antarctica are surrounded on at least three sides by ridge crests but by no trench systems. Therefore, if either continent is regarded as being fixed, the surrounding ridge crests must clearly migrate away from it as spreading occurs.

Despite the vast accumulation of near surface evidence favouring the hypothesis of sea-floor spreading, man is little nearer to an understanding of the process or processes deep within the Earth by which it is initiated and maintained. Many consider that thermal convection in some form is the only known process capable of supplying the energy requirements, but it now seems probable that there is no simple relationship between mantle convection currents and surface features. Convection in this context should be interpreted in its broadest terms; that is, the generation of horizontal temperature gradients that result in gravitational instabilities and, hence, in the vertical transport of hot and cold material. In this regard the cold descending slab of oceanic lithosphere landward of the trench systems is clearly a source of gravitational energy. That such a sinker exists and is an important driving force is reflected in the tensile nature of intermediate depth earthquakes beneath the trenches, and by the observation that the only systematic correlation between surface features and broad-scale gravity anomalies is that between regional gravity highs and the trench systems.

Present knowledge of the physical properties of the Earth's mantle is less than perfect, particularly with regard to temperature and viscosity, two all-important parameters. It now seems probable, however, that convection, if it occurs at all, is only possible in that part of the upper mantle that is near its melting point, probably at depths between 50 to 100 kilometres and 200 to 300 kilometres. Convection in this shell will produce two effects, namely a net viscous drag on the lithospheric plates above and, as a result of thermal convection at ridge crests and the resultant elevation of ridges, a downhill pull on the flanking plates that are situated in gravity potential gradients.

MENARD, "The Deep-Ocean Floor," in particular, cover marine geology and geophysics. H. TAKEUCHI, S. UYEDA, and H. KANAMORI, *Debate About the Earth* (1967), excellent readable background material on continental drift, paleomagnetism, and geomagnetism; O.M. PHILLIPS, *The Heart of the Earth* (1968), a slightly more quantitative introduction to the physics of the earth; R.A. PHINNEY (ed.), *The History of the Earth's Crust* (1968), a collection of pertinent research papers.

(F.J.V.)

Securities Trading

Securities are written evidences of ownership giving their holders the right to demand and receive property not in their possession. The most common types of securities are stocks and bonds, of which there are many particular kinds designed to meet specialized needs. This article deals mainly with the buying and selling of securities issued by private corporations. (The securities issued by governments are discussed in the article PUBLIC DEBT.)

SECURITIES ISSUED BY CORPORATIONS

Corporations create two kinds of securities: bonds, representing debt, and stocks, representing ownership or equity interest in their operations. (In Great Britain, the term

stock ordinarily refers to a loan, whereas the equity segment is called a share.)

Bonds. The bond, as a debt instrument, represents the promise of a corporation to pay a fixed sum at a specified maturity date, and interest at regular intervals until then. Bonds may be registered in the names of designated parties, as payees, though more often, in order to facilitate handling, they are made payable to the "bearer." The bondholder usually receives his interest by redeeming attached coupons.

Since it could be difficult for a corporation to pay all of its bonds at one time, it is common practice to pay them gradually through serial maturity dates or through a sinking fund, under which arrangement a specified portion of earnings is regularly set aside and applied to the retirement of the bonds. In addition, bonds frequently may be "called" at the option of the company, so that the corporation can take advantage of declining interest rates by selling new bonds at more favourable terms and using these funds to eliminate older outstanding issues. In order to guarantee the earnings of investors, however, bonds may be noncallable for a specified period, perhaps for five or ten years, and their redemption price may be made equal to the face amount plus a "premium" amount that declines as the bond approaches its maturity date.

The principal type of bond is a mortgage bond, which represents a claim on specified real property. This protection ordinarily results in the holders' receiving priority treatment in the event that financial difficulties lead to a reorganization. Another type is a collateral trust bond, in which the security consists of intangible property, usually stocks and bonds owned by the corporation. Railroads and other transportation companies sometimes finance the purchase of rolling stock with equipment obligations, in which the security is the rolling stock itself.

Although in the United States the term debentures ordinarily refers to relatively long-term unsecured obligations, in other countries it is used to describe any type of corporate obligation, and "bond" more often refers to loans issued by public authorities.

Corporations have developed hybrid obligations to meet varying circumstances. One of the most important of these is the convertible bond, which can be exchanged for common shares at specified prices that may gradually rise over time. Such a bond may be used as a financing device to obtain funds at a low interest rate during the initial stages of a project, when income is likely to be low, and encourage conversion of the debt to stock as earnings rise. A convertible bond may also prove appealing during periods of market uncertainty, when investors obtain the price protection afforded by the bond segment without materially sacrificing possible gains provided by the stock feature; if the price of such a bond momentarily falls below its common-stock equivalent, persons who seek to profit by differentials in equivalent securities will buy the undervalued bond and sell the overvalued stock, effecting delivery on the stock by borrowing the required number of shares (selling short) and eventually converting the bonds in order to obtain the shares to return to the lender.

Another of the hybrid types is the income bond, which has a fixed maturity but on which interest is paid only if it is earned. These bonds developed in the United States out of railroad reorganizations, when investors holding defaulted bonds were willing to accept an income obligation in exchange for their own securities because of its bond form; the issuer for his part was less vulnerable to the danger of another bankruptcy because interest on the new income bonds was contingent on earnings.

Still another hybrid form is the linked bond, in which the value of the principal, and sometimes the amount of interest as well, is linked to some standard of value such as commodity prices, a cost of living index, a foreign currency, or a combination of these. Although the principle of linkage is old, bonds of this sort received their major impetus during the inflationary periods after World Wars I and II. In recent years they have had the most use in countries in which the pressures of inflation have been sufficiently strong to deter investors from buying fixed-income obligations.

convection
in the
mantle

Stock. Those who provide the risk capital for a corporate venture are given stock, representing their ownership interest in the enterprise. The holder of stock has certain rights that are defined by the charter and bylaws of the corporation as well as by the laws of the country or state in which it is chartered. Typically these include the right to share in dividends and other distributions, to vote for directors and fundamental corporate changes, and to inspect the books of the corporation, and, less frequently, the "pre-emptive right" to subscribe to any new issue of stock. The stockholder's interest is divided into units of participation, called shares.

A stock certificate ordinarily is given as documentary evidence of share ownership. Originally this was its primary function; but as interest in securities grew and the capital market evolved, the role of the certificate gradually changed until it became, as it is now, an important instrument for the transfer of title. In some European countries the stock certificate is commonly held in bearer form and is negotiable without endorsement. To avoid loss, the certificates are likely to be entrusted to commercial banks or a clearing agency that is able to handle much of the transfer function through offsetting transactions and bookkeeping entries. In the United States, certificates usually are registered in the name of the owner or in a "street name"—the name of the owner's broker or bank; the bank may for legal reasons use the name of another person, known as a "nominee." When a certificate is held in the name of a broker or bank nominee, the institution is able to make delivery more readily and the transfer process is facilitated. Investors, for legal or personal reasons, may prefer to keep the certificates in their own names.

A corporation may endow different kinds or classes of stock with different rights. Preferred stock has priority with respect to dividends and, if the corporation is dissolved, to the division of assets. Dividends on preferred stock usually are paid at a fixed rate and are often cumulated in the event the corporation finds it necessary to omit a distribution. In the latter circumstance the full deficiency must be cleared before payments may be made on the common shares. Participating preferred stock, in addition to stipulated dividends, receives a share of whatever earnings are paid to the common stock. Participation is usually resorted to as an inducement to investors when the corporation is financially weak. Although a preferred issue has no maturity date, it may be given redemption terms much like those of a bond, including a conversion privilege and a sinking fund. Preferred stockholders may or may not be allowed to vote equally with common stockholders on some or all propositions or more characteristically may vote only upon the occurrence of some prescribed condition, such as the default of a specified number of dividend payments.

Common stock, in some countries called ordinary shares, represents a residual interest in the earnings and assets of a corporation. Whereas distributions to bonds or preferred stock are ordinarily fixed, dividends paid on common stock are set at the time of payment by the directors and tend to vary with earnings. The market price of common stock is likely to move in a relatively wide range, depending on investors' expectations of earnings in the future.

Options. An option contract is an agreement enabling the holder to buy a security at a fixed price for a limited period of time. One form of option contract is the stock purchase warrant, which entitles the owner to buy shares of common stock at designated prices and according to a prescribed ratio. Warrants are often used to enhance the salability of a senior security, and sometimes as part of the compensation paid to bankers who market new issues.

Another use of the option contract is the employee stock option. This is used to compensate key executives and other employees; it is normally subject to a variety of restrictions and is generally nontransferable. Stock rights, like warrants, are transferable privileges permitting stockholders to buy another security or a portion thereof at a specified price for an indicated period of time. The stock right allows stockholders to subscribe to additional shares

of stock in proportion to their present holdings. Stock rights usually have a shorter life-span than warrants, and their subscription price is below, rather than above, the market price of the common stock.

THE MARKETING OF NEW ISSUES

The marketing of securities is an essential link in the mechanism that transfers capital funds from savers to users. The transfer may involve intermediaries such as savings banks, insurance companies, or investment trusts. The ultimate user of the funds may be a corporation or any of the various levels of government from municipalities to national states.

The growth of public debt throughout the world has made governments increasingly important participants in the markets for new securities. They have had to develop financing techniques with careful attention to their influence on the markets for nongovernmental securities. The treasuries must carefully study interest rates, yield patterns, terms of financing, and the distribution of holdings among investors.

Local governments are usually subject to various statutory restrictions that must be carefully observed when offering a new issue for sale. Local government bonds are distributed through investment bankers who buy them and reoffer them to the public at higher prices and correspondingly lower yields. Sometimes the terms of the offer are negotiated. In the United States, however, a more prevalent means of selling state and local bonds is through competitive bidding, in which the issuer announces a contemplated offering of bonds for a designated amount, with specified maturity dates, and for certain purposes. Syndicates of investment bankers are formed to bid on the issue, and the award is made to the group providing the most favourable terms. The winning syndicate then reoffers the bonds to the public at prices carefully tailored to be competitive with comparable obligations already on the market and to provide a suitable profit margin.

The financial manager of a company requiring additional funds has a number of alternative courses of action open to him. He may do all of his financing through commercial banks by means of loans and revolving credit arrangements that, in essence, are formalized lines of credit. Or, he may prefer to raise capital through the sale of securities. If he chooses to do the latter, he may undertake a private sale with an institutional investor such as an insurance company, permitting him to avoid both the complicated procedures of a public distribution and the risks of unsettled market conditions. On the other hand, a private placement of this sort deprives the issuer of the favourable publicity flowing from a successful public offering; it may not afford sufficient resources for very large firms with continuing demands for capital; and it involves rather restrictive legal requirements.

A company that elects to float its securities publicly in the capital market will ordinarily utilize the services of an investment banker. The investment banker may buy the securities from the issuer and seek a profit by selling them at a higher price to the public, thereby assuming the market risks. If the issue is large, the originating investment banker may invite other houses to **join** with him in purchasing the issue from the company, while to facilitate disposal he may form a selling group to take over the issue from the buying firms for resale to the public. In lieu of buying the securities from the issuer, the investment banker may act as an agent and receive a commission on the amount sold. If the issuer negotiates the selection of an investment banker, the banker will serve as financial counsel and offer advice on the timing and terms of the new issue. If the selection is by competitive bidding, the relationship is likely to be more impersonal.

An accepted principle of modern finance is that investors are entitled to knowledge about the issuer in order to appraise the quality of the securities offered. A number of countries now require issuers to file registration statements and provide written prospectuses.

The security markets of Europe do not have the aggressive investment-banking machinery developed in the

Marketing
corporation
securities

United States. European commercial banks, on the other hand, play a much more important role in financing the needs of industry than do commercial banks in the United States and Great Britain.

In the 1960s, a number of industrial nations faced increasing difficulties in meeting their financing needs through local capital markets. Several issuers began to float securities that were payable in any of 17 different European currencies. This marked what might be called the beginning of an "international securities" market. Efforts were also made to issue bonds on a parallel basis in different countries with each portion denominated in the currency of the country in which it was sold. For various legal and technical reasons, these methods did not attract a wide following.

Another factor that hastened the growth of a European securities market was the balance of payments problem confronting the United States in the 1960s. Certain legislative enactments substantially shut the capital market of the U.S. to foreign issuers; and other restraints were imposed on foreign lending by United States financial institutions and on direct foreign investment by United States corporations. As a result, a number of multinational corporations headquartered in the United States were forced to seek financing in overseas securities markets for the expanding business of their foreign subsidiaries. United States and foreign investment bankers joined in syndicates to float these securities. The process was facilitated by the growth of an international market in Eurodollars, representing claims on dollars deposited in European banks. The bulk of the new bonds offered abroad were denominated in Eurodollars.

During the period 1957–65, when this new European market came into being, the volume of foreign bonds issued publicly rose from \$492,600,000 to \$1,489,500,000. The principal and most consistent borrowers were in Canada, Australia, Japan, Norway, Israel, Denmark, and New Zealand. In all of these countries, the major borrower was the national government, except in Canada, where the political subdivisions were the major borrowers. In West Germany, Great Britain, and the United States, the only borrowers in international markets were private units.

THE MACHINERY OF SECURITIES TRADING

Organized securities markets and stock exchanges are a product of economic development. In the early years of economic growth, most of a country's industrial units are small and their capital requirements relatively modest. The rate of saving is low, and institutions for channelling private savings into investment are generally lacking. As the economy progresses and national income grows, new institutions enter the financial picture to direct the mounting volume of savings into productive outlets. The appearance of growing numbers of individual and institutional investors creates a need for trading markets to speed up transactions and enable stockholders swiftly and easily to convert their holdings to cash.

At this stage of development, corporations usually meet less of their financing needs through direct sales of securities in the new issue market and obtain a larger percentage through reinvesting their own earnings. This plowing back of earnings is not insensitive to the judgment of investors: if the prospects of a company are good, investors bid up the price of its shares in the trading market and show a willingness to forego dividends for the possibility of long-term capital gains achieved through internal growth. Thus, when a company is able to finance its expansion by means of reinvested earnings rather than by new stock issues, the trading segment becomes the more important aspect of the capital market.

History. Stock exchanges grew out of early trading activities in agricultural and other commodities. Traders in European fairs in the Middle Ages found it convenient to use credit, which required the supporting documents of drafts, notes, and bills of exchange. The French stock exchange may be traced as far back as the 12th century, when trading occurred in commercial bills of exchange. To regulate these incipient markets, Philip the Fair

(1268–1314) created the profession of *courratier de change*, the forerunner of the modern French stockbroker, or *agent de change*. At about the same period in Bruges, then a prosperous centre of the Low Countries, merchants took to gathering in front of the house of the Van der Buerse family to engage in trading. From this custom, the name of the family became identified with trading, and eventually "bourse" came to signify a stock exchange. From similar roots in trade and commerce, the institutional beginnings of stock exchanges appeared during the 16th and 17th centuries in other great trading centres throughout the world—Amsterdam, Great Britain, Denmark, Germany.

The growth of trade created a need for banks and insurance companies. Political developments caused governments to seek new sources of funds. This combination of expanding activity and intermittent capital shortages stimulated the early issuers of securities—governments, banks, insurance companies, and some joint-stock enterprises, particularly the great trading companies. From the existing exchanges for commercial bills and notes, it was an easy and logical transition to the establishment of stock exchanges for securities. By the early 1600s, shares of the Dutch East India Company were being traded in Amsterdam; in 1773, London stock dealers who had previously been meeting in coffeehouses moved into their own building; and by the 19th century, trading in securities on a formal basis was common in the industrialized nations.

The evolution of stock exchanges continued. In Great Britain, progress has for the most part been internal and voluntary; the London Stock Exchange has regulated its own activities. The French stock exchanges, in contrast, are directly subject to law, and the operations of the *agents de change* have been affected by national decrees. At one time, there were three markets for securities in Paris: an official market called the Parquet (the "floor"); a semiofficial market, the Coullisse (the "wing"); and the Hors Côté (the "outside"), an unregulated market in unlisted securities. In 1929, the Hors Côté was subjected to official regulation and in the following decade its activities were absorbed into the Coullisse, which in turn was combined with the Parquet in a reorganization in 1961. In Belgium the exchanges have had a mixed history. Strict governmental controls were imposed in 1801 and not removed until 1867. Following the economic crisis of 1929–34, the pendulum swung the other way and the exchanges were once more placed under the control of central authority. In Switzerland, the exchanges have been governed by cantonal (state) law.

Historical events have left their mark upon the development of stock exchanges in some countries. Mining, rather than trade and commerce, was the impelling influence in the establishment of stock exchanges in South Africa and Canada. In Germany, the Berlin Stock Exchange lost its dominant role after World War II, and its position was assumed by exchanges in Frankfurt and Diisseldorf. The Japanese securities markets were revolutionized following World War II, when a new securities law was enacted patterned after the U.S. model. A campaign to distribute stock formerly held by the large *zaibatsu* (family-owned combines) and semigovernment corporations greatly increased public stock ownership, which in turn contributed to the considerable growth of trading on the nine Japanese exchanges. Another post-World War II development was the interest of the governments of developing countries in the use of stock exchanges to facilitate external financing.

Securities markets in the United States began with speculative trading in issues of the new government. In 1791, the country's first stock exchange was established in Philadelphia, then the leading city in domestic and foreign trade. An exchange in New York was set up in 1792, when 24 merchants and brokers decided to charge commissions while acting as agents for other persons and to give preference to each other in their negotiations. They did much of their trading under a tree at 68 Wall Street. Government securities formed the basis of the early trading. Stocks of banks and insurance companies added to

the volume of transactions. The building of roads and canals brought more securities to the market. In 1817 the New York brokers decided to organize formally as the New York Stock and Exchange Board. Thereafter, the stock market grew with the industrialization of the country. In 1863, the New York Stock Exchange adopted its present name. During the Civil War additional exchanges were organized, one of them the forerunner of the present American Stock Exchange, the second largest stock market in the country.

Organization. All stock exchanges perform similar functions with respect to the listing, trading, and clearing of securities. They differ in their administrative machinery for handling these functions.

The London Stock Exchange, the largest in the world in terms of the number and variety of domestic and international securities traded, is an independent institution not subject to governmental regulation. It resembles a private club with its own constitution and operating rules, administered by a council that, except for the government broker who is an *ex officio* nonvoting member, is elected by the membership. Operating responsibility is vested in the secretary and his staff.

In the United States, as in Great Britain, the government does not participate directly in the operations of the exchanges. Since 1933, however, Congress has enacted half a dozen measures that in one way or another affect the securities market. The most important are the Securities Act of 1933, which is primarily concerned with the new-issue market, and the Securities Exchange Act of 1934, which is directed toward the trading market. The latter requires that every stock exchange register with the Securities and Exchange Commission (SEC) as a national securities exchange, unless it is exempted because of the limited volume of its transactions, and that it conform to certain rules in its trading practices. This relationship between the stock exchanges and the SEC is peculiar to the United States; it involves a sort of administrative partnership between the exchanges as private associations—but functioning as quasi-public institutions—and the government. The exchanges generally may adopt policies and issue regulations governing their own operations but are subject to SEC intercession in the event that the Commission believes modifications are required in the public interest.

Most European exchanges are also subject to some form of governmental regulation. The Amsterdam Stock Exchange is a private organization, relatively free to regulate the activities of the market, but the Minister of Finance exercises some supervision under existing legislation. The Ziirich exchange is governed by a board of elected members that determines general policy and coordinates the work of the exchange's committees. Of these, the Ziirich Cantonal Committee, which directs dealings on the floor of the exchange, is chaired by the head of the Finance Department of the State of Zurich. Although the Frankfurt Stock Exchange is under the direct administration of a Board of Governors elected by its own members, the rules of the exchange must be approved by the authorities of the state of Hesse; and the official specialists, each responsible for the trading in certain securities, are appointed by the Minister of Finance in the state of Hesse. In Brussels the Ministry of Finance is involved in the appointment of members to major committees, while a governmental representative is attached to each exchange to supervise the observance of all rules and laws; in addition, the Banking Commission that is nominated by the government has substantial powers over the admission of securities to public trading. The policy-making Exchange Commission of the Paris bourse is headed by the Governor of the Banque de France, while the regular members are chosen by the Ministry of Finance; the *agents de change* who supervise the trading process are semigovernmental officials. New members of the Italian stock exchanges are appointed by the government from a list of candidates as a result of competitive examinations, and therefore have some public status.

Since 1953, membership in the New York Stock Exchange has been limited to 1,366. Only individuals may

be members, but they may be partners or stockholders of organizations that do business with the public. Their organizations in such cases are known as member firms. The exchange supervises and regulates member firms in what it considers to be the public interest: a majority of the owners must be engaged primarily in the business of brokers or dealers in securities; exchange approval is required of any shareholder with a 5 percent interest in a member corporation; and all principal officers and directors who are active in the firm must be members or allied members of the exchange. An allied member is subject to the rules of the exchange but does not have the right to engage in transactions on the floor.

To become a member, an individual must acquire, with the approval of the board of governors, a "seat" from a present member or from the estate of a deceased one. Before granting approval, the exchange will investigate such matters as the applicant's past record and financial standing; he will also have to pass an examination demonstrating his knowledge of the securities field.

There are several kinds of brokers on the floor of the exchange. They include the commission broker who executes customer orders placed at or near the current market price; the specialist in one or more issues who, as a broker, executes limited orders for other members and, as a dealer, buys and sells securities for his own account; floor brokers, or "two-dollar" brokers, who execute orders for other brokers at a commission but have no contact with the public; brokers associated with odd-lot firms, who undertake to buy or sell in quantities other than the standard 100-share lot; and "registered traders" who buy and sell for their own account.

To become a member of the London Stock Exchange, an individual must acquire a "nomination" from a retiring member at a price that varies with demand and supply. Every applicant must be approved by at least three-quarters of the stock exchange council. A member may be a broker, dealing as an agent of the public, or a jobber, dealing for his own account with other brokers or jobbers.

Membership in the Paris stock exchange is limited to 85 *agents de change* who supervise activity while the actual work of trading and executing orders is done by their employees and those of the exchange. To become an *agent de change*, an applicant must meet prescribed standards of education and experience as well as pass a written examination. He must be nominated by a retiring member or the heirs of a deceased member and make a deposit guaranty. He is formally appointed by the Minister of Finance.

Other European exchanges set eligibility requirements of character, experience, and financial standing, and some have educational requirements as well. In Brussels, in addition to the completion of six consecutive years in a broker's office, a candidate must have a degree in commercial science or economics and pass a professional examination. In Germany, Switzerland, and Sweden, the brokerage business is dominated by banks.

Members of Japanese exchanges must be corporations doing a business in securities. There are two kinds of members: regular members, who buy and sell for customers or for their own accounts, and *saitori*, who act principally as intermediaries for regular members.

Trading procedures. Most stock exchanges are auction markets, in which prices are determined by competitive bidding. In very large, active markets, the auction is continuous, occurring throughout the day's trading session and for any security in which there is buying and selling interest. In smaller markets the names of the listed stocks may be submitted in some form of rotation, with the auction occurring at that time; this process is described as a "call market."

Trading methods on all the exchanges in the United States are similar. In a typical transaction for a security listed on the New York Stock Exchange, a customer gives an order to an employee in a branch or correspondent office of a member firm, who transmits it either indirectly through the firm's New York office or, as is becoming increasingly common, directly to a receiving clerk on the floor of the exchange. The receiving clerk summons the

Member-
ship
require-
ments of
stock
exchanges

firm's floor broker who takes the order, goes to the post where the stock is traded, and participates in an auction procedure as either buyer or seller. If the order is not a market order calling for immediate action, the broker turns it over to an appropriate specialist who will execute it when an indicated price is reached.

As in any auction market, securities are sold to the broker bidding the highest price and bought from the broker offering the lowest price. Since the market is continuous, buyers and sellers are constantly competing with each other. In the New York Stock Exchange, the specialist plays an important role. As a principal, he has the responsibility of buying and selling for his own account, thereby providing a stabilizing influence; as an agent, he represents other brokers on both sides of the market when they have orders at prices that cannot be readily executed.

With the growing demand for stocks on the part of institutions such as insurance companies, mutual funds, pension funds, and so forth, the size of orders consummated on the New York Stock Exchange has grown. In 1970, for example, 17,217 trades of blocks of 10,000 shares or more were completed on the exchange, representing 15.4 percent of reported volume, compared with 2,171 such transactions in 1965, representing 3.1 percent of reported volume. The common way of handling these big blocks on the floor of the exchange has been to break them into smaller orders executed over a period of time. Another method is to assemble matching orders in advance and then "cross" them, executing the purchase or sale at current prices in accordance with prescribed rules; since the broker initially may have obtained the matching orders off the floor, this procedure assumes some of the aspects of a negotiated rather than a pure auction transaction. It is only a step from this to so-called block positioning, in which the broker functions as a principal and actually buys the block from the seller and distributes the securities over a period of time on the floor of the exchange.

When none of these methods appears feasible, the exchange permits certain special procedures. A *secondary distribution* of stock resembles the underwriting of a new issue, the block being handled by a selling group or syndicate off the floor after trading hours, at a price regulated by the exchange. In an *exchange distribution* a member firm accumulates the necessary buy orders and then crosses them on the floor. This is distinguished from an ordinary "cross" because the selling broker may provide extra compensation to his own registered representatives and to other participating firms. A *special offering* is the offering of a block through the facilities of the exchange at a price not in excess of the last sale or the current offer, whichever is lower, but not below the current bid unless special permission is obtained. The terms of the offer are flashed on the tape. The offerer agrees to pay a special commission. A *specialist block purchase* permits the specialist to buy a block outside the regular market procedure, at a price that is somewhat below the current bid.

Trading on the London Stock Exchange is carried on through a unique system of brokers and jobbers. A broker acts as an agent for his customers; a jobber, or dealer, transacts business on the floor of the exchange but does not deal with the public. A customer gives an order to a brokerage house, which relays it to the floor for execution. The receiving broker goes to the area where the security is traded and seeks a jobber stationed in the vicinity who specializes in the particular issue. The jobber serves only in the capacity of a principal, buying and selling for his own account and dealing only with brokers or other jobbers. The broker asks the jobber's current prices without revealing whether he is interested in buying or selling. The broker may seek to narrow the spread between the bid and ask quotations or he may approach another jobber handling the same issue and undertake the same bargaining process. Eventually, when satisfied that he has obtained the best possible price for his client, the broker will complete the bargain.

A broker is compensated by the commission received from the customer. The jobber seeks to maximize his profitable business by adjusting his buying and selling

prices. As the ultimate dealer in the London market, the jobber's activities provide a stabilizing factor, but unlike the specialist on the New York Stock Exchange, the jobber is under no obligation to help support prices. The growing importance of institutional customers has increased the size of transactions in the London market as it has in the U.S., and therefore the jobber has been compelled to risk larger sums. To offset this risk, arrangements for a particularly large order may be negotiated beforehand and the transaction put through the floor as a matter of procedure, with the jobber accepting a minimum "turn." Although the jobbing system provides a continuous market, it does not employ the auction bidding of the New York exchange.

The trading procedures of other major exchanges throughout the world employ the principles that have been described above, although they vary in their application of them. In the exchanges of Paris, Brussels, Copenhagen, Stockholm, and Zürich, some form of auction system is employed: prices are established through bids and offers made on specific securities at particular periods of time. In Tokyo, trading is continuous and orders are consummated through the *saitori* members, who keep order sheets on all transactions. Unlike the specialist on the New York exchange or the jobber in London, however, the *saitori* does not trade for his own account but serves only as an intermediary between regular members. In Amsterdam, trading in active securities is done directly between members during designated trading periods; specialists function as intermediaries between buyers and sellers.

Types of orders. The simplest method of buying stock is through the *market order*. This is an order to buy or sell a stated amount of a security at the most advantageous price obtainable after the order reaches the trading floor. A *limit* (or *limited*) *order* is an order to buy or sell a stated amount of a security when it reaches a specified price or a better one if it is obtainable after the order comes to the trading floor. In the Amsterdam market, the device of the "middle price" is used: an investor who gives a limit order before the opening will have it executed at the day's median level, or at a price that is better than the limit, whichever is found to be more advantageous to the client.

There are other more specialized types of orders. A *stop order* or *stop-loss order* is an order to purchase or sell a security after a designated price is reached or passed, when it then becomes a market order. It differs from the limit order in that it is designed to protect the customer from market reversals; the stop price is not necessarily the price at which the order will be executed, particularly if the market is changing rapidly. This type of order does not lend itself to the London jobbing system.

An important method of trading in stock is through the buying and selling of options. The most common option contracts are puts and calls. A *put* is a contract that permits the holder to deliver to the purchaser a specified number of shares of stock at a fixed price within a designated period of time, say six months; a *call* entitles him to buy shares from the seller within a given period. For example, a person who buys a stock hoping to sell it later at a higher price may also buy a put as a hedge against a fall in price. The put enables him to sell the stock at the price for which he bought it. If the stock rises he need not use the option and loses only the price of its purchase. Option trading is common in Brussels, Paris, London, and the United States.

In the early days of securities trading, stocks and bonds were often bought at private banking houses in the same way that commodities might be purchased over the counter of a general store. This was the origin of the term "over-the-counter." It is used today to mean all securities transactions that are handled outside the exchanges. Increasingly, this market is being subjected to regulation. The extent and nature of the over-the-counter market varies throughout the world. In the United Kingdom, there is no over-the-counter market as such. In the Netherlands, transactions are illegal if they do not involve a member of the Amsterdam exchange or one of its provin-

Unorganized, or over-the-counter, markets

cial branches as an intermediary, except with the permission of the Ministry of Finance. On the Paris bourse, one post is provided for trading in unlisted issues. In Belgium, the stock exchange committee organizes, at least once a month, public sales of stocks that are not officially quoted. In Japan a second security section has been introduced into the major exchanges to provide more effective trading procedures for over-the-counter transactions.

In the United States, the over-the-counter market includes most federal, state, and municipal issues as well as a large variety of corporate stocks and bonds. The National Quotation Bureau, which compiles over-the-counter prices, has furnished quotations on approximately 26,000 over-the-counter stocks. In early 1971, a major development occurred with the introduction of current, computerized quotations on a number of active stocks.

Transactions in the over-the-counter market are executed through a large number of broker-dealers with a complex network of private wires and telephone lines. Their operations are subject to the rules of the National Association of Securities Dealers, Inc., a self-regulating body created in 1939. In 1964 the Congress extended to the larger over-the-counter companies the same requirements as to periodic reporting, proxy solicitation, and insider trading that are applied to dealers in listed stocks.

The over-the-counter market is a negotiated market, as distinguished from the auction markets for listed securities. An investor desiring to trade an over-the-counter security gives his order to a broker functioning as a retailer, who ordinarily shops among various firms to obtain the best possible price.

Because of the difficulty that institutions often experience in disposing of large blocks of listed securities on the exchanges, nonmember firms have set up over-the-counter markets in these issues—principally in those listed on the New York Stock Exchange. Although such transactions are conducted within the framework of the over-the-counter market, their prices are tied to those on the Exchange. Accordingly, this form of trading has been labelled the "third market." In 1970 the dollar volume of third-market transactions was 7.8 percent of total volume on the New York Stock Exchange. There is now also a "fourth market," consisting of direct transactions between investors without an intermediary. This market also had its origins in the need of the institutions to find ways of executing large transactions. Impetus to such direct dealings has been given by the development of computerized systems to bring together large traders.

THE STRUCTURE OF DEMAND FOR SECURITIES

Interest in the ownership of securities has increased greatly in recent decades. Inflationary tendencies have directed attention to stocks as a means of offsetting rising prices. Stock exchanges have cultivated investors through public relations programs. Government regulation has strengthened public confidence in stock trading procedures. Many governments have given support to the capital markets in order to facilitate business financing.

In the United States, according to an estimate of the New York Stock Exchange, 30,850,000 individuals, or about 15 percent of the population, had shares of publicly held corporations during early 1970. This represented an increase of about 10,700,000 since 1965 and of more than 24,000,000 since 1952, when the Exchange made its first detailed census of shareowners. Many others own shares indirectly through institutions that are large holders of stock, such as investment companies and pension funds. It is difficult to obtain strictly comparable figures for other countries. It is estimated, however, that in Japan about 6 percent of the population owned stock in March 1969 and the same proportion in the United Kingdom in 1965. In Europe, where most of the other leading stock exchanges are located, the percentages vary; in recent years the percentage was around 8 in Finland, 4 in France, 6 in Germany, 15 in the Netherlands, and 2.7 in Sweden. A major problem of developing countries has been the absence of investors able and willing to buy shares. Many investors in these countries have preferred to place their funds in tangible assets such as land.

Institutions such as insurance companies, mutual funds, pension funds, foundations, and universities have grown very important in the security markets of the United States. Because of their financial responsibilities to others, these institutions have characteristically followed conservative investment policies stressing the purchase of fixed-income securities. The long-term trend toward inflation, along with mounting stock prices, has led the institutions to look more favourably upon common stocks. At the end of 1969, as a result, the major financial institutions held 25.4 percent of the market value of all the New York Stock Exchange listed stocks, compared with 12.7 percent in 1949. In 1969, institutions also accounted for 61.9 percent of all public dollar volume on the New York Stock Exchange compared with only 39.8 percent in 1960.

Whereas purchases of shares by institutions have been important in the United Kingdom, they have been of minor significance in Belgium, Germany, Norway, and Italy. In Japan on the other hand, the proportion of shares held by individuals in March 1969 was only 41 percent; much of the remainder was held by banks and insurance companies.

Among the most rapidly growing institutions are the mutual funds. Technically, these are known as open-end investment companies because the number of their shares outstanding constantly changes as new shares are sold to investors and old ones redeemed. Indicative of their growth, between 1941 and 1969 the mutual-fund industry in the United States realized \$54,200,000,000 from the sale of its shares and expended \$25,500,000,000 to redeem shares, resulting in a net money flow available for the purchase of securities of \$28,700,000,000 over the 29-year period.

DYNAMICS OF THE SECURITIES MARKETS

Over a long-term period, the movements of stock prices and of general business indicators tend to parallel each other. In studies of business cycles, it has been found that stock prices tend to reach their cyclical peaks and troughs somewhat ahead of general business indicators, and these are therefore generally classified as "leading indicators."

The price of a stock reflects the present value of expected future earnings, and the profits of a firm are strongly influenced by the general level of economic activity. The tendency of stocks to lead business may be attributable to investors' preoccupation with the future. Over the years, the trend of stock prices has been upward; since World War II the upward cycles has tended to be of longer duration, while declines have been relatively shorter. Within the generally expansionary movement, changes in share values of specific companies have been mixed, some showing striking long-term gains while others have suffered losses.

Dramatic events sometimes have a special influence on the psychology of investors, driving stock prices down despite improving business conditions. For example, between the fall of 1940 and the spring of 1942, the period immediately prior to and after the entry of the United States into World War II, U.S. stock prices dropped swiftly despite a continued revival of economic activity. In other cases the reasons for a fall in stock prices are not easy to discover.

Stock prices also experience daily changes of substantial size. Technical market analysts attempt to predict these changes by studying patterns in stock prices. Many theorists, however, claim that in a highly competitive market, prices fluctuate primarily as a result of new information that is not likely to appear in any organized fashion; they maintain that successive price movements are independent of each other and take place in a random fashion.

As investors' expectations change over time, their attitudes toward different types of stock change. Buoyant investors lean toward growth stocks, the value of which is expected to increase rapidly; when uncertainty prevails, the preference is for more conservative issues with stable records of earnings. Within any given period, investors' choices of particular stocks vary with their judgments of the related companies.

Security and Protection Systems

Security and protection systems guard persons and property against a broad range of hazards, including crime; fire and attendant risks, such as explosion; accidents; disasters; espionage; sabotage; subversion; civil disturbances; bombings (both actual and threatened); and, in some systems, attack by external enemies. Most security and protection systems emphasize certain hazards more than others. In a retail store, for example, the principal security concerns are shoplifting and employee dishonesty (e.g., pilferage, embezzlement, and fraud). A typical set of categories to be protected includes the personal safety of people in the organization, such as employees, customers, or residents; tangible property, such as the plant, equipment, finished products, cash, and securities; and intangible property, such as highly classified national security information or "proprietary" information (e.g., trade secrets) of private organizations. An important distinction between a security and protection system and public services such as police and fire departments is that the former employs means that emphasize passive and preventive measures.

Security systems are found in a variety of organizations, such as government agencies, industrial plants, commercial establishments, hotels, apartment buildings, hospitals, and schools and universities. Sufficiently large organizations may have their own proprietary security systems or may purchase security services by contract from specialized security organizations.

History and development of security systems. The origins of security systems are obscure, but techniques for protecting the household, such as the use of locks and barred windows, are very ancient. As civilizations developed, the distinction between passive and active security was recognized, and responsibility for active security measures was vested in police and fire-fighting agencies and similar public services. The inability of community police and fire departments to provide all of the security desired by some individuals and organizations led to supplemental efforts by private groups.

By the middle of the 19th century, private organizations such as those of Philip Sorensen in Sweden and Allan Pinkerton in the United States had begun to build efficient large-scale security services. Pinkerton's organization offered intelligence, counterintelligence, internal security, investigative, and law enforcement services to private business and government. Until the advent of collective bargaining, strikebreaking was a prime concern. The Sorensen organization, in contrast, moved toward a loss control service for industry. It provided personnel trained to deal with losses from crime, fire, accident, flood, and waste, and it established the pattern for security services in the United Kingdom and western Europe.

World Wars I and II, particularly World War II, brought an increased awareness of security systems as a means of protection against military espionage, sabotage, and subversion; such programs in effect became part of a country's national security system. After World War II much of this apparatus was retained as a result of international tensions and defense-production programs and became part of an increasingly professionalized complex of security functions. The post-World War II period also brought an increase in the business espionage hazard and a corresponding emphasis on safeguarding proprietary information. During the 1950s and 1960s, increases in theft brought more emphasis on theft-control programs.

The development and diffusion of security systems and hardware in various parts of the world has been an uneven process. In relatively underdeveloped countries, or the underdeveloped parts of recently industrializing countries, security technology generally exists in rudimentary form, such as barred windows, locks, and elementary personnel security measures. In many such regions, however, facilities of large international corporations and sensitive government installations employ sophisticated equipment and techniques purchased from abroad or produced indigenously as part of a national defense effort. Though little public information is available concerning security systems in China, the Soviet Union, and other Communist countries, key defense, atomic, and space-exploration facilities are known to be protected by sophisticated security systems. These probably have rigorous personnel security criteria, with more limited consideration for due process, privacy, and freedoms of speech, press, and assembly than in countries subscribing to Western democratic values.

Security systems are carried to new areas by the proprietary security organizations of international corporations; international defense agreements whereby the signatory countries and companies engaged in production of military items agree to abide by specified security standards; the international growth of the larger contract security agencies, particularly those with headquarters in the United States, United Kingdom, and Sweden, as they acquire or organize foreign affiliates; organization in the less developed countries of indigenous contract security companies that borrow and import security systems through various channels; and international security conferences that attract professionals in the field from all over the world.

TYPES OF SECURITY SYSTEMS

Security systems can be classified by type of production enterprise—e.g., industrial, retail (commercial), governmental, government contractor, hospital; by type of organization—contract security or proprietary; by type of security process—e.g., personnel or physical security; by

Security in the Communist countries

type of security function or emphasis—for example, plant protection (variously defined), theft control, fire protection, accident prevention, protection of sensitive (national security or business proprietary) information. Some of these categories overlap. Terminologies are not consistent.

Security for small businesses constitutes a special situation. Because small firms cannot afford specialized proprietary security staffs, measures must be incorporated into regular routines and staff training or be purchased from outside organizations. Theft, both internal and external, is a prime concern.

Residential security constitutes another special category. Sizable housing or apartment complexes, especially if under one management, can employ sophisticated security measures, including, for example, closed-circuit television monitoring of elevators and hallways, and trained security guards. Relatively simple equipment for houses or small apartment buildings, such as exterior lighting and alarms, is increasingly used. Some neighbourhoods of large cities cooperatively employ patrol services or organize resident volunteer patrols.

Physical security. Some of the most effective advances in security technologies during the past few decades have been in the realm of physical security—*i.e.*, protection by tangible means. Physical security has two main components: building architecture and appurtenances, and equipment and devices.

A building can be designed for security, for example, by such means as planning and limiting the number and location of entrances and by careful attention to exits, traffic patterns, and loading docks.

Equipment and devices may be classified in various categories depending on the criteria used. If the criterion is purpose, some of the principal categories are record containers, including safes and files; communications, such as two-way radios and scrambler telephones; identification, including badges and automatic access-control systems requiring the use of a code; investigation and detection (*e.g.*, lie detectors) and intrusion-detection devices, such as photoelectric cells and ultrasonic-wave-propagating equipment; observation and surveillance including listening and recording devices, cameras, closed-circuit television, and one-way mirrors; countermeasures for observation and surveillance, such as equipment designed to detect electronic surveillance devices; and fire protection.

A classification system based on process results in another set of categories. Examples include perimeter barriers (fences, walls) and locks to prevent or control access; and lighting systems to aid surveillance and to deter illegal entry.

For reasons of economy, security-equipment systems frequently include, or are operated in conjunction with, production-process-control systems—for example, shutdown controls and gauges to measure heat and pressure.

Research and development "breakthroughs" in security equipment are numerous. Some of the more noteworthy examples include sensor devices that report unauthorized removal of items; personal-identification and access-control systems that directly "read" unique personal characteristics such as voice quality and fingerprints; surveillance devices, such as closed-circuit television, that can scan premises at night (see illustration); and devices that permit surveillance at considerable distances, making entry to the premises unnecessary.

Security-equipment technology faces a number of problems, one of the more important being false alarms in intrusion-detection systems. Some of these devices are so sensitive that a piece of wastepaper blown into a protected area at night will trigger an alarm. In consequence, police in some jurisdictions have refused direct connections of alarm devices to the departments or have curtailed police responses. Another problem involves equipment inadequately tested, installed, or maintained. Finally, potential purchasers need careful, objective evaluation of the many devices on the market. (For more information on surveillance and intrusion detection systems, see **POLICE TECHNOLOGY**.)

Security guards at a closed-circuit television console.

Personnel-administration technology. An important component of security programs consists of measures designed to recruit and effectively use trustworthy personnel. "Personnel security" is a term frequently used to include measures designed to select only those people for whom there is a good prognosis for trustworthiness, on the premise that losses from employee untrustworthiness are more frequent and usually larger than losses from outside the system (*e.g.*, burglary, robbery, shoplifting, espionage) and that one of the best predictors of future behaviour is past behaviour.

Common synonyms are "screening" and (in Britain) "vetting." The most common technique is the background investigation, which involves obtaining all relevant available data about a person's past education, employment, and personal behaviour and making judgments concerning the individual's likely future loyalty and honesty. Thus, the dossier and computerized national data banks exemplify a response by a society in which great geographic mobility necessitates record keeping as a basis for judgments. Another technique is the polygraph, or lie detector, examination. Research has also been directed to the possible capabilities and limitations of pencil-and-paper psychological tests and stress interviews. In addition to selection techniques there are other measures designed to keep personnel trustworthy after they have been brought into the system—for example, employee indoctrination programs and vulnerability testing (discussed more fully below).

These methods are powerful tools for the attainment of security goals because screening out bad risks can do much to determine the difference between effective and ineffective security systems. Such methods, however, if used in clumsy or unsophisticated fashion, can result in a repressive social climate. Even if administered selectively and knowledgeably, they raise important questions in a democratic system, such as the possibility of unwarranted invasions of privacy, due process, and an inhibiting effect on the exercise of liberties of expression. Therefore in most countries such methods are controversial.

