Semantics is the philosophical and scientific study of meaning. The term is one of a group of English words formed from the various derivatives of the Greek verb *sēmainō* ("to mean" or "to signify"). The noun semantics and the adjective semantic are derived from *sēmantikos* ("significant"); semiotic (adjective and noun) comes from *sēmetōtikos* ("pertaining to signs"); semology from *sēma* ("sign") + *logos* ("account"); and semasiology from *sēmasia* ("signification") + *logos* ("account"). It is difficult to formulate a distinct definition for each of these terms because their use largely overlaps in the literature despite individual preferences. Semantics is a relatively new field of study, and its originators, often working independently of one another, felt the need to coin a new name for the new discipline; hence the variety of terms denoting the same subject. The word semantics has ultimately prevailed as a name for the doctrine of meaning, in particular, of linguistic meaning. Semiotic is still used, however, to denote a broader field: the study of sign-using behaviour in general.

Historical survey of the study of semantics. The concern with meaning, always present for philosophers and linguists, greatly increased in the decades following

World War II. The sudden rise of interest in meaning can be attributed to an interaction of several lines of development in various disciplines. From the middle of the 19th century onward, logic, the formal study of reasoning, underwent a period of growth unparalleled since the time of Aristotle. Although the main motivation for a renewed interest in logic was a search for the foundations of mathematics, the chief protagonists of this effort—notably the German mathematician Gottlob Frege and the English philosopher Bertrand Russell—extended their inquiry into the domain of the natural languages, which are the original media of human reasoning. The influence of mathematical thinking, and of mathematical logic in particular, however, left a permanent mark on the subsequent study of semantics.

Semantic
theories
of the
Logical
Positivists

This mark is nowhere more obvious than in the semantic theories offered by the Neopositivists of the Vienna Circle, which flourished in the 1920s and 1930s, and which was composed of philosophers, mathematicians, and scientists who discussed the methodology and epistemology of science. To such "logical" Positivists as the German-born philosopher Rudolf Carnap, for instance, the symbolism of modern logic represented the grammar (syntax) of an "ideal" language. Because the Logical Positivists were, at the same time, radical Empiricists (observationalists) in their philosophy, the semantics of their ideal language has been given in terms of a tie connecting the symbols of this language with observable entities in the world, or the data of one's sense experience, or both. Against such a rigid ideal as logic, natural language appeared to these philosophers as something primitive, vague, inaccurate, and confused. Moreover, since a large part of ordinary and philosophical discourse, particularly that concerning metaphysical and moral issues, could not be captured by the ideal language, the Positivist approach provided a way to brand all such talk as nonsensical, or at least as "cognitively" meaningless. Accordingly, the Positivists engaged in a prolonged, and largely unsuccessful, effort to formulate a criterion of meaningfulness in terms of empirical verifiability with respect to the sentences formed in natural language.

Another source of dissatisfaction with the vernacular was made apparent shortly before World War II by the work of the American anthropological linguist Benjamin Lee Whorf. Whorf's famous thesis of linguistic relativity implied that the particular language a person learns and uses determines the framework of his perception and thought. If that language is vague and inaccurate, as the Positivists suggested, or is burdened with the prejudices and superstitions of an ignorant past, as some cultural anthropologists averred, then it is bound to render the user's thinking—and his mental life itself—confused, prejudiced, and superstitious. The Polish-American semanticist Alfred Korzybski, the founder of the movement called General Semantics, believed that the cure for such vague and superstition-laden language lay in a radical revision of linguistic habits in the light of modern science.

Natural language did not remain without champions in the face of this combined onslaught from the logicians and the Whorfians. A reaction started in England, first in Cambridge, then in Oxford. Influenced by the English philosopher George Edward Moore but more so by the "converted" Vienna-born Positivist Ludwig Wittgenstein, the philosophy of "ordinary language" (also known as the Oxford school) came into its own in the 1940s. According to the philosophers of this group, natural language, far from being the crude instrument the Positivists alleged it to be, provides the basic and unavoidable matrix of all thought, including philosophical reflections. Any "ideal" language, therefore, can make sense only as a parasitical extension of, and never as a substitute for, the natural language. Philosophical problems arise as a result of a failure to see the workings of man's language; they are bound to "dissolve" with improved understanding. These assumptions provided a mighty impetus to reflect upon the vernacular language, including its minute points of grammar and fine nuances of meaning. Indeed, some of the later representatives of this approach, particularly the English philosopher John L. Austin, became re-

nowned as much among linguists as among philosophers.

In the 1950s the science of linguistics itself rose to the challenges that had been coming chiefly from philosophical quarters. The development of transformational, or generative, grammar, initiated by the work of the U.S. linguists Zellig S. Harris and Noam Chomsky, opened a deeper insight into the syntax of the natural languages. Instead of merely providing a structural description (parsing) of sentences, this approach demonstrates how sentences are built up, step by step, from some basic ingredients. In the hands of the philosopher, this powerful new grammar not only served to counter the positivistic charge of imprecision laid against natural language but aided him in his own work of conceptual clarification. Moreover, the generative approach promised further results: since the late 1960s some steps have been taken to develop a generative semantics for natural languages, in addition to a generative syntax.

mational
grammar

PHILOSOPHICAL VIEWS ON MEANING

Meaning and reference. On a rather unsophisticated level the problem of meaning can be approached through the following steps. The perception of certain physical entities (objects, marks, sounds, and so on) might lead an intelligent being to the thought of another thing with some regularity. For example, the sight of smoke evokes the idea of fire, footprints on the sand makes one think of the man who must have passed by. The smoke and the footprints are thus signs of something else. They are natural signs, inasmuch as the connection between the sign and the thing signified is a causal link, established by nature and learned from experience. These can be compared with road signs, for example, or such symbols as the outline of a heart pierced by an arrow. The connection between the symbol and the thing signified in these cases is not a natural one; it is established by human tradition or convention and is learned from these sources. These nonnatural signs, or symbols, are widely used in human communication.

In this framework the elements of language appear to be nonnatural signs. The interest in words and phrases reaches beyond their physical appearance: their perception is likely to direct attention or thought to something else. Words, in fact, are the chief media of human communication, and, as the diversity of languages clearly shows, the link involved between words and what they signify cannot be a natural one. Words and sentences are like symbols: they point beyond themselves; they mean something. Smoke means fire, the pierced heart means love. Words mean the thing they make us think of; the meaning of the word is the tie that connects it with that thing.

Words as
symbols

There are some words for which this approach seems to work very straightforwardly. The name Paris means (signifies, stands for, refers to, denotes) the city of Paris, the name Aristotle means that philosopher, and so forth. The initial plausibility of such examples created an obsession in the minds of many thinkers, beginning with Plato. Regarding proper names as words par excellence, they tried to extend the referential model of meaning to all of the other classes of words and phrases. Plato's theory of "forms" may be viewed as an attempt to find a referent for such common nouns as "dog" or for abstract nouns like "whiteness" or "justice." As the word Socrates in the sentence "Socrates is wise" refers to Socrates, for example, so the word wise refers to the form of wisdom. Unfortunately, whereas Socrates was a real person in this world, the form of wisdom is not something to be encountered anywhere, at any time, in the world. The difficulty represented by "Platonic" entities of this kind increases as one tries to find appropriate referents for verbs, prepositions, connectives, and so forth. Discussion of abstract entities such as classes (e.g., the class of all running things) and relations (e.g., the relation of being greater than . . .) abound in philosophical literature; Gottlob Frege even postulated "the True" and "the False" as referents for complete propositions.

There are many more serious problems besetting the referential theory of meaning. The first one, eloquently

Denotation
and
con-
notation

pointed out by Frege, is that two expressions may have the same referent without having the same meaning. For example, "the Morning Star" and "the Evening Star" denote the same planet, yet, clearly, the two phrases do not have the same meaning. If they had, then the identity of the Morning Star and the Evening Star would be as obvious to anybody who understands these phrases as the identity of a vixen with a female fox or a bachelor with an unmarried man is obvious to speakers of English. As it is, the identity of the Morning Star with the Evening Star is a scientific and not a linguistic matter. Thus, even in the case of names, or expressions equivalent to names, one has to distinguish between the denotation (reference, extension) of the name—*i.e.*, the object (or group of objects) it refers to—and its connotation (sense, intension)—*i.e.*, its meaning.

The second problem with the theory of referential meaning arises from phrases that, though meaningful, pretend to refer but, in fact, do not. For example, in the case of such a definite description as "the present king of France," the phrase is meaningful although there is no such person. If the phrase were not meaningful, one would not even know that the phrase has no actual referent. Russell's analysis of these phrases, and the U.S. philosopher Willard V. Quine's similar treatment of such names as Cerberus, effectively detached meaning from reference by claiming that these expressions, when used in sentences, are equivalent to a set of existential propositions; *i.e.*, propositions without definite reference. For example, "The present king of France is bald" comes out as "There is at least, and at most, one person that rules over France, and whoever rules over France is bald." These propositions are meaningful, true or false, without definite reference.