Systems and procedures constitute another area of the personnel-administration approach to security. It is possible to devise work methods and management controls in such a way that security is one of the values sought along with maximizing productivity and minimizing cost. Examples include the use of cash registers and other automated record-keeping systems; forms and reports periodically checked against physical inventories; and the principle of dual responsibility, whereby work is so subdivided that the work of one employee checks the accuracy of the work of another.

Because control systems are not self-administering, they must be periodically tested and policed. A typical procedure is the vulnerability test or "created-error" check, in which an error or breach, such as an erroneous invoice, is deliberately planted in the system to see if it is detected and reported. Undercover investigators, such as hired "shoppers" who check on the honesty of sales personnel, also play a role in monitoring the operation of control systems.

Residential security

Employee screening

Vulnerability test

Guard force training, supervision, and motivation are other important aspects of the personnel-administration approach to security. Much of the effectiveness of an organization's security posture depends on the effectiveness of its guards and watchmen; yet such positions are not highly paid, and they may involve special problems such as monotony, absenteeism, and the temptation to ignore, or be in collusion with, wrongdoers. Thus a considerable premium is placed on the knowledgeability with which standard personnel-administration measures are adapted and applied to those people in an organization with such responsibilities.

Use of operational personnel to attain security objectives is another important approach to security. Examples include engineers, production workers, and clerical staff applying government security regulations for the safeguarding of classified information, and sales people cooperating with security staff in the detection of shoplifters. The cooperation of operational personnel to attain security objectives along with production objectives demands an interplay between knowledgeable training and communication programs, supervision, employee motivation, and management example.

The personnel relations approach implicit in much of the above recognizes that the attitudes of rank-and-file employees and the social climate they create can either be conducive to security or can be its greatest enemy. If security programs are to be successful they must, therefore, be carried out in a context of considerable understanding and with the cooperation of virtually the entire work force. The security program is apt to be only as good as the overall pattern and climate of social relations and loyalties of the workers and executives of all ranks within an organization.

TRENDS IN THE SECURITY INDUSTRY

The evolution of security systems in industrialized countries shows trends that are important for an understanding of the entire field. The following generalizations are based primarily on information concerning the United States, with some limited comparable information from the United Kingdom. Developments in other industrialized or industrializing countries tend to follow in somewhat similar patterns; allowances must be made, however, for variations among countries in cultural and business habits, as well as for the unevenness in the pattern of diffusion discussed above.

Since the 1960s crime-related security systems have grown especially rapidly in most countries. Among contributing factors have been the increase in the number of security-sensitive businesses; the development of new security functions, such as protection of proprietary information; increasing computerization of sensitive information subject to unique vulnerabilities; improved reporting of crime and the wider awareness of crime that follows; the need for security of enlarged or new governmental programs (e.g., defense, atomic research, and space exploration); the need in many countries for security against violent demonstrations, bombings, hijackings, and other events; and simply the growing availability of security equipment and knowledge.

Security systems have become increasingly automated, particularly with respect to sensing and communicating hazards and vulnerabilities and, to a lesser but still considerable extent, with respect to response and action. This situation is true in both crime-related applications, such as intrusion-detection devices, and fire-protection alarm and response (extinguishing) systems. Advances in miniaturization and electronics are reflected in security equipment that is smaller, more reliable, and more easily installed and maintained.

Professional security managers increasingly tend to take a "systems approach," in which building architecture, equipment, and personnel systems are consciously and explicitly related in order to maximize security and to minimize costs.

Although many security systems are maintained in private or semipublic institutions, there is some tendency by security administrators to try to achieve better relation-

ships between nongovernmental security managements and governmental police and other agencies in several important ways. Both sets of managers are becoming increasingly aware that well-conceived security programs have important preventive and deterrent effects in law enforcement and crime prevention, an assumption long accepted in the fire-protection and safety fields. This perception results in a tendency, observable in the developed countries, for government to set crime-related security standards that nongovernment enterprises must meet as a condition for action by government, such as a business license, police response to alarms, or government insurance. Standards set by insurance companies with premium discounts as the incentive have somewhat the same effect. There is also an observable trend toward government regulation of nongovernmental security managements. A related phenomenon is reflected in efforts at self-regulation, with contract security organizations in the United Kingdom a prime example.

Despite the conscious search for better articulation of governmental and nongovernmental security programs, many nongovernmental enterprises still operate essentially private criminal justice systems in which offenders, especially those charged with the less dramatic forms of theft, such as pilferage, shoplifting, and embezzlement, are apprehended and adjudicated by confession and discharge without any report having been made to the public authorities. In such instances the criterion for disposition is usually the interest of the organization, as that is perceived by the organization itself, rather than the welfare of the individual or the community.

Sedative-Hypnotic Drugs

Sedative-hypnotic drugs act to reduce tension or to induce sleep, depending upon the dosage used. They belong to a wide spectrum of drugs that depress the central nervous system. Sedative-hypnotic drugs may exert a sedative (quieting or calming) effect in small doses and a hypnotic (sleep-inducing) effect in large doses. When sedative-hypnotic drugs are used in full dosage at the end of the day to produce sleep, the effect is hypnotic; when they are used in moderate dosage throughout the day to overcome anxiety or nervousness, the effect is sedative (an effect that also may enable a patient to sleep better). The barbiturates and the minor tranquilizers are the most widely used sedative-hypnotic drugs; other drugs with sedative-hypnotic effects include chloral hydrate, paraldehyde, and bromide compounds.

General
properties

The degree to which sedative-hypnotic drugs relieve anxiety, induce sleep, or elicit other depressive effects (*e.g.*, anticonvulsive action) varies from one drug to another, as do the effective dose, the distribution in the body, the route of metabolic degradation, and the elimination rate. In addition, the chemical nature of a drug does not necessarily govern its pharmacological effects. Sedative-hypnotic drugs have properties in common with other depressive drugs; *e.g.*, narcotic analgesics, such as morphine, and major tranquilizers, such as chlorpromazine, both have calming effects, as do moderate doses of sedative-hypnotic drugs; and anesthetics produce unconsciousness, as do sedative-hypnotic drugs in excessively high doses. Detailed descriptions of these drugs are found in NARCOTIC; TRANQUILLIZER; and ANESTHETIC.

Historical background. For centuries opium and alcohol were the only drugs available with sedative-hypnotic effects. Chloral hydrate, a chlorinated derivative of ethyl alcohol, was introduced in 1869 as the first synthetic sedative-hypnotic drug, and its widespread usage within a few years stimulated further development of drug preparations with similar action. Before 1900, paraldehyde, amylene hydrate, and sulfonmethane had been introduced, and, in 1903, barbital was synthesized. Phenobarbital became available in 1912 and was followed, during the next 20 years, by a long series of other barbiturates. In the mid-1950s new types of sedative-hypnotic drugs, different in chemical structure from the barbiturates, were synthesized. These anti-anxiety drugs, called minor tranquilizers (*e.g.*, meprobamate, chlordiazepoxide), began to replace many of the drugs then used to treat anxiety. By the 1970s, 50 to 100 different drugs with sedative-hypnotic effects had become available throughout the world.

The biological disposition of sedative-hypnotic drugs. Metabolism and excretion. Sedative-hypnotic drugs are readily absorbed from the intestinal tract into the bloodstream. With the exception of several barbiturates and a group of minor tranquilizers (the benzodiazepines), the drugs become evenly distributed throughout the body, so that their concentration in the blood equals that in other body tissues and organs. Benzodiazepines, on the other hand, are bound to specific tissues; *e.g.*, kidney, liver, and brain. After absorption from the intestinal tract, sedative-hypnotic drugs may undergo chemical transformations—mainly in the liver—into metabolic products called metabolites. Either the unchanged drugs or their metabolites are excreted in the urine.

Half-life
as a
measure of
elimination
rate

With the exception of ethyl alcohol, for any quantity of a drug a constant percentage is eliminated from the body over a given time interval. The rate of elimination is measured in terms of the half-life of a drug, defined as the amount of time required to eliminate half of it from the body. Values for the half-life vary considerably among the sedative-hypnotic drugs. Phenobarbital and barbital, for example, have a half-life of about 48 hours and 24 hours, respectively, and are commonly known as long-acting barbiturates. Amobarbital and butabarbital, each with a half-life of about 12 hours, are known as medium-to short-acting barbiturates, as is pentobarbital (half-life five to six hours).

Two minor tranquilizers, meprobamate and tybamate, as well as chloral hydrate and glutethimide, each have a

half-life of from four to eight hours. Hexobarbital is eliminated at an even faster rate and is called a barbiturate of ultra-short action. The half-life of the benzodiazepine tranquilizers, on the other hand, is relatively long; *e.g.*, several days for diazepam.

The duration of action of a barbiturate is associated with its structure insofar as structural changes—for example, the substitution of sulfur for oxygen at a specific position on the molecule—influences lipid (fat) solubility; *i.e.*, an increase in lipid solubility is associated with a decrease in the duration of action, with increases in the onset of activity and metabolic degradation and, sometimes, with an increase in hypnotic potency.

Effect on the nervous system. Although the actions of sedative-hypnotic drugs on isolated nerve cells have been studied, the actual mechanism of action has not yet been established with certainty. Sedative-hypnotic drugs depress metabolic reactions that are important for normal function of nerve cells. Other substances, however, induce the same metabolic effects. Sedative-hypnotic drugs also delay the transmission of nerve impulses through long sequences of nerve cells.

Sedative-hypnotic drugs probably induce sleep by acting on brain centres that regulate normal sleep; in this sense, sleep is defined as a state of unconsciousness that, in contrast to coma or anesthesia, can be interrupted and reversed easily and rapidly to normal wakefulness. Proper doses of these drugs facilitate the onset and maintenance of normal sleep; the wavelike pattern in the electric potential from the surface of the brain reveals, however, a reduced amount of lighter sleep, which is characterized by frequent body shifts and also by rapid eye movements (hence, the name REM sleep). The significance of such a change is not yet clear; this drug-induced sleep cannot be distinguished from regular sleep in any other way than by the observation of brain-wave patterns. After the effect of the drugs has passed, later brain-wave patterns show that REM sleep continues for a longer period than normal. The hypnotic effect of a sedative-hypnotic drug is supported by the sleep rhythm; *i.e.*, a dose that induces sleep late in the evening may not do so in the morning.

The sedative-hypnotic drugs may cause euphoria—an artificially induced feeling of intense well-being—in 3 to 10 percent of the persons who take them; development of a euphoric state varies with the drug, the dosage, and the patient. The barbiturates, especially pentobarbital, are most likely to cause euphoria, but nonbarbiturates, such as chloral hydrate, also may induce it. Euphoria may lead to drug addiction in susceptible individuals. Most persons, however, feel only drowsiness after taking a prescribed dose of a sedative-hypnotic drug.

Sedative-hypnotic drugs exert various depressant effects on the body, depending on the dosage. A dose in excess of that needed as a sedative or a hypnotic, for example, causes an increase in reaction time and an impairment of muscular coordination similar to that observed after excessive consumption of alcohol. Although certain sedative-hypnotic drugs inhibit convulsions, they usually are effective only in the large doses that produce a state of unconsciousness; a few, especially phenobarbital, are effective in small doses.

The level of consciousness may be depressed by sedative-hypnotic drugs. Doses several times greater than those necessary to induce normal sleep cause a drowsiness that is difficult to overcome; higher dosage induces a state of anesthesia, which may end with a complete coma (state of deep unconsciousness). Loss of consciousness is caused by inhibition of the transmission of nerve impulses in a region of the midbrain called the ascending reticular formation, which receives sensory impulses and transforms them into general impulses that are relayed throughout the anterior brain region, where voluntary movements are controlled and mental actions coordinated. It has not yet been established with certainty, however, that the induction of normal sleep results in part from a mild inhibition of the function of the ascending reticular formation. Deep anesthesia results from the loss of function of a number of cerebral centres.

Depressant
effects

A very large dose of a sedative-hypnotic drug may cause the respiratory centre in the brain to cease functioning, and death may occur within a few hours. In some cases, a coma may be induced without affecting respiration, and the patient may remain unconscious for several days before dying—usually either from pneumonia or impairment of a brain centre that controls the cardiovascular system.

Uses and abuses of sedative-hypnotic drugs. *Sleeplessness and anxiety.* Sedative-hypnotic drugs, including the minor tranquilizers, are used extensively. These drugs compete with antibiotics in numbers of prescriptions per year. The principal medical indications for prescribing such drugs are sleeplessness and anxiety; they usually are given to surgical patients on the night preceding surgery. Normal individuals also may have periods of sleeplessness stemming from a variety of causes—unfamiliar surroundings, sustained mental activity, excitement—and a suitable sedative-hypnotic drug is useful in such circumstances if sleep cannot be induced by other means. During acute illnesses sedative-hypnotic drugs are administered to give patients a calm sleep, but such drugs cannot eliminate pain. Insomnia, restlessness, and excitation in old people may be alleviated by periodic use of certain sedative-hypnotic drugs, chosen according to the types of sleeplessness; inability to fall asleep calls for a short-acting, rapidly eliminated barbiturate such as pentobarbital, but wakefulness during the night requires a longer acting drug.

Sedative-hypnotic drugs also are commonly prescribed as a supporting, or the sole, treatment for mild anxiety neuroses. They are helpful in overcoming sleeplessness caused by anxiety about real or imaginary worries, but their effect is symptomatic only; *i.e.*, they can relieve disturbing mental manifestations but have no lasting effect on eliminating the causes of severe neuroses. To avoid misuse or addiction, a person should not use these drugs continuously over long periods of time and should shun self-medication.

Because of their anticonvulsive effect, some sedative-hypnotic drugs are administered to treat convulsions that may result from drug overdose or from epilepsy, a disease of the nervous system. Phenobarbital was widely used in the treatment of epilepsy until it was replaced by other drugs with fewer side effects. Some short-acting sedative-hypnotic drugs, especially the thiobarbiturates, are used before surgery, either alone or in combination with other anesthetics, to produce anesthesia.

Sedative-hypnotic drugs cannot cure true psychotic states such as schizophrenia and delusions. In large doses, however, they are effective in treating the withdrawal symptoms and delirium tremens typical of alcoholism and in treating the psychotic state provoked by hallucinogens such as LSD (lysergic acid diethylamide).

In recommended doses, sedative-hypnotic drugs produce few side effects. Signs of overdose, such as lack of muscular coordination, may occur in a few hypersensitive individuals who take a normal dose. Other individuals, especially elderly ones, may become excited instead of calmed after taking a normal dose. Some of these drugs, especially the long-acting ones, may cause drowsiness or slight headache (barbiturate hangover) the morning following their use. Allergic reactions, such as skin rashes, sometimes occur; persons who develop an allergy for one type of drug, however, usually are unaffected by a different type.

Intoxication and addiction. A chronic intoxication caused by sedative-hypnotic drugs, especially the barbiturates, is relatively common among persons who continue to take a drug after the problem for which it was prescribed no longer exists. When such individuals develop a requirement for the medication and continue to use it, usually in increasing doses, they become addicts. Irrespective of the specific sedative-hypnotic drug, symptoms of chronic intake of large doses are similar. A tolerance develops; *i.e.*, increasingly large doses, two or three times the normal amount, become necessary to obtain a desired effect. If use of the drug then is stopped abruptly, a withdrawal syndrome, consisting of increased sensitivi-

ty of the central nervous system, develops. Changes occur in brain-wave patterns, which become similar to those of epileptics, and, in many instances, seizures occur. A characteristic delirium tremens may develop during chronic barbiturate intoxication, which is characterized by drowsiness accompanied, paradoxically, by sleeplessness. In some cases the drowsiness may change to a general restlessness.

In chronic intoxication from a sedative-hypnotic drug, psychotic states accompanied by displays of aggression, delusions, and hallucinations may occur. Damage to the peripheral organs, such as the liver and the kidneys, is not a sign, but loss of appetite and resultant loss of body weight are common. The treatment for chronic drug intoxication consists of a stepwise discontinuation of the drug. Suitable psychotherapy may be necessary to avoid relapses into drug use after detoxification.

Addiction to sedative-hypnotic drugs may occur among individuals who seek a euphoric effect from the drugs similar to that resulting from excessive use of alcohol; alcoholics sometimes use sedative-hypnotic drugs alone or in combination with alcohol. Addiction to drugs such as barbiturates rarely occurs from use of the sedative-hypnotic drugs alone; more often, combinations of barbiturates with amphetamine or a similar stimulant drug are the cause. The euphoric effects of stimulant and barbiturate combine, while the drowsiness caused by the barbiturate is antagonized by the stimulant. Such drug combinations are dangerous and may be fatal (see STIMULANT).

Suicide. Widespread use, comparatively easy access, and painless effects of sedative-hypnotic drugs have made them common methods for suicide in many countries. In Great Britain, for example, several thousand attempted suicides with these drugs are reported each year; and, in a Danish treatment centre serving about 1,500,000 inhabitants, as many as 2,000 cases of sedative-hypnotic poisoning are treated each year. The patients, generally in an unconscious state, are treated to remove the drug from the body, to counteract the depressive effects of the drug, and to prevent a long-lasting coma. Although the unabsorbed drugs once were removed directly from the stomachs of victims, newer and more effective ways have been developed, including the use of artificial kidneys and drugs that increase the rate of urine production. It is possible to increase the elimination rate of a drug fourfold with such procedures (see also DRUG AND DRUG ACTION).

Types of sedative-hypnotic drugs. *Barbiturates.* Barbiturates, used extensively for their hypnotic action, are derivatives of barbituric acid, which is formed from malonic acid and urea. Barbituric acid belongs to a class of organic compounds called diureides and has neither sedative nor hypnotic properties. Barbiturates with sedative-hypnotic action are formed by the substitution of various chemical groups on the barbituric acid molecule. These drugs may be arranged according to their duration of effect. Secobarbital acts rapidly to induce sleep, but its action is not prolonged; it is often administered before surgery when relatively brief sedation is desirable. Pentobarbital acts within about 30 minutes of administration to induce sleep and maintains a state of sleep overnight. Phenobarbital, the slowest acting widely used barbiturate, has the most prolonged effect and is especially valuable as a long-lasting sedative to calm persons in a nervous, jittery state.

Not only do the barbiturates exert sedative and hypnotic effects, but in excessively high dosage all of them are anesthetic and anticonvulsive. In order to produce sedation with barbiturates, a hypnotic dose normally is divided into three or four portions and administered at intervals throughout the day—usually in tablet or capsule form. Barbiturates that exert a sedative-hypnotic effect are sometimes called the true barbiturates to distinguish them from thiobarbiturates (*e.g.*, thiopental), which are used almost exclusively as anesthetics.

Minor tranquilizers. Meprobamate, tybamate, and the benzodiazepines (*e.g.*, chlordiazepoxide, diazepam, and nitrazepam) all are included among minor tranquil-

Treatment
for
chronic
drug
intoxi-
cation

lizers. Their effects are similar, but they vary widely both in chemical structure and in dosage. For instance, the amount of a benzodiazepine required to provide an active dose is 50 to 100 times less than that of either meprobamate or tybamate.

Although the effects of the minor tranquilizers resemble those of other sedative-hypnotic drugs, their mechanism of action may differ. When given to normal persons, minor tranquilizers induce a feeling of indifference to such outer disturbing influences as noise, but any actual superiority of minor tranquilizers in relieving anxiety is difficult to demonstrate. Minor tranquilizers are of some help in inducing normal sleep if sleeplessness is caused by anxiety. The anxiety-relieving effects of the minor tranquilizers generally are more pronounced than are the hypnotic ones; nitrazepam, however, does produce a definite hypnotic effect. Although the minor tranquilizers sometimes induce euphoria, they probably are less likely to do so than are some of the other sedative-hypnotic drugs.

The minor tranquilizers affect muscles and certain reflexes; some are effective in stopping convulsions and may be the preferred drugs in treating convulsions in epileptics. In large doses minor tranquilizers impair muscle coordination, produce drowsiness, and lower comprehension. In toxic doses they have an anesthetic effect, which may result in death from acute respiratory failure or from cardiovascular collapse. The minor tranquilizers probably are less dangerous, however, than most sedative-hypnotic drugs, because much higher doses are required to cause death. Further discussion of these substances may be found under TRANQUILLIZER.

Other drugs with sedative-hypnotic effects. Chloral hydrate, derived from ethyl alcohol, once was widely used. But because it is a gastrointestinal irritant, has a disagreeable taste, and is administered in liquid form (inconvenient to take throughout the day), chloral hydrate is no longer extensively used as a sedative. It is an effective hypnotic drug, however, and rapidly induces long-lasting and satisfactory sleep without causing the hangover effects commonly associated with barbiturates. Other alcohol derivatives with sedative-hypnotic action include amylene hydrate and ethchlorvynol; ethyl alcohol (ethanol) has limited hypnotic action.

Paraldehyde, a liquid polymer of acetaldehyde, is very powerful and quick-acting (10 to 15 minutes). Generally considered an innocuous drug, paraldehyde is used in a wide range of doses. It is sometimes used to treat nonepileptic convulsions, and it often induces sleep in persons suffering pain.

For many years, bromides (e.g., potassium, sodium, and ammonium bromide) were used as sedative-hypnotic drugs. When bromides are ingested, some substitution of chloride with bromide occurs in body fluids. The effects of a bromide depend not on the absolute dose of bromide but on the ratio between chloride and bromide. A calming action occurs with a ratio of one part bromide to four parts chloride. As the bromide content increases, drowsiness occurs; if the bromide concentration exceeds that of chloride, death occurs. Bromides have been replaced by newer and more effective sedative-hypnotic drugs with fewer side effects. Addiction to bromides, called bromism, once was relatively common.

A few drugs with sedative-hypnotic effects, called diphenylmethane derivatives, are related to antihistamines—substances used to treat allergic reactions and cold symptoms. The best known are hydroxyzine, azacyclonol, and an antihistamine called diphenhydramine. The anxiety-relieving effects of these drugs are less pronounced than are those of other sedative-hypnotic drugs. Diphenylmethane derivatives, therefore, often are used for reasons other than inducing sleep; in such cases the induction of sleep may be an undesirable side effect. These drugs differ from others in the sedative-hypnotic group in that they affect the autonomic nervous system, which controls involuntary body functions. When administered in controlled doses, they prevent responses of certain body structures to nerve stimulation. In addition, large doses of the diphenylmethane derivatives do not induce anesthesia

and coma, but instead cause convulsions (see HISTAMINE AND ANTIHISTAMINES).

BIBLIOGRAPHY. This subject is covered mainly in specialized journals. The best general orientation may be obtained by studying the appropriate chapters in major textbooks. Sedimentary Facies

The term facies, as applied to sedimentary rocks, derives from the work of a French-speaking Swiss geologist, Amans Gressly, in the 1830s. Gressly studied the Mesozoic strata in the Jura Mountains and was impressed by the changes in the character of the strata and their contained fossils as individual groups of beds were traced along stream valleys and mountain ridges. Previous workers had emphasized the differences among the kinds of sediments and fossils that appear in vertical succession at right angles to stratification planes. Vertical changes are responses to shifts in the environments at a particular site through spans of time or to variations in the character of material brought to the site and deposited. An abundant vocabulary for designation and description of vertical successions of strata already existed; these are the groups, formations, and members of present usage, which are the units shown on most geologic maps and cross sections. Gressly, however, had no terminology he could apply to the lateral changes observed within sequences of beds of the same age. For this purpose he used the word facies, meaning the "face" or aspect of the beds, which places stress on the differences in aspect encountered in beds of the same age.

Gressly's term was readily applied by European geologists of the 19th century, although both usage and concept evolved in directions away from the original connotation of different but concurrent sedimentary environments. A distinction was drawn, for example, between similar (isopic) facies that recur with the passage of time in an area and differing (heteropic) facies that replace one another laterally in deposits of the same age. There arose a facies law, which essentially states that the facies that are heteropic in an area are inevitably isopic or vertically successive in the same area. This condition is true because sedimentation responds to shifting patterns of coexisting specific environments and sediment sources.

A further outgrowth of the facies concept was the designation of sequences of strata that could be identified as responses to particular environments. These include shallow-water facies, reef facies, and lagoonal facies, among others. Such usage still prevails, and application of the term has been extended to the inferred tectonic (deformational) conditions at the time of accumulation (orogenic [mountain formation] facies, geosynclinal [downward flexure of the Earth's crust] facies, etc.), geographic position (boreal facies, tropical facies, etc.), or relation to mineral products (ore facies, oil-reservoir facies, etc.), among many others. All such terms are valid if they convey a sense of change or of contrast among differing conditions of sedimentary deposition.

Whereas application of the facies concept by European workers has generally stressed interpretation, especially environmental interpretation, of changes in the character of sedimentary rocks from place to place or at successive points in geologic time, the evolution of facies studies has followed a somewhat different course in North America. Two major factors contribute to the difference in ap-

Historical
back-
ground

Classical
versus
operational
concepts

Tranquilizers in anxiety relief

proach: vast areas of the interior of North America, in contrast to the areas of classical study in western Europe, are characterized by successions of layered sedimentary rocks that have suffered but little disturbance or disruption since their deposition; and these strata have been investigated by hundreds of thousands of boreholes drilled in search for minerals, mineral fuels, and water. Subsurface exploration only recently has risen to a comparable scale on other continents; in North America, it has produced an enormous array of data documenting rock type, rock geometry, and fossil content.

In response to these data, North Americans have emphasized facies studies that are primarily descriptive integrations in the form of maps and cross sections. These may assemble observations made at thousands of data points. Environmental interpretations are then derived by comparison and analogy of the synthetic integrative product with modern counterparts documented by ecologic, oceanographic, and related studies of present-day sedimentary environments. Such investigations have made it possible to decipher the evolving paleogeography and thus the geologic history of major parts of North America in great detail. The petroleum industry has made elaborate studies of the sedimentary facies associated with known oil and gas accumulations; the products of these studies are then applied to the exploration for and recognition of analogous facies patterns that are the clues to previously undiscovered oil and gas reserves. Similar methods have long been used as guides to exploration for coal, gypsum, salt, potash, phosphate, and other minerals with a well-defined relationship to sedimentary facies. More recently the approach has been extended to the search for lead, zinc, copper, uranium, and even gold.

In summary, there are at least two current concepts of sedimentary facies: classical and operational. In the classical concept, a sedimentary facies is a summation of the aspects of a sedimentary deposit, observed at a given place, that permits identification of the environment of deposition. Application of the classical concept is a highly developed art that invokes a simultaneous and commonly subjective environmental interpretation of mineralogical, textural, structural, and paleontologic criteria. The methodology of the operational concept, so called because it relies on a number of operations or procedures (some of them commonly employing electronic data processing), passes through stages of data acquisition, storage, retrieval, computation of quantitative expressions of aspect, and display of the variations of several aspects at a large number of observation points in the form of facies maps before environmental and other interpretations are made. The essentials of this operational methodology are described in later paragraphs; the following discussion of some of the principles of facies analysis derives very largely from the findings of the operational concept, combined with the findings of students of present-day depositional environments. See also **SEDIMENTARY ROCKS; MOUNTAIN BUILDING PROCESSES; STRATIGRAPHIC BOUNDARIES; PETROLEUM; and EARTH, GEOLOGICAL HISTORY OF** for some examples of the application of the facies concept.

CONTROLLING FACTORS AND KINDS OF FACIES

The controls that govern the aspects of sedimentary accumulations, their geometric form and dimensions, composition, the properties that make texture or fabric, as well as the properties that make them sources or reservoirs for fossil fuels or other economic products, comprise a complex of factors. The most significant of these are the environment of deposition and the tectonic behaviour of the depositional site, the source of the sediment and the transport medium that carries it, and, finally, the postdepositional changes that affect the accumulation. The conditions under which sediment is deposited are controlled by the complex interaction of material, energy, and boundary-condition factors that combine to exert the most important influence on sedimentary facies. The materials include the sediment made available at the depositional site by transport of pre-existing rock particles or by precipitation from solution, plus the depositional medium in

which the accumulation of sediment takes place. The latter include air, waters of a great range of chemical (and nutritional) compositions, or, much more rarely, ice. Sedimentary aspect responds strongly to the kinetic energy released in the environment by currents and water waves and to the radiant energy of the sun, which, in the form of light and heat, controls the distribution of sediment-contributing organisms. Among boundary conditions, the most significant are those that define the geometrical features of the environment, such as depth of water, shape and extent of a delta, for example, or configuration of the depositional surface.

Although continental environments (lakes, streams, deserts, etc.) are identified with many sedimentary facies, by far the greater volume of ancient sediments observed in the geologic record was deposited in marine environments or in transitional environments at and near the border of a sea. Among the latter are included beaches and barrier bars, lagoons, coastal marshes and swamps, intertidal mud flats, and the complex of subenvironments that constitute delta systems. Shallow subtidal marine facies commonly exhibiting evidences of current and wave action, an oxygenated water mass, and sunlight penetration to the bottom dominate, in combination with transitional facies, the ancient sedimentary rocks that cover great areas of continental interiors and continental shelves. A spectrum of deepwater facies, extending from below the depth of penetration of sunlight and wave energy to abyssal depths of thousands of metres, is encountered on present-day continental slopes and rises and on the ocean floors. The same facies are evident in ancient oceanic and ocean-border sediments uplifted in mountain ranges at continental margins; similar facies are much less common in the records of continental interiors where only the central areas of deeply subsiding, "sediment-starved" basins show evidence of deepwater environments.

Erosion acts to reduce the elevation of high-standing land; sedimentation acts to fill depressions; the common equilibrium surface that both of these processes tend to approach is baselevel, which for present purposes is sea level. Were it not for continued uplift (positive tectonism), high areas would be reduced to baselevel; similarly, in the absence of subsidence (negative tectonism), shallow sedimentary basins on continents and continental margins would fill with thin accumulations of sediment. It is commonplace, however, to observe thick successions of sediment (hundreds of metres to a thousand metres and more thick) all representing transitional or shallow-water facies. Such could not be the case unless tectonic subsidence at the depositional site proceeded at approximately the same rate as sediment accumulation. Indeed, tectonics controls not only the thicknesses of stratigraphic successions but also grossly affects the distribution of environmental facies and their petrology.

Consider a marine basin such as the Gulf of Mexico. If there were no further subsidence of the Gulf, or if subsidence were markedly slower in rate than sedimentation, the deltas and intervening coastal deposits of the Mississippi, Colorado, Rio Grande, and other rivers that bring sediment from the continental interior would extend farther and farther into the Gulf, causing transitional environments to replace shallow-marine environments and continental environments to occupy the former positions of deltas, lagoons, coastal swamps, and beaches. These are the conditions of marine regression; the reverse, caused by an excess of the rate of subsidence over sedimentation, is marine transgression. In each case the subparallel belts of distinct transitional and shallow-marine environments may be gradually shifted distances of kilometres or even tens or hundreds of kilometres seaward or landward. Thus, the sedimentary facies resulting from deposition in these environments, although occupying a narrow zone (a beach, for instance) during an instant of time, may be spread as relatively thin blankets over very large areas. It is clear, then, that the interplay of rates of sediment accumulation and tectonic subsidence determines the length of time that a given environment prevails at a site of deposition, and, as a corollary, the same interrelationship deter-

Tectonics

Transgression and regression of the sea

Sedimentary environments

mines the thickness and other geometric properties of the deposit representing a particular facies. Where equilibrium exists between sediment supply and subsidence, stillstand of environments occurs, and the accumulation of thicknesses of sediments of the same facies that are much greater than normal results.

Many sedimentary particles are chemically or physically unstable in the environments in which they are deposited, and tectonism at the depositional site becomes a factor in the mineralogic or textural character of the eventual deposit. Fine particles of clay or silt, for example, cannot remain long in the presence of the violent turbulent energy of a beach, nor can a feldspar grain long withstand the chemical activity induced in the same environment by alternate exposure to atmosphere and seawater. If the rate of subsidence is sufficiently high, the fine clays and chemically unstable feldspars can be buried rapidly, protected from the physical and chemical kinetics of the beach, and preserved in the rock record as grains in an impure, poorly sorted sandstone. Conversely, if subsidence is slow the beach will be reworked many times over, the clays and feldspar grains removed, and the result will be well-sorted sandstone made up almost entirely of quartz grains.

Terrigenous facies. It is convenient to separate the discussion of terrigenous facies, those sedimentary facies that result from the accumulation of particles eroded from older rocks and transported to the depositional site, from biogenic facies that represent accumulations of whole or fragmented shells and other hard parts of organisms and from chemical facies that represent inorganic precipitation of material from solution. Terrigenous sediments, often called clastic because they are formed from broken fragments of pre-existing rock, appear in many facies controlled by a number of factors other than depositional environment and tectonics.

Source and transport. The sedimentary grains carried to a depositional site reflect the mineralogy of the source area; its topographic relief and climate; and the character of the transporting rivers (or other media), their gradients and lengths, and the chemistry of their waters. A source area may expose a great variety of mineral grains for transport, but, if chemical weathering strongly predominates, only clays, fine quartz grains, and salts in solution will reach a depositional basin.

Postdepositional factors. Terrigenous facies commonly owe their aspect in large part to events and conditions that become effective after the sediment comes to rest on the depositional surface. Here, for example, detritus-feeding organisms, at the sediment-water interface or burrowing within, ingest the sediment, alter it chemically, and destroy the primary lamination, leaving trails, tubes, and castings.

Fine sediments, especially clays, are deposited with volumes of interstitial water as large as 80 percent. The increasing weight of accumulating sediment compresses the mass, squeezes out the water, and causes the clay and other mineral grains to become oriented with their long dimensions parallel to the depositional surface. This process, compaction, significantly reduces the volume of the accumulated sediment and causes large volumes of water to pass upward through the overlying deposits.

A number of other processes, lumped under the heading of diagenesis, affect sediments after deposition and reflect chemical and physical activity created as the sediments adjust to the burial environment and react with the water made available by compaction of underlying layers. Cementation, enlargement of grains, and replacement of metastable minerals by new (authigenic) species in equilibrium with the burial environment are common responses to diagenetic processes.

Biogenic facies. In common with chemical facies but in contrast to the land-derived sediments discussed above, biogenic facies almost exclusively reflect precipitation of mineral matter from the aqueous solutions that constitute the depositional medium. Coal and oil shale represent special and volumetrically trivial cases of biogenic sediments; the overwhelming mass of biogenic sediments in the geologic record consists of carbonates; silica is one to two orders of magnitude less abundant; by far the great

majority of biogenic facies are marine in origin. Within the marine environment, biogenic facies respond to many of the controls exerted on the character and distribution of terrigenous facies, plus a number of other factors.

Geologic age. Biogenic facies are strongly influenced by the stage of evolution of marine organisms at the time of sediment accumulation. Biogenic facies of the Precambrian are completely dominated by algal contributions; increasing numbers of invertebrates acquired hard parts from Cambrian into Ordovician time, and thereafter carbonates reflect the rise (and eventual decline) of successive groups of organisms that attained dominance in marine communities (see FOSSIL RECORD).

Ecology. During any part of the Paleozoic Era and since that time, the organisms capable of contributing hard parts to biogenic sediments have been distributed according to their adaptation to specific environments; the character and distribution of biogenic facies similarly reflects the environment of deposition and the complex interrelationships of organisms in the environment.

Deep-marine bottoms, below the depth of penetration of light (benthos), cannot sustain a rich, bottom-dwelling biota. There, the major contributors to biogenic sediments are floating animals and plants (plankton) living at and near the surface and, on dying, adding their shells and tests to a planktonic facies accumulating on the bottom. Chalk is a common exemplar of this facies. Below depths of approximately 3,500 to 4,000 metres (11,550 to 13,200 feet), calcium carbonate dissolves in modern oceans; and bottoms significantly deeper lack the remains of carbonate hard parts. Instead the shells of silica-precipitating planktonic forms, chiefly radiolaria and diatoms, dominate the sediment that eventually lithifies to form the rock called chert.

The greatest number of carbonates on continents, in exposure or penetrated by the drill, were deposited in shallow-water marine environments. The resulting facies intimately reflect the nature and composition of the organic communities that inhabited the depositional site; this is the benthonic facies. Crinoidal, foraminiferal, and algal facies are examples dominated by a single group of organisms, sometimes by a single species; other facies are obviously the products of highly diverse biotas with many species, especially shelled invertebrates that contribute their hard parts to the accumulation of sediment. Each facies, simple or complex, is a response to a web of environmental factors; because of the detail available for observation, benthonic facies have a very high resolving power in identifying ancient environmental settings among successions of sedimentary rocks.

Benthonic facies may be classified according to the degree of kinetic energy interpreted to have been released at the depositional surface by waves or tidal currents. Low-energy facies are characterized by shells preserved in their growth positions or but little disturbed or fragmented and by a high range of particle sizes, including much fine material within and between biogenic shells. A number of environmental settings can be identified, such as the lagoonal facies that reflect the stresses placed on organic communities by seasonal or cyclical changes in salinity.

Most high-energy facies are marked by disarticulated, fragmented, and abraded hard parts, which commonly are graded according to size in response to wave and current action. Such facies may be spread as blankets by transgressing or regressing environments, or, under conditions of stillstand, relatively thick belts of accumulation may occur, representing the positions of carbonate banks. A special case is created by bottom communities that include sediment-binding or sediment-trapping organisms (calcareous algae and certain sponges, corals, and bryozoa among others). These create the wave-resistant framework of organic reefs that characterize present-day tropical marine environments. Where ancient reefs have been spread as blanket deposits by transgression or regression, the resulting facies is referred to as biostromal; designation as reef (or biohermal) facies is reserved for cases of long-continued stillstand during which thick accumulations form by superimposition of atolls, fringing and barrier reefs, or randomly distributed mounds.

Planktonic
and benthonic
facies

Chemical facies. Facies that represent physicochemical precipitation of sediment from solution without the intervention of biological agencies are termed chemical facies. Most such facies in the geologic record are marine, although the preserved deposits of saline lakes are well known and include a number of economically valuable accumulations.

Calcium carbonate and evaporite facies

The seas are saturated with calcium carbonate. Whenever the solubility of this carbonate is exceeded by removal of dissolved carbon dioxide, precipitation may result, typically as very fine needle-shaped crystals of the mineral aragonite that accumulate on the bottom as a carbonate mud. Where carbonate supersaturation occurs over shallow, wave-agitated bottoms, the product is an oolite facies composed of sand-sized spherical grains, each of which is formed by precipitation of concentric carbonate layers.

Seawater in lagoons or other areas of impeded circulation with the open sea may undergo evaporation at a rate faster than inflow, thus raising the concentration of dissolved salts to the point of precipitation and giving rise to evaporites (*q.v.*) or deposits of the evaporite facies. Precipitation of calcium sulfate (CaSO_4 , gypsum or anhydrite) begins when the concentration is increased fivefold, and the common occurrence of this facies among ancient sediments is testimony to the frequency with which CaSO_4 solubility has been exceeded in the geologic past. A tenfold increase in concentration of seawater leads to precipitation of sodium chloride (NaCl , salt, the mineral halite). NaCl is the most abundant of marine salts, and it is not surprising that it constitutes the greatest volume of evaporite facies. Higher concentrations result in the deposition of potassium and magnesium chlorides and sulfates in various mineralogical combinations. These, the bittern salts, are much less common but are numbered among the most sought-after mineral deposits.

Phosphate and iron facies

Other chemical facies include the greatest resources of phosphates and iron ore. Some phosphate deposits are clearly the results of postdepositional replacement of carbonates, whereas others are primary marine sediments that are thought to represent precipitation from upwelling deep, phosphate-laden waters at the margins of continental shelves. Sedimentary iron ores similarly reflect unusual depositional environments, combining partially isolated basins with, perhaps, a high degree of bacterial activity.

Postdepositional changes. Many of the primary sedimentary materials that constitute biogenic and chemical facies are relatively unstable in postdepositional environments and are grossly affected by diagenetic processes. The mineral aragonite, an important constituent of organic shells and the most common chemically precipitated form of calcium carbonate, is inevitably transformed to calcite. Both calcite and aragonite are unstable in the presence of water containing high concentrations of magnesium, by which they are converted to the double calcium-magnesium carbonate, dolomite (see LIMESTONES AND DOLOMITES). Dolomitization is the result of the reaction of high-magnesium waters on previously deposited limestones. Dolomite facies are widespread, commonly observed, and appear to be the product of percolation of such waters by capillary action or reflux seepage from saline lagoons and by the movement of waters along the groundwater table.

APPLICATIONS OF SEDIMENTARY FACIES

There are as many kinds of sedimentary facies as there are aspects to consider or goals to attain in the analysis of sedimentary rocks. For purposes of simplicity the following discussion is confined to facies defined by the composition of the rocks that they comprise; these are lithologic facies or lithofacies. Figure 1 illustrates the three-dimensional geometry of successive intertonguing rock types (limestone, shale, and sandstone) that results as depositional environments shift about and replace one another through spans of geologic time. The top of the block and the plane passing through the middle of the block (and connecting points *e* and *f*) are time surfaces; that is, each was a surface of deposition at an instant of time, and the intervening sediments were deposited during the same

Figure 1: *Lithosomes, lithotypes, and lithofacies.*

Lithotypes are identified by the boundary a-b. The clastic unit is divided into two lithofacies—one more than half sand and one more than half shale—by the boundaries c-e and d-f (see text).

From H. Wheeler and V. Mallory, *American Association of Petroleum Geologists Bulletin*, vol. 40, no. 11, pp. 2711-23 (November 1956)

span of time. Some workers refer to the three intertongued masses of rock as facies or lithofacies and would recognize limestone, shale, and sandstone facies within the block. In a more precise terminology each of these is designated a lithosome (literally, a rock body), and the term facies is reserved for a special usage in application of the operational facies concept.

Operational facies mapping. The four columns of Figure 2 show the lithologic aspect of a given unit of strata (such as that between the time surfaces of Figure 1) at points of observation that may be outcrops or boreholes. At each point the lithologic aspect may be expressed, as shown, by the percentages of the component rock types or by ratios among the components. The most commonly employed of the latter are the clastic ratio (the thickness of sandstone and shale divided by the thickness of limestone, dolomite, and other biogenic or chemical sediments) and the sand-shale ratio (the thickness of sandstone divided by the thickness of shale). At points *c* and *d* of Figure 1 the sand-shale ratio is 1 (half sandstone, half shale), and the lithofacies boundary shown connects other points of equal sand-shale ratio, dividing the unit between the two surfaces into two lithofacies, one dominated by sandstone and one by shale.

From W.C. Krumbein and L.L. Sloss, *Stratigraphy and Sedimentation*, 1st ed. (1951); W.H. Freeman and Co.

Figure 2: Lithologic aspect of stratigraphic unit at four separate points of observation (boreholes or surface outcrops). The lithologic aspect at each point is expressed in terms of percentages of rock types and ratios among rock types.

Figure 3 is a facies map of an Early Cretaceous unit in the east Texas area. The points of observation are indicated, and lines connecting points of equal thickness (isopachs) of the unit are shown. Facies boundaries, defined by the ratios shown on the triangular diagram, divide the map area among eight lithofacies. Thus at any position in the large area covered, the thickness and rock character of the rock strata termed the Trinity Group in the south central U.S. can be determined from the map.

Once the raw data on the thicknesses of lithologic components are acquired, computers are capable of reducing these data to the desired percentages or ratios, plotting the figures in map form at each point of observation and

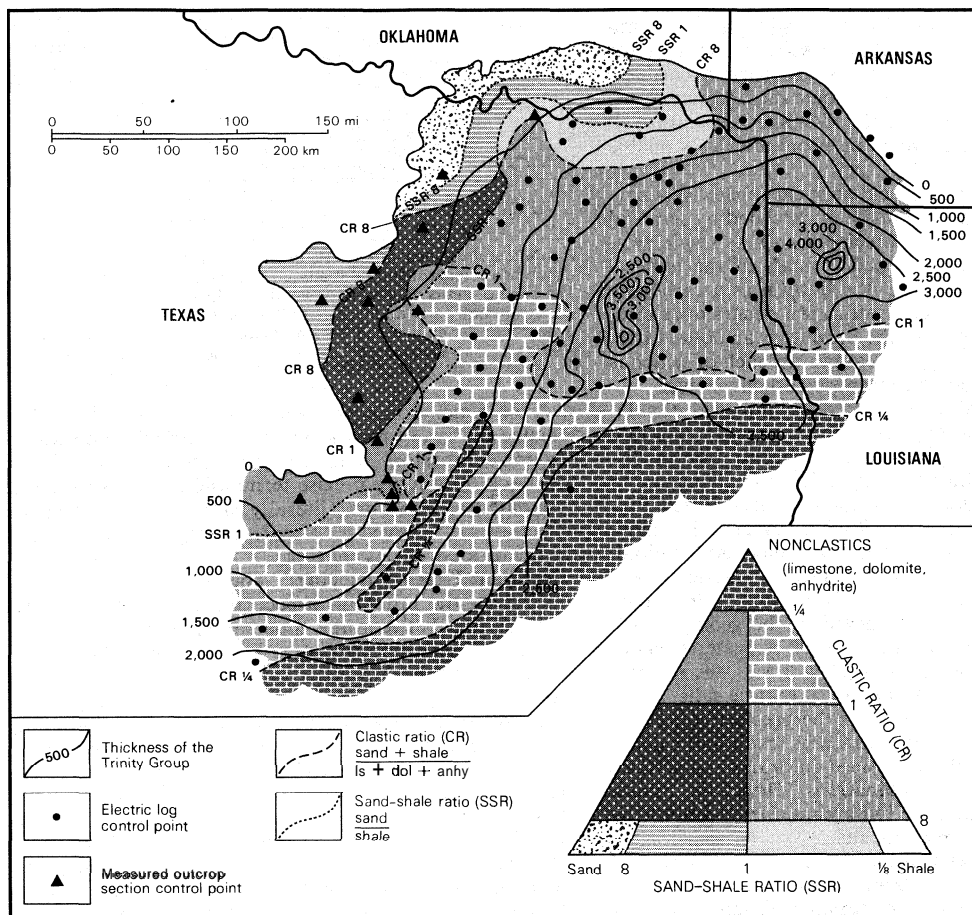

Figure 3: The Cretaceous Trinity Group showing the distribution of sand-shale nonclastic components and thickness.

Adapted from J.M. Forgoison, Jr., "Review and Classification of Quantitative Mapping Techniques," *The American Association of Petroleum Geologists Bulletin*, vol. 44, no. 1, pp. 83-100 (January 1960); The American Association of Petroleum Geologists, Tulsa

drawing the isopach lines and lithofacies boundaries to produce a finished map. Instrumental records of boreholes (electrical, geochemical, acoustic, and other digitized mechanical logs) produced in recent years can be scanned automatically to yield lithologic data suitable as input to the map-making computer program without human intervention beyond identification of the limits of the unit of strata to be mapped. The oil industry, which must cope with tens of thousands of borehole records in the search for new petroleum reserves, has been the leader in research and development of automated approaches to the production of facies maps.

Facies and paleogeography. The reconstruction of ancient lands and seas, more specifically the identification of the character and distribution of ancient environments, is enormously enhanced by interpretation of facies maps. Figure 4 is a paleogeographic interpretation of the east Texas area during the Early Cretaceous time of deposition of the Trinity Group. The sand concentrations evident along the northwest margin of the map area of Figure 3 obviously record the shifting positions of beaches. Although erosion has stripped Early Cretaceous sediments from much of Oklahoma and north central Texas, it can be presumed, by analogy with the present Gulf Coast, that the beaches formed barrier islands bounding lagoons and coastal swamps. The shales dominating the Trinity Group in the area around the common corner of Texas, Arkansas, and Louisiana are of the type formed by lithification of prodelta clays. It is probable, therefore, that the progenitor of the Mississippi River produced a large delta some 130,000,000 years ago somewhere to the northeast of the facies map area, quite possibly in central Arkansas. Seaward of the delta clays and sand beaches the sediments become increasingly limy, suggesting approach to the clear, un-muddied waters of the open Early Cretaceous Gulf. The narrow trend of nearly pure limestone sur-

rounded by a mixture of lime and shale is indicative of the position of carbonate shell banks or, possibly, reefs. Trinity Group strata dip south beneath coastal Texas and the Gulf and are too deep to be reached by the drill. The presence of abundant limestone as far Gulf-ward as the limit of observation (the scalloped margin of the patterned area of the facies map), however, shows that a relatively shallow continental shelf, well above the carbonate compensation level, existed at least as far as the present shoreline.

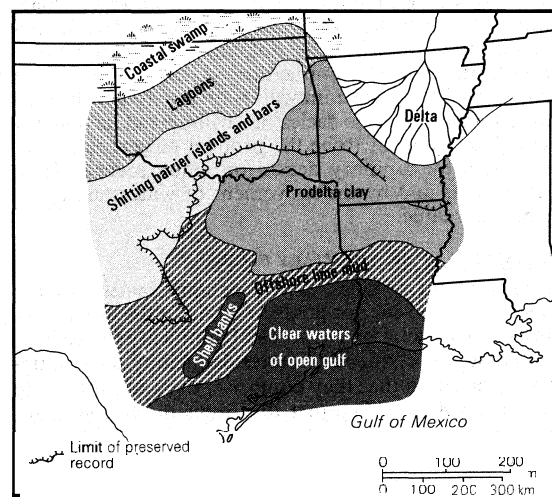

Figure 4: Early Cretaceous paleogeography in the area of deposition of the Trinity Group.

More detailed facies mapping, involving quantified expressions of aspects that relate directly to specific envi-

ronmental settings, provides the basis for much more sophisticated paleogeographic reconstruction than is possible with the relatively simple example illustrated here. The fossil assemblages associated with the sediments, analyzed in terms of their water depth, temperature, salinity, and other requirements, lead to detailed biofacies maps of readily interpreted environmental significance. Primary structures of sedimentary rocks (cross-bedding ripple mark, sole marking, etc.) commonly reveal the transport directions of sediments brought to the site of deposition; vector-property maps displaying directional data are used in reconstructing ancient river systems, longshore current orientations, the slope direction of sea floors, and other paleogeographic elements. All of these approaches, and more, find employment in paleogeographic studies initiated for the practical purposes of mineral exploration as well as for consideration of broader problems, such as the ancient motions of sea floors and continents.

FURTHER QUANTITATIVE TREATMENT OF SEDIMENTARY FACIES

The vast array of numerical data that is produced during routine operational facies mapping has allowed quantitative treatment of facies variability. The two examples below are among many that could be cited.

Trend-surface analysis. Trend analysis is a least-squares surface-fitting method by which systematic regional facies patterns are represented by low-order terms in the surface-fitting function, and local facies effects are represented by higher-order terms. The common problem is one of distinguishing local phenomena—a sandbar, for example—from regional effects created, say, by approach to a terrigenous sediment source such as an emergent landmass. If the goal of the study is location of the landmass, then it is necessary to remove the obscuring effects of local sandbars; conversely, if the problem is one of identifying sandbars, then it is the regional increase in sand toward the sediment source that clouds the picture. Least-squares mathematical surfaces are fitted to the facies data and "stripped" off to reveal underlying features that would be hidden on maps that combine both local and regional effects. Computer technology is available to perform the mathematical manipulations and produce the resulting maps.

Analysis of cyclical successions. It is a well-established characteristic of successions of sedimentary rocks that certain types of strata follow one another in a systematic, repetitive order, as in coal cyclothems (*q.v.*; cyclic, or repetitive, sequences of strata). The vertical cyclicity results from the natural systematic lateral arrangement of sedimentary environments and from the shift of these environments as the succession of strata is accumulated. It is predictable in a transgressive succession that barrier beach sands will overlie lagoonal muds and that the sands, in turn, may be followed by offshore sediments. The degree of predictability, however, is governed by both systematic and random factors. If, in a sequence of transgressive cycles, there is a progressive decrease in the supply of quartz grains, then there will be a systematic change in the kind of sediment above the lagoonal muds until the position of the beach sands is occupied, perhaps, by oolite grains or shell fragments.

Nonsystematic variations, such as responses to minor regressions or to the temporary influx of a new type of sediment, commonly referred to as "noise," are more difficult to assess. One approach is to express the likelihood that one type of rock follows another in terms of mathematical probabilities. Long study of cyclothems, for example, shows that there is a greater probability that a coal bed will be succeeded by a limestone than by a sandstone. Tabulation of the relative probabilities of each rock type in a cyclical succession forms the so-called Markov chain that postulates, within the limits of the determined probabilities, that the occurrence of each sediment type is controlled by the underlying sediment. In other words, a cyclothem limestone may be thought of as having a short-term, one-step "memory" of the underlying coal; the probability of limestone deposition is thus conditioned by the coal formed in the immediately pre-

ceding span of time. Through the use of the computer and Markovian theory, it is possible to produce detailed simulations of successions of strata; such simulated successions find application to prediction in advance of exploratory drilling and to interpretation of data derived from geophysical surveys.

Sedimentary Rocks

Sediments are deposits of solid material that accumulate upon the Earth's surface under the influence of various mediums (air, water, ice, gravity) and under the normal conditions of temperature and pressure that exist at the surface. Sedimentary rocks are the lithified equivalents of sediments, whether derived from previously formed rocks and minerals or from chemical and biochemical deposition. The processes of physical and chemical weathering prepare loose detrital sediment such as clay, silt, sand, and gravel for the processes of transportation, by gravity, mudflows, running water, glaciers, and wind action. These particles are transported to depositional sites—deserts, alluvial fans, submarine shelves and slopes, and deltas in lakes and oceans, among others. Upon reaching a site of deposition, the sediment is converted to sedimentary rocks by cementation, compaction, and induration. Hence, there is both a detrital fraction (the transported sediment) and a chemical fraction (various chemical precipitates) that make up the final sedimentary rock.

Agents of transportation may sort out discrete particles, such as gravel to form conglomerate, sand to form sandstone, or silt and clay to form siltstone and claystone, which are called shale. Chemicals in solution in water bodies are precipitated or flocculated out to form certain types of limestone, dolostone, gypstone, rock salt, and other chemical sediments. Detrital particles of limestone may accumulate mechanically like any other sand, eventually forming limesand. Sedimentary rocks form only about 5 percent by volume of all rocks of the Earth's crust. The area of outcrop and exposure of sedimentary rocks, however, is about 75 percent of the total land area. The percentage probably is greater for ocean basins, though volcanic material is also being added to the daily increment of accumulation upon ocean floors. Sediments and sedimentary rocks therefore form only a thin, surficial veneer upon the Earth. Geologists have measured the thicknesses of outcropping sedimentary rocks and have calculated that the average thickness is about 2.4 kilometres (1.5 miles); thicknesses range from eight to 16 kilometres (five to ten miles) when a composite rock section is considered.

Sedimentary rocks contain the story of past periods of geologic time, because they have accumulated in some locality during each day of the Earth's past history. Billions of years ago the Earth was formed from the dust of a cosmic cloud. It then melted completely as a result of radioactive heating up and subsequently cooled some 4,500,000,000 to 5,000,000,000 years ago, the beginning of geologic time. Shortly thereafter the atmosphere and hydrosphere were formed from cooling and condensing gases and liquids derived from within the Earth. Weather-

cal succe-
ssions of
strata

ing and running water were, therefore, among the first geological agents at work; sediment was transported from higher areas to the ocean basins, which then were gradually filling with water. Some gravelly sediment, now indurated into a conglomerate more than 3,500,000,000 years old, is known from Rhodesia, for example. During all of geologic time, sediment has formed at various places on Earth and in the oceans, ultimately to become compacted and cemented into sedimentary rocks. The process continues today, and during an average 24-hour period, for example, approximately 2,000,000 tons of sediment are transported by the Mississippi River past New Orleans, to accumulate in the Mississippi River Delta or in the Gulf of Mexico. The entire area is very slowly subsiding—i.e., the crust of the Earth beneath the northern Gulf of Mexico is sagging—and the rate of sediment income just about balances the rate of subsidence. This is, therefore, a modern depositional site, and the sediment that accumulates today will eventually be transformed into sedimentary rocks in the future.

When properly understood and interpreted, sedimentary rocks reveal the story of past life groups (fossils) and of the evolutionary advancement from simple to complex organisms in the plant and animal kingdoms. They also provide information on ancient geography, termed paleogeography (q.v.), because a map of the distribution of sediments that formed in shallow oceans will indicate relationships of seas to landmasses in the past. It is also possible to study rock deformation—the various folds or bends in the strata and the faults that displace stratified rocks—and to determine the history of the formation of ancient mountain chains.

It is almost impossible to assess the importance of sedimentary rocks in terms of economics, because these rocks contain essentially the world's entire store of oil and gas, coal, phosphates, salt deposits, groundwater, and other natural resources. Sedimentary rocks are valuable as building stones, trim stone, patio slabs, and the like, and marbles and limestones also are sedimentary in origin. Limestones are used in cement making, in toothpastes and tooth powders, and in paints and chemicals. They serve as flux in steel plants, as crushed rock for highway construction, and for making burnt lime for mortar. Shales of certain types are used in the brick industry and to make clay pipes and similar items, whereas pure quartz sands provide industry with the raw materials for glass-making, including optical glass. Other rock types, such as rock salt, phosphate rock, and gypsum (gypstone), are of tremendous value in man's economy, and many industrial minerals and metal ores are also derived from sedimentary rocks.

This article treats the classification and basic properties of sedimentary rocks, sedimentary structures and environments, and the geological distribution of sedimentary rocks. For detailed information on the more important sedimentary rock types, see the separate articles CONGLOMERATES and BRECCIAS; SANDSTONES; GRAYWACKES; SHALES; LIMESTONES and DOLOMITES; EVAPORITES; PHOSPHORITES; DURICRUSTS; and COALS. Stratigraphic aspects of sedimentary rocks are covered in detail in STRATIGRAPHIC BOUNDARIES and SEDIMENTARY FACIES, and additional information on the erosion, transportation, and deposition of sediment in several natural environments is presented in FLUVIAL PROCESSES; GLACIATION, LANDFORMS PRODUCED BY; WEATHERING; EARTH MOVEMENTS ON SLOPES; BEACHES; ALLUVIAL FANS; and JUNGLES AND RAIN FORESTS. See also CLAY MINERALS for coverage of this important sediment type.

CLASSIFICATION SYSTEMS

In general, geologists have attempted to classify sedimentary rocks on a natural basis, but some schemes have genetic implications (i.e., knowledge of origin of a particular rock type is assumed), and many classifications reflect the philosophy, training, and experience of those who propound them. No single scheme to date has found universal acceptance, and discussion here will centre on some proposals.

The early editions of *A Handbook of Rocks*, beginning

in 1896, showed that sedimentary rocks could be classified into clastic, chemical, and organic groups. A major contribution was made by the American geologist A.W. Grabau in 1904 in his *On The Classification of Sedimentary Rocks* and his revisions in 1913 of the monumental work *Principles of Stratigraphy*. Grabau combined textural and compositional terms in classifying and describing sedimentary rocks, and he distinguished between exogenetic and endogenetic types; the former are chiefly mechanical or clastic, having been derived from fragments of older rocks, whereas the latter are the nonclastic rocks and are chemical, organic, or biochemical in origin. His scheme of classifying sedimentary rocks involved the use of such prefixes as hydro- (for water-laid rocks), anemo- (for wind-deposited rocks), auto- (crushed or shattered rocks), and atmo- (rocks formed in *situ*). They were compounded with other terms designating composition and size, including rudaceous (gravelly texture), arenaceous (sandy texture), and lutaceous (silty and clayey texture). Many of Grabau's rock names have gained wide acceptance today, although the spelling has been changed slightly. The names calcirudite, calcarenite, and calcilutite—referring to calcareous conglomerate, sandstone, and shale—are popular, for example, among sedimentary petrologists. The name hydrocalcarenite in Grabau's system refers to a sandstone with discrete calcareous grains that was deposited in water. As another example, an anemosilicarenite is a wind-deposited, siliceous sandstone. The system has been criticized because some names are unwieldy and difficult to pronounce; moreover, rock origin must be known to choose the proper prefix.

The book *Rocks and Rock Minerals* was first published in 1908, and it has enjoyed various revisions. Sedimentary rocks are classified there according to their physical characteristics and composition into detrital and nondetrital rocks (see Table 1).

Table 1: Terms Designating composition and Physical Characteristics	
detrital rocks	nondetrital rocks

Other attempts were made to classify sedimentary rocks, and in 1948 a significant advance occurred. In that year three definitive articles were published in the *Journal of Geology* by the American geologists F.J. Pettijohn, R.R. Shrock, and P.D. Krynine. These classifications may be said to have provided the basis for all modern discussion of the subject. The nomenclature associated with several schemes of classifying clastic and nonclastic rocks will be discussed in the sections immediately following, but a rough division of sedimentary rocks based on chemical composition is shown in Figure 1.

Clastic rocks. An obvious physical feature of many rocks is texture; that is, the size, shape, and arrangement of the constituent grains. Texture may be coarse, medium, fine, or amorphous. When it is fragmental, and discrete grains can be recognized, the rock is a clastic sedimentary rock. Clastic material, for the most part, has been transported to the site of deposition and includes the gravelly sediment that forms conglomerate (if the particles are abraded and somewhat rounded) and breccia (if

Texture as a basis

Early proposals

(rocks with more than 90 percent quartz, approximately). Similarly, arkoses tend to lose their feldspar during weathering and erosion and then pass up the scale of maturity to grade into rocks that are called subarkoses and, again, ultimately into orthoquartzites (see further SANDSTONES).

One sandstone variety that has received much attention but whose precise definition is in question is the orthoquartzite mentioned above. To some this is no more than a handful of loose, essentially pure quartz sand, but most workers would argue that a loosely to moderately cemented quartz sandstone should be called quartzose sandstone. An orthoquartzite is properly defined as a clastic sedimentary rock composed of silica-cemented quartz sand. The cement is commonly deposited in continuity (when viewed through a microscope) with the quartz grains. Relatively pure orthoquartzites (ranging from as little as 80 percent to more than 95 percent quartz by composition) display intragranular fracture, equally across grains and cement. This is a requisite property of orthoquartzite, and quartzose sandstones, by contrast, lack this property.

Important related rock types include feldspathic orthoquartzite (or feldspathic sandstone if not truly an orthoquartzite), which contains a substantial percentage of feldspar of any kind, and protoquartzites, which are similar to orthoquartzites in all attributes but contain as much as 40 percent chlorite, micas, sericite, various other clays, and rock fragments. Such a rock is about midway between subgraywacke and graywacke in textural maturity.

Shale is a fine-textured clastic sedimentary rock with a preponderance of detrital components, having been indurated from silt and clay. Some term shale a siltstone if it has an average grain size between 1/16 and 1/256 millimetre (0.0025 and 0.0002 inch) and claystone if discrete particles are mostly smaller than 1/256 millimetre, which is clay-size detrital material.

Shales are classified as essentially noncarbonate sedimentary rocks; fine and very fine grained carbonate rocks are called calcisiltites, calcilutites, or sometimes fine-grained limestones or dolostones (dolomites). Shales are composed of the clay minerals, mostly silica and silicates, with accessory minerals of other composition. Shales can contain carbonates but not in excess of 50 percent of the bulk of the rock; otherwise, they fall into the limestone or dolostone scheme of classification (see further SHALES).

Nonclastic rocks. Nonclastic sedimentary rocks differ in many respects from their clastic counterparts, and there is no single classification that has been universally accepted. This is a reflection of the great variation in mineral composition, textures, and other properties of these rock types.

Limestones and dolostones make up the bulk among the nonclastic sedimentary rocks. Such rocks as ironstones (limonite, goethite, hematite, siderite, and chamosite), phosphorites (phosphate rock), coal- and oil-bearing rocks, carbonaceous and bituminous shales and limestones, evaporites (rock salt, gypsum, and other salts), chert, opal, and chalcedony occur in much lesser abundance, although locally these noncarbonate (or low-carbonate), nonclastic sedimentary rocks may form thick and widespread deposits. Classification schemes that would incorporate all types of noncarbonate, nonclastic sedimentary rocks have not been set forth, because no triangular or tetrahedral scheme could accommodate them all. Several of the major types of nonclastic rocks are shown in the tetrahedron in Figure 2. The organic corner of the tetrahedron identifies such nonclastic rocks as coal, lignite, and some richly bituminous rocks. Some carbonates and clastic material may be present, but these commonly compose much less than 50 percent of the bulk of such rocks. Coal consists principally of plant material that has been converted to a type of hydrocarbon, but it can pass into a carbonaceous shale, which is a clastic sedimentary rock. Similarly, an oil-rich nonclastic rock can grade into bituminous (petroliferous) shale, sandstone, or limestone. The same kinds of gradational possibilities occur in phosphatic, siliceous, and ferruginous rocks, and the tetrahedron in Figure 2 is designed to

Figure 2: Common noncarbonate, nonclastic sedimentary rocks. C—cherts; CBC—carbonaceous chert; FC—ferruginous chert; PC—phosphatic chert; CCB—cherty carbonaceous rock; CF—cherty ironstone; CP—cherty phosphorite; CB—carbonaceous rock; PH—phosphorite and IR—ironstone.

aid in locating and identifying the more common non-clastic sedimentary rocks.

Limestones are, for the most part, originally deposited carbonate rocks and consist of 50 percent or more of calcite or aragonite (both CaCO_3). Dolostones (dolomites) are mostly secondary deposits or replacements of limestones; that is, the mineral dolomite [$\text{CaMg}(\text{CO}_3)_2$] replaces the calcite of limestones during diagenesis (post-depositional processes). Some very fine textured dolostones do form directly by precipitation from marine and lake brines in restricted environments, however, and these are primary deposits.

Most limestones have a granular texture, and the constituent grains vary from millimicrons (one micron equals .001 millimetre) to visible particles—or even to limestone conglomerates (the calcirudites). The grains may be classified as detrital (fragments of previously formed limestone), skeletal (fragments of fossil carbonate material), pelletal, lumpal, or coated grains. All such grains have been removed and deposited by waves and currents to a final site of deposition. By contrast, carbonate reefs, banks, and similar structures are accumulations of carbonate rock constructed by plants and animals *in situ*. In addition to limestones, there are such chemical and biochemical calcitic rock as tufa, travertine, caliche, calcrete, some tuffaceous limestones, cave deposits (drip-stone), and others of lesser importance.

Certain limestones have been designated micritic by some authorities. Micrite is unconsolidated ooze or lime mud of chemical or mechanical origin, or consolidated equivalent. It is very fine textured and normally occurs as grains that are 0.05 millimetre (0.002 inch) in diameter or smaller. Pellets are grains of micritic material that lack significant internal structure and generally are approximately ovoid in shape. Most pellets in limestone range from silt-size to coarse sand-size (some are slightly larger); these spherical or subspherical to oval bodies are largely fecal in origin, having been excreted by shrimp, worms, snails, and the like. Coated grains include oolites, pisolites, and oncolites; these superficially resemble onions in that they have two or more accretionary rings around a central small nucleus. Oolites are spherical or subspherical accretionary grains generally less than two millimetres (0.08 inch) in diameter; pisolites are similar to oolites and range from two to about ten millimetres (0.4 inch) in diameter; and oncolites are still larger, ranging in diameter to 30 millimetres (1.2 inches), and may be spherical, subspherical, subovate, or biscuit shaped. Like oolites and pisolites, oncolites display an internal structure of concretionary rings and may (like their smaller counterparts) also have a fibro-radial structure. Lumps are composite grains possessing superficial re-entrants and are believed to have formed by a process of aggregation; lumps also may result from disruption of partially indurated lime mud at the site of deposition and incorporation in micritic or other limestone. Such limestones are called lumpal limestones.

Lime-
stones
and
dolostones

Crusts,
soils, and
weathering
products

Not really amenable to classification but of sufficient significance to warrant mention are some sedimentary crusts, soils, and weathering products. Duricrusts (*q.v.*) are peculiar deposits formed on gently sloping erosion surfaces in many parts of the world, consisting of armour-like precipitates that result from upward capillary migration of groundwaters during periods of aridity. Various carbonates are precipitated from these rising groundwaters, and aluminous, ferruginous, and siliceous materials also may form.

Residual soils are the products of weathering formed *in situ*. The character of these deposits results from the interaction of climate, drainage, and type of the parent rock. Regolith is a mantle of loose, incoherent rock material, of any origin or nature, which blankets the parent rock; saprolite is essentially the same; and saprolite is thoroughly decomposed, earthy, but not transported rock. It is a residual clay, silt, or other substance. In the piedmont area of North and South Carolina it commonly is reddish in colour and results from rather thorough decomposition *in situ* of old Paleozoic (225,000,000 to 570,000,000 years old) crystalline rocks. In humid regions the residual materials are enriched in hydroxides of aluminum and ferric iron during processes of weathering, and the end product is called laterite. It also is reddish in colour, and its formation requires high rainfall and high temperatures. Bauxite is a residual clay-size weathering product that is formed *in situ*, consisting largely of hydrated alumina (essentially $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$). The principal ores of aluminum are obtained from bauxite; it is commonly gray to light gray in colour. Scree and talus are angular fragments of rock that occur at the bases of cliffs from which they were derived by weathering and erosion. Paleosols are buried soils, especially those developed during an interglacial episode and buried by later advances of ice. They are "fossil" soils and can occur interlayered in other types of sedimentary rocks. A final sedimentary material in this general category is sapropel, an aquatic ooze and sludge rich in organic matter.

PROPERTIES OF SEDIMENTARY ROCKS

Texture. Texture concerns the physical makeup of rock, namely, the size, shape, and arrangement (packing and fabric) of the discrete grains or elements of a sedimentary rock. Whereas mineral or chemical composition of sedimentary rock must be determined in order to classify these rocks and interpret their depositional history correctly, texture relates to the physical parameters of size grades: sorting, skewness of the size distribution, and the degree of particle abrasion, among others. Two main natural textural groupings exist for sedimentary rocks, namely, clastic (or fragmental) and nonclastic (commonly crystalline). A few rare types of sedimentary rocks are said to have an amorphous texture, but with the advent of the electron microscope many of these so-called featureless rocks were found to have a detrital or crystalline texture or both.

Grain size. Particle size is an important textural parameter of clastic rocks, because it provides information on the conditions of transportation, sorting, and deposition of the sediment and provides some clues to the history of events at the depositional site prior to final induration. To determine the sizes of the discrete particles that compose a sedimentary rock can pose a problem, particularly if the rock is firmly indurated (cemented, compacted, lithified). Various methods of setting up grade scales have been devised; a grade scale is a systematic division of a continuous range of sizes into classes or grades. Thus, particulate materials that make up sediments and sedimentary rocks can be weighed and their diameters measured by sieving through screens to determine their grade scales. The grade scale given in Table 3 is still one of the best methods of standardizing terminology, because each size grade or class differs from its predecessor by the constant ratio of 1:2, and each has a specific name to identify the particles included within it. The scale is a geometric grade scale, with a constant ratio between classes, and is well adapted to the description of sediments, because it gives equal significance to size ratios,

whether the ratios relate to gravel, sand, silt, or clay. The gravels and sands can be separated into discrete grade scales or size grades by using screens or sieves whose openings correspond to metric sizes. Silts and clays are relegated to their respective size grades by utilizing their settling velocities in water or in air to separate one size from another.

Table 3: Particle-Size Classification

grade limits (diameters in mm)	name	grade limits (diameters in mm)	name
Above 256	boulder	1/2–1/4	medium sand
256–128	large cobble	1/4–1/8	fine sand
128–64	small cobble	1/8–1/16	very fine sand
64–32	very large pebble	1/16–1/32	coarse silt
32–16	large pebble	1/32–1/64	medium silt
16–8	medium pebble	1/64–1/128	fine silt
8–4	small pebble	1/128–1/256	very fine silt
4–2	granule	1/256–1/512	coarse clay
2–1	very coarse sand	1/512–1/1,024	medium clay
1–1/2	coarse sand	1/1,024–1/2,048	fine clay

Source: C.K. Wentworth (1922).

Sorting of grains. The sorting of clastic sedimentary rocks measures the thoroughness with which a sediment has been winnowed by wind, washed by water, or worked by other transporting agents. The degree of sorting is a valuable indicator of the rate of sedimentation and the probable environment of deposition.

Determination of the degree of sorting in the laboratory with unconsolidated (or disaggregated) gravels and sands is readily accomplished, using a nest of sieves (screens) whose openings correspond to the grade sizes of the Wentworth or other scale. Sizes of silts and clays are determined in the laboratory using air elutriation or in settling tubes filled with water. Discrete size grades are separated according to their settling rates, and the percentage of material occurring in each size grade is obtained directly.

In order to determine the degree of sorting of indurated sedimentary rocks, a slabbed surface is prepared by cutting the rock, and the surface is then etched with acid or otherwise treated to cause the grains to stand out in relief. The grains can then be studied and counted.

All methods of ascertaining the grade sizes of clastic sediments and of sedimentary rocks result in compilation of data relating to the size frequency distribution. These data can be plotted in tabular form, as histograms (bar graphs), as size frequency curves, or as cumulative curves. Numerous techniques have been devised to illustrate these data; Figure 3 shows a few possibilities.

Some of the characteristics of size frequency distributions include skewness (a measurement of the symmetry of a histogram or of a size frequency curve), kurtosis (degree of peakedness of the histogram or curve), and the mean, or average (a measurement of the central tendency), as well as the quartiles. Some of these characteristics are also shown in Figure 3. The advantages of using these parameters is that they systematize determination of the degree of sorting of clastics and of the precise percentages of discrete grade sizes and designation of the clastic mixture as unimodal, bimodal, or even polymodal. These facts permit interpretation of the environment of sedimentation for the particular suite of sediments or sedimentary rocks involved.

Grain roundness. Clastic rocks become abraded during their transit, and some degree of rounding usually occurs. Conglomerates, for example, are roundstones in that they have been abraded, and most (if not all) sharp corners have been worn off. Breccias, by contrast, are sharpstones and display varying degrees of angularity. The same is true of the arenites, or sandstones; thus, it is important to obtain some measurement of the degree of abrasion or perfection of roundness. Some geologists prefer to arrange sand grains in order of increasing abrasion, from those that are almost entirely unabraded and are thus angular to those that are well rounded. Figure 4 illustrates this arrangement, which is commonly used.

From Krumbein and Pettijohn. *Manual of Sedimentary Petrography* (1938): Appleton-Century-Croft

Grains that are angular have maximum sharpness around their edges and show minimum abrasion on corners. Subangular grains indicate that the edges and corners have been abraded but retain their original form,

From F. Pettijohn, *Sedimentary Rocks*, 2nd Edition (1957); Harper and Row

Figure 4: Roundness classes of sedimentary particles.

and their original surfaces are relatively little worn. Subrounded grains denote considerable attrition and abrasion, so that the entire surface has been worn from faces, angular grains, and crystal boundaries to a relatively smooth texture. Rounded grains approximate roundness and sphericity; edges, corners, and original surfaces have been so abraded that the entire remaining surface of the grain forms a smooth, broad curve. If some grains display perfect roundness and sphericity they may be termed well rounded.

Carbonate texture. Carbonate clastic rocks are similar in texture and may be lithoclastic or bioclastic. Lithoclastic means that the alloctigenic (detrital) materials are mainly inorganic and consist of grains of different kinds of minerals and rocks or rock fragments that are transported and redeposited as detrital grains and matrix. Thus, an arenite that consists of 50 percent or more (by bulk or by exposed area) of clasts of limestone derived from an earlier formed rock or partly indurated lime mud should be termed lithocalcarene. Bioclastic indicates that the texture and composition is derived from alloctigenic materials that are high in organic material, commonly containing a variety of abraded skeletal fragments that have been transported and deposited as detrital material. The source of the clastic material is skeletal fragments, ranging in size from lutites (clays) and comminuted fossil detritus to calcarenite and even to rudaceous (gravelly) textured sediment, the calcirudites. Thus, a biocalcarene is a clastic carbonate sedimentary rock consisting primarily of sand-size abraded skeletal grains; 50 percent or more of such a rock consists of sand-size fossil fragments.

Many carbonate sedimentary rocks are crystalline, however, rather than granular. In terms of crystal size, they

can range from the macrocrystalline or megacrystalline—visible to the unaided eye—through those that are microcrystalline and cryptocrystalline (not visible). The term aphanic is useful to describe the texture of most micrites (and micritic limestones) and dolomitic micrites; individual crystals and grains (if present) are less than 0.01 millimetre (0.0004 inch) in size. A second designation, phaneric, refers to discrete particles, crystals, and grains that are larger than 0.01 millimetre in size, commonly visible to the unaided eye.

In addition, some degree of perfection of crystallinity can be noted in crystalline sedimentary rocks. Euhedral is a term applied to those crystals that are bounded by their own crystal faces, resulting in a relatively high degree of crystalline geometry. Those crystals whose faces are of a lower degree of perfection than euhedral forms are termed subhedral. Those crystals that are not bounded by their own crystal faces and have their outlines impressed on them by adjacent crystals are termed anhedral. They have a degree of geometry lower than subhedral forms. For further discussion of carbonate textures see LIMESTONES and DOLOMITES.

Mass properties. Discussion of sedimentary rocks thus far has related to the problems of their classification and to some of the textural characteristics of sediments and sedimentary rocks. The association of the discrete particles in their aggregate, or bulk, state and the whole rock and its mass properties also warrant consideration. Some of the more significant of these properties are discussed here, in alphabetical order.

Cementation. The precipitation of mineral matter in the interstices of a clastic sediment provides cementation, particularly during and shortly following sedimentation. The final product is an indurated rock.

Cohesiveness. Cohering, or sticking together by surface forces, normally is displayed by unconsolidated (to weakly indurated), fine-textured clastic and carbonate sediments of particle size less than 0.01 millimetre.

Colour. The overall hue of sediment results from a combination of various grain colours, mineral inclusions, surface coating, weathered surfaces, matrix colour, and nature and hue of the cementing materials.

Compactibility. Rock becomes compacted when porosity is reduced in response to a decrease in volume under load. Finely textured sediments, such as silt and clay, normally are compacted more than sands and gravels.

Density. The mass per unit bulk volume of the sediment or rock, or its density, is a measure of the degree of packing of the components.

Elasticity. The ability of a strained body to recover its size and shape after deformation is its elasticity. If a rock such as shale, for example, is slowly bent, the degree to which it is able to regain its original size and shape without fracturing is a measure of its elasticity.

Electrical resistivity. Resistance to the passage of an electric current depends, of course, upon the nature of the sediment and the fluid content in its open spaces. Knowledge of the electrical resistivity of the various types of sedimentary rocks helps geologists to locate oil, gas, and water deposits below ground.

Magnetic susceptibility. Magnetization is acquired by rocks when in a magnetic field. In sediments, the susceptibility is largely related to the amount of magnetic minerals (magnetite, for example) that is present.

Packing. The mutual spatial relationships among the grains of a rock, or packing, reflect the degree to which grains are in contact with or interlocked among their neighbours.

Permeability. The ease of fluid flow through rocks, or permeability, is strongly influenced by particle size; coarse gravel, for example, has large openings among the cobbles and boulders, affording easy passage for fluids. Sands also have high permeability values, whereas clays (which have high cohesiveness) have low ones.

Porosity. Porosity, or the actual pore space in a rock, is expressed in percentages. Porosity is a function of the uniformity of particle size and shape and of the state of packing of the particles.

Consideration of the whole rock

Radioactivity. In sediments radioactivity is expressed in units equivalent to 10^{-12} gram of radium per gram of rock. Measured values average about 4.1 for pure quartz sandstones, 4.0 for limestone, 11.3 for gray shale, and 22.4 for dark-gray to black shale.

For further information on mass properties, see ROCKS, PHYSICAL PROPERTIES OF.

Geochemical properties. Minerals that make up sedimentary rocks are of two principal types, namely, **allogenic** (detrital) and **authigenic**. The former are obtained during the processes of weathering and are transported to or within the depositional site, whereas authigenic minerals form *in situ* within the depositional site in response to geochemical processes. The geochemical properties of sedimentary rocks, whether clastic or non-clastic, therefore result from certain chemical properties they inherited from earlier formed rocks and from the properties induced upon them during postdepositional epochs. Many igneous rocks contain minerals that are radioactive (some feldspars and zircon, for example). When such minerals occur as detrital grains in clastic sedimentary rocks, their absolute age and the source can generally be determined. Because only a few such minerals are commonly incorporated, however, the use of isotope techniques to determine the time of deposition of sedimentary rocks is limited.

Various clay minerals are present in sedimentary rocks and are of particular importance in most shales and in some limestones. Some of these clays are no more than fine to very fine textured detrital particles, whereas some may form authigenically in the site of deposition. Some of the important clays include kaolinite, halloysite, montmorillonite, illite, vermiculite, and chlorite (see further CLAY MINERALS).

Some zeolites (*q.v.*) are authigenic in origin, and their presence may shed light on the environmental conditions under which they formed. The zeolite analcite ($\text{NaAlSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$), for example, commonly indicates formation in lakes (such as the Green River Formation of Utah, Colorado, and Wyoming). Heulandite, (Ca, Na) ($\text{Al}_2\text{Si}_2\text{O}_8 \cdot 6\text{H}_2\text{O}$), results from the interaction of volcanic glass and saline waters that are commonly marine. In addition to zeolites, trace elements present in sedimentary rocks provide indications of either freshwater or marine environments. Marine clays may contain about 100 to 200 parts per million of boron, whereas freshwater clays have only about ten to 50 parts per million.

The term **diagenesis** is a designation for all processes that act on sediments after their deposition. Such postdepositional processes may take place hundreds or even millions of years after sediment finally comes to rest; they include (1) formation of new minerals, (2) redistribution and recrystallization of substances in sediments, and (3) lithification. Diagenesis, therefore, includes all physicochemical, biochemical, and physical processes modifying sediments in the time between their deposition and their lithification at the low temperatures and pressures characteristic of surface and near-surface environments. Dolomitization is one process of diagenesis, whereby limestone is changed to dolostone.

Fabric. Fabric is the orientation or the lack of it of the elements of a rock. The texture of a rock therefore defines the fabric, because it is the arrangement or orientation of clasts and crystals in these rocks that controls its fabric—it is the way the rock is put together. Packing is a factor in the fabric because it concerns the spacing of the elemental constituents of sediments and sedimentary rocks, and this in turn determines the density. Genetically, there are two principal varieties of fabric, namely, primary (depositional or appositional) and secondary (or deformational). Primary fabric is syngenetic (it is determined while sediment is accumulating), whereas a deformation fabric is produced as a postdepositional process by external stress on the rock. It results from a rotation or from movements of the constituent elements under stress or from the growth of new elements. Fabric in **clastics** such as conglomerates and sandstones can be determined by plotting dimensional directions, such as

the long axes of pebbles or quartz-sand grains. Fabric in shales can be ascertained by plotting the platelike arrangement of mica and other clays and in carbonate rocks by plotting directional properties of clasts (pellets, skeletons, oolites) or of crystals and crystal patterns.

SEDIMENTARY STRUCTURES

External stratification. Stratification (or bedding) is expressed by rock layers (units) of a general tabular or lenticular form that differ in rock type or other characteristics from the material with which they are interstratified (sometimes stated as interbedded, or interlayered). These beds, or strata, are of varying thickness and areal extent. The term **stratum** identifies a single bed, or unit, normally greater than one centimetre in thickness and visibly separable from superjacent (overlying) and subjacent (underlying) beds, or units. "Strata" refers to two or more beds, and the term **lamina** is sometimes applied to a unit less than one centimetre in thickness. Thus, lamination consists of thin units in bedded, or stratified, or layered, sequence in a natural rock succession, whereas stratification consists of bedded layers, or strata, in a geologic sequence of interleaved sedimentary rocks.

The individual beds, or layers, in an interbedded succession of rock strata will rarely be of approximately equal thickness. Examples do exist, however, notably in varved deposits (*q.v.*), which are laminated to thinly stratified layers of sediment that reflect seasonal or annual rhythms. For the preponderance of stratified sedimentary rocks the arrangement is one of unequal thickness, ranging from very thin laminae to discrete beds that measure a few to many feet in thickness. This is the normal sedimentary pattern for strata.

The terms thick and thin as applied to bedding, or stratification, are relative, reflecting the training of a particular geologist as well as his experience with a specific stratigraphic section or sections. Some quantitative values have been set forth, however, and these values and associated nomenclature are shown in Table 4.

Table 4: Quantitative Terms to Describe Layered Sedimentary Rocks

descriptive terms for stratification	descriptive terms for cross-stratification	thickness	descriptive terms for splitting
Very thick-bedded	very thickly cross-bedded	greater than 6 ft	massive
Thick-bedded	thickly cross-bedded	3 ft to 6 ft	blocky
Medium-bedded	medium cross-bedded	1 ft to 3 ft	slabby
Thin-bedded	thinly cross-bedded	1 in. to 1 ft	flaggy
Laminated	cross-laminated	2 mm to 1 in.	platy (or shaly)
Thinly laminated	thinly cross-laminated	less than 2 mm	papery

Bedding types. It is common to discover a rhythmic pattern in a pile of stratified sedimentary rocks represented by a repetitive sequence of rock types (see further CYCLOTHEMS). In most instances of such cyclic sedimentation, the bedding, or stratification, is horizontal or essentially so; that is, the transporting, sorting, and depositing agents of wind, running water, and lake and ocean currents and waves accumulated the laminae and strata in flat-lying or horizontal arrangement. They are termed **well-bedded**, a type of primary stratification.

Primary stratification in sediments and sedimentary rocks can be cross-bedded (cross-stratified), graded, and imbricate and can also display climbing laminae, ripples, and beds. A simplified classification of cross-stratification into three principal types (simple, planar, and trough) is shown in Figure 5.

Graded bedding simply identifies beds, or strata, that grade upward from coarse-textured clastic sediment at their base to finer textured materials at the top (Figure 6). The stratification may be sharply marked so that one layer is set off visibly from those above and beneath it. More commonly, however, the layers are blended. This variety of bedding results from a check in the velocity of the transporting agent, and thus coarse-textured sediment (gravel, for example) is deposited first, followed upward by pebbles, granules, sand, silt, and clay. It is commonly associated with submarine density currents (*q.v.*).

Lamination and stratification

Diagenesis of sediments

Graded and imbricate bedding

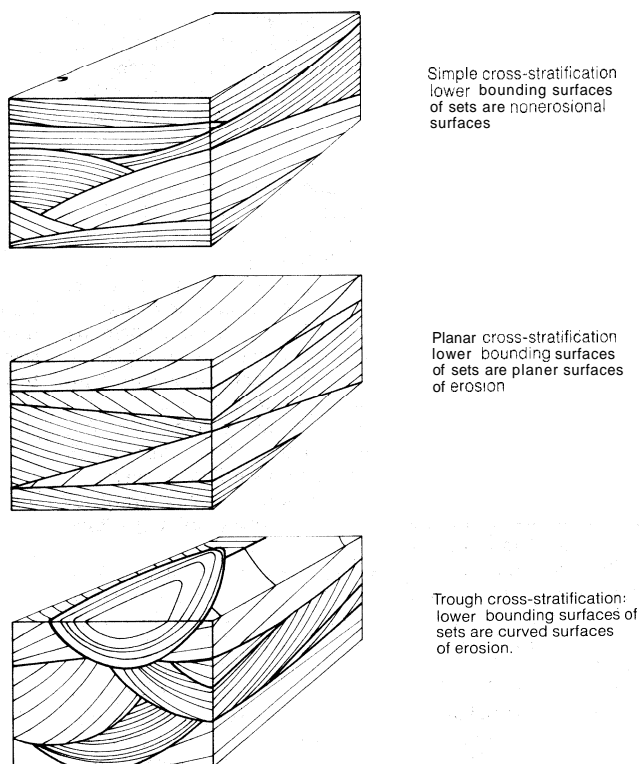

Figure 5: Basic elements of cross-stratification classification. By courtesy of E.D. McKee and G.W. Weir, *Geological Society of America Bulletin*, vol. 64 (1953); Geological Society of America.