Names, in fact, are very untypical words. The name of the Secretary General of the United Nations, U Thant, has no meaning in English. Whether it means anything in Burmese does not matter either; the reference is not affected by the meaning or the lack of meaning of the name. Names, as such, do not belong to the vocabulary of a language; most dictionaries do not list them. Thus, in spite of the initial plausibility, the idea of reference does not help in understanding the nature of linguistic meaning.

Meaning and truth. Despite the failure of referential meaning, many philosophers were quite unwilling to give up the idea that the meaning of linguistic expressions has something to do with objects, events, and states of affairs in the world. They reasoned that if language is used to talk about the physical environment, then there must be some connection between man's words and the things around him. If reference fails to provide the link, something else must.

In the face of referential failure Russell fell back on truth. The Positivists suggested verifiability as the criterion of empirical meaning. Indeed, at least in many cases, it stands to reason that to understand a sentence is to know what state of affairs would make it true or false. Such considerations motivate the alethic (Greek *alētheia*, "truth") semantic theories, which claim that the notion of meaning is best explained in terms of truth rather than reference.

The most influential discussion of the notion of truth was offered by the Polish-born mathematician and logician Alfred Tarski in the 1930s. His semantic definition of truth is contained in the following formula (which he called [T]):

(T) X is true if, and only if, *p*

in which "*p*" is a variable representing any sentence and "*X*" is a variable representing the name, or unique description, of that sentence. The easiest way to obtain such a unique description is to put the sentence in quotation marks. Thus, we get such instances of (T) as

"Snow is white" is true if, and only if, snow is white.

The above formula implies a distinction between the object language and the metalanguage. "*X*" represents the name of a sentence in the object language—*i.e.*, roughly, the language used to talk about things in the world. The

instances of (T) themselves, however, are in the metalanguage, the language in which one can talk about both things in the world and sentences of the object language. Tarski claimed that no language can contain its own truth predicate, for if it did then it would permit the formation of such sentences as:

(S) This very sentence is false.

Is the sentence (S) true or false? Clearly, it is true if, and only if, it is false, which is an intolerable paradox. Consequently, for any language the predicate ". . . is true" and other semantical predicates must belong to a language of a higher order (a metalanguage).

For this reason Tarski restricted his theory to clearly formalized, artificial languages, a decision that was very much in line with the positivistic tendencies of the 1930s. Nevertheless, the Tarski formula remained attractive even to some semanticists concerned with meaning in natural languages. For one thing, it seemed to succeed in pairing linguistic entities (named by the values of "*X*"; *e.g.*, the sentence "Snow is white") and nonlinguistic entities (named by the values of "*p*"; *e.g.*, the fact, or possible state of affairs, that snow is white). This correlation, however, is not very helpful because each one of the nearly infinite number of sentences one may form would have its "fact" as a counterpart, identifiable only by means of that very same sentence. Consequently, if linguistic meaning consisted in these correlations, no one could learn the meaning of any sentence at all and certainly not the meaning of all the sentences the speakers of a language are able to understand.

What was needed was a theory explaining the contribution of individual words—a clearly finite set—to the truth of sentences. Tarski himself, as well as other writers, suggested a repeatable procedure based on the notion of satisfaction. Snow, for example, satisfies the sentential function "*x* is white" because "Snow is white" is true. In much the same way, 3 satisfies the function " $2 \cdot x = 6$ " because " $2 \cdot 3 = 6$ " is true. Simply stated, the meaning of the predicate ". . . is white" is determined—and is learned—in terms of the set of objects of which it is true.

As this approach is extended to cover the wide variety of words that exist in a natural language, however, its initial simplicity—and thereby its attractiveness—becomes progressively lost. This can be illustrated by "egocentric" words like "I," "you," "here," and "now"; by connectives like "since," "however," and "nevertheless"; and, if these appear trivial, by such crucial words as "believe," "know," and "intend," on the one hand, and "good" and "beautiful" on the other. Whereas it is plausible to say that, for instance, Joe and Mary satisfy the function "*X* loves *Y*," provided Joe loves Mary, it is more complicated to determine what would satisfy such functions as "*X* believes *Y*," "*X* knows *Y*," or "*X* intends *Y*." "*X*" is satisfiable by people, but the satisfaction of "*Y*" poses a problem. If one suggests such things as propositions, facts, and possibilities, one is confronted with abstract entities of a kind similar to those encountered in the Platonic theory of referential meaning. Again, can it be said that John and a unicorn will satisfy the function "*X* looks for *Y*"—if it is true that John looks for a unicorn?

Another difficulty arises concerning "good," "beautiful," and other words of moral or aesthetic judgment. If, for example, beauty is indeed "in the eye of the beholder," then what one person calls beautiful might not appeal to another, yet two people might keep arguing as to whether the thing is beautiful or not. Thus, people may seem to agree on the meaning of the word, yet remain at odds about its application. The meaning of such "emotive" words cannot be decided in terms of truth alone.

A more serious objection to the alethic (truth) theory arises from the fact that many significant utterances of natural language are not true or false at all. Whereas statements, testimonies, and reports are true or false, orders, promises, laws, regulations, proposals, prayers, curses, and so forth are not assessed in terms of truth or falsity. It is not obvious that the employment of words in these speech acts is less relevant to their meaning than their use in speech acts of the truth-bearing kind.

definition
of truth

Meaning and use. The difficulties just mentioned lead to another view concerning the notion of meaning, a theory that may be called the use theory. This view admits that not all words refer to something, and not all utterances are true or false. What is common to all words and all sentences, without exception, is that people use them in speech. Consequently, their meaning may be nothing more than the restrictions, rules, and regularities that govern their employment.

The use theory has several sources. First, in trying to understand the nature of moral and aesthetic discourse certain authors suggested that such words as "good" and "beautiful" have an emotive meaning instead of (or in addition to) the descriptive meaning other words have; in using them one expresses approval or commendation. If one says, for instance, that helping the poor is good, one does not describe that action, but says, in effect, something like "I approve of helping the poor, do so as well." Such is the role of these words, according to these thinkers, and to understand this role is to know their meaning.

The second, and more important, stimulus for the use theory was provided by the work of Ludwig Wittgenstein. This philosopher not only pointed out the wide variety of linguistic moves mentioned above but in order to show that none of these moves enjoys a privileged status proposed the idea of certain language games in which one or another of these moves plays a dominant or even an exclusive role. One can imagine, for instance, a tribe whose language consists of requests only. Members of the tribe make requests and the other members comply or refuse. There is no truth in this language, yet the words used to make requests would have meaning. Human language as it exists in reality is more complex; it is a combination of a great many language games. Yet the principle of meaning, according to this theory, is the same: the meaning of a word is the function of its employment in these games. To Wittgenstein the question "What is a word really?" is analogous to "What is a piece in chess?"

Finally, John L. Austin offered a systematic classification of the variety of speech acts. According to him, to say something is to do something, and what one does in saying something is typically indicated by a particular performative verb prefixing the "normal form" of the utterance. These verbs, such as "state," "declare," "judge," "order," "request," "promise," "warn," "apologize," "call," and so on, mark the illocutionary force of the utterance in question. If one says, for instance, "I shall be there," then, depending on the circumstances, this utterance may amount to a prediction, a promise, or a warning. Similarly, the words of the commanding officer, "You will retreat" may have the force of a simple forecast, or of an order. If the circumstances are not clear, the speaker always can be more explicit and use the normal form; e.g., "I promise that I shall be there" or "I order you to retreat."

To rephrase the conclusion already stated: the dimension of truth and falsity is not invoked by all the utterances of the language; therefore, it cannot provide an exclusive source of meaning. There are other dimensions, such as feasibility (in case of orders and promises), utility (in case of regulations and prescriptions), and moral worth (in case of advices and laws). These dimensions may be as much involved in the understanding of what one said and, consequently, in the meaning of the words the speaker used, as the dimension of truth.

As previously mentioned, philosophers professing the alethic theory claimed that the meaning of a word should be explained in terms of its contribution to the truth or falsity of the sentences in which it can occur. The latest form of the use theory is an appropriate extension of the same idea. According to some exponents, the meaning of a word is nothing but its illocutionary act potential—i.e., its contribution to the nature of the speech acts that can be performed by using that word. One difficulty with this view is that the definition is too broad, to the extent of being unilluminating or useless. Given this definition, nobody would know what any word means without knowing the entire language completely because the possibilities of employing a given word are not only

without limit but extend to every conceivable context and circumstance. As Wittgenstein stated so forcefully,

The sign (the sentence) gets its significance from the system of signs, from the language to which it belongs. Roughly: understanding a sentence means understanding a language.