Imbricate bedding is of a shingle structure in a deposit of flattened or disk-shaped pebbles or cobbles (Figure 6). That is, elongated and commonly flattened pebbles and cobbles in gravelly sediment are deposited so that they overlap one another like roofing shingles. Imbricate bedding forms where high-velocity currents move over a stream bed or where strong currents and waves break over a gradually sloping beach, thereby forming beach shingle.

Figure 6: (A) Graded bedding. (B) Imbricate bedding.

Growth structures in sedimentary rocks are *in situ* features that accumulate largely as the result of organic buildups within otherwise horizontal or nearly flat-lying strata. Reefs and stromatolites are two common varieties of such growth structures. Reefs can consist of corals or any other organisms capable of constructing a rigid topographic deposit of carbonate in strongly agitated but shallow lake or ocean realms. Stromatolites are largely wavy-crinkly laminae or thin layers of carbonate that form when algae precipitate the lime from solution into a

buildup superficially resembling heads of cabbage or lettuce. A rather exotic growth structure is travertine; this calcium carbonate deposit is more common to caves in the form of stalactites, stalagmites, columns, and other dripstone, but it can also form in other openings in limestones, such as faults and joints.

Bedding-plane features. Upper surfaces of beds commonly display primary sedimentary features that are classified as bedding-plane structures. A three-dimensional view may be obtained if some of these can be seen from the side as well as from the top of a pile of strata. They include such features as ripples (ripple marks), climbing ripples, rills, pits, mud cracks, trails and tracks, salt and ice casts and molds, and others. Bedding-plane markings and irregularities can be allocated to one of three classes: (1) those on the base of a bed (load and current structures and organic markings); (2) those within a bed (parting lineation); and (3) those on top of a bed (ripple marks, pits, impressions, mud cracks, tracks and trails of organisms, and others).

Deformation structures. In addition to sedimentary structures that are normally associated with bedding planes, there are other sedimentary structures that result from deformation during or shortly after sedimentation but before induration of the sediment into rock. These are nontectonic features; that is, they are not bends and folds brought about by metamorphism or other causes. Deformation structures can be grouped into several classes, as follows: (1) founder and load structures, (2) convoluted structures, (3) slump structures, (4) injection structures, such as sandstone dikes or sills, and (5) organic structures. Pillow and convoluted structures are shown in Figures 7 and 8, and a plunge-trough structure in Figure 9.

Figure 7: Cross section of a large pillow structure in Thorold Sandstone (Silurian). New Jolly road cut, Hamilton, Ontario, Canada.

Structures found on the bottom of a bed are called sole markings, because they formed on the "sole" of the bed. Sole marks are commonly formed on sandstone and limestone beds that rest upon shale beds. They are termed casts, because they are fillings of depressions that formed on the surface of the underlying mud. They originate (1) by unequal loading upon the soft and plastic wet mud, (2) by the action of currents across the upper mud surface, or (3) by the activities of organisms on this surface. Load casts form as the result of downsinking of sandstone or limestone into the mud beneath. Current marks can form by the action of water currents on upper surfaces of the beds or by "tools" (such as wood and fossils) that are transported by currents over soft sediment.

A special variety of deformation structure that is common (but not necessarily limited) to limestones is the stylolite, a unique zigzag line that crosses rock surfaces. Stylolites may result from pressure-solution phenomena, which form a sutured pattern during compaction of wet sediment. Being common to limestones, they ordinarily

form parallel to the horizontal bedding, or they parallel foreset bedding and cross-bedding. They may form at other angles in newly deposited sediment. The amplitude of the zigzag or up-and-down suture pattern is a measure of the amount of material that was dissolved and removed during compaction of the sediment.

SEDIMENTARY ENVIRONMENTS

"Sedimentary environment" refers to the complex of physical, chemical, and biological conditions under which a sediment accumulates. These conditions largely determine the properties of sediments deposited within the environment. A sedimentary rock, however, is a product not only of the environment but also of the transporting agent(s) involved. Moreover, its composition, texture, and other characters are determined to a large degree by the makeup of the source area (the provenance).

Any attempt to classify environments of sedimentation must take into account that there are not only marine and nonmarine realms of sedimentation but also mixed or transitional environments in nature.

Marine environments include the nearshore, rather shallow littoral zone, the offshore, moderately shallow zone, and deepwater realms. For mixed marine and nonmarine environments, such names as supralittoral, supratidal, and foreshore may be applied to that realm between the beach (or berm) and the water's edge at normal high tide. Other environments include the beach, estuary, and delta. Each environment, regardless of the name assigned, is associated with a set of criteria that constitutes the hallmark of the environment. The most commonly cited criteria for the recognition of sedimentary environments and source areas are given below.

Harold J. Bissell

Figure 9: Plunge-trough filling in Queantowap Sandstone (Permian) southwest of Las Vegas, Nevada.

Marine environment. The marine environment consists of the shallow and deep littoral zones and the deep-water realm, as previously stated. The shallow littoral zone (high-energy or agitated realm) has the following characteristics: (1) gravelly, coarse bioclastic, and other materials are common; (2) moderately high textural range (boulders to mud) is present; (3) marine fossils are common and may be mixed with some nonmarine forms; (4) there is interbedding into beds of gravel, sand, silt, and clay, some of which are lenslike; (5) sedimentary structures such as ball-and-pillow, roll-and-plunge, and high-angle cross-bedding (Figure 10) may be present; (6) the map pattern of outcropping sediments or sedimentary rocks consists of elongate and linear belts parallel to the shoreline; (7) different textural variations grade laterally as well as vertically; (8) sedimentary features such as ripple marks, rill marks, rain and bubble pits, and mud cracks should be present in some beds; (9) within short distances (particularly at right angles to the depositional strike) there should be an apparent range in thickness of the various strata; (10) individual beds, lenses, and smaller units may display fair to excellent sorting, both texturally and mineralogically; (11) fossil bivalves and related invertebrates commonly are broken and disarticulated and, when cemented and indurated, form a conglomeration of shell debris termed coquina; (12) reefs, bioherms, and other organic buildups are common in limestone successions; and (13) disconformities are present or rather common.

Figure 10: Cross-bedding in calcareous sandstone of Loyalhanna Limestone (Mississippian), current from right to left. From abandoned quarry, Westmoreland County, Pennsylvania.

The deeper littoral zone (low-energy, minor agitated realm) has the following characteristics: (1) the average sediment is fine-sandy, silty, clayey, and limestone-dolostone; (2) moderately low textural range (local lenses only of gravelly material) is present; (3) lamination and stratification are fair to excellent; sorting is excellent; (4) marine fossils range from bedded shells with articulated valves to sparse isolated remains; (5) individual units as well as bedded geologic successions will be areally extensive, recognizable over a range from scores to hundreds of kilometres; (6) discrete strata, members, and formations do not vary greatly in thickness within short to moderate distances; (7) ripple marks may be present but commonly lack shells in the troughs, and mud cracks and raindrop prints are absent; (8) clastic and chemical sediments may interleave, or be interbedded; sandstones, siltstones, and shales may have limestone or dolostone interbeds; (9) lateral lithologic changes are subtle and extend over large areas; vertical lithologic changes are abrupt and sharp; (10) bedding or stratification planes are essentially horizontal; and (11) disconformities are not pronounced.

The bathyal, abyssal, and hadal zone (deepwater realm) has the following characteristics: (1) there are very fine textured silty and clayey sediments; (2) the textural

The shallow and deeper littoral

range is extremely low, particularly among sediments that are silty and clayey only; (3) radiolarian and ribbon cherts and siliceous shales are present; (4) turbidites (graded sediments), graded bedding, chaotic, and other "out-of-place" coarse-textured materials may be sharply interbedded with finer sediments; (5) fossils of deepwater realms are present but scanty; turbidites may contain fossils obtained from the littoral zone or even from land areas; (6) burrowing structures may be present; (7) red and blue muds, possibly of volcanic-ash source, may be present; and (8) beds commonly range from thin to laminated and finely laminated and are not areally extensive.

Mixed marine and nonmarine environment. The mixed environment consists of the supralittoral zone, the beach, and the deltaic zones. The supralittoral zone has the following characteristics: (1) restricted environments have aphanic dolostone with algal crusts; (2) deposits are thin and not areally extensive, in bands parallel to coastline; (3) high-energy, high-storm deposits may have littoral fossils crudely mixed with supralittoral dolostones; (4) mud cracks and raindrop prints may be present; and (5) tree stumps may be in place or logs may be present in chaotic jumble.

The beach zone has the following characteristics: (1) sandstones are cross-bedded with moderate- to high-inclination on foreset beds; (2) low textural range is present within cross-bedded sands; (3) stranded shells interlayered in beach sands display wave abrasion; some may represent life-forms common to the littoral zone, now stranded on the beach; (4) where beach shingle of flattened, disk-shaped pebbles is present, an imbricate structure is evident; (5) beach gravel (conglomerate) contains shells derived from the littoral zone crudely intermixed with gravel; (6) deposits are arranged in linear bands parallel to the coastline; (7) beach conglomerates are well cemented, in modern and ancient deposits; (8) land-derived logs and stumps and land-derived sediments are present; and (9) wind ripple marks and excellent sorting is present locally.

The deltaic zone has the following characteristics: (1) sandstones are arranged in linear bodies and are well sorted, with low textural range; (2) foreset dips (even in excess of 35°) are prevalent in the direction of streamflow; (3) lenses, pockets, and thin layers of carbonaceous shales are present; (4) much vegetation is derived from land; (5) there are rapid lateral and vertical lithologic changes; (6) tree stumps may occur in growth position; (7) mixtures of marine and nonmarine fossils are present; (8) there is a high textural range, except for localized thin units; (9) there are various sedimentary structures: scour, ball-and-pillow, burrowed units, roll-and-plunge, and slump overturning; (10) channel cut-and-fill features are present; (11) coarse-textured sediments grade into finer textured sediments; and (12) localized lacustrine deposits are present.

Nonmarine environment. The nonmarine environment consists of the lacustrine, eolian, fluvial, and glacial realms. The lacustrine realm (nearshore) has the following characteristics: (1) sediments are medium to coarse textured (sandstones to conglomerates); (2) there is a high textural range (boulders to clay—conglomerates to shales); (3) there is a strong contrast in bed thickness and areal extent; (4) some well-sorted pockets, lenses, and thin beds are present; (5) cross-bedding is characteristic; (6) fossils from surf or high-energy realm and some from land are present; (7) shingle gravels may be present; (8) there are contrasting vertical and lateral lithologic changes; (9) stratification planes may dip in all directions; (10) marsh mucks, delta lobes, channel cut-and-fill structures are present; (11) units are not uniformly thick or of areal extent; and (12) washed-in land plants (stumps, logs, and leaves) are present.

In areas of still water the lacustrine realm will exhibit different characteristics, which may be summarized as follows: (1) material is fine textured, and siltstones, shales, and mudstones are common; (2) there is a low textural range (silt to clay), except where turbidity currents have introduced coarse materials from land or nearshore; (3) definite, well-sorted layers and varves are common; (4)

laminae and beds are rather uniform in thickness; (5) fossil fish, bivalves, and other organisms of lake origin are present; (6) sediment is distributed continuously over large or small areas, according to the size of the lake; (7) evaporites and saline sediments may be present; (8) aphanic dolostones may be common; (9) oolites, pisolites, oncolites, and other accretionary limestone accumulations may be present; (10) tufa, travertine, and similar limestone buildups may be present; (11) bioherms are common and extensive; (12) montmorillonite clays are common; and (13) if present, illite clays contain little (ten to 50 parts per million) boron.

The eolian realm has the following characteristics: (1) the textural range is low (fine-textured sandstones, extremely well sorted; if silty, well-sorted "adobes" or loess); (2) sediments are prominently cross-bedded into large-scale, sweeping, and festoon types; (3) they are sorted into irregular beds and lenses; (4) sediment is porous if original depositional fabric is preserved; (5) stratification planes are rarely horizontal and commonly dip up to 33°; (6) stratification planes may be criss-crossed and dip in all directions; (7) sand grains may display tiny pits resulting from sand blasting; (8) sand grains commonly are rounded to well rounded and spherical; (9) there is a strong contrast in thickness laterally and vertically; (10) fossils, if any, are of terrestrial forms; footprints may be present; and (11) ripple marks and raindrop imprints may show on cross-beds.

The fluvial realm has the following characteristics: (1) the textural range is high (blocks and boulders to mud or shale); (2) the sediment is nonsorted to poorly sorted; (3) it is lenticular in form—units thicken and thin rapidly and change in lithology; (4) channel sands and cut-and-fill structures are common; (5) log jams and logs in ancient stream channels may be common; (6) lenses and pockets of gravel may occur in fine sediment; (7) the sediment is distributed in belts (river flats and piedmont alluvial plains); some beds are linear "shoestring" sands with definite trends as distributaries or master-channel deposit; (8) when discrete sands of shoestring nature are mappable, a prevailing one-direction dip is characteristic; only locally are small opposing dips present; (9) the deposit diminishes in thickness uniformly in the direction of the divergence of dips; (10) lithologically, the sediment is likely to be heterogeneous; and (11) fossils, if present, are disarticulated, broken, and highly mixed.

The glacial realm has the following characteristics: (1) sediment is heterogeneous and largely nonsorted and may rest on glacially striated bedrock; (2) there is a high textural range, ranging from rock flour to unusually large blocks and boulders; (3) there is no stratification, except by glaciofluvial streams or as varves in glacial lakes; (4) most sediment is angular to subangular, unless derived from an already rounded conglomerate or gravel; (5) variation in thickness within short distances is unusually high; (6) sediment commonly is foreign to the area of outcrop (e.g., granitic and metamorphic rocks may occur far from their source area); (7) large angular and subangular blocks enclosed in tillites may display striations; (8) bases of glacial deposits contrast sharply with the substrate on which they rest; (9) deposits may contain paleosols (i.e., buried soil horizons); and (10) fossils, if any, are of terrestrial origin, save for fossils ripped from sediments over which the glacial material was transported.

DISTRIBUTION OF SEDIMENTARY ROCKS THROUGH TIME

Rock-type variation. Some of the oldest sedimentary rocks are of clastic origin; conglomerates dated in excess of 3,500,000,000 years old are known in Rhodesia. Other coarse-textured sedimentary rocks (or their metamorphic equivalents, the metaconglomerates) occur in many parts of the Earth. Sandstones (and their metamorphic equivalent, metaquartzites) and some carbonate rocks also are common in the Precambrian record (older than 570,000,000 years).

Sedimentary rocks of the Paleozoic Era (from 225,000,000 to 570,000,000 years ago) compose a vast spectrum of sandstones (commonly in the Lower Cambrian),

The eolian, fluvial, and glacial environments

Beach, deltaic, and lacustrine environments

Precambrian through Cenozoic sediments

shales, limestones, and dolostones. Lower Cambrian rocks commonly are sandstones, succeeded upward by shales, limestones, and dolostones. This oversimplified pattern is repeated at many places on Earth. Ordovician rocks (430,000,000 to 500,000,000 years old) are quite shaley, and the graptolite-bearing dark shales are common to many continents. Limestones and dolostones are abundant, and sandstones are less so in these marine sequences. Throughout the Silurian (395,000,000 to 430,000,000 years ago) and Devonian (345,000,000 to 395,000,000 years ago) periods much carbonate sediment was deposited—limestones and dolostones, with lesser amounts of sandstone and shale. During Late Paleozoic time (225,000,000 to 345,000,000 years ago) there accumulated much shale, limestone, sandstone, and orthoquartzite (the latter is a fine-grained, tightly silica-cemented quartz sandstone), with minor dolostone. Of great significance is the presence of thick and areally extensive beds of workable coal at many places on various continents; the Upper Carboniferous (about 290,000,000 years ago) is rich in economically valuable coal seams in North America, the British Isles, Europe, Asia, Australia, and Antarctica. Limestones, which underlie coal-bearing shales and sandstones in North America, are locally valuable as building stones. Many of the Paleozoic limestones, dolostones, and sandstones are rich in oil and gas.

Rocks of the Mesozoic Era (from 225,000,000 to 65,000,000 years ago) include thick and extensive sandstones and shales, with thick conglomerates in some places. In other localities limestones are important. Numerous Triassic sedimentary rocks (190,000,000 to 225,000,000 years old) are reddish in colour and are termed red beds; the colour results mainly from the presence of admixed iron oxide compounds. Jurassic strata (136,000,000 to 190,000,000 years old) range from clay shales through siltstones, sandstones, and conglomerates. Limestones, interestingly enough, are very fine textured (micrite) on some continents, and those that contain clay are useful in production of cement. Evaporites (halite, potash, gypsum, and other salt deposits) are also present in Jurassic rocks. Cretaceous sedimentary rocks (65,000,000 to 136,000,000 years old) contain thick sandstone, shale, conglomerate, and coal beds. Chalky sediments are present in the Cretaceous of Britain and in some other parts of the world.

During the Cenozoic Era (the last 65,000,000 years) great thicknesses of coarse- and medium-textured clastic rocks formed in many localities in subsiding depositional sites throughout the world. Shale, limestone, dolostone, and evaporites also formed. Nonmarine sediments of eolian, pluvial, fluvial, paludal, and lacustrine origin accumulated in continental-interior areas.

Few general summary statements can be made about glacial deposits. Continental ice sheets affected portions of the Northern Hemisphere during the Late Precambrian and the Pleistocene Epoch (from 10,000 to 2,500,000 years ago) and left evidence of their presence in the form of till and tillite deposits and glacial scratches during the Permian in parts of India, Australia, Antarctica, South Africa, South America, and a few other places. Wind action seems to have been at work throughout the geologic past, and some of the better known eolian deposits of the geologic column (the record of the rocks) include some Permian and Jurassic rocks. Marine deposits are characteristic of the Paleozoic and Mesozoic and on peripheral parts of most continents for the Cenozoic.

Rates of accumulation. The total thickness of some of the Cenozoic sedimentary rocks of the northern Gulf of Mexico that have been penetrated by drilling operations is more than 6,000 metres (20,000 feet). The total thickness of Cenozoic sedimentary rocks in this region, which have much clastic material, may be as great as 12,000 metres (40,000 feet). The duration of the Cenozoic Era was about 65,000,000 years, and a rate of sediment accumulation can therefore be obtained by simple division. Sedimentation in the Gulf of Mexico has probably not been uniform from day to day during the past 65,000,000 years; times of accelerated dumping of sediment into this

sinking geosyncline probably have alternated with times of reduced increment of materials. Furthermore, if compaction is not yet complete, the thickness value of 12,000 metres should be reduced somewhat. Nevertheless, on the average there has been a bit more than 0.0002 metre (0.0006 foot) of deposition per year (two metres in 10,000 years) in this area.

For some Paleozoic sections, sampled from various places on different continents, the rate of sedimentation is estimated to have ranged from about 70 metres (230 feet) to as much as 800 metres (2,500 feet) per million years of geologic time. An average rate of about 200 metres (600 feet) per million years is realistic, and this is comparable to the Gulf of Mexico calculation.

Rate of sediment accumulation are not the same for every depositional site, nor do they maintain unusually rapid or unusually slow rates throughout all of geologic time. An illustration of this fact is found in the total Permian System exposed near the Hermit Trail in the Grand Canyon. The thickness is slightly less than 550 metres (1,800 feet), which gives an accumulation rate of roughly 11 metres (35 feet) per million years. The complete Permian section crops out just east of Las Vegas, Nevada, however, where the total thickness is about 2,100 metres (7,000 feet)—an accumulation rate of 40 metres (140 feet) per million years for the same system. The reason for this seeming disparity is that during the Permo-Triassic time what is now the Grand Canyon was a shelf, and the area to the west, near Las Vegas, was a different kind of depositional site—a geosyncline that subsided faster than the Grand Canyon shelf, thus permitting the accumulation of more sediment.

Sedimentary models. In any sedimentary environment, the sediment is derived from some source area, it is transported to the site of deposition by some agent, it is deposited, and under suitable conditions it may then be affected by organisms in the environment. This sequence has been formally designated a sedimentary model, one that can be further organized into a process-response environmental model; that is, certain processes and conditions lead to certain consequences, or responses. In this case, the process elements are the geometry, materials, energy, and biological elements of the environment, and the response elements are the geometry of the deposits, the properties of the sediments formed, and the areal variations in the sedimentary properties.

Perhaps hundreds of examples could be cited, but an outstanding one is the Queantowep Sandstone (Permian), which is superbly exposed in the walls of the Grand Canyon of the Colorado River and from there westerly in outcrops and quarries west and southwest of Las Vegas. The boundary that encloses the outcropping Queantowep Sandstone involves the Esplanade along the Grand Canyon region and proceeds westerly into southern Nevada in a relatively narrow band in a north-south direction but of considerable east-west extent. The geometry of the environment, therefore, is that of a delta plain across which mid-Permian streams meandered, developing delta lobes as the streams transported sand westerly toward the geosyncline that lay to the west in Nevada. The materials of the environment included mostly fine- to medium-grained quartz sand, which was washed clean by the energy of waves and currents in this environment. Biological entities included burrowing organisms, which churned up some of the sediment, particularly west and southwest of Las Vegas; there, the westerly flowing streams and currents during Permian time veered toward the south and progressively extended the delta lobes into a trough-like basin in the ancient geosyncline. Various organisms were effective in modifying the sediments there.

In response to the foregoing process elements, the westerly delta lobes formed superb cross-bedded clean quartz sandstones. By plotting the direction of inclination of the cross-strata (in this case, mostly westerly almost to Las Vegas), a determination of the direction of ancient current flow is made possible. Also, by mapping and plotting the areal extent of the outcropping Queantowep and by measuring the thickness of the entire formation, a three-dimensional model results. West of Las Vegas, the azi-

Geosyncline in the Gulf of Mexico

Process-response models

mouth of dip direction of cross-beds gradually but perceptibly changes, and foresets dip in a general southerly direction. Furthermore, numerous sedimentary structures such as ball-and-pillow, plunge-and-flow, flame structures, slump-and-overturn, and many others are developed. In general, foreset bedding defines the direction of the stream and other current flow from east to west out of what is now the Grand Canyon region nearly as far as Las Vegas; then these currents plunged into a linear down-warp or trough of the geosyncline and filled this trough from north to south. Sands were cleaned by the current winnowing of clay and silt, and in some places pure quartz sandstones are preserved in the outcrops as thin- to thick-bedded units.

Areal variations in the sedimentary properties of the Queantoweap Sandstone from the Grand Canyon region to the present Spring Mountains southwest of Las Vegas are not unusually striking. The easternmost outcrops are not as clean (i.e., finer material is admixed with the sands) as those farther west, and most sedimentary structures are those of small-scale cross-bedding. Progressively westward and thence southerly, the sandstones are better sorted, are cleaner, and have a low textural range. By contrast to those farther east, they display numerous sole markings and other sedimentary structures. Also, the formation progressively becomes thicker in overall vertical dimension from east to west.

BIBLIOGRAPHY. F.J. PETTIJOHN, *Sedimentary Rocks*, 2nd ed. (1957), a comprehensive, modern text that discusses and classifies all types of sedimentary rocks and treats various of their properties, with a bibliography at the end of each chapter; W.C. KRUMBEIN and L.L. SLOSS, *Stratigraphy and Sedimentation*, 2nd ed. (1963), a modern text that discusses and classifies sedimentary rocks relating them to the twin subject of stratigraphy, with emphasis on properties of sedimentary rocks and sedimentary processes, environments, and sedimentary tectonics, with a bibliography at the end of each chapter; HOWELL WILLIAMS, FRANCIS J. TURNER and CHARLES M. GILBERT, *Petrography* (1954), discusses and classifies Igneous, metamorphic, and sedimentary rocks; ALBERT V. CAROZZI, *Microscopic Sedimentary Petrography* (1960), a fairly recent text that discusses sedimentary rocks both petrologically (field) and petrographically (laboratory), including a list of references at the end of each chapter; ROBERT E. CARVER, (ed.), *Procedures in Sedimentary Petrology* (1971), a modern up-to-date text that treats in an excellent manner the procedures that should be followed in any investigation of sedimentary rocks, with 29 outstanding scholars each contributing a section of his specialty, including lists of references at the end of each section.

Sediment Yield of Drainage Systems

When precipitation falls on the Earth's surface, that part of the total that does not evaporate or infiltrate into the soil is runoff. As it moves over the land surface, the runoff carries sediment eroded from the hillslopes. This water and the entrained sediment move for relatively short distances before they become concentrated and collected in stream channels. The network of streams that collect the runoff and its sediment load and that provide an efficient means of draining away the runoff is a drainage system. A drainage system is composed of a stream and its tributaries, to which water and sediment are contributed from the drainage area or drainage basin of the stream system (Figure 1). The rim of the basin or the boundary between adjacent drainage basins is the drainage divide. Each drainage basin has its own divide that delineates the drainage area of that stream system, the area from which both runoff and sediment are derived.

Drainage basins can be of any size, and they range from a few acres in areas with poorly defined divides to truly continental features (Table 1). The Continental Divide of the United States, for example, located largely on the crest of the Rocky Mountains, forms the boundary between the drainage basins of the Mississippi-Missouri river system and the Columbia, Colorado, and Rio Grande river systems. The drainage systems of major rivers are composed of smaller units, such as the third-order drainage system shown in Figure 1.

The individual channels of a system are frequently classified by number. Channels that receive no tributary contribution are first-order streams. The junction of two first-order streams forms a second-order stream, and so on. Of course, each small first-order stream has its own drainage area and drainage divide (Figure 1). Within this

Figure 1: Third-order drainage basin with dendritic pattern (see text).

drainage area are the components of the drainage basin, hillslopes or valley-side slopes and stream channels. Climate, morphology of the basin, rock type, and soil characteristics influence both runoff and the total quantity of surface water and sediment moving out of a drainage basin. The quantity of sediment moving through a specific cross section on a stream is the sediment yield of the drainage basin above that point. Sediment yield is, therefore, the total quantity of sediment exported from a drainage basin. Depending on the size of the basin, sediment yield may be almost negligible or it may amount to hundreds of tons of sediment per year (Table 1). The sediment yield of drainage basins—both large and small—is of considerable economic as well as aesthetic importance to man

Definitions and governing factors

concern to man, especially in those areas where sediment yields are high. Large quantities of sediment moving out of drainage basins during floods may shorten the life of reservoirs, permanently damage agricultural lands, partially or completely fill stream or irrigation channels, destroy the spawning grounds of fish, and—perhaps of most immediate concern—partly fill one's residence with mud, silt, and sand.

Large sums of money are spent annually in an effort to decrease sediment yields or to restore property damaged by sediment deposition to its former value and use. The sediment yield of a drainage basin is one of a host of modern environmental factors of concern to the land manager, geologist, forester, civil engineer, and citizen.

This article treats the measurement of sediment yield, the sources of sediment and nature of deposition, and the variability of sediment yield in terms of the causative factors—i.e., climate, soils and vegetation, and drainage basin morphology. The sediment-yield data employed in this article are largely derived from studies made in the United States. This is because records of long term are required for statistically valid conclusions, and such records are largely unobtainable elsewhere in the world.

For further information on the transportation of sediment by flowing water, see RIVERS AND RIVER SYSTEMS; FLUVIAL PROCESSES. See also HILL SLOPES; SOILS; WEATHERING; and EARTH MOVEMENTS ON SLOPES for insight into the origins of sediment; and LANDFORM EVOLUTION for a discussion of the consequences of the erosion processes involved. The article PHYSIOGRAPHIC EFFECTS OF MAN is of particular relevance with respect to the results of urbanization on sediment yield that are cited herein.

MEASUREMENT OF SEDIMENT YIELD AND SEDIMENT LOAD

The sediment yield of a drainage basin is expressed generally in two ways: either as a volume or as a weight—that is, as acre-feet (one-foot depth of material over one acre) or as tons. In order to adjust for the very different sizes of drainage basins, the yield frequently is expressed as a volume or weight per unit area of drainage basin—that is, as acre-feet per square mile or as tons per acre or as tons per square mile. The conversion between the two forms of expression is made by obtaining an average weight for the sediment (usually between 80 and 100 pounds per cubic foot) and calculating the total weight from the measured volume of sediment. Further, sediment yield is usually measured during a period of years, and the results are therefore expressed as an annual average—that is, as acre-feet or tons per square mile per year.

The sediment delivered to and transported by a stream is its sediment load. This can be classified into three types, depending on sediment size and the competence of the river. The coarsest sediment, consisting of boulders and cobbles as well as sand, moves on or near the bed of the stream and is the bed load of the river. The finer particles, silts and clays, are carried in suspension by the turbulent action of flowing water; and these fine particles, which are moved long distances at the velocity of the flowing water, comprise the suspended load of the river. The remaining component of the total sediment load is the dissolved load, which is composed of chemical compounds taken into solution by the water moving on or in the soils of the drainage basin. These three types of sediment comprise the total sediment load of the stream and, of course, the sediment yield of the drainage basin.

The sediment load can be measured in different ways. Collection of water samples from a river and measurement of the sediment contained in each unit of water will, when sufficient samples have been taken and the water discharge from the system is known, permit calculation of annual sediment yield. Because sediment in a stream channel is transported in suspension, in solution, and as material rolling or moving very near the bed, the water samples will contain suspended and dissolved load and perhaps some bed load; but much of the bed load cannot be sampled by currently used techniques, as it moves too near the bed of a stream. It is fortunate, therefore, that the greatest part of the total sediment load is in the form of suspended load.

When a dam is constructed, the sediment transported by a stream is deposited in the still waters of the reservoir. In this case, both bed load and suspended load are deposited, but the dissolved load eventually moves out with the water released from the reservoir. Frequent, precise surveys of the configuration of the reservoir provide data on the volume of sediment that accumulates in the reservoir (Figure 2). Water samples can be taken to provide data

Figure 2: Cross section of sediment deposits, Lake Barcroft, Virginia.

on the dissolved load transported into the reservoir; and when this quantity is added to the measurements of suspended and bed load, a reasonably accurate measure of sediment yield from the drainage basin above the reservoir can be obtained.

In areas where information on sediment yield is required but the necessary samples have not been taken (perhaps because of the infrequent occurrence of flow in ephemeral streams), estimates of sediment yields may be obtained from measurements of hillslope and channel erosion within the basin or by the evaluation of erosion conditions. As will be discussed later, certain characteristics of the drainage basin—such as the average slope of the basin or the number and spacing of drainage channels—may be used to provide an estimate of sediment yield.

All of the techniques utilized to measure sediment yield are subject to considerable error, but data sufficiently accurate for the design of water-regulatory structures can be obtained by sampling or by reconnaissance surveys of the drainage systems.

SOURCES OF SEDIMENT AND NATURE OF DEPOSITION

Erosion in drainage basins. The ultimate source of the sediment that is measured as sediment yield is the rock underlying the drainage basins. Until the rock is broken or weathered into fragments of a size that can be transported from the basin, the sediment yield will be low. The diverse mechanisms, both chemical and physical, that produce sediment and soil from rock are termed weathering processes. Depending on type of rock and type of weathering process, the result may be readily transported silts, clays, and sands or less easily transported cobbles and boulders.

Most rocks have been fractured during the vicissitudes of geologic history, thereby permitting penetration of water and roots. Wedging by ice and growing roots produces blocks of rock that are then subject to further disintegration and decomposition by chemical and physical agencies. These rocks, if exposed on a hillslope, move slowly down the slope to the stream channel—the rate of movement depending on slope inclination; density of vegetation; frequency of freeze and thaw events; and the size, shape, and density of the materials involved. In addition, water moving through rocks and soil can dissolve soluble portions of rock or weathering products. This is especially important in limestone regions and in regions of warm, humid climate, where chemical decomposition of rocks is rapid and where the dissolved load of streams is at a maximum.

When sediment eroded from the hillslopes is not delivered directly to a channel, it may accumulate at the base of the slope to form a colluvial deposit (Figure 1). The sediment derived directly from the hillslope may be stored temporarily at the slope base; therefore, sediment

Effects of weathering and breakdown of rocks

Sediment in storage

Measurement of the load

once set in motion does not necessarily move directly through the stream system. It is more likely, in fact, that a given particle of sediment will be stored as colluvium before moving into the stream. Even then, it may be stored as alluvium in the floodplain, bed, or bank of the stream for some time before eventually moving out of the drainage system. Thus there is a steady export of sediment from a drainage basin, but an individual grain of sediment may be deposited and eroded many times before it leaves the system.

The preceding suggests that, over a period of time, the total erosion within a drainage basin is greater than the sediment yield of the system. Proof of this statement is the fact that the quantity of sediment per unit area (area-feet or tons per mile) that leaves a drainage system decreases as the size of the drainage basin increases. This is partly explained by the decrease in stream gradient and basin relief in a downstream direction. That is, much sediment is produced in the steeper areas near drainage divides, and sediment production decreases downstream. Moreover, the increasing width of valleys and floodplains downstream and the decreasing gradient of the streams provide an increasing number of opportunities for sediment to be deposited and temporarily stored within the system.

Factors
related to
quantity
of
sediment

Each of the components of the drainage system—hillslopes and channels—produces sediment; but the quantity provided by each will vary during the erosional development of the basin and during changes of the vegetational, climatic, and hydrologic character of the drainage system. Most rivers are flowing on the upper surface of an alluvial deposit, and considerable sediment therefore is stored in most river valleys. During great floods or during periods when floodplain vegetation is not an effective stabilizer of this sediment, large quantities may be flushed from the system as the channel widens and deepens. At these times, the sediment produced by stream-channel erosion is far greater than that produced by the hillslopes, and sediment yields will be far in excess of rates of hillslope erosion. Such cycles of rapid channel erosion or gullying and subsequent healing and deposition are common in arid and semi-arid regions.

Environments of deposition. It is clear that a great range of sediment sizes may be transported by a river. Sediment of small size (*e.g.*, suspended load), when set in motion by erosive agents, may be transported through a river system to the sea, where it may be deposited as a deep-sea clay. Most sedimentary particles, however, have a more eventful journey to their final resting place. (In a geologic context, this may be a temporary resting place; sediment, for example, when it reaches the coast, may be incorporated in a delta at the river mouth or be acted upon by tides, currents, and waves to become a beach deposit.)

Effects of
climate
and man on
deposition

If sediment is moved downstream into a progressively more arid environment, the probability of deposition is high. Thousands of feet of alluvial-fan deposits flank the mountains of the western United States, the basin-and-range terrain of Iran and Pakistan, and similar desert regions. In the arid climates of these areas, the sediment cannot be moved far, because the transporting medium—water—diminishes in a downstream direction as it infiltrates into the dry alluvium. In extremely arid regions, wind action may be important: the transport of sand-size and smaller sediment by wind may be the only significant mechanism for the transport within and out of some drainage systems in deserts.

Man's influence on river flow has become a major factor determining the place of deposition of sediment. The many dams that have been constructed for flood control, recreation, and power generation hold much of the sediment load of rivers in reservoirs. Furthermore, the contribution of sediment from the small upstream drainage systems has been decreased by the construction of stock-water reservoirs and various erosion-control techniques aimed at retaining both water and sediment in the headwater areas. Diversion of water for irrigation also decreases the supply of water available to transport sediment; and in many cases, the diversion actually moves

sediment out of the streams into irrigation canals and back onto the land.

Vast tonnages of sand and gravel, which have been deposited as floodplain and valley sediments, are being excavated and used in highway construction and all manner of concrete structures. This sediment is being permanently removed from the cycle of sediment movement and deposition.

FACTORS THAT INFLUENCE SEDIMENT YIELD

Of most concern to man are the factors that cause rapid rates of erosion and high sediment yields. The quantity and type of sediment moving through a stream channel are intimately related to the geology, topographic character, climate, vegetational type and density, and land use within the drainage basin. The geologic and topographic variables are fixed; but short-term changes in climatic conditions, vegetation, and land use produce abrupt alterations in the intensity of erosion processes and in sediment yields.

The sediment yield from any drainage system is calculated by averaging the data collected over a period of years (Table 1). It is, therefore, an average of the results of many different hydrologic events. The sediment yield for each storm or flood will vary, depending on the meteorological character of the storm event and the resulting hydrologic character of the floods. High-intensity storms may produce sediment yields well above the norm, whereas an equal amount of precipitation occurring over a longer period of time may yield relatively little sediment. During short spans of time (days or years), sediment yields may fluctuate greatly because of natural or man-induced accidents (floods and fires, for example); but over longer periods of time, the average sediment yield will be typical of the geologic and climatic character of a region.

Short-term variations. An example of a short-term change in sediment yield is provided by data on the sediment transported by the Colorado River in Arizona for the years 1926–54 (Figure 3). It is evident that sediment yield varied widely from year to year. It is greatest for years of highest runoff, but for a given amount of runoff,

Drought-
induced
variations

Figure 3: Relation of sediment yield and runoff for the 1926–40 and 1941–54 periods on the Colorado River at the Grand Canyon.

the maximum sediment yield may be twice the minimum sediment yield. These variations reflect the frequency of storms and their duration and intensity during the years of record.

Another interesting aspect of the relation is that in each of the years after 1940 the annual sediment load at the Grand Canyon was 50,000,000 to 100,000,000 tons less than would be expected on the basis of the curve fitted to the data for the period 1926–40 (Figure 3). This major decrease in sediment yield reflects some significant change in the hydrology of the Colorado River drainage basin. A study of the precipitation patterns for the years 1926–54 suggests that the change in the sediment yield–runoff relation beginning in 1941 is the result of a drought in the southwestern United States. The high-sediment-producing, weak-rock areas of the Colorado plateaus were affected by the drought; but the low-sediment-producing, hard-rock areas of the Rocky Mountains were not affected. Thus, during the years 1941–50 the amount of water delivered from the principal runoff-producing areas in Colorado, Wyoming, and northern Utah was normal; but runoff was considerably reduced from the high-sediment-producing areas in southern Utah and Arizona. The result was essentially normal runoff but greatly reduced sediment yield. Beginning in 1950 the drought encompassed the entire Colorado River Basin, and low runoff was recorded for the years 1950, 1951, 1953, and 1954; but the proportion of runoff produced by the high-sediment-producing areas remained low, as did the sediment yield.

It can be expected that sediment-yield rates will fluctuate with climatic variations. An average value of sediment yield obtained for a short period of record, therefore, may not provide a valid measure of the characteristic sediment yield to be expected over a longer period of years.

A further example of short-term variation of sediment yield, in this case the result of man's activity on the landscape, is provided by data illustrating the change from natural conditions to conditions produced by upland farming and from farming conditions to urban conditions in the Piedmont region of the eastern United States. Sediment yields for forested regions normally are about 100 tons per square mile, and this was the case during the early part of the 19th century in this region (Figure 4). A

Variations induced by man and urbanization

Figure 4: Schematic sequence of land use, sediment yield, and channel response from a fixed area.

significant increase in sediment yield occurred after 1820 as the land was occupied and farmed. During the period of intense farming, 1850–1930, the sediment yield reached 800 tons per square mile; but a decrease occurred between 1930 and 1960, as much land was permitted to revert to forest or grazing land. With the onset of construction and real estate development, however, vegetation was destroyed, and large quantities of sediment were eroded. The sediment yields for some small areas reached 2,000 tons per square mile during urbanization; but with the paving of streets, completion of sewage systems, and the planting of lawns, the sediment yields decreased markedly. In the future, they may eventually decrease to, or below the level of, the sediment-yield rates of natural conditions (pre-1810; Figure 4). This example demonstrates very clearly both long-term and short-term effects of man on sediment yield rates.

Another example of these short-term, man-induced fluctuations of sediment yield is provided by measurement of sediment accumulating in a reservoir in Fairfax County, Virginia (Figure 2). Before 1944 the sediment yield into the reservoir was about four acre-feet per square mile. At this time, the area was 76 percent pasture and woodland, with only 18 percent of the land under cultivation and 6 percent residential. After World War II, the population increased rapidly; and by 1953 much of the land formerly in pasture and woodland was converted to homesites, shopping centres, and streets; e.g., 39 percent was pasture and woodland, less than 1 percent was cultivated, and 61 percent had become residential. Most of this change occurred between 1947 and 1957. The result of this conversion was a sixfold increase in sediment yield rates to 25 acre-feet per year. The increase was rapid as the percentage of watershed area under construction increased; however, sediment-yield rates decreased quickly following the peak of construction, as streets were paved and lawns became established.

In any drainage basin, even one not affected unduly by man, short periods of high sediment yield will alternate with periods of little export of sediment. Prime examples are small drainage basins in arid or semi-arid regions, where sediment yield occurs only during and following precipitation. Runoff and sediment yield can be zero between storms but high during and immediately following precipitation.

Seasonal and accidental variations

Even temperature variations have been demonstrated to influence sediment transport and sediment yields. Cooler water is more viscous, and this decreases the fall velocity of sediment particles and enables the stream to transport a larger amount of sediment. The sediment load of the Colorado River, for example, is greater during winter months because of this effect.

The disastrous effect of fire on sediment yields may be seen in the example of the conditions that followed a major storm and flood in the steep drainage basins of the San Gabriel and San Bernardino mountains of California in 1938. Maximum vegetational cover on these drainage basins is only 65 percent at best, and they are notoriously high sediment producers under the most favourable conditions. Sediment-yield rates were established for several drainage basins that had been subjected to fires as recently as one year before the storm and as long as 15 years before the storm. The results shown (Figure 5) further demonstrate the great effect of vegetational disturbance on sediment yields; for example, a drainage area with only 40 percent of the area burned had a 340 percent increase in sediment yield if the fire occurred one year before the storm. According to the information provided, the burned area one year after the fire had a 10 percent vegetational cover. Obviously, a storm immediately following the fire would have had even more disastrous consequences. Three years after the burn, a 35 percent vegetation cover had been established on the burned area, and sediment yields decreased markedly to only twice the yield preceding the fire. After seven years a 45 percent cover had been established on the burned area, and sediment yields were only 50 percent greater than preburn values. After 15 years, a 55 percent vegetal cover had been established, and sediment yields were almost normal. The decrease in sediment yield with increased plant cover is apparent. It is also obvious that an average value of sediment yield from a burned drainage basin for a 15-year period would be meaningless; with progressive re-establishment of vegetation, sediment-yield rates progressively decrease with time.

Long-term or average sediment yield. It has been estimated that modern sediment loads of the rivers draining to the Atlantic Ocean may be four to five times greater than the prehistoric rates because of man's influence. Even where man's influence is large, however, it is possible to recognize several other independent variables that exert a major influence on long-term sediment yield. These variables can be grouped into three main classes: geologic, geomorphic, and climatic–vegetational.

The major geologic influence on sediment yield is through lithology or the composition and physical prop-

Figure 5: Increase in the sediment yields of southern Californiadrainage basins following the 1938 storm. The several curves show the percentage increase in sediment yield in relation to the area burned and the date of burning (see text).
From Anderson and Trobitz, *Journal of Forestry*, vol. 47, p. 347 (1949)

Influence of rock type and soils

erties of rocks and their resistance to weathering and erosion. An easily weathered and eroded shale, siltstone, or poorly cemented sandstone will provide relatively large quantities of sediment, whereas a lava flow, a well-cemented sandstone, or metamorphic and igneous rocks produce negligible quantities of transportable sediment. The highest known sediment yields that have been recorded are produced by the erosion of unconsolidated silts (loess). Loess is readily eroded, especially when the protecting vegetational cover is disturbed, as has happened in the high-sediment-producing areas of western Iowa and the Huang Ho Basin of China.

In general, sediment yield from drainage systems underlain by granitic rocks is from one-fourth to one-half that of drainage basins underlain by sedimentary rocks. There are exceptions. Limestone, which may be a massive rock, is highly resistant to erosion in arid regions, where mechanical or physical weathering is dominant; but it is highly susceptible to chemical weathering, especially solution, in humid regions. Most of the earth material removed from a limestone terrain will be transported as dissolved load, with some suspended load derived from erosion of the residual soil.