If this be the case, how can one account for the obviously gradual and prolonged process of learning a language? Indeed, the definition of the meaning of a word as illocutionary act potential seems to overstate the case. The obvious truth that the meaning of performative verbs, and other words closely tied to one illocutionary aspect or other, cannot be divorced from the nature of that type of speech act, does not entail that the meaning of an ordinary word, like "cat" or "running" is affected by any illocutionary force. Such words can occur in utterances bearing all kinds of illocutionary forces, so the contribution of these forces, as it were, cancel out. Nevertheless, what remains is the fact that all words are used to say something, in one way or another. The use theory would put a strong emphasis on the word "used" in the previous sentence. The next, and final, approach to meaning would stress the word "say."

Meaning and thought. In Wittgenstein's chess example, moves are made by moving the pieces. In a language, moves (saying something) are made by using words. And, according to the use theory, as a piece is defined by its move potential, so (the meaning of) a word is defined by its "saying" potential.

This analogy works only up to a certain limit. Whereas chess is only a game, the use of language is much more. One plays chess—or any other game—for its own sake; one speaks, however, with other ends in mind. Games, as it were, do not point beyond themselves; speech does. In order to see this, compare an ordinary conversation with such word games as children play—e.g., exchanging words that rhyme, or words that begin with the same letter. These word games are language games and nothing more because the children use words according to certain rules. In doing so, however, they do not say anything except in the trivial sense of uttering words; nor are they called to understand what the other children say beyond the minimal feat of recognizing the words.

In real speech the situation is radically different. The point of using words in a real speech act is to be understood. If someone says, "It will rain tomorrow," his aim is to make the hearer believe that it will rain tomorrow. It is possible, of course, that the hearer or listener will not believe the speaker. Nevertheless, if the hearer understands what the speaker says, he will at least know that this is what the other person wants him to believe by saying what he says. Similarly, if one says, "Go home," and the listener understands what is said, then, whether or not the listener will actually go, he will at least know that this is what the speaker wants to bring about by using these words. Thus, the notion of saying something is inseparably tied to such concepts as belief, intention, knowledge, and understanding.

The view just outlined is a reformulation of a very traditional idea, namely, that speech is essentially the expression of thought. Words are used not to play a game with fixed rules but to express beliefs and judgments, intentions and desires; that is, to make others know, by the use of words according to fixed rules, that one has certain beliefs, desires, and so forth, and that one invites others to share them.

"Expression of thought" sounds rather vague. For one thing, what is a thought? Suppose John believes that Joe has stolen his watch. John can express this belief by saying, "Joe has stolen my watch" or "My watch has been stolen by Joe" or "It is Joe who has stolen my watch" and so on. Moreover, if John is a multilingual person, he can express the same belief in German, French, and so forth. These variants, called paraphrases and translations respectively, will express the same belief, the same thought. But whereas it makes sense to ask for the exact words of John's statement or to ask about the language in which it was made, it would be foolish to ask for the exact words of John's belief or to ask about the language in which it is framed. The alternative in "Do you believe

Speech as an expression of thought

Wittgenstein's language games

Difficulties with the use theory

that Joe has stolen the watch, or that the watch was stolen by Joe?" does not make sense. Consequently, the same thought—the same proposition, as some philosophers prefer to call it—can be expressed by using various linguistic media. In other words, the same thought can be encoded in various codes (languages) and in various ways in the same code (paraphrases) in much the same way as the same idea can be expressed in speech or in writing and the same numbers can be written by using Roman or Arabic numerals.

From this point of view, it appears that saying something involves encoding a thought and that understanding what one said involves decoding and recovering the same thought. The meaning of a sentence will consist in its relation to the thought it is used to encode. This may be viewed as the fundamental thesis of the psychological theory of meaning.

As previously explained, no theory of meaning can be adequate as long as it treats sentences as indivisible units. For, in the first place, the potentially infinite number of sentences would defy any attempt to learn their meaning one by one, and, second, such a theory could not account for the obvious ability of fluent speakers to understand entirely novel sentences. There must be, therefore, a correlation between certain recurring elements of sentences (roughly, words) and certain recurring elements of thoughts (roughly, concepts or ideas). Accordingly, the learning of the semantic component of a language will consist in the learning of these connections.

In this learning process two notions play a prominent role: synonymy and analyticity. As the sentences that express the same thought stand in the relation of paraphrase (or translation), so words or phrases that code the same idea are related as **synonyms**—e.g., "vixen" and "female fox." Again, because one concept may include another, the sentence expressing this relation will record a conceptual truth or analytic proposition; e.g., "A dog is an animal." A definition, finally, will exhibit all parts of a concept by a combination of such propositions.

What concepts are and how they are related to words are topics that have been discussed throughout the history of philosophy. The following problems related to concepts pertain to the core of philosophical psychology: whether all concepts are derived from experience, as Aristotle and the Empiricists believed, or whether some of them at least are innate, as Plato and the Rationalists maintained; whether concepts exist prior to and independent from their verbal encodings, as the Realists and Conceptualists claimed, or whether they are nothing but a certain "field of force" accompanying the words, as the Nominalists thought.

It should be noted that these disputes, in a modern garb, still continue with undiminished force. Contemporary Empiricists still try to reduce most concepts to a configuration of sense data, or a pattern of nerve stimulation, while the Behaviourists attempt to explain understanding in terms of overt behaviour. Modern-day Rationalists reply by insisting on the unique spontaneity of human speech and by reviving the theory of innate ideas.

MEANING IN LINGUISTICS

Semantics in the theory of language. The science of linguistics is concerned with the theory of language expressed in terms of linguistic **universals**—i.e., features that are common to all natural languages. According to the widely adopted schema of the U.S. scholar Charles W. Morris, this theory must embrace three domains: pragmatics, the study of the language user as such; semantics, the study of the elements of a language from the point of view of meaning; and syntax, the study of the formal interrelations that exist between the elements of a language (i.e., sounds, words) themselves. Subsequently, certain authors spoke of three levels: the phonetic, the syntactic (the phonetic and syntactic together are often called grammatical), and the semantic level. On each of these levels a language may be studied in isolation or in comparison with other languages. In another dimension, the investigation might be restricted to the state of a language (or languages) at a given time (synchronic

study), or it might be concerned with the development of a language (or languages) through a period of time (diachronic study).

Semantics, then, is one of the main fields of linguistic science. Yet, except for borderline investigations, the linguist's interest in semantic matters is quite distinct from the philosopher's concern. Whereas the philosopher asks the question "What is meaning?", the typical questions the linguist is likely to ask include: "How is the meaning of words encoded in a language?" "How is this meaning to be determined?" "What are the laws governing change of meaning?" and "How can the meaning of a word be given, expressed, or defined?"

A few examples will suffice to illustrate some of these problems, and to show how the linguist's approach differs from that of the philosopher. In the matter of encoding, words are arbitrary signs; to some authors, particularly to the Swiss linguist Ferdinand de Saussure, this feature of arbitrariness represents an essential characteristic of all real languages. Nevertheless, in all languages there are clear cases of **onomatopoeia**—i.e., the occurrence of imitative words, such as "whisper," "snore," "slap," and, more remotely, "cuckoo."

There are several other issues that pertain to the question of encoding. Certain languages show a marked preference for very specific words, at least in certain domains, while lacking the corresponding general terms, which are the only ones occurring in other languages. The Eskimos, for instance, have a number of words denoting various kinds of snow, but no single word for snow. Similarly, in English, although there are distinct names for hundreds of animal species, there is no name for the very familiar animal species of which the female member is called cow and the male member bull.

There are also certain languages, such as English or Chinese, that for the most part prefer single words rather than the compounded phrases that other languages (e.g., German) seem to favour. Accordingly, whereas the English vocabulary is larger, the German words are more pliable, capable of entering into compounds often of great length and complexity. Such differences support De Saussure's distinction between **lexicological** and **grammatical** languages.

Another distinction can be drawn concerning the relative frequency and importance of context-bound and context-free words. The meaning of such English words as "take," "put," and "get" depends almost entirely on the context—e.g., putting up with somebody has very little to do with putting off something or other. These can be compared with verbs like "canter" or "promulgate," which, by their very specific meaning, almost determine the context, rather than having their meaning determined by the context. Clearly, the context-bound type of word, such as "take" or "put," lends itself to idiomatic use, rather than the context-free word.

There are some obvious regularities in the change of meaning that are of interest to the linguist. One such regularity is the extension or transference of meaning based upon some similarities—i.e., the phenomenon of metaphor. For example, one can speak of the leg of the table, the mouth of the river, the eye of the needle, and the crown of the tree. These are anthropomorphic metaphors: the transfer goes from something belonging to an individual or close to him (his body, garments) to something more remote. The same principle operates in the extension of meaning from a domain close in interest rather than in physical proximity. Baseball-minded people are apt to speak of "not getting to first base," "striking out," or "scoring a hit" in contexts often remote from baseball. For a similar reason, many abstract concepts are denoted by words transplanted from the concrete domain. Such phrases as "grasping ideas," "seeing the point of a joke," "body of knowledge," "in the back of my mind," and many others, are the result of this very important move from the abstract to the concrete.