Another factor of importance in determining erosion rates is the permeability of earth materials. When soils are permeable, much of the water delivered to the surface infiltrates and does not produce surface runoff, thereby inhibiting surface erosion. This condition is characteristic of very sandy soils. When, on the other hand, soil materials are of low permeability (e.g., clayey soils), a greater part of the precipitation runs off on the surface, thereby causing greater erosion and higher sediment yields. An example of this effect is provided by the five lithologic units underlying the Cheyenne River basin in eastern Wyoming. Each geologic formation is listed (Table 2) in order of decreasing permeability and infiltration capacity of the soils that were developed on these geologic units. All five of the units are relatively weak sedimentary rocks; therefore, the difference in sediment yield

rates apparently is caused primarily by the increasing percentage of precipitation that flows on the surface and causes erosion. Soils derived from the Wasatch Formation are extremely permeable, whereas the weathered and unweathered earth materials associated with the White River Group of sediments are highly impermeable.

Table 2: Sediment Yield from Rock Units of Cheyenne River Basin	
rock unit	average annual sediment yield (ac-ft per sq mi)
Wasatch Formation (sandstone)	0.13
Lance Formation (sandy shale)	0.50
Fort Union Formation (sandstone and shale)	1.30
Pierre Shale Formation	1.40
White River Group (claystone)	1.80

Most drainage areas are composed of more than one rock type. In some areas, the sedimentary rocks have been folded, and rocks of different resistance are exposed, with hard rocks forming ridges and mountains and weak rocks forming valleys. The erosional development of such a terrain is complex, and the sediment produced by such a drainage basin will reflect the complex geologic situation, the greater part of the sediment yield being derived from the areas underlain by the rocks that are most susceptible to erosion.

The character of the topography of a drainage basin significantly influences the quantity and type of runoff and sediment yield. The steeper a slope, the greater is the gravitational force acting to remove earth materials from the slope. In fact, the rate of movement of rocks and soil particles is directly related to the sine of the angle of slope inclination.

Steep slopes are readily eroded, and it follows that drainage basins with a great range of relief or steep average slope will produce not only higher sediment yields but coarser sediment. The average slope of a drainage basin can be expressed simply as a ratio of basin relief to basin length. Sediment yields increase exponentially with an increase in this relief-length ratio.

Another important characteristic of a drainage system is the spacing and distribution of drainage channels within the drainage basin (Figure 1). This is referred to as the texture of the topography, and it can be described by a ratio of total channel length to drainage area. This ratio is the drainage density of the system. A drainage density of five indicates that five miles of channel occur for every square mile of drainage basin. This number is an index of the efficiency of the drainage system; that is, high drainage density indicates numerous, closely spaced channels that provide an escape route for both runoff and its entrained sediment load.

When relief-length ratio (r), expressing the role of gravity, is combined with drainage density (d), expressing the efficiency of the drainage system, this yields a texture-slope product (rd), a parameter that describes the gross morphology of a drainage system. Hence it is not surprising that it is closely related to sediment yield of small drainage basins of similar geology and land use.

The relation between the texture-slope product and sediment yield is such that a high sediment yield can be expected from basins with a large drainage density and steep slope. For basins with similar relief-length ratios, those with the highest drainage density produce the greater quantity of sediment. In general, however, the basins with the highest drainage density are also those with the steepest slope.

Many geomorphic characteristics can be related to sediment yield, but it can be stated with assurance that the steeper and the better drained the system, the greater will be the quantity of sediment produced per unit area.

The relationship may be used to estimate yield from other drainage basins in the region from which these data were obtained. Similar relations may be developed for other regions when sufficient geomorphic data become available.

Geomorphic variables

In all studies, the sediment yield per unit area has been found to decrease as the size of the drainage basin increases. This reflects the previously discussed downstream decrease in gradient and slope, and the increase in area available for temporary storage of sediment. Thus total sediment yield per unit area invariably is related inversely to drainage area (Table 3). This relation can

Table 3: Effect of Size of Drainage Basins on Unit Sediment Yield

basin size (sq mi)	average annual sediment yield (ac-ft per sq mi)
Under 10	3.8
10-100	1.6
100-1000	1.0
Over 1,000	0.5

also be detected among the data in Table 1. Other factors are involved, of course, but the largest drainage basins listed do not produce the largest quantity of sediment per unit area of drainage basin.

The morphology of a drainage basin is significantly related to sediment yield, but sufficient research has not yet been done to enable prediction of sediment yields from drainage basins in the diverse regions of the world.

It is difficult to separate the influences of climate and vegetation on erosion and sediment yield, because the primary effect of climate on sediment yield is determined by the interaction between vegetation and runoff. This effect is displayed by the contrast between the dissolved load and the suspended load and bed load transported by streams. Dissolved load increases from a negligible amount in arid regions to 150 tons per square mile in humid regions, where chemical weathering and groundwater contribution to river flow is greatest. The dense vegetational cover of humid regions retards runoff and aids infiltration, thereby enhancing the effects of chemical decomposition of the rocks and soils to produce soluble material. The available data also show a sharp increase in sediment yield (suspended and bed load) as precipitation increases from low to moderate amounts (Figure 6). In

Relation-
ship
between
climatic
and
vegeta-
tional
influences

Figure 6: Effect of temperature on the relation between average annual sediment yield and mean annual precipitation.

semi-arid regions, however, the increase of vegetation density with increased precipitation exerts a significant influence on erosion; and sediment transport and sediment yield decrease as the climate becomes increasingly humid (Figure 6). This relationship can, of course, be significantly modified by man's activities. As the previously mentioned effect of urbanization demonstrates, removal of vegetation from the land in humid regions greatly accelerates erosion, and it may increase sediment yield to the maximum expected in semi-arid regions.

The graphs (Figure 6) also show the effects of average temperature on sediment yields. The hotter the climate, the more water is lost to evapotranspiration, and the critical zone where vegetation becomes dominant consequently shifts to areas of higher precipitation.

The effect of vegetational cover on sediment yield has been discussed previously for areas where fires have destroyed much of the cover and catastrophically increased erosion and export of sediment from the system (Figure 5). Additional data on the effect of vegetation on erosion rates reveal that with a 65 percent plant cover little erosion will occur, but as plant cover decreases erosion increases significantly. This relation may appear to be in conflict with that of Figure 6, which shows low sediment yields occurring in very arid regions, where vegetation cover should be least. It is true that the sediment concentration in the runoff from these arid regions is great, but runoff occurs so infrequently that the total quantity of sediment moved out of the system each year is scant.

Although erosion increases greatly with a decrease in plant cover between 20 percent and 15 percent, it cannot continue to increase at this high rate. At some point, the maximum rate of erosion of the soil will be achieved, and the curve will bend sharply to the left to intercept the vertical axis of the graph. At some value of low-plant-cover density, the influence of vegetation must be negligible; erosion then will be determined only by soil erodibility.

Although average precipitation significantly influences vegetation type and density and the sediment yield, it has been demonstrated that, for a given quantity of annual precipitation, sediment yields will be greatest where highly seasonal (e.g., monsoonal) climates prevail. Precipitation, when concentrated during a few months of the year, produces large quantities of sediment because of the higher intensity of the precipitation events and the long dry season when vegetational cover is weakened by drought.

Climate also plays a role in determining the type of sediment produced by a drainage basin. A study of the type of sediment deposited on the inner continental shelf reveals that the type of sediment (mud, sand, or gravel) is indeed influenced by climate. Mud, for example, is most abundant off shores of high temperature and rainfall, where chemical weathering is important. Gravel is common off areas of both low temperature and rainfall, where mechanical weathering is dominant. Sand is found everywhere, but it is most abundant in areas of moderate climate and in arid areas. Average temperature also may be important where the annual temperature is below the freezing point.

The preceding discussion of sediment yields has dealt solely with drainage basins subject to the common fluvial processes; however, in high mountains and at high latitudes, glaciers may occupy a drainage basin. The sediment yields from basins containing glaciers are significantly higher than from similar basins without glaciers. An unglaciated drainage basin in the Austrian Alps, for example, has an annual sediment yield of 91 tons per square mile, whereas an adjacent basin, 46 percent of which is occupied by a glacier, produces 3,900 tons per square mile of sediment annually.

BIBLIOGRAPHY. VEN TE CHOU (ed.), *Handbook of Applied Hydrology* (1964), contains 29 sections on all aspects of the hydrologic cycle. Chapters relevant to the topic of sediment yield are the following: H.A. EINSTEIN, "River Sedimentation," Sect. 17, pt. 2, pp. 35-67; L.C. GOTTSCHALK, "Reservoir Sedimentation," sect. 17, pt. 1, pp. 1-34; and A.N. STRAHLER, "Quantitative Geomorphology of Drainage Basins and Channel Networks," sect. 4, pt. 2, pp. 39-76. R.J. CHORLEY (ed.), *Water, Earth, and Man: A Synthesis of Hydrology, Geomorphology, and Socio-Economic Geography* (1969), contains 37 chapters by 25 authors. Of special interest are the following: DR. STODDART, "World Erosion and Sedimentation," pp. 43-66; R.J. CHORLEY, "The Drainage Basin as the Fundamental Geomorphic Unit," pp. 77-100; M.J. KIRKBY, "Erosion by Water on Hillslopes," pp. 229-238; and M.A. MORGAN, "Overland Flow and Man," pp. 239-258. UNITED STATES DEPARTMENT OF AGRICULTURE, *Proceedings of the Federal Interagency Sedimentation Conference, 1963* (1965),

includes information on land erosion and control, sediment in streams, sedimentation in estuaries, harbours, and coastal areas, and sedimentation in reservoirs. J.J. HOLEMAN, "The Sediment Yield of Major Rivers of the World," *Wat. Resour. Res.*, 4:737-747 (1968), is a compilation of data on the sediment yield from all parts of the world.

(S.A.S.)

Seed and Fruit

A seed is the characteristic reproductive body of both angiosperms (flowering plants) and gymnosperms (conifers, cycads, and ginkgos). Essentially, it consists of a miniature, undeveloped plant (the embryo), which, alone or in the company of stored food for its early development after germination, is surrounded by a protective coat (the testa). Frequently small in size and making negligible demands upon their environment, seeds are eminently suited to perform a wide variety of functions: the relationships of which are not always obvious: multiplication, perennation (surviving seasons of stress such as winter), dormancy (a state of arrested development), and dispersal. Pollination and the "seed habit" are considered the most important factors responsible for the overwhelming evolutionary success of the flowering plants, which number more than 300,000 species.

The superiority of dispersal by means of seeds over the more primitive method involving single-celled spores, lies mainly in two factors: the stored reserve of nutrient material that gives the new generation an excellent growing start and the seed's multicellular structure, which provides ample opportunity for the development of adaptations for dispersal, such as plumes for wind dispersal, barbs, and others.

Economically, seeds (and the fruits that contain them) are important primarily because they provide man with his most important foods; for example, the cereal grains, such as wheat, rice, and maize; the seeds of beans, peas, peanuts, soybeans, almonds, sunflowers, hazelnuts, walnuts, pecans, and Brazil nuts; the fruits of date palm, olive, banana, avocado, apple, and orange. Many fruits, especially those in the citrus family—limes, lemons, oranges, grapefruits—are rich in vitamin C (ascorbic acid); unpolished cereal grains in vitamin B₁ (thiamine); and wheat germ in vitamin E. Other useful products provided by seeds and fruits are abundant. Oils for cooking, margarine production, painting, and lubrication are available from the seeds of flax, rape, cotton, soybean, poppy, castor bean, coconut, sesame, safflower, sunflower, the cereal grains of maize, and the fruits of olive and oil palm. Essential oils are obtained from such sources as juniper "berries," used in gin manufacture. Waxes such as those from bayberries (wax myrtles) and vegetable ivory from the hard fruits of a South American palm species are important products. Stimulants are obtained from such sources as the seeds of coffee, kola, guarana, and cocoa; and drugs, such as morphine, come from opium-poppy fruits. Spices—from mustard and nutmeg seeds; from the aril ("mace") covering the nutmeg seed; from fruits of anise, cumins, caraway, dill, vanilla, black pepper, red or chili pepper, allspice, and others—form a large group of economic products. Dyes (Persian berries, butternut brown, sap green) and ornaments (*Job's tears* from the grass *Coix*, used for curtains; *Abrus*, *Adenanthera*, and *Rhynchosia* seeds for necklaces; others for rosaries) are also provided by seeds and fruits.

GENERAL FEATURES

Seeds. Angiosperm seeds. In the typical flowering plant, or angiosperm, seeds are formed from bodies called ovules contained in the ovary, or basal part of the female plant structure, the pistil. The mature ovule contains in its central part a region called the **nucellus** that in turn contains an embryo sac with eight nuclei, each with one set of chromosomes (*i.e.*, they are haploid nuclei). The two nuclei near the centre are referred to as polar nuclei; the egg cell, or oosphere, is situated near the micropylar ("open") end of the ovule. With very few exceptions (*e.g.*, the dandelion), development of the ovule into a seed is dependent upon fertilization, which in turn follows pollination. Pollen grains that land on the receptive upper surface

(stigma) of the pistil will germinate, if they are of the same species, and produce pollen tubes, each of which grows down within the style (the upper part of the pistil) toward an ovule. The pollen tube has three haploid nuclei, one of them, the so-called vegetative, or tube, nucleus seems to direct the operations of the growing structure. The other two, the generative nuclei, can be thought of as nonmotile sperm cells. After reaching an ovule and breaking out of the pollen tube tip, one generative nucleus unites with the egg cell to form a diploid zygote (*i.e.*, a fertilized egg with two complete sets of chromosomes, one from each parent), which, through a limited number of divisions gives rise to an embryo. The other generative nucleus fuses with the two polar nuclei to produce a triploid (three sets of chromosomes) nucleus, which divides repeatedly before cell-wall formation occurs, producing the triploid endosperm, a nutrient tissue that contains a variety of storage materials—such as starch, sugars, fats, proteins, hemicelluloses, and phytic acid (a phosphate reserve). The events just described constitute what is called the double-fertilization process, one of the characteristic features of all flowering plants. In the orchids and in some other plants with minute seeds that contain no reserve materials, endosperm formation is completely suppressed. In other cases it is greatly reduced, but the reserve materials are present elsewhere—*e.g.*, in the cotyledons, or seed leaves, of the embryo, as in beans, lettuce, and peanuts, or in a tissue derived from the nucellus, the perisperm, as in coffee. Other seeds, such as those of beets, contain both perisperm and endosperm. The seed coat, or testa, is derived from the one or two protective integuments of the ovule. The ovary, in the simplest case, develops into a fruit. In many plants, such as the grasses and lettuce, the outer integument and ovary wall are completely fused, so that seed and fruit form one entity; thus seeds and fruits can logically be described together as "dispersal units," or diaspores. More often, however, the seeds are discrete units attached to the placenta on the inside of the fruit wall through a stalk, or funiculus. The hilum of a liberated seed is a small scar marking its former place of attachment. The short ridge (**raphe**) that sometimes leads away from the hilum is formed by the fusion of seed stalk and testa. In many seeds, the micropyle of the ovule also persists as a small opening in the seed coat. The embryo, variously located in the seed, may be very small (as in buttercups) or may fill the seed almost completely (as in roses and plants of the mustard family). It consists of a root part, or radicle, a prospective shoot (plumule or epicotyl), one or more cotyledons (one or two in flowering plants, several in *Pinus*), and a hypocotyl, which is a region that connects radicle and plumule (see Figure 1). A classification of seeds can be based on size and position of the embryo and on the proportion of embryo to storage tissue; the possession of either one or two cotyledons is considered crucial in rec-

Double fertilization in angiosperms

Figure 1: Longitudinal sections of mature seeds. (Left) *Zea mays*, maize or Indian corn, a monocotyledonous caryopsis, or grain, which is actually both seed and fruit through the fusion of the seed coat with the ovary wall. (Centre and right) *Ricinus communis*, castor bean, a dicotyledonous seed, edge and face views.

ognizing two main groups of flowering plants, the Monocotyledones and Dicotyledones.

Seedlings, arising from embryos in the process of germination, are classified as epigeal (cotyledons above ground, usually green and capable of photosynthesis) and hypogeal (cotyledons below ground; see Figure 2). Particularly in the monocots, special absorbing organs may develop that mobilize the reserve materials and withdraw them from the endosperm; e.g., in the grasses, the cotyledon has been modified into an enzyme-secreting scutellum ("shield") between embryo and endosperm.

From A.M. Mayer and A. Poljakoff-Mayber, *The Germination of Seeds* (1963); Pergamon Press Ltd

Figure 2: Seedling morphology and germination modes. (Left) Epigeal germination. (Right) Hypogeal germination.

Gymnosperm seeds. In gymnosperms (plants with "naked seeds"—conifers, cycads, ginkgos) the ovules are not enclosed in an ovary but lie exposed on leaflike structures, the megasporophylls. A long time span separates pollination and fertilization, and the ovules begin to develop into seeds long before fertilization has been accomplished; in some cases, in fact, fertilization does not occur until the ovules ("seeds") have been shed from the tree. In the European pine *Pinus sylvestris*, for example, the female cones (essentially collections of megasporophylls) begin to develop in winter and are ready to receive pollen from the male cones in spring. During the first growing season, the pollen tube grows slowly through the nucellus, while within the ovule the megaspore nucleus, through a series of divisions, gives rise to a collection of some 2,000 nuclei, which are then individually enclosed by walls to form a structure called the female gametophyte or prothallus. At the micropylar end of the ovule, several archegonia (bottle-shaped female organs) develop, each containing an oosphere ("egg"). The pollen tube ultimately penetrates the neck of one of the archegonia. Not until the second growing season, however, does the nucleus of one of the male cells in the tube unite with the oosphere nucleus. Although more than one archegonium may be fertilized, only one gives rise to a viable embryo. During the latter's development, part of the prothallus is broken down and used. The remainder, referred to as "endosperm," surrounds the embryo; it is mobilized later, during germination of the seed, a process that occurs without delay when the seeds are liberated from the female cone during the third year after their initiation.

Fruits. The concept "fruit" is based on such an odd mixture of practical and theoretical considerations that it accommodates cases in which one flower gives rise to several fruits (larkspur) as well as cases in which several flowers cooperate in producing one fruit (mulberry). Pea and bean plants, exemplifying the simplest situation, show in each flower a single pistil, traditionally thought of as a megasporophyll or carpel. The carpel is believed to be the evolutionary product of an originally leaflike organ bearing ovules along its margin, but somehow folded along the median line, with a meeting and coalescing of the margins of each half, the result being a miniature, closed but hollow pod with one row of ovules along the

suture. In many members of the rose and buttercup families each flower contains a number of similar single-carpelled pistils, separate and distinct, which together represent what is known as an apocarpous gynoecium. In still other cases, two to several carpels (still thought of as megasporophylls, although perhaps not always justifiably) are assumed to have fused to produce a single compound gynoecium (pistil), whose basal part or ovary may be uniloculate (one cavity) or pluriloculate (with several compartments), depending on the method of carpel fusion. Most fruits develop from a single pistil. A fruit resulting from the apocarpons gynoecium (several pistils) of a single flower may be referred to as an aggregate fruit; a multiple fruit represents the gynoecia of several flowers. When additional flower parts, such as the stem axis or floral tube, are retained or participate in fruit formation, as in the apple, an accessory fruit results.

Certain plants, mostly cultivated varieties, spontaneously produce fruits in the absence of pollination and fertilization; such natural parthenocarpy leads to seedless fruits such as bananas, oranges, grapes, grapefruits, and cucumbers. Since 1934 seedless fruits of tomato, cucumber, peppers, holly, and others have also been obtained for commercial use by administering growth hormones, such as indoleacetic acid, indolebutyric acid, naphthalene acetic acid, and beta-naphthoxyacetic acid to ovaries in flowers (induced parthenocarpy).

Classification systems for mature fruits take into account the number of carpels constituting the original ovary; dehiscence (opening) versus nondehiscence; and dryness versus fleshiness. The properties of the ripened ovary wall, or pericarp, which may develop entirely or in part into fleshy, fibrous, or stony tissue, are important. Often, three distinct pericarp layers can be distinguished: the outer (exocarp), the middle (mesocarp), and the inner layer (endocarp). All purely morphological systems (i.e., classification schemes based on structural features), including the one given in the Table and in Figure 3, are artificial. They ignore the fact that fruits can only be understood functionally and dynamically.

As strikingly exemplified by the word nut, popular terms often do not properly describe the botanical nature of certain fruits. A Brazil "nut," for example, is a thick-walled seed enclosed in a likewise thick-walled capsule along with several sister seeds. A coconut is a drupe (a stony-seeded fruit; see the Table) with a fibrous outer part. A walnut is a drupe in which the pericarp has differentiated into a fleshy outer husk and an inner hard "shell"; the "meat" represents the seed—two large, convoluted cotyledons, a minute epicotyl and hypocotyl, and a thin, papery seed coat. A peanut is an indehiscent legume fruit. An almond "nut" is the "stone"—i.e., the hardened endocarp of a drupe usually containing a single seed. Botanically speaking, blackberries and raspberries are not "berries" but aggregates of tiny drupes. A juniper "berry" is comparable to a complete pine cone. A mulberry is a multiple fruit (see the Table) composed of small nutlets surrounded by fleshy sepals; a strawberry represents a much swollen receptacle (the tip of the flower stalk bearing the flower parts) bearing on its convex surface an aggregation of tiny achenes (small, single-seeded fruits; see the Table).

FORM AND FUNCTION

Seedsize. In the Late Carboniferous Period (about 280,000,000 to 325,000,000 years ago) some seed ferns produced large seeds (12 × 6 centimetres [5 × 2 inches] in *Pachytesta incrassata*). This primitive, ancestral condition of large seeds is reflected in certain gymnosperms (*Cycas circinalis*, 5.5 × 4 centimetres; *Araucaria bidwillii*, 4.5 × 3.5 centimetres) and also in some tropical rain-forest trees with nondormant, water-rich seeds (*Mora excelsa*, 12 × 7 centimetres). The "double coconut" palm *Lodoicea maldivica* represents the extreme, with seeds weighing up to 27 kilograms (about 60 pounds). Herbaceous, nontropical flowering plants usually have seeds weighing in the range of about 0.0001 to 0.01 grams. Within a given family (e.g., the pea family, Fabaceae or Leguminosae) seed size may vary greatly; in others it

is consistently large or small, justifying the recognition of "megaspermous" families (e.g., the beech, nutmeg, palm, and soursop families) and "microspermous" ones (e.g., the milkweed, daisy, heather, nettle, and willow families). The smallest known seeds, devoid of food reserves, are found in orchids, saprophytes (non-green plants that absorb nutrients from dead organic matter—e.g., Indian pipe, *Monotropa*; coral root, *Coralorhiza*), carnivorous plants (sundews, pitcher plants), and total parasites (members of the families Rafflesiaceae and Orobanchaceae, or broomrapes, which latter have seeds weighing about 0.001 milligrams—about 3.5 hundred-millionths of an ounce). Clearly, seed size is related to life-style—total parasites obtain food from their host, even in their early growth stages, and young orchids are saprophytes that receive assistance in absorbing nutrients from fungi that associate closely with their roots. In both cases only very small seeds that lack endosperm are produced. Dodders (*Cuscuta*) and mistletoes (*Viscum*, *Phoradendron*) live independently when very young and accordingly have relatively large seeds. Many plant species possess seeds of remarkably uniform size, useful as beads (e.g., *Abrus precatorius*) or units of weight—one carat of weight once corresponded with one seed of the carob tree, *Ceratonia siliqua*. In wheat and many other plants, average seed size does not depend on planting density, showing that seed size is under rather strict genetic control. This does not necessarily preclude significant variations among individual seeds; in peas, for example, the seeds occupying the central region of the pod are the largest, probably as the result of competition for nutrients between developing ovules on the placenta. Striking evolutionary changes in seed size, inadvertently created by man, have occurred in the weed *Camelina sativa* subspecies *linicola*, which grows in flax fields. The

The smallest seeds

Classification of Fruits

major types	structure	
	one carpel	two or more carpels
Dry dehiscent	<p>Follicle—at maturity, the carpel splits down one side, usually the ventral suture; milkweed, columbine, peony, larkspur, marsh marigold</p> <p>Legume—dehiscence along both dorsal and ventral sutures, forming two valves; most members of the pea family</p>	<p>Capsule—from compound ovary, seeds shed in various ways—e.g., through holes (Papaver—poppies) or longitudinal slits (California poppy) or by means of a lid (pimpernel); flower axis participates in <i>tristylis</i>; snapdragons, violets, lilies, and many plant families</p> <p>Silique—from bicarpellate, compound, superior ovary; pericarp separates as two halves, leaving persistent central septum with seed or seeds attached; dollar plant, mustard, cabbage, rock cress, wall flower</p> <p>Silicle—a short silique; shepherd's purse, pepper grass</p>
Dry indehiscent	<p>Peanut fruit—(nontypical legume)</p> <p>Lomentum—a legume fragmenting transversely into single-seeded "mericarps"; sensitive plant (<i>Mimosa</i>)</p>	<p>Nut—like the achene (see below); derived from 2 or more carpels, pericarp hard or stony; hazelnut, acorn, chestnut, basswood</p> <p>Schizocarp—collectively, the product of a compound ovary fragmenting at maturity into a number of one-seeded "mericarps"; maple, mallows, members of the mint family (Lamiaceae or Labiatae), geraniums, carrots, dills, fennels</p>
Fleshy (pericarp partly or wholly fleshy or fibrous)	<p>Achene—small, single-seeded fruit, pericarp relatively thin; seed free in cavity except for its funicular attachment; buttercup, anemones, buckwheat, crowfoot, water plantain</p> <p>Cypsel—achene-like, but from inferior, compound ovary; members of the aster family (Asteraceae or Compositae), sunflowers</p> <p>Samara—a winged achene; elm, ash, tree-of-heaven, wafer ash</p> <p>Caryopsis—achene-like; from compound ovary; seed coat fused with pericarp; grass family (Poaceae or Graminae)</p> <p>Drupe—mesocarp fleshy, endocarp hard and stony; usually single-seeded; plum, peach, almond, cherry, olive, coconut</p> <p>Berry—both mesocarp and endocarp fleshy; one-seeded: nutmeg, date; one carpel, several seeds: baneberry, may apple, barberry, Oregon grape; more carpels, several seeds: grape, tomato, potato, asparagus</p> <p>Pepo—berry with hard rind; squash, cucumber, pumpkin, watermelon</p> <p>Hesperidium—berry with leathery rind; orange, grapefruit, lemon</p>	<p>Two or more carpels of the same flower plus stem axis or floral tube</p> <p>Carpels from several flowers plus stem axis or floral tube plus accessory parts</p>
Fleshy (pericarp partly or wholly fleshy or fibrous)	<p>Pome—accessory fruit from compound, inferior ovary; only central part of fruit represents pericarp, with fleshy exocarp and mesocarp and cartilaginous or stony endocarp ("core"); apple, pear, quince, hawthorn, mountain ash</p> <p>Inferior berry—blueberry</p> <p>Aggregate fleshy fruits—strawberry (achenes borne on fleshy receptacle); blackberry, raspberry (collection of drupelets); magnolia</p>	<p>Multiple fruits—fig (a "syconium"), mulberry, osage orange, pineapple, flowering dogwood</p>

customary winnowing of flax seeds selects forms of *Camelina* whose seeds are blown over the same distance as flax seeds in the operation, thus staying with their "models." Consequently, *Camelina* seeds in the south of Russia now mimic the relatively thick, heavy seeds of the

oil flax that is grown there, whereas in the northwest they resemble the flat, thin seeds of the predominant fibre flax.

Seed size and predation. Seeds form the main source of food for many birds, rodents, ants, and beetles. Harvester ants of the genus *Veromessor*, for example, exact a toll of about 15,000,000 seeds per acre per year from the Sonoran Desert of the southwestern United States. In view of the enormous size range of the predators, which include minute weevil and bruchid-beetle larvae that attack the seeds internally, evolutionary "manipulation" of seed size by a plant species cannot in itself be effective in completely avoiding seed attack. With predation inescapable, however, it must be advantageous for a plant species to invest the total reproductive effort in a large number of very small units (seeds) rather than in a few big ones. The mean seed weight of those 13 species of Central American woody legumes vulnerable to bruchid attack is 0.26 gram; for the 23 species invulnerable by virtue of toxic seed constituents it is three grams.

Seed size and germination. Ecologically, seed size is also important in the breaking of dormancy. Being small, a seed can only "sample" that part of the environment immediately adjacent to it, which is not necessarily representative of the generally prevailing conditions. For successful seedling establishment, there is clearly a risk in "venturing out" too soon. The development in seeds of mechanisms acting as "integrating rain gauges" (see below) should be considered in that light.

The shape of dispersal units. Apart from the importance of shape as a factor in determining the mode of dispersal (e.g., wind dispersal of winged seeds, animal

dispersal of spiny fruits), shape also counts when the seed or diaspore is seen as a landing device. The flatness of the enormous tropical *Mora* seeds prevents rolling and effectively restricts germination to the spot where they land. In contrast, *Eusideroxylon zwageri* does not grow on steep slopes because its heavy fruits roll downhill. The grains of the grass *Panicum turgidum*, which have a flat and a round side, germinate much better when the flat rather than the convex side lies in contact with wet soil. In very small seeds, the importance of shape can be judged only by taking into account soil clod size and microtopography of the soils onto which they are dropped. The rounded seeds of cabbage species, for example, tend to roll into crevices, whereas the reticulate ones of lamb's quarters often stay in the positions in which they first fall. Several seeds have appendages (awns, bristles) that promote germination by aiding in orientation and self-burial. In one study, for example, during a six-month period, awned grains of *Danthonia penicillata* gave rise to 12 times as many established seedlings as de-awned ones.

Polymorphism of seeds and fruits. Some plant species produce two or more sharply defined types of seeds that differ in appearance (colour), shape, size, internal structure, or dormancy. In common spurry (*Spergula arvensis*), for example, the seed coat (part of the mother plant) may be either smooth or papillate (covered with tiny nipple-like projections). Here, the phenomenon is genetically controlled by a single factor, so that all the seeds of a given plant are either papillate or smooth. More common is somatic polymorphism, the produc-

Functional aspects of seed shape

tion by individual plants of different seed types, or "morphs." Somatic polymorphism occurs regularly in *Atriplex* and *Chenopodium*, in which a single plant may produce both large brown seeds capable of immediate germination and small black ones with some innate dormancy. Somatic polymorphism may be controlled by the position of the two (or more) seed types within one inflorescence (flower cluster) or fruit, as in cocklebur, or it may result from environmental effects, as in Halogeton, in which imposition of long or short days leads to production of brown and black seeds, respectively. Since the different morphs in seed (and fruit) polymorphism usually have different dispersal mechanisms and dormancies, so that germination is spread out both in space and in time, the phenomenon can be seen as an insurance against catastrophe. The most spectacular example of heterocarpy (*i.e.*, production of differing fruit) is found in the Mediterranean *Fedia cornucopiae* (family *Valerianaceae*), which has three astonishingly different kinds of fruits that show adaptations to dispersal by wind and water, ants, and larger animals, respectively.

DISPERSAL

The dispersing agents for seeds and fruits are indicated in such terms as anemochory, hydrochory, and zoochory, which mean dispersal by wind, water, and animals, respectively. Within the zoochorous group further differentiation according to the carriers can be made: saurochory, dispersal by reptiles; ornithochory, by birds; myrmecochory, by ants. Or the manner in which the diaspores are carried can be emphasized, distinguishing endozoochory, diaspores carried within the animal; epizoochory, diaspores accidentally carried on the outside; and synzoochory, diaspores intentionally carried, mostly in the mouth as in birds and ants. See Figure 4 for examples of fruits and seeds that are adapted for dispersal by various means.

Dispersal by animals. Snails disperse the small seeds of a very few plant species (*e.g.*, *Adoxa*). Earthworms are more important as seed dispersers. Many intact fruits and seeds can serve as fish bait, those of *Sonneratia*, for example, for the catfish *Arius maculatus*. Certain Amazon River fishes react positively to the audible "explosions" of the ripe fruits of *Eperua rubiginosa*. Fossil evidence indicates that saurochory is very ancient. The giant Galapagos tortoise is important for the dispersal of local cacti and tomatoes. The name alligator apple for *Annona palustris* refers to its method of dispersal, an example of saurochory. Many mammals, ranging in size from mice and kangaroo rats to elephants, eat and disperse seeds and fruits. In the tropics, chiropterochory (dispersal by large bats such as flying foxes, *Pteropus*) is particularly important. Fruits adapted to these animals are relatively large and drab in colour, with large seeds and a striking (often rank) odour; they are accessible to bats because of the pagoda-like structure of the tree canopy, fruit placement on the main trunk, or suspension from long stalks that hang free of the foliage. Examples include mangoes, guavas, breadfruit, carob, and several fig species. In South Africa, a desert melon (*Cucumis humifructus*) participates in a symbiotic relationship with armadillos—the animals eat the fruit for its water content and bury their own dung, which contains the seeds, near their burrows. Furry terrestrial mammals are the agents most frequently involved in epizoochory, the inadvertent carrying by animals of dispersal units. Burrlike seeds and fruits, or those diaspores provided with spines, hooks, claws, bristles, barbs, grapples, and prickles, are genuine hitchhikers, clinging tenaciously to their carriers. Their functional shape is achieved in various ways—in cleavers, or goose grass (*Galium aparine*), and enchanter's nightshade (*Circaea lutetiana*) the hooks are part of the fruit itself; in common agrimony (*Agrimonia eupatoria*) the fruit is covered by a persistent calyx (the sepals, parts of the flower, which remain attached beyond the usual period) equipped with hooks; in wood avens (*Geum urbanum*) the persistent styles have hooked tips. Other examples are bur marigolds, or beggar's-ticks (*Bidens* species); buffalo burr (*Solanum rostratum*); burdock (*Arctium*); *Acaena*;

and many *Medicago* species. The last named, with dispersal units highly resistant to damage from hot water and certain chemicals (dyes), have achieved wide global distribution through the wool trade. A somewhat different principle is employed by the so-called trample burrs, said to lodge themselves between the hooves of large grazing mammals. Examples are mule grab (*Proboscidea*) and the African grapple plant (*Harpagophytum*). In water burrs, such as those of the water nut *Trapa*, the spines should probably be considered as anchoring devices.

Dispersal by birds. Birds, being preening animals, rarely carry burrlike diaspores on their bodies. They do, however, transport the very sticky (viscid) fruits of *Pisonia*, a tropical tree of the four-o'clock family, to distant Pacific islands in this way. Small diaspores, such as those of sedges and certain grasses, may also be carried in the mud sticking to waterfowl and terrestrial birds.

Synzoochory, deliberate carrying of diaspores by animals, is practiced when birds carry diaspores in their beaks. The European mistle thrush, *Turdus viscivorus*, deposits the viscid seeds of mistletoe (*Viscum album*) on potential host plants when, after a meal of the berries, it whets its bill on branches or simply regurgitates the seeds. The North American mistletoes (*Phoradendron*) are dispersed by various birds, and the comparable tropical species of the plant family Loranthaceae by flowerpeckers (of the bird family Dicaeidae), which have a highly specialized gizzard that allows seeds to pass through but retains insects. Plants may also profit from the forgetfulness and sloppy habits of certain nut-eating birds that cache part of their food but neglect to recover everything, or drop units on their way to the hiding place. Best known in this respect are the nutcrackers (*Nucifraga*), which feed largely on the "nuts" of beech, oak, walnut, chestnut, and hazel; the jays (*Garrulus*), which hide hazelnuts and acorns; the nuthatches; and the California woodpecker (*Balanosphyra*), which may embed literally thousands of acorns, almonds, and pecan nuts in bark fissures or holes of trees. Secondarily, rodents may aid in dispersal by stealing the embedded diaspores and burying them. In Germany an average jay may transport about 4,600 acorns per season, over distances of up to four kilometres (2.5 miles). Woodpeckers, nutcrackers, and squirrels are responsible for a similar dispersal of *Pinus cembra* in the Alps near the tree line.

Most ornithochores (plants with bird-dispersed seeds) have conspicuous diaspores attractive to such fruit-eating birds as thrushes, pigeons, barbets (members of the bird family Capitonidae), toucans, and hornbills (family Bucerotidae), all of which excrete the hard part undamaged. Such diaspores have a fleshy, sweet, or oil-containing edible part; a striking colour (often red or orange); no pronounced smell; a protection against being eaten prematurely in the form of acids and tannic compounds that are present only in the green fruit; a protection of the seed against digestion—bitterness, hardness, or the presence of poisonous compounds; permanent attachment; and, finally, absence of a hard outer cover. In contrast to bat-dispersed diaspores, they occupy no special position on the plant. Examples are rose hips, plums, dogwood fruits, barberry, red currant, mulberry, nutmeg fruits, figs, blackberries, and others. The natural and abundant occurrence of *Evonymus* (cardinal's hat), essentially a tropical genus, in temperate Europe and Asia, can be understood only in connection with the activities of birds. Birds also contributed substantially to the repopulation with plants of the island Krakatau after the catastrophic eruption of 1883. Birds have made Lantana (originally American) a pest in Indonesia; the same is true of wild plums (*Prunus serotina*) in parts of Europe and *Rubus* species in Brazil and New Zealand.

Mimicry—the protection-affording imitation of a dangerous or toxic species by an edible, harmless one—is shown in reverse by certain bird-dispersed "coral seeds" such as those of many species in the genera *Abrus*, *Ormosia*, *Rhynchosia*, *Adenantha*, and *Erythrina*. Hard and often shiny red or black and red, many such seeds deceptively suggest the presence of a fleshy red aril and thus invite the attention of hungry birds.

Adapta-
tions of
seeds and
fruits to
bird
dispersal

Water dispersal: red mangrove seedling (*Rhizophora mangle*) ready to drop into the water after germinating on tree.

Wind dispersal: woolly seeds produced by the seed pods of the kapok tree (*Ceiba pentandra*).

Wind dispersal: winged fruits of the silver maple (*Acer saccharinum*).

Wind dispersal: magnified view of seeds of lady's slipper (*Cypripedium*), an example of the tiny seeds produced by orchids.

Water dispersal: a coconut (*Cocos nucifera*), transported by the sea from a distant tropical island, germinating on a mainland beach.

Self-dispersal: plumes on the fruits of mountain mahogany (*Cercocarpus*), which coil and uncoil to drive seeds into the soil.

Wind, water, and self-dispersal

Naras melons (*Acanthosicyos horrida*) growing in the Namib Desert, South West Africa. Seeds are dispersed by the gemsbok oryx (*Oryx gazella*), which feeds on the melons.

Seeds of rosary pea (*Abrus precatorius*), which mimic fleshy red arils (accessory seed coverings) attractive to seed-eaters.

Acorns stored in the trunk of a digger pine (*Pinus sabriniana*) by the acorn woodpecker (*Melanerpes formicivorus*).

Fleshy red appendages of fruits of the yew (*Taxus*), which attract birds.

Animal dispersal

Epauletted fruit bat (*Epomophorus wahlbergi*) feeding on wild figs (*Ficus*).

Curve-bill thrasher (*Toxostoma curvirostre*) with a berry in its beak.

Dispersal by ants. Mediterranean and North American harvester ants (*Messor*, *Atta*, *Tetramorium*, and *Pheidole*) are essentially destructive, storing and fermenting many seeds and eating them completely. Other ants (*Lasius*, *Myrmica*, and *Formica* species) eat the fleshy, edible appendage (the fat body or elaiosome) of certain specialized seeds, which they disperse (see Figure 5). Most myrmecochorous plants (species of violet, primrose, hepatica, cyclamen, anemone, corydalis, *Trillium*, and bloodroot) belong to the herbaceous spring flora of northern forests. Tree poppy (*Dendromecon*), however, is found in the dry California chaparral; *Melica* and *Centaurea* species in arid Mediterranean regions. The so-called ant epiphytes of the tropics (*i.e.*, species of *Hoya*, *Dischidia*, *Aeschynanthus*, and *Myrmecodia*—plants that live in "ant gardens" on trees or offer the ants shelter in their own body cavities) constitute a special group of myrmecochores, providing oil in seed hairs, which in ancestral forms must have served in wind dispersal. The primary ant attractant of myrmecochorous seeds is not necessarily oil; instead, an unsaturated, somewhat volatile fatty acid is suspected in some cases. The myrmecochorous plant as a whole may also have specific adaptations; for example, *Cyclamen* brings fruits and seeds within reach of ants by conspicuous coiling (shortening) of the flower stalk as soon as flowering is over.

Fritz Schremmer

Figure 5: Seed dispersal by ants. (Top left) Fruit of greater celandine (*Chelidonium majus*) opened to show dark seeds with light elaiosomes (fat bodies). (Top right) Ant (*Myrmica laevinodis*) dispersing celandine seeds. (Bottom) Harvester ant (*Messor barbarus*) transporting cereal grains.

Dispersal by wind. In the modern world, wind dispersal (although numerically important) reflects the climatic and biotic poverty of certain regions; it is essentially a feature of pioneer vegetations. The flora of the Alps is 60 percent anemochorous, that of the Mediterranean **garigue** 50 percent. By making certain assumptions (*e.g.*, for average wind velocity and turbulence) the "average limits of dispersal"—that is, the distance that 1 percent of the diaspores can reach—can be calculated for dispersal units of various construction and weight. This calculation yields values of ten kilometres (six miles) for dandelion (*Taraxacum officinale*) and 0.5 kilometre (0.3 mile) for European pine (*Pinus sylvestris*). Storms result in higher values—30 kilometres (20 miles) for poplar and 200 kilometres (125 miles) for *Senecio congestus*.

Too much success in dispersal may be ecologically futile, as exemplified by certain Florida orchids that arise from windblown West Indian seeds but do not multiply

because of the lack of specific pollinators; usually certain bees or wasps. Anemochorous diaspores can be subdivided into flyers, dust diaspores, balloons, and plumed or winged diaspores; rollers, chamaechores or tumbleweeds; and throwers, ballistic anemochores. Dispersal by means of minute dust diaspores produced in huge quantities is comparable to spore dispersal in lower plants—a "saturation bombing" is required to find the very limited number of targets, or favourable growth habitats, that exist. Not surprisingly, it is practiced mostly by total parasites, such as broomrapes (in which the finding of the specific host is a problem), and saprophytes. The inflated, indehiscent pods of *Colutea arborea*, a steppe plant, represent balloons capable of limited air travel before they hit the ground and become windblown tumbleweeds. Winged fruits are most common in trees and shrubs, such as maple, ash, elm, birch, alder, and dipterocarps (a family of about 600 species of Old World tropical trees). The one-winged propeller type, as found in maple, is called a samara. When fruits have several wings on their sides, rotation may result, as in rhubarb and dock species. Sometimes accessory parts form the wings—for example, the bracts (small green leaflike structures that grow just below flowers) in *Tilia* (linden). Seeds with a thin wing formed by the testa are likewise most common in trees and shrubs, particularly in climbers—jacaranda, trumpet vine, catalpa, yams, butter-and-eggs. Most famous of these is the seed with a giant, membranaceous wing (15 centimetres) of *Macrozanonia macrocarpa*, a tropical climber of the cucumber family.

Many fruits form plumes, some derived from persisting and ultimately hairy styles, as in clematis, avens, and anemones; some from the perianth, as in the sedge family (Cyperaceae); and some from the **pappus**, a calyx structure, as in dandelion and Jack-go-to-bed-at-noon (*Tragopogon*). Plumed seeds usually have tufts of light, silky hairs at one end (rarely both ends) of the seeds—*e.g.*, fireweed, milkweeds, dogbane. In woolly fruits and seeds, the pericarp or the seed coat is covered with cotton-like hairs—*e.g.*, willow, poplar or cottonwood, kapok, cotton, balsa, silk-cotton tree, and some anemones. In some cases, the hairs may serve double duty, in that they function in water dispersal as well as wind dispersal. In tumbleweeds, the whole plant or its fruiting portion breaks off and is blown across open country, scattering seeds as it goes; examples include Russian thistle, pigweed, tumbling mustard, perhaps rose of Jericho, and "windballs" of the grass *Spinifex* of Indonesian shores and Australian steppes. Poppies have a mechanism in which the wind has to swing the slender fruitstalk back and forth before the seeds are thrown out through pores near the top of the capsule.