Meaning changes of another type are the result of emotive factors. The word democracy, for instance, has all but lost its original meaning and has become a word applicable to any system the speaker wants to praise. The

words

contrary development is exhibited in the recent history of such words as "Fascist" and "aggression." In order to avoid derogatory connotations one is often forced, by social pressure, to use euphemisms, often to the detriment of clarity. Examples of this include the switch from "underdeveloped nations" to "developing nations," from "retarded children" to "exceptional children," and from "old people" to "senior citizens."

The preceding are but a few examples concerning coding and meaning change. The questions about the ways of finding out what a word means and about the manner of giving an adequate definition of a word deserve a more detailed account.

Meaning, structure, and context. Foreigners in a strange country and linguists are often confronted with the task of learning a new language. It is important to realize that in doing so they do not set out with a completely blank mind: they expect to learn a language (*i.e.*, a system of communication describable in terms of a large set of linguistic universals). They expect—consciously in the case of the linguist and unconsciously in the case of the layman—to find words and sentences, grammatical structures, and illocutionary forces in that language. And, on the semantic level, they expect words that will fit into the familiar semantic classes. They are confident, in other words, that the language they intend to master will be intertranslatable with their own.

Therefore, although at the very beginning their learning remains on the ostensive level (trying to find out the name of this or that kind of object), very soon they proceed to the level of first guessing, then establishing, the meaning of words from the contexts in which they occur. This has to be the case, for words that in any way can be viewed as "names" of objects (*i.e.*, that could be learned ostensively) form but a fraction of the vocabulary of any language. Anyone who doubts this should but try to list the words from this paragraph that could be learned ostensively. Moreover, linguists find no great difficulties in learning dead languages—*e.g.*, that of the ancient Egyptians—without any contact with any speaker, provided that a sufficiently large corpus of texts is available and that some clues are provided to the meaning of at least some words.

If any more evidence concerning this point is needed, one should remember that "pictorial" dictionaries are bound to remain on the kindergarten level, and that the mark of a good dictionary is the abundance of appropriate contexts. Thus, the contexts show the concept.

These intuitions are behind the U.S. philosopher Paul Ziff's semantic theory. According to Ziff, the meaning of a word is a function, first, of its complementary set, which consists of all the acceptable sentences in which the word can occur, and, second, of its contrastive set, which consists of all of the words that can replace that word in all of these sentences without rendering the sentences deviant. Clearly, the elaboration of the contrastive set will produce words more and more similar in meaning to the word in question, the limiting case being synonyms that can occur wherever the word in question can occur.

This theory is in need of further refinement. In the sentence "The cat sleeps," the fact that "cat" can co-occur with "sleep" undoubtedly casts some light on the meaning of these words (a cat is a kind of thing that can sleep). But there are a great number of sequences that could complete the frames "The cat sleeps and . . .," ". . . said that the cat sleeps," and so forth. Clearly, the near infinity of the resulting sentences will not contribute anything to the meaning of "cat" beyond what the segment "the cat sleeps" already contributes.

Transformational grammar can be of assistance at this point. According to this approach, the sentences just considered are simply surface forms, each corresponding to an underlying structure, in which "cat" and "sleep" appear as forming an elementary, or kernel sentence (roughly: "a cat sleeps"). The essence of Ziff's insight can be reinterpreted in terms of the notions developed by Zellig S. Harris: co-occurrence (instead of complementary set) and co-occurrence difference (instead of contrastive set), both restricted to kernels. Because the voca-

bulary of a language is limited and the number of kernel structures is very small, the meaning of a word can be determined on the basis of a finite set of elementary sentences.

The contribution of grammar to semantic theory is by no means exhausted by this step. For the grammatical restrictions on a word represent, as it were, the "skeleton" of its meaning before the "flesh" is put on by the co-occurrences. The very first step in giving the meaning of a word is to specify its grammatical category—noun, verb, adjective, adverb, connective, and so forth—and not to speak of grammatical constants (such as the first, but not the second, "to" in "I want to go to Paris"), the meaning of which, if any, is entirely determined by their grammatical role. A refined grammar yields much more: the fact that the adjective "good," for example, unlike adjectives like "yellow" or "fat," can occur in the frames "(He is) good at (playing chess)"; "(The root is) good to (eat)"; "It is good that (it is raining)"; "It was good of (him) to (come)" says a great deal about the meaning of that word. The co-occurrences then complete the picture.

Lexical entries. Good dictionaries offer a variety of contexts for the items listed, but, obviously, this is not enough. For one thing, no dictionary can list all the co-occurrences. There must be devices to sum up, as it were, the information revealed by the contexts. This is the role of dictionary definitions. The branch of scientific semantics that is concerned with the form and adequacy conditions of dictionary entries is called lexicography.

A systematic study of dictionary entries was presented in the 1960s by the U.S. philosophers Jerrold J. Katz and Jerry A. Fodor. According to them, the standard form of a dictionary entry comprises three kinds of ingredients: grammatical markers, semantic markers, and distinguishers. The grammatical markers describe the syntactic behaviour of the item in question in terms of a refined system of grammatical categories. The traditional division of words into nouns, adjectives, verbs, adverbs, and so on is but the first step in this direction. The class of nouns, for example, has to be subdivided into count nouns (like "cat"), mass nouns (like "water"), abstract nouns (like "love"), and so forth. The class of adjectives must be classified into subclasses that are fine enough to capture the grammatical peculiarities of such adjectives as "unlikely" or "good." The traditional subdivision of verbs into transitives and intransitives has to be completed to account for such verbs as "compare" or "order," which obviously involve three noun phrases ("someone compares something to something"), often of a particular kind ("human" nouns or noun clauses).

The idea of a semantic marker is merely a further elaboration of the traditional notions of genus and species. The result is a system of semantic markers that comprise such items as "physical object," "animate," "human," "male," "young" (in the case of the entry for "boy"), and others. Katz claims that the problems of synonymy, analyticity, and contradiction can be handled, at least in part, in terms of lexical items sharing some or all of their semantic markers.

Finally, the distinguisher completes the dictionary entry by giving, as it were, the leftover, if any, of the semantic information. There is no general form for the distinguisher; it may give the atomic weight (for elements), purpose (for tools), concise description (for animals), and so forth.

Generative semantics. According to the original formulation of generative or transformational grammar, the semantic and the syntactic components were regarded as distinct elements in the deep structure of a sentence. The syntactic component consisted of a relation of phrase markers giving the transformational structure of the sentence, usually represented by a "tree" diagram with the phrase markers as nodes (*e.g.*, "S" for sentence, "NP" for noun phrase). The semantic content entered through the process of lexical insertion—*i.e.*, the replacement of the phrase markers by words, the carriers of meaning. Lexical insertion was supposed to take place at the very beginning of the series of transformations leading up to the surface form of the sentence. The original input of mean-

and
language
learning

Surface
forms
and
underlying
structures

Lexical
insertion
in a
generative
grammar

ing, as it were, was carried through the transformations yielding the semantical reading, or sense, of the whole sentence.

Several modern studies have attempted to demonstrate that this separation between syntax and semantics cannot be maintained. It appears that certain words in themselves indicate a structure analogous to syntactic structures. For example, consider "harden" and "break." To harden something is to cause that thing to become hard (or harder); to break something is to cause something to become broken. Because "harden" consists of two elements, "hard-" and "-en," it could be argued that the word itself is structured; "break" does not indicate any structure, yet its meaning clearly involves one. "Broken," therefore, carries a more basic semantic unit than "break." Again, in the case of such verbs as "remind," "allege," "blame," or "forgive," one feels that their meaning is highly structured, and, with some thinking, one can articulate the presuppositions of these words, which involve a great number of semantic units in a very complex relationship.

These and similar reasons support the theory of generative semantics, which denies a clear distinction between the semantic and the syntactic components. According to this theory the transformations connect the surface structure of the sentence with its semantic representation (or according to some linguists, its logical form). Words, then, can encode either a semantic primitive (such as "blue") or a whole structure (such as "forgive") within the semantic representation. Thus, there is no definite point in the transformational history of the sentence at which lexical insertion must occur. The ultimate conclusion of this view is that, instead of the threefold division of semantics, syntax, and phonetics, all that is needed is the simple distinction between semantics and phonetics, corresponding to the distinction between meaning (as structured) and its verbal encoding. How much of the semantic structure can be attributed to a particular language, and how much can be ascribed to common (and possibly innate) elements of the human mind, remains a fascinating problem for continued study.

Collections of essays: Comprehensive selections of relevant papers are J.F. ROSENBERG and C. TRAVIS, *Readings in the Philosophy of Language* (1971); and D.D. STEINBERG and L.A. JAKOBOVITS (eds.), *Semantics* (1971). A good collection of earlier contributions, mainly from the Positivistic school, is found in L. LINSKY (ed.), *Semantics and the Philosophy of Language* (1952, reissued 1972). J.A. FODOR and J.J. KATZ (eds.), *The Structure of Language* (1964), contains some fundamental papers on transformational grammar. J.H. GREENBERG (ed.), *Universals of Language* (1963), includes some key articles on scientific semantics. V.C. CHAPPELL (ed.), *Ordinary Language* (1964, reprinted 1981), offers some typical articles on ordinary language philosophy.