Dispersal by water. Many beach, pond, and swamp plants have waterborne seeds, which are buoyant by being enclosed in corky fruits or air-containing fruits or both; examples of these plants include water plantain, yellow flag, sea kale, sea rocket, sea beet, and all species of Rhizophoraceae, a family of mangrove plants. Sea dispersal of the coconut palm has been well proved; the fibrous **mesocarp** of the fruit, a giant drupe, provides buoyancy. Once the nuts are ashore, the **mesocarp** also aids in the aboveground germination process by collecting rainwater; in addition, the endosperm has in its "milk" a provision for seedling establishment on beaches without much freshwater. A sea rocket species with seeds highly resistant to seawater is gaining a foothold on volcanic Surtsey Island south of Iceland. Purple loosestrife, monkey flower, *Aster tripolium*, and *Juncus* species (rushes) are often transported by water in the seedling stage. Rainwash down mountain slopes may be important in tropical forests. A "splashcup mechanism," common in fungi for spore dispersal, is suggested by the open fruit capsule with exposed small seeds in the pearlwort (*Sagina*) and mitrewort (*Mitella*). Hygrochasy, the opening of fruits in moist weather, is displayed by species of Mesembryanthemum, *Sedum*, and other plants of dry environments.

Self-dispersal. Best known in this category are the active ballists, which forcibly eject their seeds by means of

Plant and
ant
interrela-
tionships

Winged
fruits

Explosive
fruits

various mechanisms. In the fruit of the dwarf mistletoe (*Arceuthobium*) of the western United States, a very high osmotic pressure (pressure accumulated by movement of water across cell membranes principally in only one direction) builds up that ultimately leads to a lateral blasting out of the seeds over distances of up to 48 feet with an initial velocity of about 60 miles per hour. Squirt-cucumber (*Echallium elaterium*) also employs an osmotic mechanism. In Scotch broom and gorse, however, drying out of the already dead tissues in the two valves of the seed pod causes a tendency to warp, which, on hot summer days, culminates in an explosive and audible separation of these valves, with violent seed release. Such methods may be coupled with secondary dispersal mechanisms, effected by ants in the case of Scotch broom and gorse or by birds and mammals, to which sticky seeds may adhere, in the case of *Arceuthobium* and squirt-cucumber. Other active ballists are species of geranium, violet, wood sorrel, witch-hazel, touch-me-not (*Impatiens*), and acanthus; probable champions are *Bauhinia* purpurea, with a distance of 15 metres and the sandbox tree (*Hura crepitans*) with 14 metres. Barochory, the dispersal of seeds and fruits by gravity alone, is demonstrated by the heavy fruits of horse chestnut.

Creeping diaspores are found in grasses such as *Avena sterilis* and *Aegilops ovata*, the grains of which are provided with bristles capable of hygroscopic movements (coiling and flexing, in response to changes in moisture). The mericarps (a fruit fragment—see the Table: *Schizocarp*) or stork's bill (an *Erodium* species), when moistened, bury themselves with a corkscrew motion by unwinding a multiple-barbed, beak-shaped appendage, which, in the dry state, was coiled.

Atelchory, the dispersal over a very limited distance only, represents a waste-avoiding, defensive "strategy" that functions in further exploitation of an already occupied, favourable site. This aim is often achieved by synaptospermy, the sticking together of several diaspores, which makes them less mobile, as in beet and spinach; also, by geocarp, which is either the production of fruits underground, as in the arum lilies *Stylochiton* and *Biarum*, in which the flowers are already subterranean, or the active burying of fruits by the mother plant, as in the peanut, *Arachis hypogaea*. In the American hog peanut (*Amphicarpa bracteata*), pods of a special type are buried by the plant and are cached by squirrels later on. Kenilworth ivy (*Cymbalaria*), which normally grows on stone or brick walls, stashes its fruits away in crevices after strikingly extending the flower stalks. Not surprisingly, geocarp, like synaptospermy, is most often encountered in desert plants; however, it also occurs in violet species, in subterranean clover (*Trifolium subterraneum*)—even when it grows in France and England—and in *Begonia hypogaea* of the African rain forest.

GERMINATION

Dormancy and life-span of seeds. Diaspore dormancy has at least three functions: (1) immediate germination must be prevented even when circumstances are optimal so as to avoid exposure of the seedling to an unfavourable period (e.g., winter), which is sure to follow; (2) the unfavourable period has to be survived; and (3) the various dispersing agents must be given time to act. Accordingly, the wide variation in diaspore longevity can be appreciated only by linking it with the various dispersal mechanisms employed, as well as with the climate and its seasonal changes. Thus, the downy seeds of willows, blown up and down rivers in early summer with a chance of quick establishment on newly exposed sandbars, have a life-span of only one week. Tropical rain forest trees frequently have seeds of low life expectancy also. Intermediate are seeds of sugarcane, tea, and coco palm, among others, with life-spans of up to a year. *Mimosa glomerata* seeds in the herbarium of the Muséum National d'Histoire Naturelle in Paris were found viable after 221 years. In general, viability is better retained in air of low moisture content. Some seeds, however, remain viable under water—those of certain rush (*Juncus*) species and *Sium cicutaefolium* for at least seven years. Salt water

Seeds with
short life
expectan-
cies

can be tolerated for years by the pebble-like but floating seeds of *Caesalpinia* (*Guilandina*) *bonduc* and *C. bonducella*, species that, in consequence, possess an almost pan-tropical distribution. Seeds of the sacred lotus (*Nelumbo nucifera*) found in a peat deposit in Manchuria and estimated by radioactive-carbon dating to be 1,400 (± 400) years old, rapidly germinated (and subsequently produced flowering plants) when the seeds were filed to permit water entry. In 1967 seeds of the arctic tundra lupine (*Lupinus arcticus*), found in a frozen lemming burrow with animal remains established to be at least 10,000 years old, germinated within 48 hours when returned to favourable conditions. The problem of differential seed viability has been approached experimentally by various workers, one of whom buried 20 species of common Michigan weed seeds, mixed with sand, in inverted open-mouthed bottles for periodic inspection. After 80 years, three species still had viable seeds.

Lack of dormancy. In some plants, the seeds are able to germinate as soon as they have matured on the plant, as demonstrated by wheat, sweet corn, peas, and beans in a very rainy season. Certain mangrove species normally form foot-long embryos on the trees; these later drop down into the mud or seawater. Such cases, however, are exceptional. The lack of dormancy in cultivated species, contrasting with the situation in most wild plants, is undoubtedly the result of conscious selection by man.

Immature embryos. In plants whose seeds ripen and are shed from the mother plant before the embryo has undergone much development beyond the fertilized egg stage (orchids, broomrapes, ginkgo, dogtooth violet, ash, winter aconite, and buttercups), there is an understandable delay of several weeks or months, even under optimal conditions, before the seedling emerges.

Role of the seed coat. There are at least three ways in which a hard testa may be responsible for seed dormancy: it may (1) prevent expansion of the embryo mechanically (pigweed); or (2) block the entrance of water; or (3) impede gas exchange so that the embryos lack oxygen. Resistance of the testa to water uptake is most widespread in the bean family, the seed coats of which, usually hard, smooth, or even glassy, may, in addition, possess a waxy covering. In some cases water entry is controlled by a small opening, the strophilar cleft, which is provided with a corklike plug; only removal or loosening of the plug will permit water entry. Similar seeds not possessing a strophilar cleft must depend on abrasion, which in nature may be brought about by microbial attack, passage through an animal, freezing and thawing, or mechanical means. In horticulture and agriculture, the coats of such seeds are deliberately damaged or weakened by man (scarification). In chemical scarification, seeds are dipped into strong sulfuric acid, organic solvents such as acetone or alcohol, or even boiling water. In mechanical scarification, they may be shaken with some abrasive material such as sand or be scratched with a knife.

Frequently seed coats are permeable to water yet block entrance of oxygen; this applies, for example, to the upper of the two seeds normally found in each burr of the cocklebur plant. The lower seeds germinate readily under a favourable moisture and temperature regime, but the upper ones fail to do so unless the seed coat is punctured or removed or the intact seed is placed under very high oxygen concentrations.

Afterripening, stratification, and temperature effects. The most difficult cases of dormancy to overcome are those in which the embryos, although not underdeveloped, remain dormant even when the seed coats are removed and conditions are favourable for growth. Germination in these takes place only after a series of little-understood changes, usually called afterripening, have taken place in the embryo. In this group are many forest trees and shrubs such as pines, hemlocks, and other conifers; some flowering woody plants such as dogwood, hawthorn, ash, linden, tulip poplar, holly, and viburnum; fruit trees such as apples, pears, peaches, plums, and cherries; and flowering herbaceous plants such as iris, Solomon's seal, and lily-of-the-valley. In some species, one winter suffices for afterripening. In others, the pro-

Methods

over-
coming
resistant
seed coats

Signif-
icance of
after-
ripening
require-
ment

cess is drawn out over several years, with some germination occurring each year. This can be viewed as an insurance of the species against flash catastrophes that might completely wipe out certain year classes.

Many species require moisture and low temperatures; for example, in apples, when the cold requirement is insufficiently met, abnormal seedlings result. Others (cereals, dogwood) afterripen during dry storage. The seeds of certain legumes—for example, the seeds of the tree lupin, the coats of which are extremely hard and impermeable—possess a hilum with an ingenious valve mechanism that allows water loss in dry air but prevents re-uptake of moisture in humid air. Of great practical importance is stratification, a procedure aimed at promoting a more uniform and faster germination of cold-requiring, afterripening seeds. In this procedure, seeds are placed for one to six months, depending on the species, between layers of sand, sawdust, sphagnum, or peat and kept moist as well as reasonably cold (usually 0° to 10° C [32° to 50° F]). A remarkable "double dormancy" has thus been uncovered in lily-of-the-valley and false Solomon's seal. Here, two successive cold treatments separated by a warm period are needed for complete seedling development. The first cold treatment eliminates the dormancy of the root; the warm period permits its outgrowth; and the second cold period eliminates epicotyl or leaf dormancy. Thus, almost two years may be required to obtain the complete plant. The optimal temperature for germination, ranging from 1° C (34° F) for bitter-root to 42° C (108° F) for pigweed, may also shift slightly as a result of stratification.

Many dry seeds are remarkably resistant to extreme temperatures, some even to that of liquid air (−140° C or −220° F). Seeds of Scotch broom and some *Medicago* species can be boiled briefly without losing viability. Ecologically, such heat resistance is important in vegetation types periodically ravaged by fire, such as in the California chaparral, where the germination of *Ceanothus* seeds may even be stimulated. Also important ecologically is a germination requirement calling for a modest daily alternation between a higher and a lower temperature. Especially in the desert, extreme temperature fluctuations are an unavoidable feature of the surface, whereas with increasing depth these fluctuations are gradually damped out. A requirement for a modest fluctuation—e.g., from 20° C (68° F) at night to 30° C (86° F) in the daytime (as displayed by the grass *Oryzopsis miliacea*)—practically ensures germination at fair depths; and this is advantageous because a seed germinating in soil has to strike a balance between two conflicting demands, both depending on depth—on the one hand, germination in deeper layers is advantageous because a dependable moisture supply simply is not available near the surface; but, on the other hand, closeness to the surface is desirable because it allows the seedling to reach air and light rapidly and become self-supporting.

Light and seed germination. Many seeds are insensitive to light, but in a number of species germination is stimulated or inhibited by exposure to continuous or short periods of illumination. So stimulated are many grasses, lettuce, fireweed, peppergrass (*Lepidium*), mullein, evening primrose, yellow dock, loosestrife, and Chinese lantern plant. Corn (maize), the smaller cereals, and many legumes, such as beans and clover, germinate as well in light as in darkness. Inhibition by light is found in chive, garlic, and several other species of the lily family, jimson weed, fennel flower (*Nigella*), Phacelia, *Nemophila*, and pigweed (*Amaranthus*). Sometimes, imbibed (wet) seeds that do not germinate at all in darkness may be fully promoted by only a few seconds or minutes of white light. The best studied case of this type, and one that is a milestone in plant physiology, concerns seeds of the Grand Rapids variety of lettuce, which is stimulated to germination by red light (wavelength about 660 nanometres) but inhibited by "far red" light (wavelength about 730 nanometres). Alternations of the two treatments to almost any extent indicate that the last treatment received is the decisive one in determining whether the seeds will germinate.

Ecological role of light. Laboratory experiments and field observations indicate that light is a main controller of seed dormancy in a wide array of species. The absence of light, for example, was found in one study to be responsible for the nongermination of seeds of 20 out of 23 weed species commonly found in arable soil. In regions of shifting sands, seeds of Russian thistle germinate only when the fruits are uncovered, often after a burial period of several years. Conversely, the seeds of *Calligonum* comosum and the melon *Citrullus colocynthis*, inhabiting coarse sandy soils in the Negev Desert, are strongly inhibited by light. The survival value of this response, which restricts germination to buried seeds, lies in the fact that at the surface fluctuating environmental conditions may rapidly create a very hostile micro-environment. The seeds of *Artemisia monosperma* have an absolute light requirement but respond to extremely low intensities, such as is transmitted by a two millimetre thick sand filter. In seeds buried too deeply, germination is prevented. The responsiveness to light, however, increases with the duration of water imbibition. Even when full responsiveness to light has been reached, maximal germination occurs only after several light-exposures are given at intervals. In the field, this combined response mechanism acts as an integrating (cumulative) rain gauge because the seeds (as indicated) become increasingly responsive to light, and thus increasingly germinable, the longer the sand remains moistened. Certain *Juncus* seeds have an absolute light requirement over a wide range of temperatures; consequently, they do not germinate under dense vegetation or in overly deep water. In combination with temperature, light (in the sense of day length) may also restrict germination to the most suitable time of year. In birch, for example, seeds that have not gone through a cold period after imbibing water remain dormant after release from the mother plant in the fall and will germinate only when the days begin to lengthen the next spring.

Stimulators and inhibitors of germination. A number of chemicals (potassium nitrate, thiourea, and ethylene chlorhydrin) and plant hormones (gibberellins and kinetin) have been used experimentally to break seed dormancy. Their mode of action is obscure, but it is known that in some instances thiourea, gibberellin, and kinetin can substitute for light.

Natural inhibitors, which completely suppress germination (coumarin, parasorbic acid, ferulic acid, phenols, protoanemonin, transcinamic acid, alkaloids, essential oils, and the hormone dormin) may be present in the pulp or juice of fruits or in various parts of the seed. The effect of seed coat phenols, for example, may be indirect—being highly oxidizable, they may screen out much-needed oxygen. Ecologically, such inhibitors are important in at least three ways. Their slow disappearance with time may spread germination out over several years (a protection against catastrophes). Furthermore, when leached out by rainwater, they often serve as agents inhibiting the germination of other competitive plants nearby. Finally, the gradual leaching out of water-soluble inhibitors serves as an excellent integrating rain gauge. Indeed, it has been shown that the germination of certain desert plants is not related to moisture as such but to soil water movement—i.e., to the amount and duration of rain received.

Seine River

The Seine River, 485 miles (780 kilometres) long, with its tributaries drains an area of 30,000 square miles (78,000 square kilometres) in northern France; it is one of Europe's great rivers, and its drainage network carries most of the French inland waterway traffic. Since the early Middle Ages it has been above all the river of Paris, and the mutual interdependence of the river and the city that was established at its major crossing points has been indissolubly forged. The fertile centre of its basin in the **Île-de-France** was the cradle of the French monarchy and the nucleus of the expanding nation-state and is still its heartland and metropolitan region.

The Seine rises at 1,545 feet (471 metres) above sea level on the Mont Tasselot in the **Côte d'Or** region of Bourgogne (Burgundy) but is still only a small stream when it traverses porous limestone country beyond Châtillon. Flowing northwest from Bourgogne, it enters Champagne above Troyes and traverses the dry chalk plateau of Champagne in a well-defined trench. Joined by the **Aube** near Romilly, it bears west to skirt the **Île-de-France** in a wide valley to Montereau, where it receives the Yonne on its left bank. This tributary is exceptional in rising beyond the sedimentary rocks of the Paris Basin on the impermeable crystalline highland of the Morvan, a northward extension of the Massif Central. Turning northwest again, the Seine passes Melun and Corbeil as its trenched valley crosses the Xle-de-France toward Paris. As it enters Paris, it is joined by its great tributary the Marne on the right, and after traversing the metropolis, it receives the Oise, also on the right. In its passage through Paris, the river has been trained and narrowed between the riverside quays that constitute France's major inland port. Flowing sluggishly in sweeping loops, the Seine passes below Mantes-la-Jolie across Normandie (Normandy) toward its estuary in the English Channel. Rouen, although 78 miles from the sea, is a major seaport but has been outstripped by the deepwater port of Le Havre on the broad estuary, which opens rapidly and extends for 16 miles below Tancarville. It experiences

the phenomenon of the tidal bore, which is known as the **mascaret**.

From its source to Paris, the Seine traverses concentric belts of successively younger sedimentary rocks, infilling a structural basin, the centre of which is occupied by the limestone platforms of the fle-de-France immediately surrounding Paris. The rocks of this basin are inclined gently toward Paris at the centre and present a series of out-waid-facing limestone (including chalk) escarpments (**cbtes**) alternating with narrower clay vales. The **côtes** are breached by the Seine and its tributaries, which have made prominent gaps. As they converge upon Paris, the trenchlike river valleys separate a number of island-like limestone platforms covered with very fertile, easily worked windblown soil (**limon**). These have provided rich cereal-growing land from time immemorial and constitute the fle-de-France. The lower course of the Seine, below Paris, is directed in a general northwesterly direction towards the sea, in conformity with the trend of the lines of structural weakness affecting the northern part of the basin. The English Channel breaches the symmetry of the basin on its north side, interrupting the completeness of the concentric zones. Still in the chalk belt, the river enters the sea.

The basin of the Seine presents no very striking relief contrasts. Within 30 miles of its source the river is already below 800 feet, and at Paris, 227 miles from its mouth, it is only 80 feet above sea level. It is thus slow flowing and eminently navigable, the more so because its regime is generally so regular. Most of the river basin is formed of permeable rocks, the absorptive capacity of which mitigates the risk of river floods. Precipitation throughout the basin is modest (generally 25 to 30 inches) and evenly distributed over the year as rain, with snow infrequent except on the higher southern and eastern margins. The Yonne, unique among the tributaries in being derived from impermeable, crystalline highlands, where there is also considerable winter snow, contributes most irregularly; but the Seine is the most regular of the great rivers of France and the most naturally navigable. Occasionally the summer level is considerably reduced, but sandbanks such as are so typical of the Loire do not appear; and low water is further masked by the regularization of the river that has been carried out to improve its navigability. Winter floods are rarely dangerous; but in January 1910 exceptionally heavy rainfall caused the river to rise above 28 feet at Paris, flooding the extensive low-lying quarters along its ancient meander loop (the Marais). To match this high level it is necessary to go back to February 1658; but in January 1955 again the river rose to more than 23 feet in Paris. The average flow at Paris is 10,000 cubic feet per second, as compared with the 1910 flood rate of 83,000. To regulate the flow, maintain the summer level, and protect the city from winter floods, large reservoirs have been built above Paris on the Yonne and Marne; and in 1960 work was begun on additional reservoirs on the Seine near Troyes and on the Marne at Champaubert-aux-Bois.

The Seine, especially below Paris, is a great traffichighway. It links Paris with the sea and the great maritime ports of Le Havre and Rouen. Vessels drawing up to 10 feet (3.20 metres) can reach the quays of Paris. Most of the traffic, which chiefly consists of heavy petroleum products and building materials, passes upstream to Paris. It more than doubled over the 1960s and was expected to reach 40,000,000 tons by 1975. The Lower Seine system is connected with that of the Rhine by way of the Marne, and the Oise links it with the waterways of Belgium. There are plans for further developing the inland waterways of this northwestern maritime gateway of Europe. The links with the Loire waterway and with the Saône-Rhône, dating from the 17th and 18th centuries, when connecting canals were built, are now of minor importance.

Seismograph

A seismograph is an instrument that makes a record of the ground oscillations caused by an earthquake, explosion, or other earth-shaking phenomenon. Although originally designed to record natural earthquakes, it now has many other uses.

An earlier seismic instrument called the seismoscope made no record of the ground oscillations but simply indicated that shaking had occurred. The term seismometer originally referred to an instrument that measures the amount of ground motion. Some seismographs are equipped with an electromagnetic device called a sensor that translates ground motions into electrical changes. A seismogram is a record made by a seismograph.

HISTORICAL DEVELOPMENT

A Chinese scholar, Chang Heng, invented a seismoscope that registered the occurrence of an earthquake as early as AD 132. Judging from the available descriptions of this device, it was cylindrical in shape with eight dragon heads arranged around its upper circumference, each with a ball in its mouth. Around the lower circumference were eight frogs, each directly under a dragon head. When an earthquake occurred, one of the balls dropped from the dragon's mouth and was caught by the frog's mouth, generating a sound. The ball probably was pushed out of the dragon's mouth by a loose vertical rod inside the device, which was shaken by the tremor. A device involving water spillage was made in 17th-century Italy. Later, a water-filled bowl and still later a cup filled with mercury were used for detecting earthquakes and tremors.

In 1855 Luigi Palmieri of Italy designed a seismometer that consisted of several U-shaped tubes filled with mercury and oriented toward the different points of the compass. When the ground shook, the motion of the mercury made an electrical contact that stopped a clock and simultaneously started a recording drum on which the motion of a float on the surface of mercury was registered. This device thus indicated time of occurrence and the relative intensity and duration of the ground motion.

Pendulums. The basic problem in measuring ground motions is to attain a steady point that remains steady when the ground moves. Various types of pendulums have been used for this purpose. The simplest type is a common pendulum in which a heavy mass is suspended by a wire or rod from a fixed point. (as in a clock). Other forms are the inverted pendulum, in which a heavy mass is fixed to the upper end of a vertical rod pointed at its lower end, and the horizontal pendulum, in which a rod with a mass on its end is suspended at two points so as to swing in a nearly horizontal plane instead of a vertical plane. In 1840 a seismometer based on the common pendulum was installed near Comrie in Perthshire, Scotland. In 1841 a seismometer based on the inverted pendulum was installed at six places near Comrie to register local shocks. This instrument recorded deflections of the pendulum on a fixed paper.

Milne's seismograph. Seismograph developments occurred rapidly in 1880 when Sir James Alfred Ewing, Thomas Gray, and John Milne, British scientists working in Japan, began to study earthquakes. Following a severe earthquake that occurred at Yokohama near Tokyo in that year, they organized the Seismological Society of Japan. This society continued active for about ten years; under its auspices, various devices, forerunners of today's seismograph, were invented. Among the instruments constructed in this period was Milne's now famous horizontal pendulum seismograph (Figure 1). A boom (B), to which the mass (M) is attached, is suspended horizontally by the pivot (P) and a silk thread (T) fixed to a point above the pivot. A thin plate (C), in which a narrow slit is cut parallel to the boom, is attached to the end of the boom (B). A similar plate with a slit at right angles to the upper plate is fixed on the top of the box containing a

Figure 1: Milne horizontal pendulum seismograph (see text).

From *Bulletin of the Seismological Society of America* (1969), vol. 59, No. 1, p. 212

recording drum (D). A ray of light from an oil lamp passes through both slits and forms a small spot of light on a sheet of light-sensitive graph paper (bromide paper) wrapped on the recording drum. Milne successfully used this seismograph to record several earthquakes in Japan; then in England he established a small seismographic network using such instruments. Today's worldwide seismographic network was founded soon after.

Omori Fusakichi, the founder of Japanese seismology and inventor of the Omori horizontal pendulum seismograph, was a student of Milne and graduated from the science department of the University of Tokyo in 1890. He was among the Japanese scientists who began study of earthquakes in 1891 after the Mino-Owari earthquake struck central Japan. Japanese seismologists made significant contributions, particularly after they revived the Seismological Society of Japan following the great earthquake of 1923.

THE MODERN SEISMOGRAPH

General principles. If a common pendulum is free to swing in one direction and if the ground moves rapidly in the direction of freedom of the pendulum while the pendulum is motionless, the pendulum will remain in place through inertia. The same phenomenon will occur if the ground moves back and forth (oscillates). If the period of oscillation of the ground (the time necessary for one complete oscillation) is sufficiently shorter than the period of free oscillation of the pendulum, the pendulum will again remain motionless, and the movement of the ground relative to the pendulum can be recorded. The magnitude of this movement is commonly amplified in some way. This is the basic principle of the seismograph.

In actual practice, it often works out that the period of the pendulum is comparable to that of the ground oscillation; under these circumstances, the seismograph will not correctly record the earth's movement. The error, however, can readily be computed mathematically. A graphic curve showing the variation of magnification according to the oscillation period of the ground is called a magnification curve or response curve.

In general, then, the seismograph is an instrument in

which the relative motion of pendulum and ground is recorded. It is equally possible to take the ratio between the deflection of the pendulum and the velocity (or acceleration) of the ground. This ratio is called the velocity (or acceleration) sensitivity of the seismograph.

If free oscillation of the pendulum is not minimized, it will mask the proper recording of earth movements. The simplest way to reduce (damp out) the free oscillation of a pendulum is to suspend it in a viscous (thick) liquid of which the resisting force is proportional to the velocity of the pendulum. In practice, the required resisting force is exerted by a special device called a damper. An air damper produces its resisting force by the use of a piston moving in a cylinder. In an electromagnetic damper, the resisting force is created by electrical currents induced in a copper plate moving in a strong magnetic field.

Recording pendulum movement. The ground can move in any of three directions, two horizontal and one vertical. Since each kind of movement must be separately recorded, three pendulums, one for each direction, are needed for a complete seismograph.

In the mechanical method of recording movement, a sheet of smoked paper is wrapped around a rotating drum, so mounted as to move with the earth. A moving pen connected to the pendulum presses lightly on the paper. The rotating drum shifts slightly with each revolution so that recorded lines are not superimposed on each other. The drum rotates without interruption; one sheet of paper usually lasts 24 hours. Deflection of the pendulum is commonly magnified mechanically by single or double multiplying levers. Though this lever method is simple and economical the seismograph must have a heavy mass to overcome the friction between pen and paper. In consequence, some mechanical seismographs weigh one ton or more. In the optical lever method, pendulum motion causes a mirror to move; light is reflected by this mirror onto photosensitive paper wrapped on a drum. Thus there is no friction to affect the pendulum.

In the electromagnetic method, widely used today, a coil fixed to the mass of the pendulum moves in a magnetic field; the electric current generated in the coil operates a galvanometer exactly as a dynamo operates a motor. A mechanical damper is not needed, for damping force can be conveniently produced by electromagnetic action between the current in the coil of the pendulum and the magnetic field. If the current produced in the coil of the pendulum is amplified electronically, high magnification is obtainable. Certain short-period seismographs of this type used for the observation of micro-earthquakes attain a magnification as high as 1,000,000 or more. In ordinary seismographic observation, the time of initiation of ground oscillations is recorded. Marks are placed on the seismogram paper once a minute; an extra one identifies the hour.

Types of seismographs. Seismographs differ in the type of pendulum and magnifying and recording elements they employ. The horizontal pendulum seismograph was first used by John Milne of England, in 1883, though the horizontal pendulum had been used earlier by other scientists to observe the effect of the moon on the earth's gravity. Ernst von Rebeur-Paschwitz of Germany devised a horizontal pendulum for the same purpose in which two pivots were employed to suspend the pendulum. One day in 1889 he noticed that an unusual train of oscillations had been recorded by his instrument. He later learned that these coincided with a severe earthquake in Kyushu, Japan. This discovery demonstrated the feasibility of observing distant earth tremors by the use of a long-period pendulum and consequently gave European scientists an opportunity to make seismographic observations in their own countries, where no earthquakes occurred. The Milne seismograph was improved in 1927 by an optical lever that increased magnification. B.B. Galitzin of Russia also used a horizontal pendulum; he suspended a beam (with a weight attached) by two lines to make an electromagnetic seismograph.

The horizontal pendulum seismograph was improved greatly after World War II. The Press-Ewing seismograph, developed in the United States for recording long-period waves, is widely used throughout the world. This

device employs a Milne-type pendulum, but the pivot supporting the pendulum is replaced by an elastic wire to avoid friction.

The inverted pendulum seismograph was first used by Emil Wiechert in Germany in 1904 (Figure 2). A large

From Bulletin of the Seismological Society of America (1969)

Figure 2: Wiechert inverted pendulum seismograph.

mass (M) is attached at the upper end of a strong pillar (P), and a double set of flat springs supports the pillar at its lower end (C). The mass has two-dimensional freedom; its movement is divided into two horizontal components by levers. A rigid framework supports a mechanical recording device (R) and piston-type air dampers (D).

A torsion pendulum seismograph was devised by J.A. Anderson and Harry O. Wood in the U.S. in 1924 (Figure 3). A small copper cylinder (C) is attached to a

Figure 3: Anderson-Wood torsion pendulum seismograph.

tungsten wire (T) stretched nearly vertically. The mass can swing in a nearly horizontal plane around the wire; damping force is given to the mass by a strong magnetic field produced by U-shaped permanent magnet (M). Magnification as large as 2,800 is attainable by an optical lever using the mirror (m). This is the seismograph that was used by Charles F. Richter in the U.S. to define the magnitude scale of an earthquake (see EARTHQUAKES).

The vertical component seismograph employs a pendulum that oscillates vertically. The simplest pendulum of this type is a mass suspended by a helical spring. If a long oscillation period is desired, a long weak spring must be used; this is quite convenient. In 1881 Thomas Gray devised a vertical component seismograph employing a pendulum so suspended that the oscillation period can be increased without using a longer spring. Then J.A. Ewing showed that the period could be lengthened still more by lowering the point of attachment of the spring. This

method of suspension was later applied to vertical component seismographs by Galitzin and Wiechert. Galitzin's instrument employs an electromagnetic recording device, while Wiechert's instrument uses a mechanical recording device with a heavy mass. Both were used widely in the first half of this century. In 1935 Lucien LaCoste in the U.S. devised a long-period vertical component pendulum using a new and different means of suspension. The LaCoste pendulum is so suspended that the upper end of the spring is fixed nearly above the rotation axis of the pendulum, which is composed of a horizontal rod and the mass. This method of suspension is very simple; the spring employed is of such a character that its initial length before the load is added is zero. The Press-Ewing vertical component seismograph uses a pendulum of the LaCoste type, with the period adjustable up to 30 seconds.

The electromagnetic seismograph was devised by Galitzin in 1907. A coil attached to a pendulum is arranged to move in the field produced by a magnet; the output of the coil indicates the magnitude of the earth's seismic movement, since the more rapidly the coil swings the larger is its output. A magnetic damper checks the oscillations, which would otherwise continue and prevent detection of the next tremor. More recently designed electromagnetic seismographs generally take advantage of coil movements parallel to the coil's axis, somewhat like the moving coil of a dynamic loudspeaker. Damping is accomplished by the current induced in the coil.

In 1932 Hugo Benioff, in the United States, applied an electromagnetic transducer to a short-period seismograph in a new way. Figure 4 is a schematic drawing of the Beni-

Adapted from H. Benioff, *Advances in Geophysics*

Figure 4: Benioff transducer.

off transducer as later improved. (M) is a permanent magnet that supplies magnetic field to the pole pieces (B,B). From the pole pieces, the field crosses the air gaps, dividing equally between two moving components (A,A). The structure consisting of magnet and pole pieces is fixed to the ground, and the armature assembly is fastened rigidly to the pendulum. Motion of the pendulum relative to the ground varies the lengths of the air gaps, one pair increasing while the other is decreasing. The resulting change in the magnetic field through the armatures induces an electromotive force (voltage) in the coils (C,C) surrounding the armatures that is proportional to the rate of change of the relative displacement. This voltage is measured by a galvanometer, a device for detecting small electrical currents. If an electronic amplifier is placed between transducer and galvanometer, a high-grain (magnification) seismograph is attainable. In instruments equipped with an electronic amplifier, magnetic tape recording is also possible.

All the seismographs hitherto described measure oscillatory motions of the ground at a given point. The strain seismograph, in contrast, employs no pendulum, and its operation depends on oscillation in the distance between two points on the ground. In Figure 5, (A) and (B) are

Figure 5: Strain seismograph.

From *Bulletin of the Seismological Society of America* (1935)

two piers separated by a distance, which may be 20 metres or more. One end of the rod (R) is fixed to the pier (B), and the other placed near the pier (A). Earth strains resulting from seismic waves produce variations in the separation of the two piers; these variations are observable as changes in the distance between the free end of the rod and pier (A). This seismograph was first devised in 1935.

APPLICATIONS OF THE SEISMOGRAPH

Detection and location of earthquakes. A seismograph records oscillation of the ground caused by seismic waves that travel from their point of origin through the earth or along its surface. The seismogram of a nearby earthquake is of simple pattern, showing the arrival of P waves, waves that vibrate in the direction of propagation; S waves, waves that vibrate at right angles to the direction of propagation; and surface waves. In case of distant earthquakes, the seismogram pattern is more complicated because it shows various sorts of seismic waves that originate from one point but then may be reflected or refracted within the earth's crust before reaching the seismograph. The relation between the arrival time of these seismic waves and the epicentral distance—i.e., the distance from the point of origin—is expressed by a time-distance curve, in which the arrival time is read on the vertical axis and the epicentral distance on the horizontal axis. If the arrival times of various seismic waves are read on the seismogram at a station and compared with the standard time-distance curves, the epicentral distance from that station (the distance of the centre of the earthquake from the recording station) can be determined. Knowing the epicentral distance from at least three stations, the origin of the earthquake can be calculated by simple trigonometric methods.

Detection of microseisms. Seismographs sometimes detect small and long-continuing oscillations of the ground, called microseisms, that do not originate in earthquakes. The occurrence of some microseisms is related to storms at sea. The detectability of earthquakes is reduced by the masking effects of microseisms.

Detection and prediction of volcano activity. Eruption of a volcano is commonly accompanied by many small earthquakes, especially when a volcano resumes activity after a long dormant period. Observation with sensitive seismographs therefore plays an important role in the prediction of volcanic activity. Often a strong earthquake is preceded by small earthquakes. Observation of very small tremors with sensitive seismographs is helpful in predicting disastrous earthquakes.

Detection and policing of nuclear tests. The seismograph can be used for detecting remote nuclear underground tests. In this activity, the relatively faint seismic waves generated by an underground explosion must be distinguished from natural tremors. In one American installation, the Large Aperture Seismic Array (LASA), established in Montana in 1965, 525 seismometers were spread over an area of 30,000 square kilometres. Their signals are combined to attain a high degree of sensitivity to seismic events.

Seismic prospecting. If the seismic waves generated by an explosive charge are recorded by sensitive seismographs installed at various points in the neighborhood of the explosion, the underground structure can be determined by analyzing the time-distance curves of P waves, both direct waves and those reflected or refracted at the boundaries of underground layers. Depths of underground layers, their angle of inclination, and the speed of seismic waves in each layer can be determined. Velocity measurement of seismic waves caused by explosions was tried in England in 1851. Since discovery of a large oil field in the U.S. by this method in 1923, seismic prospect-

ing has made rapid progress and is now used for oil and gas exploration. The improvement in the instruments and techniques achieved after World War II made it possible to determine the structure of the earth's crust to as deep as 40 or 50 kilometres by detonation of a small amount of explosive.

Other uses. Ground shocks caused by dynamite blasts in mines, quarries, public works, etc. can be measured by the seismograph. Preliminary examinations based on seismographic measurements make it possible to estimate the intensity of shocks, and thus evaluate the possibilities of damage, caused by a given amount of dynamite. Rock bursts, in which rocks are ejected suddenly in deep pits or tunnels, are caused by increase of stress in the surrounding rocks. Experience in mines shows that an increase of small shocks detectable by highly sensitive Geophones—portable seismometers for field use—generally indicates a rock burst hazard.

A strong motion seismograph is designed particularly to register strong motions of the ground for engineering purposes—i.e., antiseismic construction in earthquake-prone areas such as Japan.

Detection of vibrations on the moon's surface by use of seismographs is of fundamental importance in determining the internal structure, physical state, tectonic (crust) activity, and composition of the moon. The first moon seismograph was installed and operated at Tranquility Base by Apollo 11 astronauts in 1969. It contains three long-period seismometers and a single-component, short-period, vertical seismometer. The remote recording device is operated from the earth.

SEISMOGRAPHIC STATIONS

Construction, operation, and essential equipment. A seismographic station is commonly built up on a hard rock foundation. It is desirable to install the seismographs in a vault to reduce temperature variation and artificial noise. A modern seismographic station is equipped with at least two sorts of seismographs; one is a short-period instrument like the Benioff short-period seismograph, and the other one a long-period instrument like the Press-Ewing seismograph. A correct time-marking system is essential. If seismic signals are noticed on the seismograms, the arrival time, amplitude, period of oscillation, etc. of each seismic phase (a train of oscillations caused by the arrival of a different sort of seismic wave) are read off. A station commonly publishes these data periodically in its seismological bulletins.

Number and location. The number of seismographic stations has been increasing since the end of World War II. The global seismographic network was improved greatly during the course of The International Geophysical Year (IGY) beginning in 1957. About 800 seismographic stations were in operation around the world in 1970. Many belong to national networks, such as those of the U.S.S.R. (about 100 stations), Japan (about 100 stations), and Canada (about 21 stations). Some belong to universities and other organizations. As part of a U.S. program, a worldwide network of standardized seismograph stations (116 stations) was built up in 61 countries after 1960 under the auspices of The U.S. Coast and Geodetic Survey (USCGS).

The International Association of Seismology, founded in 1905 and renamed the International Association of Seismology and Physics of the Earth's Interior (IASPEI) in 1951, began in 1918 to publish the International Seismological Summary (ISS), which contains lists of seismological data computed from information taken from the global stations. The ISS will soon move to the International Seismological Center newly established at Edinburgh. The Bureau Central Séismologique at Strasbourg publishes a list of the same kind, in the form of a fast bulletin. The USCGS works for rapid determinations of locations and magnitudes of earthquakes anywhere in the world. Certain stations, including many of those of World-Wide Standardized Seismograph Network, send their data promptly to the USCGS.

Selachii

The sharks, together with their close relatives, the rays, belong to one of the two great groups of living fishes, the class Chondrichthyes, or Selachii. The latter name is also used for an order that includes only the sharks. Many structural, physiological, biochemical, and behavioral peculiarities make these fishes of particular interest to scientists. The dissection of a small shark is the biology student's introduction to vertebrate anatomy. These fishes are, in a sense, living fossils, for many of the living sharks and rays are assigned to the same genera as species that swam the Cretaceous seas over 100,000,000 years ago. Although by any reckoning a successful group, the modern chondrichthyeds number far fewer species than the more advanced bony fishes, or teleosts; 200 to 250 species of sharks and 300 to 340 species of rays are known.

The danger some sharks and stingrays present to humans makes these animals fascinating and, at the same time, abhorrent. Perhaps for this reason, they figure prominently in the folklore and art of many tropical peoples whose living depends on the sea.

GENERAL FEATURES

Problems of taxonomy. The name Selachii refers to a category of fishlike vertebrates, which are given a variety of treatments by ichthyologists. Some consider the Selachii to be a class or subclass comprising all the modern sharks and rays; others restrict the name to an order limited to the modern sharks and certain extinct ancestral forms. Under the latter system, the rays (including the sawfishes, guitarfishes, electric rays, skates, and stingrays) are ranked as a separate order, and the two orders are placed in a class or subclass.

The chimaeras (Holocephali) bear many similarities to sharks and rays; e.g., in skeletal structure, internal organs, and physiology. Ichthyologists commonly, although not unanimously, emphasize these similarities by grouping the modern and ancient sharks, rays, and chimaeras in the class Chondrichthyes, the cartilaginous fishes. Under this system, which is used in the present article, the sharks, skates, and rays are further grouped into one subclass, Elasmobranchii, and the chimaeras into another, Holocephali. A classification in which the elasmobranchs constitute one class (Selachii) and the chimaeras another (Holocephali) is found in FISH. Assigning the two groups class rank implies a degree of distinctness equal to that of the amphibians (Amphibia), reptiles (Reptilia), birds (Aves), and mammals (Mammalia).

Distribution and abundance. The majority of sharks and rays are marine fishes, but many enter estuaries; some travel far up rivers, and a few are reported to be permanent residents of freshwater. Most species live in the relatively shallow waters of continental margins or around offshore islands; a few roam far out in the vast spaces of the oceans. Some live at great depths, in midwaters or on the bottom; others are surface swimmers or inhabit the bottom in shallow waters.

Figure 1: Body plans of representative sharks.

Sharks and rays are poorly represented in fish markets of most countries. With limited demand for them, the damage they do to ordinary fishing gear, and the special care required to keep them marketable, fishermen avoid them if possible, or even discard those they happen to catch rather than bring them to port. Consequently, as a source of animal protein sharks and rays are generally underexploited, while the more highly valued bony fishes are generally overexploited. A possible consequence of this may be an increasing prominence of sharks and rays in the marine biota.

IMPORTANCE TO MAN

Economic uses of elasmobranchs. *Sharks as food.* The Food and Agriculture Organization of the United Nations reports the world's total annual commercial catch of cartilaginous fishes in 1968 at 507,000 tons. Of these, 51 percent were sharks, 25 percent rays and their relatives, less than 1 percent chimaeras, and 24 percent various cartilaginous fishes. Countries of Asia accounted for 50 percent of the total; western Europe, 25 percent; U.S.S.R., 7 percent; Africa, 2 percent; South America, 10 percent; North America, 4 percent; and Oceania, 2 percent. The combined catch of these fishes by all the fisheries of the world has never exceeded 1.5 percent of all fish taken from the sea. Apart from their being generally less highly valued as food than bony fishes and therefore underexploited, they are much less numerous (e.g., about 4 percent as many were taken during one systematic survey in the western Atlantic), and there are about 3 percent as many species.

The meat of sharks is marketed for food in all maritime countries. It may be prepared in various ways—fresh, salted, smoked, or pickled—offered in such forms as steaks, fillets, or flakes and under such names as shark, whitefish, grayfish, swordfish, sea bass, and halibut. The flesh is often rather strong tasting; this quality, however,

is one that can be removed by cleaning and washing and soaking the flesh in brine.

Since ancient times, Chinese people have used the dorsal fins of certain sharks and rays as the basis of an epicurean soup. To meet the demand for this product, they have imported fins from far-distant countries. The fins are prepared for market by removing the skin and flesh, leaving only the gelatin-rich cartilaginous rays, which are dried before shipment. Shark liver oil is used in various regions for tanning leather; for preserving wood; as a lubricant; as a folk medicine against rheumatism, burns, and coughs; as a general tonic; as a laxative; and as an ingredient of cosmetics. The liver of a basking shark yields 80 to 600 gallons of oil, which was used in lamps until petroleum products replaced animal oils for illumination. The discovery around 1940 that the liver of the *soupin* shark of California is peculiarly rich in vitamin A led to an explosive development of a special fishery in California for this species and a search in other parts of the world for sharks having livers of comparable potency. Within a few years, however, the economic bubble burst, with the invention of a method for manufacturing synthetic vitamin A. The Australian school shark, that was used originally for vitamin A, is now caught for fish fillets.

Other shark products. The hard scales provide an abrasive surface to the skin of sharks and some rays, giving it a special value, as a leather called shagreen, for polishing hard wood. When heated and polished, shagreen is used for decorating ornaments and, in Japan, for covering sword hilts.