Books: W.P. ALSTON, *Philosophy of Language* (1964), is a good introduction to philosophical semantics; D.L.F. and A.P. NILSEN, *Semantic Theory* (1975), is an introductory text on linguistic semantics; and J.D. FODOR, *Semantics* (1977), introduces competing theories within the field of generative grammar. Two critical surveys of leading modern semantic theories are G.N. LEECH, *Semantics* (1974); and J. LYONS, *Semantics*, 2 vol. (1977). L. BLOOMFIELD, *Language* (1933, reprinted 1963), contains a classic discussion of scientific semantics. B.L. WHORF, *Language, Thought and Reality*, ed. by J.B. CARROLL (1956), raises the issue of linguistic relativism. J.J. KATZ, *Semantic Theory* (1972), offers a semantic theory of natural languages; N. CHOMSKY, *Studies on Semantics in Generative Grammar* (1972); W.V. QUINE, *Word and Object* (1960); and P. ZIFF, *Semantic Analysis* (1960), represent different but influential semantic theories. Some of the leading ideas for modern philosophical semantics come from C.L. STEVENSON, *Ethics and Language* (1944); J.L. AUSTIN, *How to Do Things with Words* (1962); L. WITTGENSTEIN, *Philosophical Investigations*, 3rd ed. (1968); and *The Blue and Brown Books: Preliminary Studies for the Philosophical Investigations*, 2nd ed. (1969).

(Z.V.)

Semiconductor Devices

Semiconductor devices are electronic circuit components, such as transistors, fabricated from a material that is neither a good conductor of electricity nor a good insulator;

hence the name semiconductor. This article covers the preparation of semiconductor materials and the design, manufacture, and application of the more popular semiconductor devices. Specific devices are covered in greater detail in the articles THERMOELECTRIC DEVICES; LASER AND MASER. A more theoretical treatment of semiconductor action is given in SEMICONDUCTORS AND INSULATORS, THEORY OF. All the devices described in this article are discrete devices, as opposed to the more recent integrated devices described in the article INTEGRATED CIRCUITRY.

Semiconductor and junction principles. A wide range of semiconductor devices is available, made from a number of materials and by a variety of processes. The applications for these semiconductor devices cover the whole electromagnetic spectrum from ultraviolet frequencies to the control of direct current. There are semiconductor devices suitable for practically all electronic applications, even at extremely high frequencies and powers.

The materials known as semiconductors have electrical resistivities (the resistance of a cube of the material one centimetre on a side) in the range between insulators and metals. The resistivity of elemental semiconductors always decreases with increasing temperature, and these materials often show some decrease in resistivity when illuminated with light (photoconductivity). The most commonly used semiconductors are the elements germanium and silicon, but certain compounds, such as gallium arsenide, indium antimonide, and copper oxide, have useful semiconductor properties.

Electrons in an isolated atomic structure can exist only at certain energy levels. If an electron moves from one level to another, energy is either absorbed or emitted. The electrons in an atom that possesses relatively little energy move in orbits close to the atomic nucleus. If the electron absorbs energy from an outside source (for example, ultraviolet light), it may jump to a higher energy electron orbit, but these jumps always occur in discrete steps.

When a number of atoms are assembled in a group, as in a regular crystalline structure, the electrons are influenced by the electrical fields of neighbouring atoms as well as by the parent nucleus, causing the discrete energy levels to spread out into energy bands. These bands do not normally overlap; for any given atomic spacing there are permissible energy bands interspersed with gaps called forbidden energy gaps.

The outermost electrons of an atom are normally in what is called the valence band. If one of these electrons absorbs energy it is said to be excited; it may absorb enough energy to cause it to leave the valence band and jump temporarily to a conduction band, where it is free of the attractive force of the nucleus. In semiconductor materials these conduction bands are often empty or only partially filled.

Electrons in the conduction band may be made to move easily by an electric field, and this drift is commonly known as a conduction current. The energy gap between the top level of the valence band and the lower level in the conduction band is the minimum energy (usually expressed in electron volts) required to produce a free electron in a crystal. A wider energy gap is generally related to a higher melting point.

The electrical conductivity of any material depends on the number of charge carriers available in the conduction bands, per unit volume, and on the rate at which these carriers move under the influence of an electric field. If a negatively charged electron is moved into a vacant level in the conduction band, this leaves a corresponding positive imbalance, or "hole," in the valence band.

Because of this concept it is convenient to think of electrical conduction as consisting of negative charges carried by electrons and positive charges carried by holes. In a pure semiconductor, conduction takes place by electron-hole pairs, but the electron and the hole have different mobilities; that is, they move with different velocities in an electric field. The differing electron and hole mobilities are caused by the fact that they start at different energy levels and travel under differing forces in opposite directions.

Electrical conduction in highly pure semiconductors

Electrical conductivity volts

(called intrinsic semiconductor material, with a ratio of impurities of about one part in 10^{12}) is poor and largely temperature dependent. The intentional addition of impurities, typically to a concentration of one part in 10^6 , is known as doping and modifies the electrical characteristics to produce a much greater conduction. Such materials are called extrinsic, since the condition results from the external addition of impurities. Semiconductor materials have four electrons in the outer or valency shell, whereas the impurities have either five or three valency electrons. The elements antimony, arsenic, and phosphorus add electrons, or n (negative) carriers; and the elements aluminum, boron, and indium effectively provide more holes, known as p (positive) carriers. The small concentration of added impurities does not change the metallurgical characteristics of the basic semiconductor but modifies its electrical properties.

If a change in doping takes place over a short distance within a single crystal structure (described later), this produces a p - n junction, as illustrated in Figure 1A.

Figure 1: (A) A p - n junction. (B) The p - n - p transistor.

There will be an excess of holes in the p region, and so these holes are called majority carriers. A few thermally generated electrons will also exist in this region, and they are called minority carriers. Conversely, in the n region, the electrons are the majority carriers and the holes minority carriers. In the area of the p - n junction there are no free-charge carriers. This region is called the depletion layer and it acts as a dielectric (electrical insulator).

When a voltage is applied across this elementary junction with the polarities as shown, the charge carriers introduced by the impurities move in opposite directions away from the junction, and only a very small intrinsic current flows across the junction. If the polarity of the voltage is reversed, then the majority charge carriers flow across the junction. This means that the p - n junction acts as a rectifier, that is, it will conduct with one input-voltage polarity but will not conduct if this polarity is reversed.

Rectifiers made from semiconductor materials were introduced commercially in the 1930s, long before the mechanism of the p - n junction was understood. The copper oxide diode, in which the boundary between copper and cuprous oxide forms the rectifying junction, is rarely used now. On the other hand, the selenium rectifier has a junction consisting of selenium and a tin-cadmium alloy. Due to the low cost of manufacture, selenium rectifiers, which give reasonable efficiency for power outputs up to ten kilowatts, are widely used and have been used in installations up to one megawatt, although it appears likely that junction devices will eventually replace such rectifiers.

The transistor. The transistor was invented by the U.S. scientists John Bardeen, Walter Brattain, and William Shockley in 1948. The name of this amplifying device was derived from the phrase "transfer resistor," since that is how the device appeared to operate in an electronic circuit. Early transistors were known as point-contact devices, in which the rectifying junctions were formed by two closely spaced fine wire springs in contact with a semiconductor surface. The point-contact transistors had a family resemblance to the simple "cat's whisker" diodes (rectifiers) that were used in early radio receivers. All modern transistors are of the junction type, usually produced by one of the processes to be described later. The transistor in its various forms is the most significant of the many semiconductor devices that have appeared so far.

The junction transistor exists in two complementary forms, the p - n - p and n - p - n transistors. The p - n - p

transistor may be regarded as two p - n diodes joined back to back, with the first, forward biased, providing the minority carriers for the second, reverse biased, diode. This is illustrated in Figure 1B, in which the three terminals of the transistor are labelled with their usual names of emitter, base, and collector.

The construction of the p - n - p transistor is such that the impurity content of the narrow n -type base region is very much less than that in the p regions. This means that in the forward-biased input circuit (from emitter to base) the flow of current carriers across the junction is mainly in the form of holes from the p to n regions. Some of these holes, which are minority carriers as far as the n -type region is concerned, recombine with electrons there. The majority, however, diffuse across the narrow base and flow to the collector, which is a high-resistance output circuit due to the applied reverse bias.

The circuit arrangement shown in Figure 2A is known as the common, or grounded, base configuration. The current gain is defined for the common-base connection as the change in collector current divided by the change in emitter current when the base-to-collector voltage is constant.