Shark leather is made in several countries, including the United States, from the skin of certain shark species after removal of the scales by a chemical process. A luxury product, much more durable than cowhide, shark leather is used for footwear, belts, wallets, and other accessories. The most suitable skins for leather are from tiger, dusky, brown, sand, blacktip, and nurse sharks.

In Greenland some Eskimos make rope from strips of the skin of the sleeper shark. Polynesians once added to the effectiveness of their war clubs with sharks' teeth. Sharks' teeth have some commercial value as curios. The Maori of New Zealand formerly paid high prices for mako sharks' teeth, which they wore as earrings.

Economic value of rays. About 126,000 tons of rays are marketed for food in various countries about the world, principally in Europe and Asia. By-products in local demand are skins of scaleless species for drumheads; those of scaly species are used for shagreen. Livers are used for oil, fins for gelatin. People of many tropical countries—Polynesia, Oceania, Malaysia, Central America, and Africa—have used the spines of stingrays for such various items as needles and awls, spear tips and daggers, and for the poison they contain. The entire tails of stingrays, complete with spines, have been used as whips in various tropical areas.

The electric rays, or numbfish, have little commercial value today. The ancient Greeks and Romans used the electric shock of *Torpedo* to relieve diseases of the spleen, chronic headaches, and gout. From the Greek word for electric ray, *narke*, comes the word narcotic. Today these fishes are of general interest chiefly as a source of acute irritation (if not danger) to bathers who happen to step on them and to fishermen who may be shocked when hauling in their wet nets.

Danger to man. Among the known shark species, 27 have been authoritatively implicated in attacks on persons or boats. Hospital and other records attest to many attacks on bathers, divers, and people awash in the sea following sea or air disasters. There are also many documented cases of sharks attacking small boats. A number of surviving victims have been able to identify the attacking animal as a shark; a few even reported the type of shark, such as a hammerhead. In many instances, witnesses have seen the assailant clearly enough to determine the species. Fragments of teeth left in wounds of victims or in the planking of boats have often been large enough to provide ichthyologists with the means for precise identification.

Attacks
by sharks

World
catch of
sharks and
rays

In 1958 the American Institute of Biological Sciences established a Shark Research Panel at the Smithsonian Institution and Cornell University in order to gather historical and current records of shark attacks throughout the world. For the 35 years from 1928 to 1962, inclusive, the panel listed 670 attacks on persons and 102 on boats. Attacks occur most frequently throughout the year in the tropical zone between 21° north and south of the Equator; from midspring to midfall they extend as far north and south as the 42° parallels.

In Australia, New Zealand, South Africa, and along other coasts heavily infested with sharks, public beaches have been provided with lookout towers, bells, and sirens or nets, to protect bathers. Since 1937 Australia has used meshing offshore to catch the sharks. Gill nets suspended between buoys and anchors running parallel to the beach and beyond the breaker line have proved very effective in decreasing the danger of attack. The nets enmesh sharks from any direction, and even while touching neither the surface nor the bottom, and spaced well apart, they provide simple, effective control. South Africa has been using a similar protection system, although experiments with electrical barriers there were also in progress in the 1960s and 1970s.

The great majority of shark attacks seem to be in water warmer than 21° C (70° F), which presumably is also the habitat of the most dangerous species. Unfortunately, this rule does not apply to the most dangerous shark, the white shark, or man-eater (*Carcharodon carcharias*), which ranges into the cooler waters of both hemispheres.

By courtesy of New York Zoological Society

Sand shark (*Odontaspis taurus*).

The 27 species implicated by the Shark Research Panel in attacks on persons or boats are mostly large sharks with large, cutting teeth. Size, however, is not a dependable criterion, for man-eaters become dangerous when they are about one metre (three or four feet) long; and the largest ones, the basking shark and the whale shark, which grow to 12 and 18 metres (40 and 60 feet), respectively, subsist on minute planktonic organisms and on small schooling fishes. Although either might attack a boat if provoked, only two records of such occurrences have been reported, both in Scotland and both identified with the basking shark. More than 85 percent of all the

shark species are too small, too unsuitably toothed, or too sluggish or live at depths too great to be potentially dangerous. The most dangerous sharks include in addition to the white shark, the hammerheads (*Sphyrna*), tiger (*Galeocerdo*), blue (*Prionace*), and sand sharks (*Odontaspis*).

Most stingrays live in shallow coastal waters. Some move with the tides to and from beaches, mud flats, or sand flats. Anyone wading in shallow water where these fishes occur runs some risk of stepping on one and provoking an instant response—the ray lashes back its tail, inflicting an agonizingly painful wound that occasionally leads to fatal complications. Rays can be serious pests to shellfisheries, for they are extremely destructive to oyster and clam beds.

NATURAL HISTORY

Food habits. All sharks are carnivorous and, with a few exceptions, have broad feeding preferences, governed largely by the size and availability of the prey. The recorded food of the tiger shark (*Galeocerdo cuvieri*), for example, includes a wide variety of fishes (including other sharks, skates, and stingrays), sea turtles, birds, sea lions, crustaceans, squid, and even carrion such as dead dogs and garbage thrown from ships. Sleeper sharks (*Somniosus*), which occur mainly in polar and subpolar regions, are known to feed on fishes, small whales, squid, crabs, seals, and carrion from whaling stations. Many bottom-dwelling sharks, such as the smooth dogfishes (*Triakis* and *Mustelus*), take crabs, lobsters, and other crustaceans, as well as small fishes.

The two giant sharks, the whale shark (*Rhincodon typus*) and basking shark (*Cetorhinus maximus*), resemble the baleen whales in feeding mode as well as in size. They feed exclusively or chiefly on minute passively drifting organisms (plankton). To remove these from the water and concentrate them, each of these species is equipped with a special straining apparatus analogous to baleen in whales. The basking shark has modified gill rakers, the whale shark elaborate spongy tissue supported by the gill arches. The whale shark also eats small, schooling fishes.

The saw sharks (Pristiophoridae) and sawfishes (Pristidae) share a specialized mode of feeding that depends on the use of the long, bladelike snout, or "saw." Equipped with sharp teeth on its sides, the saw is slashed from side to side, impaling, stunning, or cutting the prey fish. Saw sharks live in midwaters; sawfishes, like most other rays, are bottom inhabitants.

Thresher sharks (*Alopias*) feed on open-water schooling fishes, such as mackerel, herring, and bonito, and on squid. The long upper lobe of the tail, which may be half the total length of the shark, is used to frighten the fish (sometimes by flailing the water surface) into a concentrated mass convenient for slaughter.

Most sharks and probably most rays segregate according to size, a habit that protects smaller individuals from predation by larger ones. Even among sharks of a size category, dominance between species is apparent in feeding competition, suggesting a definite nipping order. Other sharks keep clear of hammerheads (*Sphyrna*), whose manoeuvrability, enhanced by the rudder effect of the head, gives them an advantage. When potential prey is discovered, sharks circle it, appearing seemingly out of nowhere and frequently approaching from below. Feeding behaviour is stimulated by numbers and rapid swimming, when three or more sharks appear in the presence of food. Activity soon progresses from tight circling to rapid crisscross passes. Biting habits vary with feeding methods and dentition. Sharks with teeth adapted for shearing and sawing are aided in biting by body motions that include rotation of the whole body, twisting movements of the head, and rapid vibrations of the head. As the shark comes into position, the jaws are protruded, erecting and locking the teeth into position. The bite is extremely powerful; a mako shark (*Isurus*), when attacking a swordfish too large to be swallowed whole, may remove the prey's tail with one bite. Under strong feeding stimuli, the sharks' excitement may intensify into what is termed a feeding frenzy, in which not only the prey but

Feeding methods of larger sharks

also injured members of the **feeding** pack are devoured, regardless of size.

In most cases the initial attraction to the food is by smell. Laboratory studies have shown that sharks do not experience hunger in the normal sense of the word, and they are much more prone to be stimulated to feeding by the olfactory or visual cues announcing the appearance of prey.

Figure 2: Body plans of representative selachii.

The majority of batoid fishes (members of the order Batoidei; *i.e.*, rays and allies) are bottom dwellers, preying on other animals on or near the sea floor. Guitarfishes (Rhynchobatidae and Rhinobatidae), butterfly rays (Gymnuridae), eagle rays (Myliobatidae), and cow-nosed rays (Rhinoptera) feed on invertebrates, principally mollusks and crustaceans. Whip-tailed rays (Dasyatidae) use their broad pectoral fins to dig shellfish from sand or mud. Skates (Rajidae) lie on the bottom, often partially buried, and rise in pursuit of such active prey as herring, trapping the victims by swimming over then settling upon them, a practice facilitated by the skates' habit of hunting at night.

Electric rays (Torpedinidae) are characteristically bottom fishes of sluggish habits. They feed on invertebrates and fish, which may be stunned by shocks produced from the formidable electric organs. With their electricity and widely extensible jaws, these rays are capable of taking very active fishes, such as flounder, eel, salmon, and dogfish. Shallow-water electric rays have been observed to trap fishes by suddenly raising the front of the body disk, while keeping the margins down, thereby forming a cavity into which the prey is drawn by the powerful inrush of water.

Most of the myliobatoid rays (seven recognized families of the suborder Myliobatoidea, which includes all of the typical rays) swim gracefully, with undulations of the broad, winglike pectoral fins. Some species, especially the eagle rays, frequently swim near the surface and even

jump clear of the water, skimming a short distance through the air.

Manta, or devil, rays (Mobulidae) swim mostly at or near the surface, progressing by flapping motions of the pectoral fins. Even the largest often leap clear of the water. In feeding, a manta moves through masses of macroplankton or schools of small fish, turning slowly from side to side and using the prominent cephalic fins, which project forward on each side of the mouth, to fan the prey into the broad mouth.

Chimaeras and ghost sharks (Chimaeridae) dwell near the bottom in coastal and deep waters, to depths of at least 2,500 metres (about 8,000 feet). They are active at night, feeding almost exclusively on small invertebrates and fishes.

Reproductive behaviour. Mature individuals of some species of sharks segregate by sex, coming together only during the mating season, when the males, at least those of the larger, more aggressive species, stop feeding. Segregation is a behavioral adaptation to protect the females, one principal courting activity used by the male to induce cooperation of the female in mating being that of slashing her with teeth especially developed for that purpose. After mating, the sexes again separate. The pregnant females also tend to keep apart from the other females of like size. As the time of parturition approaches, the pregnant females move to particular areas, which presumably have properties of environment especially suitable as nursery grounds. When giving birth to their young, they stop feeding, and, soon after parturition is completed, they depart.

Nursery areas vary with species. Some sharks—*e.g.*, the bull and sandbar sharks—use shallow waters of bays and estuaries; the silky shark uses the bottom far out on oceanic banks such as the Serrana Bank in the western Caribbean. The Atlantic spiny dogfish (*Squalus acanthias*) bears its young mostly during the winter far out on the continental shelf of northeastern America almost two years after mating.

A few skates that have been observed mating may be characteristic of other rays. The male seizes the female by biting the pectoral fin and presses his ventral surface against hers while inserting one, or in some species, both claspers into her cloaca. Male skates have one to five rows of clawlike spines on the dorsal side of each pectoral fin. These are retractile in grooves of the skin and are used to hold the female during mating.

The eggs of skates in aquaria have been observed to be extruded in series, usually of two but sometimes one, with rests of one to five days between extrusions. A female of a European skate, *Raja brachyura*, laid 25 eggs over a 49-day period in the aquarium located at Plymouth, England.

Although the mating of chimaeroids has not been observed, it is generally presumed that the mode of copulation is similar to that of sharks and that the male's frontal spine and anterior appendage of the pelvic fins are probably used in securing the female. Two eggs are laid simultaneously, one from each oviduct. They are often carried for a relatively long period before being laid, several hours or even days, each protruding for the greater part of its length.

FORM AND FUNCTION

Distinguishing features. The elasmobranchs are fish-like vertebrates differing from bony fishes in many respects. The skeleton is composed of cartilage and, although partly calcified (especially in the vertebrae), lacks true bone. There are five to seven fully developed gill clefts, opening separately to the exterior. Most sharks and all rays have an opening behind each eye, called a spiracle, which is a modified first gill cleft. The dorsal fin or fins and fin spines are rigid, if present. Scales, if present, are structurally minute teeth, called dermal denticles, each consisting of a hollow cone of dentine surrounding a pulp cavity and covered externally by a layer of hard enamel-like substances called vitrodentine. The scales covering the skin do not grow throughout life as they do in bony fishes, but have a limited size; new scales form

Care of the young

Shark scales

between existing ones as the body grows. Certain other structures, such as the teeth edging the rostrum (beak) of sawfishes and saw sharks, the stinging spines of sting rays, and the teeth in the mouth, are structurally modified scales. The teeth, arranged in rows in the mouth, are not firmly attached to the jaws but are imbedded in a fibrous membrane lying over the jaws. When a tooth becomes broken, worn, or lost, it is replaced by one moving forward from the next row behind; at the base of the innermost row are rudimentary teeth and tooth buds that develop and move forward as needed. A spiral membranous fold (spiral valve) extends through the intestine of all sharks, rays, and chimaeras.

The rays differ externally from sharks in having the gill openings confined to the lower surface; the eyes of the rays are on the dorsal surface, and the edges of the pectoral fins are attached to the sides of the head in front of the gill openings. Some rays lack scales, and others are variously armed with thorns, tubercles, or prickles, all of which are modified scales; the tails of some have long, saw-toothed spines equipped with poison glands. In the sawfishes the snout is prolonged into a long, flat blade armed on either side with teeth. Some skates and a few rays have electric organs by which they can administer electric shocks to enemies or prey.

The chimaeras have only one external gill opening. In the adult the skin on each side of the head is smooth and lacks scales; the teeth consist of six pairs of grinding plates. The dorsal fin and spine are erectile. Like male sharks and rays, male chimaeras have claspers that serve to transfer sperm to the female, but, in addition, they have an erectile clasp device, the *tantaculum*, in front of each pelvic fin; most species have another such organ on top of the head.

Senses. Although sharks are often said to have a low order of intelligence, they, as well as rays and chimaeras, have survived successfully over a long period of geologic time. They are well equipped to locate prey and their own kind; to direct the course of their seasonal migrations; to discriminate specific localities; to respond to variations of temperature; to react to attractive or repelling substances in the water; and perhaps even to feel objects some distance away from them. They can see, hear, **smell**, taste, feel, and maintain their equilibrium. The roles of the sense organs have been studied in only a few species, principally sharks, and consequently remain imperfectly understood.

The sense of smell is highly developed and probably the principal means of locating prey and guiding the predator toward it. Given a favourable direction of current, sharks can detect incredibly minute concentrations—fractions of a part per million (*i.e.*, less than 1×10^{-6} parts)—of certain substances in the water, such as blood.

Although their eyes are structurally and functionally adapted for seeing, it is believed that their visual acuity in discerning the form and **colour** of an object is limited. The importance of sight relative to smell increases as a shark approaches its target.

The hearing apparatus, located in the auditory capsule of the cranium, includes a system of semicircular canals, which are responsible for maintaining equilibrium. Sharks seem to be remarkably sensitive to sounds of low frequency and to possess extraordinary faculty for directional hearing. Whether or not hearing is more sensitive than smell has not yet been established.

Sensory organs identified as taste buds are located on the floor, sides, and roof of the mouth and on the throat, as well as on the tongue. Experiments on several species of large sharks indicate that they do discriminate food types, preferring tunas, for example, to other fish species. Under some conditions, however, they become less fastidious, going into a feeding frenzy in which they attack anything, including others of their own kind.

Sensory organs located in the skin of all sharks, rays, and chimaeras receive a variety of **information**—vibrations of low frequencies, temperature, salinity, pressure, and minute electrical stimuli, such as are produced by another fish in the vicinity. These organs are located in the lateral line system (a series of sensory pores along the

side), in groups of pores on the head (ampullar organs), and in pit organs distributed on the back, flanks, and about the jaws.

Salt and water balance. Most marine vertebrates maintain lower concentrations of salts and other chemicals in their blood than are found in seawater, and so face a continuous problem of water loss to the environment, because of the tendency of water to move through membranes from regions of low salt concentration to regions of higher concentration. The marine cartilaginous fishes differ from almost all of the bony fishes (except the coelacanths and aestivating lungfishes) in being able to reabsorb in the renal (kidney) tubules most of their nitrogenous waste products (urea and trimethylamine oxide) and to accumulate these products in their tissues and blood, an ability termed the **urea retention habitus**. The concentration within the body thus exceeds that of the surrounding seawater, and water moves into the body with no expenditure of energy. When any of these fishes moves into freshwater, as many do, the urine flow to the outside increases; hence, the concentration of urea in the blood decreases. In the sawfish, for example, the increase of urine output is more than twentyfold; the blood urea concentration decreases to less than one-third the amount observed in marine forms. Purely freshwater elasmobranchs, such as the stingrays of the Orinoco and Amazon drainage systems, seem to lack the urea retention habitus.

Respiration. Sharks with spiracles take in some water through them, but they breathe chiefly by opening the mouth while expanding the mouth-throat (bucco-pharyngeal) cavity and contracting the gill pouches to close the gill slits. With the mouth closed, they contract the bucco-pharyngeal cavity while dilating the gill pouches, thus drawing the water over the gills where the exchange of oxygen and carbon dioxide takes place. Then, with the mouth still closed, they contract the bucco-pharyngeal cavity and gill pouches and open the gill slits to expel the water. Most of the rays, on the other hand, take in water chiefly through the spiracles; these then close by contraction at their anterior margins, which bear rudimentary gill filaments and a spiracular valve. Folds of membrane on the roof and floor of the mouth prevent the water from passing down the throat and direct it to the gill openings. Skates, which usually hold the lower surface of the head slightly above the bottom, inhale some water through the mouth; mantas, which have small spiracles and live near the surface, respire chiefly through the mouth. Skates, stingrays, guitarfishes, and angel sharks frequently reverse the direction of flow through the spiracles, apparently to clear them of foreign matter. Chimaeras take in water chiefly through the nostrils, keeping the mouth closed for the most part. The water reaches the mouth primarily through grooves leading there from the nostrils.

Reproduction and development. All species of sharks, rays, and chimaeras produce large, yolk-rich eggs. These are fertilized internally, for which the males are equipped with two copulatory organs called claspers along the inner edges of the pelvic fins. Each clasper has a groove for guidance of sperm. The few published descriptions of mating sharks and rays are probably characteristic of the entire group. The male grasps one of the female's pectoral fins with his teeth to hold her in position as he inserts a clasper through a cavity (cloaca) and into a tube (oviduct). Males of most species probably use only one clasper at a time. The sperm travel to the anterior end of the oviduct, where they fertilize the eggs. The eggs then move down the oviduct past the shell gland, where they are covered by a shell or capsule.

In oviparous (egg-laying) species, which include some of the sharks, probably all the skates, possibly some of the guitarfishes, and all of the chimaeras, the eggs are enveloped in a horny shell, usually equipped with tendrils for coiling around solid objects or with spikelike projections for anchoring in mud or sand. The egg cases of most species are more or less pillow shaped; those of the horned sharks (Heterodontidae) are screw shaped with a spiral flange. The eggs of chimaeras are elliptic, spindle

The urea retention habitus

Egg characteristics

shaped, or tadpole shaped and open to the exterior through pores and slits that permit entrance of water during incubation. An egg of the whale shark found in the Gulf of Mexico measured 30 centimetres (12 inches) long by about 14 centimetres (5½ inches) wide and was eight centimetres (three inches) thick. Protected by the shell and nourished by the abundant yolk, the embryo of an oviparous species develops for 4½ to 14 months before hatching.

The majority of sharks and most, possibly all, rays other than the skates are ovoviviparous (*i.e.*, the egg hatches within the mother). In this case, the egg is first coated in the shell gland with a temporary membranous capsule that lasts only during early development. After emerging from its capsule, the embryo remains in the oviduct of the mother, nourished by the yolk sac to which it remains attached. Embryos of some ovoviviparous sharks, notably the porbeagle (*Lamna nasus*), mako (*Isurus oxyrinchus*), and sand shark (*Odontaspis taurus*), ingest yolks of other eggs and even other embryos within the oviduct of the mother after the contents of their own yolk sacs are exhausted. In the majority of ovoviviparous sharks and rays, organically rich uterine secretions provide supplemental nourishment, which is absorbed by the yolk sac and in many cases by appendages borne on its stalk. In some genera of rays, vascular filaments producing these secretions extend through the spiracles and into the digestive tract of the embryos.

Several shark species are viviparous—*i.e.*, the yolk sac develops folds and projections that interdigitate with corresponding folds of the uterine wall, thus forming a yolk placenta through which nutrient material is passed from the mother.

Growth. Growth of a few shark species has been measured or estimated by the differences in length at the times of tagging and recapturing specimens, by statistical analysis of length in systematically collected samples, by the space between concentric circles on the centra of the vertebrae, and by periodic measurements of specimens kept in aquariums. All studies indicate a slow growth rate. During the ten years between birth and maturity, male Atlantic spiny dogfish grow an average of 47 centimetres (19 inches) and females 67 centimetres (26 inches). The Greenland shark (*Somniosus microcephalus*), which attains 6.5 metres (21 feet) or more (although rarely taken larger than about four metres [13 feet]), grows only about 7.5 millimetres (about 0.3 inch) per year. The annual growth increments of tagged juvenile whitetip reef and Galápagos sharks, both species that become at least 2.5 metres (eight feet) long, were found to be 31 to 54 millimetres (1.2 to 2.1 inches) and 41 millimetres (1.6 inches), respectively. The Australian school shark (*Galeorhynchus australis*) grows about 80 millimetres (three inches) in its first year and 30 millimetres (one inch) in its 12th year. By its 22nd year, it is estimated to be approaching a maximum length of 160 centimetres (just over five feet).

The disk of the eastern Pacific round stingray (*Urolophus halleri*) increases in width on the average from 75 millimetres (three inches) at birth to 150 millimetres (six inches) when mature, when 2.6 years old. In the next five years it grows about 60 millimetres (2.4 inches) more toward its maximum recorded width of 25 centimetres (ten inches) in males or 31 centimetres (12.4 inches) in females. The males of European thornback rays (*Raja clavata*) are about 50 centimetres (20 inches) wide when they reach first maturity, about seven years after birth; females are 60 to 70 centimetres (24 to 28 inches) at first maturity, nine years after birth.

EVOLUTION AND CLASSIFICATION

Evolution. The earliest fossil remains of fishlike vertebrates are too fragmentary to permit tracing the modern fishes precisely to their origins. It is believed that the ancestral forms evolved during the Silurian Period (from about 430,000,000 to 395,000,000 years ago) in the upper reaches of streams. During the end of the Silurian and the beginning of the Devonian that followed, there appeared an exceedingly diverse group of armour-plated

Figure 3: Primitive sharklike fishes. (Above) *Hybodus* from the Mesozoic Era. (Below) *Cladoselache* from the Late Devonian Period.

fishes with jawlike structures, paired fins, and bony skeletal tissue. Paleontologists refer these to a distinct class, Placodermi (*q.v.*). Between the beginning and end of the Devonian (the latter about 350,000,000 years ago), the placoderms reached their peak in diversity and numbers and almost completely died out; only a few lingered another 10,000,000 years into the Early Mississippian (roughly, the Lower Carboniferous). During their flowering, the placoderms evidently gave rise to the Osteichthyes (the bony fishes) and the Chondrichthyes (the cartilaginous fishes). Although the lines of evolution remain to be discovered, it seems quite clear that the two groups evolved independently, the Chondrichthyes appearing much later than the Osteichthyes. Although a few sharklike forms remained in freshwater, the vast majority soon invaded the sea, perhaps in response to the arid Devonian climate. There they adapted to life in salt water by evolving the urea retention habitus (see above *Salt and water balance*). Their cartilaginous skeleton, far from representing an evolutionary stage antecedent to the Osteichthyes, as was once believed, is probably degenerate rather than primitive. Possibly their precursors were the petalichthyids, a group of Devonian sharklike placoderm fishes with ossified skeletons and well-developed fins.

The phyletic relationship of the chimaeras and the sharks and rays is a moot subject. Although both groups have many characteristics in common, such as the possession of a cartilaginous skeleton, placoid scales, teeth simply imbedded in gums, a spiral valve in the intestine, urea retention habitus, internal fertilization (for which the males have claspers) and absence of a swim bladder, the two groups may have evolved independently along parallel lines, the chimaeras from the pycnodonts, an order of Devonian placoderms with body form and tooth structure very suggestive of modern chimaeras.

The first fishes clearly identified with the Chondrichthyes were sharklike in form. One order, the Pleurocanthodii, consisting of one family of freshwater, sharklike fishes, appeared in Late Devonian, was abundant in the Carboniferous and Early Permian (until about 250,000,000 years ago), and disappeared during the Triassic Period, which followed. These fishes were characterized by the following features: the skeletal structure of both pectoral and pelvic fins had an axis with side branches (called the archipterygial type); the tail was almost symmetrical, being only slightly tilted upward; a long movable spine projected backward from the back of the head; the teeth had two divergent prongs and a central cusp set on a button-like base; the anal fin was two-lobed; and the males had claspers.

The other order, Cladoselachii, consisted of marine fishes known only from fossils of the late Middle Devonian, Carboniferous, and Early Permian periods. Their distinguishing characteristics were that each tooth had a long base composed of a bonelike tissue, from which rose three conical cusps, a tall central one and two smaller ones on either side; the body scales had several lobes or cusps; the jaws had double articulation, extending for-

Fossil

fishes

Relation-
ship to
bony
fishes

ward to the snout; claspers were lacking; the outline of the caudal (tail) fin was almost symmetrical but with differing internal structure of the upper and the lower lobes.

The cladoselachians were probably ancestral to a group closer to modern sharks, the order Hybodontii. They probably represent an intermediate state in selachian evolution and are classified by some authorities in the order Selachii. Although the jaws had the primitive double articulation, the skeletal support of the pectoral and pelvic fins was close to that of modern selachians, with basal elements projecting outward into the fins. The teeth near the front of the mouth were generally sharp cusped; the cusps of those further back were sometimes reduced to a rounded crown. The front teeth were suitable for seizing prey; those in the back were suitable for crushing mollusks. The hybodonts appeared toward the end of the Devonian, flourished in the Late Paleozoic, and died out during the latter half of the Mesozoic, a few lasting into the Late Cretaceous (about 80,000,000 years ago).

The great period of radiation (diversification) in marine vertebrates characterizing the Mesozoic ended in the Permian, and the chondrichthyes fishes, which had reached their greatest flowering during the Carboniferous, became greatly reduced, remaining so until the Jurassic (about 190,000,000 years ago), when the areas of the seas expanded and those of the land diminished. Then the six-gilled shark (*Hexanchus*), horned shark (*Heterodontus*), and guitarfishes appeared. By the end of the Cretaceous, most of the families and many genera of modern sharks, as well as those of skates and rays, were represented. The evolution of elasmobranch fishes, much as they are known today, had been accomplished.

Annotated classification. The most recent approaches to a comprehensive review of the chondrichthyes are that of U.S. ichthyologists H.B. Bigelow and W.C. Schroeder and that by U.S. paleontologist Alfred S. Romer. The following synopsis, based on their work, provides principal identifying characteristics of all major Recent groups.

CLASS CHONDRICHTHYES (OR SELACHII)

Subclass Elasmobranchii (sharks and rays)

Chondrichthyes with 5–7 pairs of gill clefts not covered by a fold of skin, opening separately to the exterior.

Order Selachii (sharks)

Elasmobranchs with gill clefts opening at least partly on the side of the body.

Suborder Notidanoidei. Sharks having 6 or 7 gill openings. Anal fin present.

Family *Hexanchidae* (cow shark and 7-gilled sharks). Lower Jurassic to present; marine. The cow shark (*Hexanchus griseus*), in deep water, down to 1,875 metres (about 6,000 feet). Distinguished by presence of 6 gill slits; teeth of lower jaw strikingly unlike those of upper, the 5 or 6 on either side of the central tooth being about twice as broad as high, their inner edges saw-toothed with 5–8 pointed cusps. Size up to at least 5 metres, estimated length at maturity about 2 metres. Ovoviviparous; 4.5-metre specimen contained 108 embryos. The 7-gilled sharks (*Heptranchias* and *Notorhynchus*) are widely distributed in warm and temperate continental waters.

Suborder Chlamydoselachioidei.

Family Chlamydoselachidae (frilled shark). Miocene to present. One modern species known, rather rare. Distinguished by 6 gill slits, the margins of the first being continuous across the throat. Size to about 2 m. Moderately deep water of the eastern North Atlantic from Portugal to Norway and in the North Pacific off California and Japan.

Suborder Heterodontoidae. Upper Devonian to present. Five gill openings on each side of body; anal fin present; 2 dorsal fins, each preceded by a spine. Marine.

Family Heterodontidae (Horned sharks, bullhead, Port Jackson shark). With 1 Recent genus and about 10 species. Oviparous; egg case screw shaped, a double spiral flange extending from apex to large end. Teeth in upper and lower jaws alike, those in front incisor-like, those on sides much larger and molar-like. Bottom dwellers out to about 180 m depth. Australia, New Zealand, East Africa, East Indies, China, Japan, eastern Pacific, north as well as south. Not known in Atlantic or Mediterranean. Size up to about 1.4 m.

Suborder Galeoidei (typical sharks). Five gill openings on

each side of body; anal fin present; dorsal fin or fins not preceded by spines.

Family Odontaspidae (formerly Carchariidae) (sand sharks). Upper Jurassic to present. Marine. Caudal peduncle (narrow "stalk" of the tail) without lateral keels; with a distinct pit on its upper surface, but none on its lower. Teeth large, slender, smooth edged, lower eyelid without a nictitating membrane (a transparent extra eyelid). Development is ovoviviparous; maximum size varies with species, from around 2.8 to 6 m. One recent genus (*Odontaspis*) recognized, with some 6 species, found in warm temperate and tropical coastal waters of all oceans. Frequent shallow water near shore; sluggish except when feeding.

Family Scapanorhynchidae (goblin sharks). Lower Cretaceous to present. Marine. One genus, known from Japan, Portugal, and India, perhaps from Australia. Prominent elongation of the snout; protruding jaws. Maximum size to about 3.4 m. Probably ovoviviparous. A deepwater shark, fished commercially in Japan for its liver and flesh.

Family *Isuridae*. Upper Cretaceous to present. Three genera, marine, although at least 1 species (the white shark) occasionally strays into estuaries. Distinguished by 2 dorsal fins, of which the first is much larger than the second and the rear end of its base situated well in advance of the pelvic fins; caudal fin lunate (crescent shaped), its axis steeply raised. Teeth large. Ovoviviparous or viviparous. Circumglobal, occurring in boreal to warm temperate belts of all oceans in both hemispheres. Size in the great white shark (*Carcharodon carcharias*), to about 11 m.

Three genera, *Lamna*, *Isurus*, and *Carcharodon*, the last 2 dangerous to man, the great white shark unquestionably the most dangerous of all fishes.

Family Cetorhynchidae (basking shark). Oligocene to present. Marine. Two dorsal fins, the first well in advance of pelvis; lunate caudal fin; gill openings extending around sides almost meeting at throat. Hundreds of minute teeth. Ovoviviparous. Embryonic development undescribed. Size at birth probably 1.5–1.8 m; maximum size to 13–14. Single genus (*Cetorhinus*) inhabiting temperate and boreal zones around the world. Whether basking sharks of the Northern and Southern hemispheres belong to a single species (*C. maximus*) is undetermined. Sluggish, inoffensive sharks, living at or near the surface, feeding wholly on plankton, which they sieve out of the water with their gill rakers.

Family Alopiidae (thresher sharks). Eocene to present. One genus, 5 species. Distinguished by the elongated upper lobe of the tail fin, which is almost as long as the rest of the body. Teeth small, bladelike. Ovoviviparous. Total length to about 6 m. Cosmopolitan at low and middle latitudes of all oceans. Harmless to man. Occasionally sold for food.

Family Orectolobidae (carpet and nurse sharks, wobbegongs). Upper Jurassic to present. Marine. Distinguished by the presence of 2 dorsal fins, the origin of the first over or behind the pelvic fins; nostril connected with mouth by a deep groove, its anterior margin with a well-developed fleshy barbel (tentacle). Teeth small, with several cusps; development ovoviviparous in some, oviparous in others. Some species (carpet sharks) live on the bottom and are ornamented with fleshy flaps along the sides of the head. Large family of many genera and species occurring mostly in western Pacific, Australasia, Indian Ocean, Red Sea. Only 1 species, the nurse shark, in Atlantic.

Family Rhincodontidae (whale shark). Distinguished from all other sharks by large, lunate tail, mouth at end of snout, 3 prominent ridges extending the length of body along the sides, back marked with round white or yellow spots and a number of white or yellow transverse stripes. Oviparous. Size said to reach over 18 m, the largest of modern fishlike lower vertebrates. One species only (*Rhincodon typus*); open waters of all oceans, mostly in tropics, but north to 42° north latitude (near New York) and to 33°55' south (Table Bay, South Africa). Sluggish and inoffensive.

Family Scyliorhinidae (cat sharks, European dog shark, swell sharks). Upper Jurassic to present. Most with 2 dorsal fins (1 genus with 1); first dorsal fin situated far back on body, at least half of it behind the origin of the pelvic fins. Furrows are more or less developed at the angle of the jaws; teeth small, numerous, with several cusps. A large group of small sharks comprising many genera and species, occurring in temperate to tropical latitudes around the world. The swell sharks (*Cephaloscyllium*) can inflate the belly with air or water, presumably a defense mechanism. Of little, if any, commercial value: harmless to man.

Family Pseudotriakidae (false cat sharks). Distinguished by the base of the first dorsal fin being at least as long as the caudal fin. Teeth minute, numerous. One genus, *Pseudotriakis*; 2 species, 1 on both sides of the North Atlantic, the other in the western Pacific. Size to nearly 3 m. Deepwater sharks

(taken down to 1,477 metres) rarely straying near shore and known only from a few specimens.

Family Triakidae (smooth dogfishes). Upper Cretaceous to present. The principal distinguishing feature is small, closely crowded teeth in series, rounded or somewhat compressed and with 3 or 4 cusps. True nictitating membrane lacking in eye. Development ovoviparous or viviparous. Small sharks of coastal waters in tropical to temperate zones of all oceans. The family comprises at least 7 genera and numerous species. Smallest species, *Triakis barbours*, reaches only about 40 cm (16 in.); maximum size for others of family 150–175 cm. Although sharks of this family are generally considered harmless, there is one authenticated case of a California leopard shark (*Triakis semifasciata*) attacking a man in northern California.

Family Carcharhinidae. The largest family of sharks, with 13 genera and numerous species, including the tiger shark, the great blue, whalers, and many with various local common names. Upper Cretaceous to present. Two dorsal fins, the first in front of the pelvis. All species except 1 with well-developed nictitating membrane. Teeth bladelike, with only 1 cusp, only 1 or 2 rows functional along sides of jaws. Development either ovoviparous or viviparous. The species range in maximum size from about 1.4–5.5 m. Members of this family occur from tropical to temperate zones in all oceans. Although most species are marine, several frequent brackish water or freshwater, and some occur in lakes that connect with the sea. The *Carcharinus leucas-gangeticus* group, a collection of several closely related species or subspecies, has a bad reputation; several cases of unprovoked attacks on persons are on record in both salt water and freshwater.

Family Sphyrinidae (hammerhead sharks). Upper Cretaceous to present. The most obvious distinguishing feature is the lateral expansion of the head in a hammer or bonnet form, with the eyes at the outer edges. Teeth large, triangular, smooth edged in some species, serrate in others. Viviparous or ovoviparous; size varies with species, the largest (*Sphyrna mokarran*) is said to reach 6 m. Predacious. Marine, but occasionally straying into estuaries. Occur in tropical and temperate zones of all seas. Hammerheads have a sinister reputation of initiating unprovoked attacks, documented by authoritative cases on record.

Suborder Squaloidei (spiny dogfishes, bramble sharks, sleeper sharks, pygmy sharks). Upper Cretaceous to present. Widely distributed in all oceans from tropical to Arctic and sub-Antarctic latitudes; from shallow to deep depths. Anal fin lacking; snout not elongated into a beak; body subcylindrical (nearly round in section); not flattened dorsoventrally; margins of pectoral fin not expanded forward past first pair of gill openings.

Family Squalidae (spiny dogfishes, sleeper sharks and several others lacking common names). Upper Cretaceous to present. Distinguished by having about as many upper teeth in anterior row as in succeeding rows. Diverse forms, habits, and sizes. Spiny dogfishes (*Squalus*) grow to about 120 cm; the Greenland sleeper shark to over 6 m; a pygmy shark (*Euprotomiscus*) to about 26 cm. Sleeper sharks (*Somniosus*) taken for food in waters around Iceland and west Greenland, but the fish must be dried before eating; otherwise it produces a mild poison.

Family Oxynotidae (prickly dogfish). Miocene to present. Distinguished by number of functional upper teeth increasing in each row from front to rear; dermal denticles large and prominent. Taken from depths of 60–530 m; 2 species known in eastern North Atlantic, Tasmania, and New Zealand.

Suborder Pristiophoroidei

Family Pristiophoridae (saw sharks). Cretaceous to present. Anal fin lacking, snout greatly elongated, each edge studded with sharp toothlike structures; upper eyelid is free; gill slits at the side of the head, not underneath as in the sawfish. Ovoviparous. Marine. Indo-Pacific, South Africa, Tasmania, Australia, Philippines, Korea, Japan. The order comprises 1 family, 2 genera, *Pristiophorus*, with 5 gill openings, and *Pliotrema*, with 6. Good food fish, harmless to man.

Suborder Squatinoidei

Family Squatinidae (angel sharks). Upper Jurassic to present. Marine, widely distributed in continental temperate and warm waters of Atlantic and Pacific oceans, on or close to the sea bottom. Characterized by flattened body, eyes on upper surface; anterior margin of pectoral fins far overlapping gill openings, which are partly on side of body; no anal fin. Largest up to about 2.4 m. Ovoviparous. One genus; possibly as many as 11 species.

Order Batoidei (rays, sawfishes, guitarfishes, skates, and sting-rays)

Jurassic to present. Five gill openings, wholly on ventral

surface; pectoral fins united with sides of head forward past the gill opening. Differ from all sharks in lacking upper free eyelid.

Suborder Pristioidei

Family Pristidae (sawfishes). Jurassic to present. Distinguished by extension of snout into long, narrow, flattened blade armed on either side with teeth but without barbels; gills on lower side of body, as in other batoids. Ovoviparous. Size varies with species; common Atlantic sawfish to at least 5.5 metres; species in Indian and Australian waters to over 7 metres. Widely distributed in tropical and subtropical zones of all oceans; occur in estuaries and run far up large rivers into freshwater; but whether they remain resident and reproduce in freshwater lakes is not clearly established. Six species are known.

Suborder Rhinobatoidei (guitarfishes). Lower Jurassic to present. Electric organs lacking; well-developed dorsal and caudal fins present; base of tail stout, not sharply marked off from rest of body. Most species ovoviparous, some perhaps oviparous.

Family Rhynchobatidae. Cretaceous to Recent. Distinguished by caudal fin being conspicuously bilobed and somewhat unate; posterior edge of pectorals does not reach foremargin of pelvis. Two genera, widely distributed in tropical and subtropical shallow waters of Indo-Pacific. Maximum size over 2 m.

Family Rhinobatidae. Caudal fin not bilobed; posterior edges of pectoral fins extending rearward at least as far as the origin of the pelvis. Small, rounded, closely set teeth. About 7 genera and 26 species; tropical and warm temperate shallow coastal waters of all oceans, in some localities entering freshwater and perhaps even permanently residing and breeding there. Size to about 1.8 m. Harmless to bathers.

Suborder Torpedinoidei (electric rays, numbfishes, torpedoes). Eocene to present. Distinguished principally by highly developed electric organs on either side of the head and gill chambers; the outlines of these organs visible externally in most species. Pectoral fins with the head form a circular or ovate disk. Skin of most species soft and entirely scaleless. Eyes small, functional in most species but rudimentary or obsolete in deepwater forms. Mostly sluggish bottom dwellers in all the oceans from tropical to temperate latitudes and from the intertidal zone to depths of at least 1,100 m. Three families, Torpedinidae, Narkidae, and Temeridae, distinguished by whether 1, 2, or no dorsal fins are present. Numerous genera and species. The largest electric rays of the genus *Torpedo* reach a length of about 180 cm; the smallest, of the genus *Narke*, less than 30 cm.

Suborder Rajoidei (skates). Lower Cretaceous to present. Moderately slender tail, on which the caudal fin is reduced to membranous fold or entirely lacking; outer margins of the pelvic fin are more or less concave or notched. Probably all species are oviparous. Three families are distinguished by whether 1, 2, or no dorsal fins are present.

Family Rajidae (the great majority of skates). Two dorsal fins. Upper surface of the body disk more or less rough with spines, thornlike denticles, or both. Some species with electric organs along the sides of the tail, which, as far as known, produce very weak shocks. Six genera, widely distributed from tropical to sub-Arctic belts of both hemispheres but with curious gaps in distribution; scarce, if present, in the Micronesian, Polynesian, and Hawaiian islands in the Pacific, in the western Atlantic between Yucatan and mid-Brazil, and in West Africa between Cape Verde and Walvis Bay. They occur from estuaries seaward, several species down to depths of over 500 m. Several species inhabit deep water, at last one being found at over 2,700 m. They live mostly on the bottom, often partially buried.

Family Arhynchobatidae. Distinguished from other skates by having a single dorsal fin. Single genus and species, *Arynchobatis asperimus*, known only from New Zealand.

Family Anacanthobatidae. No dorsal fin; completely smooth skin; the pelvic fins so deeply notched as to form leglike structures anteriorly. Two genera, *Awacanthobatis* from Natal coast, South Africa, and *Springeria* from Gulf of Mexico.

Suborder Myliobatoidei. Upper Cretaceous to present. Distinguished by a slender tail, usually whiplike toward the tip; outer margin of the pelvic fins being straight or convex. Most with 1 or more saw-toothed, poisonous spines on upper surface of tail. Seven families are recognized. Tropical to warm temperate waters of all oceans, most abundant in shallow depths, entering brackish water and freshwater freely. One family is confined to freshwater.

Family Dasyatidae (whip-tailed rays). Lower Cretaceous to present. Caudal fin lacking; no distinct dorsal fin; tail,

measured from the anus to the tip, longer than the breadth of the disk. Oviparous. Tropical to warm temperate latitudes in all oceans. Generally in depths less than about 100 m, most abundant close to shore, including tidal embayments. The largest reaches at least 2 m in breadth. Five genera, 2 in tropical and subtropical rivers of South America. A peculiarity in the structure of the pelvis has been used to differentiate a separate family, Potamotrygonidae.

Family Gymnuridae (butterfly rays). Miocene to present. Distinguished by the body being more than 1.5 times as broad as long and the tail considerably shorter than the body. Saw-toothed spine on the back of the tail in some species but not all. Maximum breadth about 2 m. Shallow coastal waters of tidal embayments and river mouths in tropical to warm-temperature latitudes of all oceans.

Family Urolophidae (stingrays). Eocene to present. Distinguished by having well-developed tail fin supported by cartilaginous rays; tail with at least one large saw-toothed spine. Oviparous. The numerous species look very much alike; the largest does not exceed about 70 cm in breadth. Tropical to warm temperate coastal waters less than about 70 m deep in western Atlantic and both sides of the Pacific from Japan to Tasmania, including the East Indies; they are unreported from eastern Atlantic or the Indian or African coasts of the Indian Ocean.

Family Myliobatidae (eagle rays). Upper Cretaceous to present. Distinguished from other myliobatoids by the forepart of the head projecting conspicuously beyond the rest of the body; eyes and spiracles on the sides of the head; tail as long as the disk or much longer and in most species bears a serrate venomous spine. Oviparous. Some attain a width of about 2.5 m. Cosmopolitan, occurring in continental waters and around islands and island groups from tropical to temperate latitudes; 4 genera.