The other possible transistor circuit configurations are shown in Figures 2B and 2C. and are known as common emitter and common collector. The most useful amplifier circuit is common emitter, in which a small change in signal current to the base requires little power but can result in much greater power in the output circuit. This characteristic makes transistors useful as amplifiers, oscillators, and other circuit elements, as described later. A problem common to all transistors is the small "leakage current" that flows in the output circuit when the input current is zero. Since leakage current increases as the temperature increases, it increases the inherent power dissipation within a transistor as the environmental temperature is increased. However small the leakage current may be at room temperature, for any transistor there is a junction temperature at which thermal instability occurs, thus placing an upper limit on the temperature at which a transistor will operate satisfactorily.

Leakage current efficiency

Figure 2: (A) Common base, (B) common emitter, and (C) common collector circuit configurations.

In the n - p - n transistor there are two n regions that sandwich in a narrow p region. Current flow from input to output is by means of free electrons. Because of the higher mobility of electrons compared with holes, n - p - n transistors can operate usefully at higher frequencies than can p - n - p transistors of the same dimensions. Since for the first decade of transistor history it was much more difficult to manufacture n - p - n than p - n - p transistors, most of the early semiconductor technology revolved around the p - i - p germanium transistor. This condition is no longer true, and the circuit designer can now choose from a variety of semiconducting devices that is almost bewildering in its range.

Preparation of semiconductor materials

TYPES OF SEMICONDUCTOR MATERIALS

Elemental materials. Semiconductor materials are divided into two categories: elemental and compound. Elemental semiconductors are usually composed of one element only in the undoped, or intrinsic state and are divided into valency groups according to the number of valence electrons they have, as shown in Table 1.

Germanium and silicon are by far the most commonly used elements in modern semiconductor devices.

Most semiconductor devices are constructed from a thin wafer, or slice, of properly doped material. Preparation involves the processing of germanium or silicon to pro-

Rectifier action

Table 1: Significant Semiconductor Elements (giving common chemical nomenclature)

group II 2 valence electrons	group III 3 valence electrons	group IV 4 valence electrons	group V 5 valence electrons	group VI 6 valence electrons
beryllium Be	boron B	carbon C	phosphorus P	sulfur S
magnesium Mg	aluminum Al	silicon Si	arsenic As	selenium Se
zinc Zn	gallium Ga	germanium Ge	antimony Sb	tellurium Te
cadmium Cd	indium In	lead Pb	bismuth Bi	
	thallium Tl			

duce thin, smooth, and polished wafers (typically two inches, or five centimetres, in diameter, 0.01 inch, or 0.025 centimetre, thick) that are properly doped with *n* or p-type impurities. The basic steps in wafer preparation are: material purification, single crystal growing, wafer processing, and epitaxy.

Material purification. Germanium occurs in nature as a low-level impurity in zinc and copper ores. It is extracted by chemical processes in the form of germanium dioxide and reduced to the elemental state by heating in hydrogen.

Semiconductor manufacturers purchase raw germanium that is fairly pure by commercial standards in the form of rods two inches (five centimetres) in diameter and five to six inches (13 to 15 centimetres) long. For semiconductor use, this raw germanium must be refined to a very pure condition. Refining is based on the principle that impurities are generally more soluble in molten than in solid germanium. The industrial process is called zone refining (see **ZONE MELTING**). The final product contains less than one impurity atom in 10¹² of the pure germanium or silicon atoms.

Silicon is one of the most common of all the elements, occurring in the earth's crust as sand, mainly silicon dioxide, and in various silicate compounds. Also, large quantities of silicon tetrachloride, SiCl₄, and silicon trichlorosilane, SiHCl₃, are produced in the manufacture of silicones, and this source of supply is utilized for the preparation of very pure silicon for the semiconductor industry. The use of trichlorosilane is favoured because it is easier to remove such impurities as phosphorus and boron compounds from it. The trichlorosilane is purified by direct distillation (boiling point 32° C, or 91° F) using quartz containers to avoid contamination during the process. After purification, the trichlorosilane is reduced to pure silicon by heating in the presence of hydrogen. The hydrogen is bubbled through the trichlorosilane, which vaporizes and is taken with the hydrogen into a reaction chamber containing a thin, high-purity silicon rod heated to about 950° C (1,742° F). When the trichlorosilane decomposes, pure silicon is deposited onto the surface of the rod, building it up to a diameter between one and four inches (2.5 and ten centimetres), depending on the requirement. The hydrochloric acid vapour produced in the reaction is vented away.

Zone refining, as used with germanium, is not effective in purifying silicon. The high temperature needed to melt silicon, 1,420° C (2,588° F), causes problems. When in the molten state, silicon is easily contaminated by impurities in the container. Moreover, a common impurity in the low-grade silicon is boron, a Group III acceptor element (see Table 1). Boron has roughly equal solubilities in molten and solid silicon and so is difficult to remove by zone refining. Because of these factors, all purification of silicon is usually carried out by the chemical process described earlier, and purity levels of one part in 10¹⁰ are achieved. The silicon produced by the subsequent decomposition process is sufficiently pure for semiconductor use.

Crystal growing. The successful fabrication of a semiconductor device depends not only on the purity of the elemental semiconductor used but also on the regularity of the crystal structure. Polycrystalline or irregular crystal structure results in reduced carrier mobility and re-

duced carrier lifetime and so is not suitable for device fabrication. Most materials referred to as crystals are not single crystals but a collection of many single crystals of various shapes, sizes, and orientations. Such crystals are said to be polycrystalline.

A germanium bar that has been purified by zone refining is a polycrystalline material. For it to be useful as a semiconductor material, it must be grown into a single crystal. The process used to obtain single crystals of germanium large enough for device fabrication is called the Czochralski crystal-pulling technique. Solid polycrystalline germanium is placed in a graphite crucible inside a transparent quartz chamber through which a flow of argon is passed. Heat is applied to the germanium, generally from a radio-frequency power source. When the material is molten, the temperature is lowered to a value just above the melting point of germanium.

Next, a seed crystal (*i.e.*, a small single crystal of germanium) is lowered into the chamber until it just enters the top of the melted germanium. The seed is held in a clamp at the end of a long shaft. After the seed crystal has been dipped into the melt, it is rotated and raised by means of the shaft. Because the seed crystal is at a lower temperature than the melt, heat flows from the melt near the seed. The melt in contact with the seed solidifies onto it, the atoms arranging themselves into cubes to have the same orientation as the elementary cubes in the seed crystal. The heat that flows to the seed is radiated by the portion of the crystal above the melt.

The finished crystal is usually round, with a diameter depending on the melt temperature, the speed of rotation, and rate of withdrawal. The speed of rotation may be as high as 100 revolutions per minute and pull rates of one-half or two inches (1.3 or five centimetres) per hour are typical.

The growth of the crystal continues as it is rotated and raised. Typical germanium pulled crystals are two inches (five centimetres) in diameter by ten inches (25 centimetres) in length. When a crystal is grown from a high-purity germanium melt, a single crystal of intrinsic germanium results. It is the doped, or extrinsic, germanium, however, that is often desired for device fabrication. To grow a single crystal of n-type or p-type germanium, it is only necessary to add the donor- or acceptor-impurity atom to the melt before the growing process begins. Typical impurity concentrations are of the order of one atom to every 1,000,000 to 100,000,000 atoms of germanium or silicon.

The Czochralski method of growing single crystals is not often used with silicon because its higher melting point results in contamination from impurities in the quartz tube, especially when extremely pure crystals are required. Another problem is that when a doping material is added to the melt, the dopant impurity tends to vaporize from the molten silicon because of the high temperature. The method used in growing single-crystal silicon is known as the floating-zone method.

A cylindrical rod of polycrystalline silicon is supported vertically with a single crystal seed of the same diameter positioned under it. A molten zone is formed in the seed by radio-frequency heating and is slowly passed up the seed into the polycrystalline rod and up the rod to its top. As the silicon resolidifies onto the single-crystal seed, it does so in single-crystal form with the same orientation as the seed.

In addition to its use for single-crystal formation, this technique is sometimes used for final purification by making several zone passes up the single-crystal rod from bottom to top to reduce the concentration of many impurities. The impurity concentration and profile of the doped, single-crystal bar are checked by locally measuring the resistivity of the material as a function of the distance along the bar. This is carried out by a technique known as the four-point-probe method. The apparatus consists of a probe with four metal points arranged in a straight line. A conductor connects each metal point to an external circuit. To measure the resistivity of a sample at a particular spot, the probe is set down on the sample at that spot with all four points making contact with the

Czochralski
crystal-
pulling
technique

Floating-
zone
method

Zone
refining

surface of the semiconductor sample. Current is supplied to the crystal through the two outer probes and the voltage developed between the two inner probes, is measured with a voltmeter. The resistance of the material in the vicinity of the probe is equal to the measured voltage divided by the measured current. Resistivity depends on the voltage-to-current ratio and also on the probe dimensions. The device can thus be calibrated to read resistivity directly.

The tested semiconductor bar is then cut into wafers (typically 0.01 inch, or 0.025 centimetre, thick) with diamond-tipped saws. Subsequently, at least one side of each wafer is lapped (*i.e.*, the wafer is rubbed against a metal surface with a fine abrasive in between) and polished until it is smooth and flat. The wafers are then chemically treated to smooth the surface further and to remove any portion of the wafer surface in which the crystal structure has been damaged by the lapping and polishing operations.

Epitaxy. Epitaxy is a process in which a thin film of single-crystal silicon or germanium is deposited from a gaseous compound upon an existing wafer of the same material. The epitaxial film may be either *p*-type or *n*-type of specified impurity concentration. A reactor for the production of an epitaxial layer is composed of a long cylindrical quartz tube encircled by a radio-frequency induction coil. The wafers are placed on a rectangular graphite boat that is inserted in the inductively heated reactor. At the input of the reactor the different gases required for the reaction are introduced and controlled at a control terminal. For a silicon epitaxial film, the gases include silicon tetrachloride, hydrogen, nitrogen, and phosphine for *n*-type doping or diborane for *p*-type doping. The reaction produces either pure or doped silicon, as desired, which then deposits on the wafers. The gases from the reaction together with any inert gases used are carried at the end of the chamber to an exhaust vent. At the end of the epitaxial process the wafer is ready for device fabrication.

Intermetallic compound materials. Early developments in solid-state electronics were made with compound materials. The galena (lead sulfide) crystal detector and the selenium rectifier are examples of these early developments. A semiconductor compound is a substance containing two or more elemental semiconductors in a fixed ratio. Binary compounds contain two elemental semiconductors in a one-to-one ratio. The most useful types of binary compounds are those averaging four valence electrons per atom. They can usually be obtained from a one-to-one combination of Group III and Group V elements or Group II and Group VI elements (see Table 1). Intermetallic binary compounds (compounds formed of two metals) have crystal structures somewhat similar to elemental germanium and silicon and most have similar electrical characteristics. These compounds can be made extrinsic either by doping them (using Group VI atoms as donors and Group II atoms as acceptors) or by changing the compound ratio. Some of the intermetallic compounds have also shown electrical properties very different from those of elemental germanium and silicon, particularly in carrier mobilities and energy gaps. These properties are the bases of many useful new devices. Examples of compound semiconductor materials are gallium arsenide, indium antimonide, and zinc and cadmium sulfides.

Gallium arsenide. This material has a high energy gap and good carrier mobility and so is useful for microwave tunnel diodes, mixers, and the Gunn-effect diodes (see below). It is also used in light-emitting diodes and to make transistors for operation at very high temperatures.

Indium antimonide. This material has a low energy gap and very high mobility that makes it useful in infrared detectors, magnetoresistive (changes in electrical conductivity when a magnetic field is applied) and piezoresistive (changes in resistance when pressure is applied) devices.

Zinc and cadmium sulfides. These two materials, besides having high energy gaps and low mobilities, have electroluminescent properties (crystalline phosphors that

glow when struck by a beam of electrons), which make them useful for photoelectric devices.

Organic materials. There is a group of organic materials that exhibit semiconductor-like properties. Polyvinylidene chloride (saran) films, for example, can exhibit *p-n*-junction properties that are sensitive to ultraviolet radiation. Minute crystals of polyethylene, on the other hand, exhibit negative-resistance effects. In the early 1970s most work in organic semiconductors was at the research stage. The results indicated that the best hope for the utilization of these semiconductors lies in the field of biochemistry and biological systems.

Amorphous materials. These are amorphous (non-crystalline, lacking a lattice structure) materials such as certain glasses (*i.e.*, chalcogenide) and amorphous oxides that are neither crystalline nor pure. In other words, they are the antithesis of the crystalline materials that have traditionally been used in semiconductor devices. They do show, however, many striking electrical and optical similarities to crystalline semiconductors. The electrons in such amorphous materials, for instance, have bandlike energy structures, somewhat like those prevailing in crystals. They also exhibit reasonably distinct wavelength limits in their ability to absorb light, and their electrical conductivity varies exponentially with temperature over a wide temperature range.

Chalcogenide glasses lend themselves to a variety of processing techniques; they can be cast, extruded, rolled, hot-pressed, blown, painted, and deposited by evaporation. A thin-film Ovonic (after the United States scientist S.R. Ovshinsky) device exhibits switching characteristics. The attractiveness of amorphous materials lies in the fact that the essential characteristics of devices made from them do not depend critically on the fabrication method, and they are remarkably insensitive to accidental trace impurities. These materials, however, are still at the research stage, and many problems associated with their basic physics have to be solved before they gain wide acceptance.

Ovonic
devices

BASIC FABRICATION TECHNIQUES

Doping. The techniques used to make all the semiconductor devices have many features in common, whether these be diodes, transistors, four-layer controlled rectifiers, or other devices. For this reason, the processes employed to fabricate transistors are of general application.

To achieve as large a current gain as possible within a transistor, the lifetime of the majority-charge carrier, in the base region, must be relatively long before recombination of a hole-electron pair takes place. This requires that the transistor be made from a single crystal of high quality. At the same time, to obtain other desirable transistor properties, the impurity content of the crystal must be accurately controlled. This is best achieved by refining the semiconductor material to maximum possible purity, as described previously, and then adding impurities under carefully specified conditions through one of the available doping techniques. In general terms, the high-frequency performance of a transistor depends on the base width, the impurity profile, and the transit time of the minority-charge carriers. In some devices it is possible to include different impurity concentration levels and profiles by sequential processes.

Alloying. During the decade from 1950 most transistors were made by the alloyed-junction process. Common examples are of indium alloyed into germanium wafers or aluminum into silicon wafers, to form *p-n-p* transistors. In the manufacture of a germanium-alloyed transistor, an 11-type crystal is usually cut into small wafers 0.08 inch (two millimetres) square and 0.004 inch (0.1 millimetre) thick. When the indium melts, it dissolves a small amount of the germanium base and then, as the structure cools, the germanium recrystallizes, but it now contains some indium in the crystal structure, giving a *p*-type region. The alloying process is repeated on the other side of the base crystal to obtain the required two-junction structure. Contacts are soldered to the *n*-type base region and to the collector and emitter pellets. To minimize the base resistance the base contact is often in the form of a

Extrinsic
com-
pounds

ring around the emitter. Since most of the power is developed at the collector, this part of the transistor is made physically larger than the emitter.

It is difficult to alloy into a wafer of a thickness of less than 0.002 inch (about 0.05 millimetre) and extremely difficult to make alloyed-junction transistors with a base width narrower than 0.001 inch (0.025 millimetre) consistently. Also, the alloying process produces only a poorly defined boundary for the p-n junction. This results in a usable upper frequency limit of about ten megahertz for germanium-alloyed transistors. This technique has been superseded for the most part by other doping methods.

Diffusion. A region of semiconductor material may be converted from one type to another by solid and gaseous diffusion (the movement of impurity atoms into the crystalline structure of the material) without actually melting it. This process permits excellent control of impurity penetration, to within a few millionths of an inch, and is, therefore, attractive as a way of producing the thin base region necessary for a successful very high frequency device.

If a p-type germanium wafer is heated to near melting temperature in a donor-impurity atmosphere, such as antimony, then some of the impurity condenses on the wafer surface and tends to diffuse into the crystal. When the wafer is cool, the thin surface layer of the germanium will have changed from p to n type. The position of the junction below the germanium surface will be determined by the concentration of original impurity in the semiconductor wafer, the nature and temperature of the impurity vapour, and the time allowed for solid diffusion. Since the depth of impurity diffusion can be made extremely small with only moderate control of time and temperature, this method is attractive for industrial purposes.

One fact not properly understood is that n-type impurities diffuse fairly rapidly into germanium, but the diffusion rate of p-type impurities into germanium is so slow as to make it an unusable process. Diffusion of either n or p impurities into silicon is a viable process and can be employed to give a double-diffusion n-p-n transistor. With the use of this technique it is possible to make a transistor having a base width of 0.0005 millimetre (0.5 micrometre).

Ion implantation. This technique involves the doping of a semiconductor by implanting a dose of ions of the dopant into the semiconductor crystal. This is achieved by bombarding the semiconductor surface with an electrically controlled ion beam of high energy, approximately 10,000 electron volts. The motion and penetration of an ion beam into a crystal results from the kinetic energy of the beam and does not depend much on the crystal temperature. This means that the semiconductor processing steps can be varied substantially from those used in diffusion doping, giving the manufacturer more versatility in achieving his design objectives. The independence of crystal temperature allows the doping of a cold crystal, which, despite the fact that a final annealing (heating and slow cooling) step is usually required, allows the utilization of low-melting-temperature materials, and also high-diffusion-temperature materials, as dopants. The electrically controlled nature of the ion beam allows an extremely precise control of the number of ions implanted per unit surface area, which means electrical rather than thermal control of the p-n-junction depth and impurity profile. The flexibility of ion-implantation doping allows the creation of deep and shallow regions, high and low concentration of n and p dopants of very precise dimensions and penetration depths. The narrow emitter width required for high-frequency operation can be easily achieved by a 10,000-electron-volt boron beam directed through an emitter window of an aluminum mask 0.75 micrometre thick.