Family Rhinopteridae (cow-nosed rays). Upper Cretaceous to present. Similar to eagle rays except that the projecting head is deeply incised at the midline, forming two distinct lobes. Oviparous. Maximum breadth about 2 m. Coastal waters of tropical and warm temperate latitudes of all oceans.

Family Mobulidae (devil rays, or mantas). Pliocene to present. Continental waters and around offshore island groups of tropical to warm temperate belts of all oceans. Distinguished by a pair of armlike structures (cephalic fins) projecting forward, on each side of the head. Tail whiplike; with or without a serrate edged spine. Teeth minute, arranged in many rows. Maximum size (breadth) of smallest species about 60 cm; largest species at least 7 m.

Subclass Holocephali (chimaeras, ghost sharks)

Upper Devonian to present. Cartilaginous skeleton, 4 pairs of gills, covered on each side of the body by an opercular fold of skin leading to a single external gill opening. First dorsal fin and spine erectile. Skin with small denticles along midline of back in some species and on tentacula and claspers of males. Teeth united to form grinding plates. Claspers of males are supplemented by an erectile organ, called tentaculum, in front of the pelvic fins, and all except one genus (*Harriotta*) have another club-shaped tentaculum on the forehead. Oviparous, laying elliptical, spindle-shaped, or tadpole-shaped eggs enclosed in brown horny capsules, remarkably large in proportion to the size of the parent. In breathing, chimaeroids take in water chiefly through the nostrils and thence through grooves leading to the mouth, which is generally kept closed. Various distributed in temperate and boreal zones of all oceans, in coastal waters, and river estuaries and seaward down to over 2,500 m.

Order Chimaerae

Family Chimaeridae (ghost sharks, ratfishes, chimaeras). Lower Jurassic to present. Rounded short or conical snout. Claspers of males bifid or trifid. Size to about 1.5 m. Warm temperate and boreal latitudes of all oceans. Two genera, each with several species.

Family Callorhynchidae (elephant fish). Hoe-shaped proboscis. One genus (*Callorhynchus*) with a few species, which may eventually prove to be identical. Size to about 1.3 m. Restricted to cool temperate and boreal latitudes of Southern Hemisphere, generally taken in rather shallow water, sometimes entering estuaries and rivers.

Family Rhinochimaeridae (long-nosed chimaeras). Snout projecting into a long, straight point. Lateral line an open groove. Size to about 1.3 m. Probably cosmopolitan in middle latitudes of both hemispheres, taken in depths of 685–2,000 m.

Critical appraisal. Many of the elasmobranchs are particularly difficult subjects for taxonomic study. Differences between species are often subtle and hard to mea-

sure. Lacking skeletal support such as that possessed by the bony fishes, captured sharks collapse along the soft undersides of the body when taken out of the water, thus reducing the accuracy of measurements. A satisfactory taxonomic study of any species requires adequate samples over a full range of sizes, representing the full geographical distribution of the species. The sampling must take into account rather large variations in body proportions between individuals of like size and different size groups and between populations inhabiting different regions of the total distribution. Hence, the identity of many species remains unsettled. The number of living species of sharks, now estimated at 200 to 250, tends to diminish as ichthyologists working in different parts of the world accumulate and exchange careful anatomical measurements of fresh specimens, discovering that fishes from widely separated areas, formerly thought to be distinct, are actually of the same species.

The rays, except the larger ones, are somewhat easier to work with. About 300 to 340 species have been described. Here again, however, the number tends to diminish as comparative studies in different parts of the world show many of them to be cosmopolitan.

The classification of chondrichthyan fishes is a somewhat controversial subject. An authoritative opinion as to how sharks, rays, and chimaeras should be grouped can be reached only from a comprehensive critical review of all available pertinent living and fossil material. Students continuously add to the accumulation of field measurements and museum specimens, and so such a classification needs to be revised from time to time. Because this revision involves a vast amount of work, it is not undertaken often.

Seleucid Kingdom

The Seleucid Kingdom, or Empire (312–64 BC), one of the great powers of the Hellenistic Age, was created, along with Ptolemaic Egypt and other states, out of the Macedonian Empire of Alexander the Great. Originally it included a vast area extending from European Thrace east to the borders of India; when it was finally conquered by the Romans in the 1st century BC, the authority of the Seleucid kings was confined to Syria and Cilicia.

The Seleucid Kingdom c. 185 BC.

The dynasty. The kingdom's name is derived from that of its founder, Seleucus I Nicator, a Macedonian general who became prominent after Alexander's death. Seleucus was satrap (governor) of Babylonia under the Macedonian king Antigonus I from 321 to 316. In 312, allied with Ptolemy I of Egypt, he seized Babylonia for himself. From there he extended his domain eastward across Iran to the Indus River, establishing friendly relations with the Indian king Candragupta Maurya in 305. Around 304 he was proclaimed king of all the lands he had conquered (he had held that title in Babylonia since 309/308). He then pushed westward into Syria and Anatolia, defeating his rival Antigonus at Ipsus in 301 and completing his conquests by the annexation of the Thracian Cherronesus in 281. In the same year he was assassinated. Seleucus was succeeded by his eldest son, Antiochus I Soter (reigned 281–261). After Antiochus II (261–246), Seleucus II (246–225), and Seleucus III (225–223) came Antiochus III the Great (223–187), under whom the kingdom entered a new stage of its historical development. Antiochus III thoroughly reformed its administration; his innovations became a prototype for the states that succeeded the Seleucid Kingdom. The defeat of the Seleucids by Rome at Magnesia at the end of 190 or beginning of 189 marked the beginning of their decline.

Even among the later Seleucids there were significant personalities. This was less apparent in Seleucus IV (187–175) than in Antiochus IV Epiphanes (175–164/163), famous for his clashes with the Jewish Maccabeans. Antiochus V (164/163–162) was a minor and unable to rule. From the time of Demetrius I, the son of Seleucus IV (162–150), and Alexander Balas (150–145), who claimed to be the son of the fourth Antiochus, two mutually hostile branches of the dynasty existed. Demetrius II (145–139 and 129–125) was particularly opposed to Antiochus VII (139/138–129), the representative of the other line. When the latter fell in battle against the Parthians in 129, the ascendancy of this line in the Seleucid Empire was permanently ended. The last rulers, Antiochus XIII and Philip II, reigned from 69 to 64 BC and from 65 to 64 BC, respectively. A final attempt by Philip II to seize the crown was thwarted by the Romans in the year 56 BC.

Significant regions of the kingdom. The Seleucid Kingdom reached its greatest extent at the death of Seleucus I, in the year 281.

The possession of the entire central and southern parts of Anatolia and, above all, the ancient Greek cities on

Anatolia's west coast gave the Seleucids great economic power and cultural influence. (The Greek cities on the northern coast—Cyzicus, Heraclea, Trapezus, and others—retained their independence.) By controlling the Taurus passes between Anatolia and Syria and the Hellespont between Thrace and Anatolia, the Seleucids were able to dominate the important trade and communications routes between Europe and Asia. The invasion of Anatolia by the Celts in 278 did change the situation, but only temporarily. Possession of the ancient cultural areas of Syria and Phoenicia was equally important. The trade routes from the Middle and Far East passed through these lands and terminated at the Phoenician port cities. The trade of the Phoenician cities of Tyre, Sidon, and Berytos dominated almost the entire Mediterranean area. The settlements of the first Seleucids in northern Syria, such as Antioch, Seleucia, Laodicea, and Apamea, were not only manufacturing centres but also important garrisons for the army.

Seleucid culture and Hellenization. Syria became the centre of the Seleucid state and was the area most heavily influenced by the Greek culture of the Macedonians. In Babylonia, on the other hand, the traditions of the past lived on; the Mesopotamian cuneiform script, for example, continued to be used by the influential priestly caste, just as in pre-Seleucid times.

The ruling class in the Seleucid state was a Greek-speaking Macedonian aristocracy descended from the original conquerors. Below them was a class of Greek settlers, mostly soldiers, officers, and functionaries, located in the eastern provinces as well as in the Greek cities of Anatolia. Greek was spoken everywhere and Greek schools were to be found throughout the realm. Inscriptions in Greek have been found even in the areas farthest removed from traditional Greek centres. In many places, Greek theatre, performed by travelling actors, became popular. Inscriptions of Euripidean verse have been found in Armenia, and Greek was used for legal purposes at Susa in Iran.

On the whole, the Hellenistic culture was limited to the cities; in the countryside the indigenous national characteristics as well as the native languages of the Near East survived.

Thus resistance to Macedonian rule was centred mostly in rural areas (e.g., the movement that established the Parthian state in the 3rd century BC, and the rising of the Maccabeans in the 2nd century). Antiochus IV (175–164/163), in his zeal to propagate Greek culture, raised a statue of the god Zeus in the temple at Jerusalem. He was supported by Hellenized Jewish aristocracy, but beginning in 165, upholders of traditional Judaism rose against him under Judas Maccabeus. After 25 years of struggle the Maccabeans won Judaea from the rule of the Seleucids.

For the Macedonians and Greeks who left their homelands in great numbers during the 3rd century BC, a broad new field of activity opened up under the Seleucids. In their domains, Greek-speaking people banded themselves into organizations; in these clubs as well as in private life, the traditions of Greek culture and the Greek language were zealously cultivated. Greek law was also important, as it formed the basis of personal and economic relations; and, indeed, the Greeks of the privileged class dominated the political and economic life of the kingdom.

Greek religion accompanied the Greeks to the Near East. Throughout the Seleucid domains, the cult of the Olympian gods coexisted with that of local deities. Greek temples were to be found everywhere—in Phoenicia, Syria, and even in distant Iran. Social contact with the indigenous peoples gave the Macedonians and Greeks access to the most diverse religions of the Near East—the cult of Mithra in Iran, Marduk and Ishtar in Babylonia, As-tarte and Hadad in Syria and Phoenicia, the Magna Mater (Cybele) in Anatolia, and many others. They assimilated many of these, identifying the foreign gods with their own; but the capacity for assimilation was limited, and the wider Hellenistic civilization spread, the thinner the cover of genuine Greek religiosity became.

Sources of Seleucid strength

Resistance to the Seleucids

The later Seleucids

The "royal
cult"

The kings themselves were accorded diverse honours, again in emulation of Alexander the Great, who had adopted this custom in his Asian territories. The "royal cult" was organized during the second generation of Seleucids by Antiochus I (281–261). The rulers adopted cult names, such as Soter ("the saviour"), Theos ("god"), and Epiphanes ("appearance of god"). This cult was intended to be a unifying influence on the various peoples and nations of the kingdom, but it was mainly official in character and does not seem to have had much popularity.

Because of the prestige of Greek culture, indigenous people often tried to become assimilated into the Greek class, assuming Greek names and participating in the life of the grammar schools. After the 2nd century BC, just when the initial impact of Hellenic culture was declining in the Near East, it was re-enforced by the arrival of the Hellenized Romans in the area; thus, Greek culture continued to be a strong influence there after the demise of the Seleucids.

Government and society. The fact that the Seleucid state had been formed through military conquest was apparent in all aspects of the administration. Seleucus I, like Alexander, adopted many features of the old Persian imperial administration, notably its division into satrapies. This form of administration had proved itself under the Achaemenian Persians and was, therefore, maintained, at least in the east. The provinces of Anatolia and the central areas of the kingdom were administered by *stratēgoi*, who combined military and civil authority. In the Iranian provinces satraps still controlled civil matters; military units, however, were commanded by their own officers, and controlling the entire Iranian East, probably from the Euphrates on, there was a "Supervisor of the Higher Satrapies." In the reforms of Antiochus III (223–187), this dualism was abolished; the heads of the provincial administration throughout the realm from that time on were *stratēgoi*, with special officials for financial affairs (*hoi epi tōn prosodōn*) to assist them. The entire empire was divided into satrapies, hyparchies, and toparchies, an organizational system that served as a model for the Parthians. Administrative centres were located at Sardis in the west and at Seleucia near the Tigris River in the east. Few details are known about the central government, but if the king was incompetent or a minor, a chancellor (*ho epi tōn pragmatōn*) was appointed (for example, Heliodorus during the reign of Seleucus IV).

The backbone of Seleucid power was the army, which included both the Macedonians, settled in military colonies throughout the kingdom, and mercenaries. The prestige of the Macedonians derived from the martial tradition of Alexander; from the end of the 3rd century their numbers began to decline, and gradually increasing numbers of the indigenous population were pressed into military service. Their contingents were of varying ability; the best being the Iranians and some of the peoples of Anatolia. The great Seleucid frontier fortresses were garrisoned mostly by mercenaries.

Taxation

The Seleucids in large measure continued the revenue policies of the Achaemenians and of Alexander. The most important direct tax was the *dekate*, a tithe; indirect taxes included a duty on salt. There were also occasional special levies known as *stephanoi*. Though certainly less exacting than the Ptolemaic kings of Egypt in the demands they made on their subjects, the Seleucids must have drawn large revenues. The expenses involved in maintaining the court and army were heavy, but the surplus of revenue and the general prosperity of the kingdom were sufficient to make the kings and the leading men in the state very rich. All the categories within the empire—subject kings, dynasts, peoples, and cities—were liable to taxation in money or kind, but only in the case of the royal domains, where the land was cultivated by royal serfs ("the king's people"), were taxes collected directly by royal officials; in all other cases, collection was indirect and by stages. In accordance with their preference for a decentralized mode of government, and in order to encourage the growth of city life, the Seleucids commonly allotted large tracts of royal land to Greek cities and compelled feudal landowners and temple states to do the

same. This process led to the gradual emancipation of the serfs on the land affected.

The social organization of the Seleucid Kingdom was that of most traditional Near Eastern states. Below the king were the *stratēgoi* and satraps in the imperial administration. The property-owning class and landed gentry were next. After this were the soldiers—Macedonians and mercenaries. At the bottom of the hierarchy was the great mass of serfs and peasants who formed the bulk of the population. In general, the bourgeois class was numerically weak and economically unproductive.

Territorial losses and decline. The kingdom lost much of its territory in Anatolia in the 3rd century. The Greek cities of the Aegean coast threw off their allegiance, and such states as Cappadocia and Attalid Pergamum achieved independence. Other territories were ceded to the Celts and to the kings of Pontus and Bithynia. The hill country of the Taurus Range in southern Anatolia was never properly subjugated, and the Seleucid possessions to the north and west of Cilicia were reduced, before the end of the century, to parts of Caria, Lydia, Aeolis, and the Troad (all on the Aegean seaboard), connected by a narrow corridor running through Phrygia and Lycania to Cilicia and Syria.

In the northeastern area of the empire, Parthia, Bactria, and Sogdiana became independent after the middle of the 3rd century. The submission of these districts to Antiochus III later (209–206) was of only passing effect. Coele Syria (Lebanon) and Palestine had been fought over by the Seleucids and the Ptolemaic kings of Egypt ever since the accession of Antiochus I (281); not until the reign of Antiochus III did they pass finally into Seleucid possession (c. 200). This acquisition and the short-lived subjugation of Armenia and the former eastern provinces of the empire counterbalanced the loss of all Anatolia north of Mt. Taurus by the Treaty of Apamea (188), which resulted from the defeat of Antiochus III at the hands of Rome and Pergamum.

After the death of Antiochus IV (164/163), the small state of Commagene in northern Syria emerged as an independent kingdom, as did Judaea in Palestine. In the east, all the provinces to the east of Media, Susiana, and Persis had been lost by the same date, either to the Parthians or to the kings of Bactria. In 145 Ptolemy VI of Egypt reoccupied Coele Syria and Palestine. In 141 the Parthians annexed Babylonia and Mesopotamia. By then everything to the east of the Euphrates, apart from a small foothold in northern Mesopotamia, had been lost; and the utter failure of the expeditions led by Demetrius II in 140–139 and Antiochus VII in 130–129 to recover the lost provinces meant that the kingdom was reduced to Syria and eastern Cilicia. Even this limited area was held only precariously in the final period of the dynasty.

(He.B.)

Seleucus I Nicator

Seleucus I Nicator was the founder of the Seleucid dynasty and of the Seleucid Empire in Asia. A Macedonian noble and companion of Alexander the Great, he was one of the diadochoi ("successors") engaged in the struggle for the control of the empire after Alexander's death.

Born between 358 BC and 354 BC in Europus, Macedonia, the son of Antiochus (a general of Philip II of Macedonia, the father of Alexander the Great), he participated in the conquest of the Persian Empire as one of Alexander's officers, and in 326 he commanded the Macedonian infantry against King Porus of India in battle on the Hydaspes River. In 324 Alexander ordered a mass wedding ceremony at Susa (in Persia) to put into practice his ideal of uniting the peoples of Macedonia and Persia. On

this occasion Seleucus married Apame, the daughter of Spitamenes, the ruler of Bactria. Of all the Macedonian nobles, he was the only one who did not repudiate his wife after Alexander's death.

Seleucus I, coin, late 4th–early 3rd century BC. In the British Museum.

Ascension
to power

After Alexander died (323), Seleucus was given the command of the *hetairoi* (companions) cavalry and took part in the regent Perdiccas' campaign to oust Ptolemy, the governor (satrap) of Egypt. In Egypt, however, he joined with others in the assassination of Perdiccas. When the empire was divided in 321, he was given the governorship (satrapy) of Babylon. At the same time Antigonus Monophthalmus (the One-Eyed) had been placed in command of a campaign against Eumenes of Cardia, a supporter of Perdiccas. In 317 Seleucus aided Antigonus but, after Eumenes' execution in 316, Antigonus demanded that Seleucus give an accounting of the income from his satrapy. Seleucus refused to give the accounting and escaped capture by fleeing to Ptolemy in Egypt.

From 316 to 312 Seleucus remained in Ptolemy's service. He took the initiative in forging a coalition among Ptolemy, Lysimachus (the ruler of Thrace), and Cassander (who laid claim to Macedonia) against Antigonus, whose desire to become the ruler of the whole of Alexander's empire was a threat to them all. In the resulting coalition war (315–311), Seleucus was made one of Ptolemy's generals and jointly with him commanded the Ptolemaic troops that defeated the force of Demetrius, the son of Antigonus, at the Battle of Gaza in southern Syria (312).

Seleucus once again turned his attention to returning to Babylonia, and in August 312 he was able to reconquer Babylon with only a small army. This conquest marked the beginning of the Seleucid era, which is dated Dios 1 (October 7), 312, in the Macedonian calendar and Nisan 1 (April 3), 311, in the Babylonian calendar. Antigonus ordered Nicanor, one of his generals, to invade Babylonia from the east and his son Demetrius to attack it from the west, but they failed to oust Seleucus. When Antigonus made peace with his enemies in 311, Seleucus was not included.

Consolidation of
gains

Little is known about the next few years of Seleucus' reign; he presumably used them to consolidate his gains. In the year 305 he followed the example of the other successors and assumed the title of king (*basileus*). He embarked on an expansion of his kingdom throughout the Iranian east (the upper satrapies) as far as India, but his advance was eventually halted by Candragupta, the founder of the Maurya dynasty of India. In a pact concluded by the two potentates, Seleucus agreed to territorial concessions in exchange for 500 elephants.

Developments in the west also caused Seleucus to end his campaign in India (303). He had joined a coalition that Ptolemy, Cassander, and Lysimachus had once again formed against Antigonus and Demetrius. In the winter of 302 Seleucus was back in Asia Minor and, together with Cassander and Lysimachus, defeated Antigonus in the Battle of Ipsus (301). The victors divided the lands of

their enemy among them, with Seleucus being given Syria. The southern part of Syria, Coele Syria, had in the meantime been occupied by Ptolemy, who had not taken part in the war. This gave rise to the long series of Syrian wars between the Seleucids and Ptolemies. For the time being, however, Seleucus declined to enforce his claim; he merely transferred his capital from Seleucia on the Tigris to the newly founded city of Antioch on the Orontes (301–300).

Ptolemy, anxious to improve relations with Lysimachus, had given him his daughter Arsinoe in marriage. To provide a counterbalance, Seleucus asked for the hand of Stratonice, the daughter of Demetrius, and in 298 the wedding was held with much pomp at Rhosus in Syria. Soon, however, Seleucus' territorial demands (e.g., the surrender of Cilicia and the cities of Tyre and Sidon) ruptured the previously harmonious relationship with Demetrius.

In 294 a sensational scandal occurred at the court of Seleucus. Antiochus, his son by Apama, fell in love with his beautiful stepmother, Stratonice, and his unrequited passion affected his health. Seleucus gave him Stratonice, assigned him as commander in chief to the upper satrapies, and appointed him coregent.

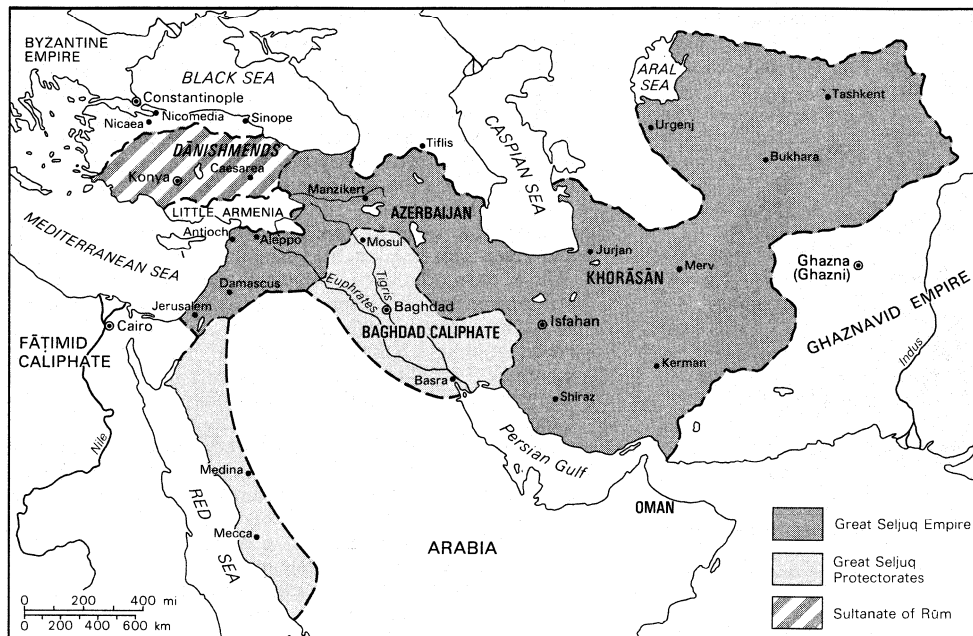

In 285 Seleucus took Darnetius prisoner, thus foiling his attempt to conquer Asia, and interned him in Apamea, where he died in 283. Subsequently, Seleucus intervened in dissensions in the house of Lysimachus, who had had his son Agathocles assassinated. In February 281 Lysimachus fell in a battle against Seleucus at Corupedium, and Seleucus gained control of Lysimachus' kingdom. He was now near his goal of re-establishing Alexander's empire. He crossed over to Europe to enter Macedonia, but at the end of August or beginning of September 281, he was murdered by Ptolemy Ceraunus, who had been passed over by his father, Ptolemy, as successor to the Egyptian throne. Seleucus' son and successor, Antiochus I, entombed his father's ashes in Seleucia, initiated (probably) the posthumous cult of his father, and ordered his veneration as Zeus Nicator.

Seleucus was an energetic ruler, creating the Seleucid Empire, which gained its greatest expansion under his rule. He took great interest in the administration of his territories and founded many new cities. He also encouraged scientific research: Patrocles explored the Caspian Sea and Megasthenes the Ganges River. A bronze bust—a very impressive likeness of him, conveying his imposing personality—was found in Herculaneum (in Italy) and is now in Naples. (J.Se.)

Seljuqs

The Seljuqs (Seljuks) were the ruling family of the Oğuz (Ghuzz) Turkmen tribes who invaded western Asia in the 11th century and founded a powerful empire, later to be divided into the principalities of Iran, Syria, and Asia Minor. The history of these invaders forms the first part of the history of the Turks in the Near and Middle East.

During the 10th century, in the course of the migrations and struggles of the Turkish peoples of Central Asia and southeast Russia, a group of nomadic Turks under a chief named Seljuq settled in the lower reaches of the Syr-Darya (Jaxartes) and later embraced Islām (see also ISLAM, HISTORY OF; INNER ASIA, HISTORY OF). They were incorporated in the frontier defense forces of the Sāmānids and moved to the vicinity of Bukhara c. AD 985. After the fall of the Sāmānids, they were established by Mahmiid of Ghazna in the border regions of Khorāsān, but it was difficult to induce warlike nomads to live peacefully within a settled empire. While Maḥmūd's son Mas'ūd was busy waging war in northern India, the two grandsons of Seljuq, Chaghri (Chagri) Beg and Toghril (Tughril) Beg, saw the chance to win a realm of their own with the support of Persian nobles and religious leaders who were anxious to meet the threatening progress of heretic Shi'ite sects reinforced by the Buiyid princes of western Iran and Iraq and the Fāṭimid Ismā'īlī caliphate of Egypt (see IRAN, HISTORY OF; EGYPT, HISTORY OF). When Mas'ūd saw the danger, it was too late: he was ut-

Seljuq Empire during the reign of Malik-Shāh (1073–92).

terly defeated at Dendenkan (Dandānqān) near Merv in 1040. Thereafter Chaghri Beg remained in control of the greater part of Khorāsān while Toghril, with a mixed army of Turkmen and regular Mamlūk (slave) troops, set out to conquer new territories in the west.

The great Seljuqs. Toghril Beg, a strong leader of men and a clear-headed statesman, achieved the creation of an empire that at his death (1063) included central and western Iran and Mesopotamia with Baghdad itself. There in 1055 Toghril undertook to deliver the caliph al-Qā'im from Biiyid domination and to ally the house of Seljuq with the caliphate through marriage. Thereby the Seljuq conquests were identified with a restoration of the unity of the Muslim world under the Sunni caliphate. Alp-Arslan (1063 to 1072 or 1073), who succeeded both Chaghri and Toghril, and Malik-Shāh completed his conquering work. When Malik-Shāh I died in 1092, the Seljuq Empire included the whole of Iran, with the exception of the Ghaznavid realm of the Indian borderland, the whole of Mesopotamia, and Syria, including Palestine, to the frontier of Egypt. Furthermore, other Turkmen invaders closely akin to the Seljuqs had occupied the Asiatic provinces of the Byzantine Empire up to the Aegean Sea. The organization of the empire was the task of the vizier Nizām al-Mulk (q.v.), who remained in power during the reigns of both Alp-Arslan and Malik-Shāh.

The main problem facing the Seljuqs was to persuade the Turkmen invaders, to whom they owed their victory, to live within the framework of the bureaucratic Iranian-Iraqi state. This problem was never completely solved. The Turkmen tribesmen had no interest in victory over heretics if their lands were unsuitable for stockbreeding or if pillage was not allowed; but on the northwestern frontier of Iran lay the Byzantine Empire, including half of Armenia, which was lacking religio-national homogeneity and the kind of military force able to fight against nomadic invaders. Love of plunder and zeal for a holy war drew the Turkmen into Byzantine territory, and, to prevent them from becoming quite estranged from him, the sultan had sometimes to lead them himself. Thus Alp-Arslan won immortal fame in the Muslim world when he defeated a huge Byzantine army at Manzikert in 1071, capturing the Byzantine emperor Romanus IV Diogenes. Thenceforth the Turkmen were able to settle in Asia Minor undisturbed.

The main feature of the Seljuq Empire was its religio-political character. The regime had to fight not only external wars but also wars against heretics within its frontiers, and to the Seljuqs Islām owes much of its later achievements.

Although *Madrasahs* (colleges) had been founded before the Seljuq period, Nizām al-Mulk was the first official to establish a network of such institutions with the intention, presumably, of giving uniform training to administrators and religious scholars associated with the state. The head of orthodox Islam was the 'Abbāsīd caliph, but, though he was permitted a degree of veneration and independence in Baghdad, he had little real political power in the empire. The sultans as well as the caliph considered it their duty to promote religious works; for this reason as well as to show their power they built many mosques, including the great mosque of Isfahān (the Masjed-e-Jāmī).

Strange as it may seem, the rule of the Turkish Seljuqs fostered rather than hampered the progress of Persian cultural autonomy. Before the Seljuq era a new form of Persian literature had developed in the Sāmānīd territories of northeastern Iran and Transoxania. This was no longer written in the pure old language or in the alphabet of pre-Islāmic Iran but in the Arabic script with a number of borrowed Arabic words. At the same time the Biiyids had favoured a form of Persian tradition that expressed itself in Arabic. Seljuq rule, on the other hand, led to the spread of literary Persian to the whole of Iran. The Turks had no cultural Islāmic tradition and almost no written literature. As the Iranians had been their instructors in Islām, they knew no cultural language other than Persian and showed no interest in the achievements of scholars or poets writing in Arabic. From the time of the Seljuqs onward, the Arabic language disappeared from the Iranian lands except in works of religious scholarship.

It is wrong to believe, as many have, that the pursuance of an Islamic policy and of conquest in Anatolia led the Seljuqs to persecute the Christians. The plundering of the Turkmen armies in the Byzantine Empire no doubt caused much suffering and loss to Eastern Christianity, but inside the Seljuq Empire, as soon as order was restored, the lot of Christians was much the same as it had been before: the crusaders, who thought it must be otherwise, were judging conditions in Jerusalem by those prevailing in Anatolia (see also CRUSADES).

The later Seljuqs. Despite its successes there were weaknesses in the Seljuq Empire. It could not prevent the growth of the new terrorist sect, the Assassins, which was to inspire such dread in the medieval East and which began its activities with the murder of Nizām al-Mulk (1092). Furthermore the Seljuqs, like the Biiyids before them, could not rid themselves of the idea that sovereignty belonged to a family rather than to a single man; thus even the most powerful sultans thought it necessary to

give provinces as appanages to their relatives. In the early years of the Seljuq conquests a practically independent principality had been founded in Kerman by a son of Chaghri Beg, Qāwurd (Kavurt), who extended his conquests to Oman on the Persian Gulf. Another independent but short-lived principality was created in Syria, partly for military reasons, by Malik-Shāh in favour of his brother Tutush.

When Malik-Shāh died, leaving several sons by different wives, all of them very young, the quarrels between them and their supporters resulted in a partition of the Seljuq heritage among Berk-yaruq, the eldest son; his brother Muhammad, who received northwestern Iran; and a third brother, Sanjar, who was given charge of Khorisiiin. When Berk-yaruq died in 1104, Muhammad was able to establish only a measure of control in central and western Iran, and this broke down at his death (1118). Sanjar's realm in Khorāsān, however, attained a new power and glory, which were magnified in the eyes of posterity by the length of his reign and the disasters that befell him in his last years. It is necessary here only to recall his victories over the rival Turkish kingdom of the Qarakhanids in Transoxania and over the Ghaznavids of the Indian borderland. This was followed by his defeat in 1138 by new invaders from central Asia, the Karakitai, and by the revolt of his vassal in Khwārazm (Khorezmia). Finally came the general uprising of the Ghuzz (1153), which resulted in Sanjar's captivity, from which he escaped only to die in 1157. Years of disorder and misery ensued for Khorāsān until its final incorporation in a new Khorezmian empire in the reign of Tekish (Takash; 1172–1200).

Thereafter no territory was left in the former Seljuq Empire where a sultan could enjoy real power. When pretenders quarrelled they sought the help of high military officers, to whom they were obliged to abandon the government of whole provinces. This was especially so in the case of the atabegs, officers who were entrusted with a kind of tutorship over minor princes. Tribal chiefs also profited by the disorders to make themselves independent, and the caliph himself thought the time ripe, if not to recover the ancient power of the 'Abbiisids over the whole of the Muslim world, at least to secure a principality of his own in Iraq.

The first of the Seljuq lines to disappear was that in Syria. There Tutush's sons, Ridwīn (Ruḍwān) of Aleppo and Duqīq of Damascus, had quarrelled and were weakened by the attacks of the crusaders. Tughtigin, son of Biiri, the atabeg of Duqīq, founded a dynasty of his own (the Būrids) when his master died in 1104. In Aleppo the general feeling was against "Easterners," and the dynasty scarcely survived Ridwān's death (1113). Atabegs also were governing upper Mesopotamia around Mosul, and one of them, Zangī, united this province and Aleppo under his sway in 1128, thus creating a new dynasty there. Another atabeg dynasty, which was to last until the beginning of the 13th century, came to power somewhat later in Azerbaijan. These atabegs "protected" the last Seljuqs of the Iranian line, who resided in Hamadān but had no powers except those granted them by their all-powerful tutors.

In the mid-12th century, the caliph again became independent, and when the last of the Iranian Seljuqs, Toghrīl III, tried to recover some of his lost influence, the caliph appealed to the *shāh* of Khorezmia the (Khwārazm-Shāh) for help. As a result Toghrīl died on the battlefield in 1194. Meanwhile other parts of the Seljuq heritage had met their fate at the hands of tribal chiefs. Even Arab tribes, such as the Maziyadids on the Iraqi borders, had taken advantage of the situation to win at least temporary autonomy. The principality of Kerman did not long survive the death (1170) of its sultan Toghrīl-Shāh. His sons quarrelled and called in foreign aid, with the result that the country was utterly devastated and fell an easy prey to a band of Ghuzz from Khorisiiin under their chief, Malik Diniir (1185). Ten years later it was incorporated in the Khorezmian Empire. Only in Anatolia did Seljuq power survive, and there it did not reach its peak until the 13th century.

The sultanate of Rum. The invasion of Anatolia began as an uncoordinated movement of Turkmen tribesmen from Azerbaijan, and the expeditions of Toghrīl Beg and Alp-Arslan were aimed as much at controlling the tribesmen as at conquest. Alp-Arslan's victory at Manzikert (1071) destroyed the Byzantine frontier organization and enabled the Ghuzz to establish themselves in Byzantine territory, where they engaged as mercenaries in the struggles between the local commanders. Among a host of tribal chiefs the leading place was taken about 1075 by the sons of Toghrīl Beg's cousin Qutalmīsh (Kutlumush), who were violently hostile to Malik-Shah. During the struggles of rival generals for the throne of Constantinople (1078–81), one after another of the contestants called for aid from the sons of Qutalmīsh and opened to them the gates of their cities, including Nicaea and Nicomedia (Izmit). By 1080 Sulaymān ibn Qutalmīsh held the greater part of Anatolia as the ally of the Byzantine emperor and rival sultan to Malik-Shah. In 1084 Antioch (Antakya) was surrendered to him, but in 1086 he was killed near Aleppo in battle with Tutush and a coalition of Syrian princes. Malik-Shāh attempted to take advantage of Sulaymān's death, both by proposals for an alliance with the Byzantine emperor Alexius I Comnenus and by military expeditions into western Anatolia, but with little success; and on his death (1092), Sulaymān's son, Qīlīch (Kilij) Arslan (who had been captured by Malik-Shihh at Antioch), escaping from his captivity, reconstituted the sultanate. In the interval, however, northeastern Anatolia had been occupied by a rival Turkmen chief, Dānishmend of Sivas, whose successors engaged in a prolonged conflict with the Seljuq sultans.

The new sultan was immediately confronted with the First Crusade. The first crusader bands, under Walter the Penniless, were defeated at Nicaea (1096), but the Turks were severely defeated before Nicaea and at Dorylaeum (Eskişehir) in 1097 and driven into the interior, while the emperor Alexius reoccupied western Anatolia. After his victory over the next wave of crusaders (1101), Qīlīch Arslan, tempted by the disorders that had weakened the Seljuqs in Iraq, made a bid for the greater sultanate. He succeeded in capturing Mosul but was defeated by the forces of his kinsman of Aleppo and drowned in the Khābūr (Habor) river (1107).

This event proved decisive in determining the future development of the Sultanate of Rūm (the name used by the Turks for the Byzantine Empire). The Seljuqs, hemmed in between Byzantines and the crusading states in Syria and increasingly isolated from the east, gradually established an organized and settled Anatolian kingdom. Qīlīch Arslan was succeeded by his son Malik-Shāh (1107–16), and he by his brother Mas'ūd I (1116–55), who established his capital at Konya (Iconium). Mas'ūd's long reign was occupied by resistance to the encroachments of the Byzantines and by engagements and negotiations with the Diinshmendids, the crusaders, and his Muslim neighbours. During the reign of his son and successor, Qīlīch Arslan II (1155–92), the Armenians established a principality in Cilicia, but the Dānishmendids were finally subdued and their territories annexed to the sultanate.

Qīlīch Arslan's numerous sons, each of whom held the command of a city of the empire, embittered his old age by their mutual rivalry; and the eldest Quṭb ad-Din, tyrannized over him in his own capital, exactly at the time that Frederick I Barbarossa entered the sultan's dominions on his way to the Holy Sepulchre (1190). Konya itself was taken, and the sultan was forced to provide guides and provisions for the crusaders. Qīlīch Arslan lived two years longer, finally under the protection of his youngest son, Kay-Khusraw (Kaikhosrau), who held the capital after him until 1196, when his elder brother, Rukn ad-Din Sulaymān II, having vanquished his other brothers, ascended the throne and obliged Kay-Khusraw to seek refuge at the Byzantine emperor's court. Rukn ad-Din, who died in 1204, saved the sultanate from destruction and conquered Erzurum, which had been ruled for a considerable time by a separate dynasty; but Rukn ad-Din's son, Qīlīch Arslan III, was soon deposed, with Greek assistance, by Kay-Khusraw.

Arslan I

The
disinte-
gration
of the
empire

After the establishment of the Latin empire of Constantinople (1204), the Turks were the natural allies of the Greeks and the enemies of the crusaders and their allies, the Armenians. Kay-Khusraw, therefore, in 1207 took the important harbour of Attalia (Antalya) from the Italian Aldobrandini; but in 1211 he perished in battle with Theodore I Lascaris, emperor of Nicaea. His son and successor, Kay-Kā'ūs, made peace with Lascaris and extended his frontiers to the Black Sea by the conquest of Sinope (Sinop; 1214). On this occasion he took prisoner the Comnenian prince Alexius, who ruled the independent empire of Trebizond (Trabzon), and compelled him to acknowledge the supremacy of the Seljuqs, to pay tribute, and to serve in the armies of the sultan. Elated by this great success and by his victories over the Armenians in Cilicia, Kay-Kā'ūs attempted the capture of Aleppo, at this time governed by the descendants of Saladin, but the project was defeated by Ayyiibid resistance.

Kay-Kā'ūs's brother, 'Alā' ad-Din Kay-Qubādh (Kaikobad) I (1219–37), was the most powerful and illustrious prince of this branch of the Seljuqs. He extended his rule as far as Seleucia and desisted from further conquest only on condition that the Armenian princes would enter into the same kind of relation to the Seljuqs as had been imposed on the Comnenians of Trebizond. But his greatest military fame was won by a war that, however glorious, was to prove fatal to the Seljuq Empire in the future; in conjunction with his ally, the Ayyiibid prince Ashraf, he defeated the Khwārazm-Shāh, Jalāl ad-Din, near Erzincan (1230). During this war Kay-Qubādh put an end to a collateral dynasty of the Seljuqs of Erzurum and annexed its possessions. He also gained the city of Khilāt with dependencies that had recently been taken from the Ayyiibids by Jalāl ad-Din. This acquisition, however, led to a new war, as Kay-Qubādh's ally, the Ayyiibid prince, contested it. Sixteen Muslim princes, mostly Ayyiibids, of Syria and Mesopotamia, under the leadership of al-Malik al-Kamil, prince of Egypt, marched with considerable forces into Asia Minor against him. Happily for Kay-Qubādh, the other princes mistrusted the power of the Egyptian, and it proved a difficult task to penetrate through the mountainous, well-fortified accesses to the interior of Anatolia. The advantage thus rested with Kay-Qubādh, who extended his power in upper Mesopotamia. This expansion was pursued by his son Kay-Khusraw II.

The Seljuq sultanate of Anatolia can now be seen to have been one of the most important Muslim states of its age. Its population was a mixed one, including Christians, Armenians, Greeks, Syrians, and Iranian Muslims; but, when compared with the other Seljuq realms, of which the Turks had been only a small, if leading, element, it was really "Turkey" and was so called by its contemporaries. The Seljuqs of this line succeeded in establishing an administration largely based on the institutions of their Iranian-Seljuq neighbours, but it was modified by the Byzantine heritage and by its own evolution. With order and tolerance of all races and religions established, agriculture and mining activity revived, so that to foreigners Turkey seemed one of the richest of countries; meanwhile commerce was developed with the assistance of Italian merchants. In the cities beautiful buildings, several of which still survive, show the purity of an art related to, though not exactly identical with, the Iranian-Seljuq art of the same period. Literature, mostly in Persian, flourished, and, with it, mystical movements, such as that inspired by Jalāl ad-Din ar-Rūmī.

Yet this political organization and civilization were not really soundly based. The Seljuqs failed to tame, particularly in the frontier districts, the Turkmens, who, though partially settled, were impatient of centralized administration; they remained fond of petty wars against their Christian neighbours and still adhered to their traditional social and religious beliefs and practices. Newcomers from the countries invaded by the Khorezmians and Mongols added to their feeling of unrest. This helps to explain why, when the Mongol flood reached the frontiers of Turkey, which were no longer protected by the Khorezmian state, the Seljuq realm was no more able to resist than had been

the Muslim principalities of Iran. At the Battle of Kose Dagħ (1243), between Erzincan and Sivas, the independence of the Seljuqs was lost forever.

The Mongol protectorate. The Mongols did not destroy the Seljuq state, but, in accordance with their plan, reduced it to vassalage. After the death of Kay-Khusraw II (1245) the quarrels between his sons led to a division of Asia Minor, 'Izz ad-Din Kay-Kā'ūs II taking the part west of the Halys and Rukn ad-Din Qilich Arslan IV the part to the east. When the former intrigued with the Mamluks of Egypt and the Byzantine emperor, however, he was driven out and fled to Constantinople. The unity of the realm was thus restored, but the financial requirements of the Mongols and the intrigues of the great chiefs with them against one another quickly brought about a breakdown of the Seljuq administrative system. In the central provinces and cities, the all-powerful minister, the *perwane* Mu'in ad-Din Sulaymān, who had Rukn ad-Din executed c. 1265, succeeded in maintaining the Iranian-Islamic civilization of the recent golden age; to this end he co-operated with the Muslim viziers of the Mongol Il-Khān of Iran, the suzerain of Anatolia. In the distant and mountainous districts, however, the Turkmen amirs, free from any form of government, established small principalities of their own: in the Taurus, on the Byzantine frontier; on the south Aegean coast, later even near the straits and the Black Sea. With their help and that of Baybars, the powerful Mamluk sultan of Egypt, the most dreaded enemy of the Mongols, a group of Muslim nobles in Anatolia revolted during 1276–77 against the Mongol protectorate. The *perwane* himself had negotiated with them, and although he finally refused to join them, thus assuring the victory of the Mongols, he was executed. For a time the Seljuq sultanate was then no more than a Mongol province. Seljuq sultans, Kay-Khusraw II (died 1283), Mas'ūd III, and Farāmūz, still reigned nominally, but in the first years of the following century the dynasty ended in obscurity.

Thereafter the power of the Turkish amirates increased and the control of the Mongol Il-Khāns of Iran became less effective until it also finally disappeared, in the 1330s. (Ed.)

BIBLIOGRAPHY. Three works have been published in recent years that to a great extent supersede previous studies of the Seljuqs. The *Cambridge History of Iran*, vol. 5, *The Seljuq and Mongol Periods*, ed. by J.A. BOYLE (1968), contains chapters on all aspects of Seljuq history—government, religion, institutions, literature, and art. CLAUDE CAHEN, *Pre-Ottoman Turkey: A General Survey of the Material and Spiritual Culture and History, c. 1071–1330* (1968), covers the same topics for the sultanate of Rūm. Finally, GEORGE MAKDISI, *Ibn 'Aqil et la résurgence de l'islam traditionnel au XI^e siècle* (1963), is of great importance for its analysis of politics and religion under the early Seljuqs.