Masking and etching. The area of a wafer into which an impurity is diffused from a vapour may be approximately determined by masking the areas where diffusion is not desired. The final shape of the resulting p or n region may then be further defined by the use of an etching technique. The combination of these techniques together with that of epitaxy enables the production of

semiconductor devices within closely specified physical limits. Aluminum, for example, may be evaporated from a vapour into the surface of an n-type layer through a mask placed above the wafer surface. It is more common to have the mask as the surface material of the semiconductor wafer itself; *i.e.*, as an integral part of the semiconductor. The technique of making double-diffused silicon transistors depends on the selective-masking property of silicon dioxide. At high temperatures (above 1,300° C, or 2,370° F) a layer of this dioxide about five micrometres thick has very little inhibiting effect upon the diffusion of gallium into silicon from a gallium-rich atmosphere. But below 1,300° C, this same dioxide layer effectively masks the diffusion of boron, phosphorus, arsenic, or antimony. Using this property of silicon dioxide, together with photolithographic techniques of etching precisely defined holes in the dioxide layer (*i.e.*, by exposing a light-sensitive surface to light through a photographic mask), it is possible to produce high-performance double-diffused transistors. The cross section of a typical epitaxial-planar silicon transistor is shown in Figure 3. The impurity

Double
diffusing

Controlling
impurity
penetration

Figure 3: Cross section of an epitaxial-planar silicon transistor. The n^+ indicates heavy doping to give low resistivity.

diffuses laterally, under the surface of the dioxide, about the same distance that it diffuses normally to the surface. In this way the collector-base and base-emitter junctions are produced under the inert oxide layer and are thus sealed from contaminating chemicals during manufacture and encapsulation.

Design and manufacture of semiconductor devices

DEVICE ASSEMBLY AND PROCESSING

Several hundred semiconductor devices such as transistors, diodes, and thyristors can be formed on a single wafer of semiconductor material by the techniques described. These devices must be separated into individual chips, which are then individually packaged.

Chip separation. Several techniques are used in industry, of which the most important are the following:

Scribing and cleaving. The finished wafer is placed on a vacuum chuck capable of being moved and rotated horizontally. A diamond tool is then used to cut lines into the surface of the wafer in a grid pattern. The wafer is fractured along these lines, producing individual chips. These chips are then chemically cleaned from scribing dust and other foreign materials.

Etch cutting. The individual chips are masked with photo resist, a thin photosensitive film that is not affected by the etching solution, and the regions between them are removed (cut) by etching.

Ultrasonic cutting. A plane metal tool with numerous holes having the shape of the desired chip is placed in firm contact with a silicon wafer that is bathed in an abrasive slurry, a water mixture of fine abrasive powder. An ultrasonic transducer (a device that produces ultrasonic vibrations) drives the tool and causes it to grind completely through the silicon wafer, producing individual chips.

Laser scribing. A powerful laser beam mounted to permit motion of the beam along two axes (grid pattern) in a plane parallel to the wafer is used to scribe individual chips from the wafer.

Packaging. Semiconductor packages are prepared separately and serve the combined function of a heat sink (a device for dissipating heat from a heat-vulnerable component), a means of interconnecting one device with an-

Basic packages

other, and a means of protecting the device against chemical contamination and mechanical damage. The two basic types of packages used in modern devices are the metal-can package and the plastic-epoxy package. Examples of different packages are shown in Figure 4.

By courtesy of Motorola Inc., Semiconductor Products Division

Figure 4: Semiconductor packages. (Top, left to right) Small plastic, small signal metal, and medium power stud mounted. (Bottom, left to right) Power metal and rf (radio frequency) power.

Chip attachment. The attachment of a chip to its package is usually done by brazing (high-temperature soldering) using a brazing alloy such as gold-germanium. Two different methods are used.

The belt-furnace, or continuous, method employs a furnace with a long hollow tube surrounded by a suitably controlled heating element and containing a moving conveyor belt. Riding on the belt are metal or graphite jigs that can be loaded with headers, brazing preforms, and chips. These jigs progress through the furnace, where the thermal profile (temperature gradient) has been designed to bring them up to the bonding temperature (melting temperature of the brazing alloy) and, then, to cool them so that they can be safely handled.

The single-station method uses individually heated stations in which a single header or package is placed. The chips are picked up individually by an operator using a micromanipulator (a device for handling small articles) and placed on the package for bonding. The operator can observe the operation directly over the heated part.

Lead attachment. After the semiconductor chip has been attached to the package, it is necessary to make electrical connections between the chip and the package leads. A number of processes have been developed for making these connections.

The thermocompression bonding process involves the simultaneous application of heat and pressure to a very fine gold wire that makes the electrical connection between the proper contact point on the chip and the package leads.

In the wedge bonding technique, the header containing the chip is mounted on a heated column and positioned so that the point to which a lead attachment is desired is brought directly under a cross hair in the microscope. This cross hair has been previously aligned with the terminal positions of a swinging wedge that is to do the bonding. A second micromanipulator is used to bring the gold wire from a wire feeder into the position over the contact point. By pushing a button, the operator automatically brings the bonding wedge down on the wire to achieve the bonding. The header is then manipulated so that the cross hair is over the lead on the package, and the second bond is made at this point.

In the ball bonding method the bonding tool consists of a capillary tube whose bore is slightly larger than the

bonding wire to be used. The bonding wire is initially fed through this capillary. A flame is used to melt the end of the wire to form a ball whose diameter is approximately twice that of the wire. This ball is then automatically drawn back snug against the end of the capillary, and the capillary is manipulated to the point at which bonding is desired. Then, in one continuous motion, the capillary is lowered and zeroed in on the target, and the ball is firmly compressed against the contact area of the chip, deforming the ball into a nailhead thermocompression bond. The capillary is then withdrawn an appropriate distance, and the flame is used to sever the wire and, also, to form a new ball.

These two techniques can be described as gold-wire-to-aluminum-contact-area bonding techniques. In recent years, the use of aluminum-alloy-to-aluminum bonding has been widely used because similar metals perform better in such circumstances than do dissimilar metals.

The soldering technique used for semiconductor device lead attachment is a modified version of the soldering process used in printed-circuit applications. The alloys of lead, together with silver, are usually the materials used. If compatibility with high-temperature processes such as hermetic sealing is required, however, such low-melting solders can be replaced with higher melting ones.

The beam-lead technique was developed primarily to batch-fabricate semiconductor devices. The technique consists of depositing an array of thick contacts on the surface of the semiconductor chip and then removing the excess semiconductor from under the contacts, thereby separating the individual devices and leaving them with semirigid beam leads cantilevered (supported at only one end) beyond the semiconductor. The contacts serve not only as electrical leads but also as the structural support for the devices; hence, the name beam leads. Chips of beam-lead circuits are mounted directly by the leads without aluminum or gold wire.

Beam-lead technique

Encapsulation. The semiconductor chip is welded into a metal package, and the metallized areas are connected to the package leads, usually by thermocompression bonding. Total protection of the device is then provided by means of a hermetically sealed (airtight) welded can that completely surrounds the device. The cans are generally baked out at a high temperature before welding in order to drive off any solvents or other contaminants on the surface. They are then brought into a controlled-atmosphere dry box, and the cans are welded to the header (the part that provides support and insulation), sealing in a portion of this controlled atmosphere.

The principal disadvantage associated with the metal package is the high cost associated with the individual sealing and leak-testing steps. Requirements of extreme reliability, as in military or aerospace applications, can justify the higher costs. The bulk of the other applications of semiconductor devices are satisfied by the use of plastic packages. Following the bonding of the chip and its wire leads to a metal lead frame, the whole assembly is coated with a plastic. When the plastic is set, the perimeter of the lead frame is cut away and the leads bent and trimmed to length. The process lends itself to more automation, and hence economy, than the hermetically sealed metal package. No plastics used at present, however, are completely impervious to water vapour, which can cause serious degradation of the semiconductor device's properties.

MOS technique. The metal-oxide-semiconductor (MOS) technique is employed in the construction of planar semiconductors; e.g., the planar-epitaxial transistor of Figure 3. In this transistor structure all the junctions of the device (emitter to base and collector to base) are brought to the same plane, or surface (hence the name planar), which is eventually covered with silicon dioxide (SiO_2) except for a window opening to connect the terminals to the different regions. The major advantage of the silicon dioxide is the reduction of surface contaminants and impurities that cause surface leakage currents, degrading the transistor operation. When the coating of silicon dioxide is applied, the surface is said to be passivated, and the method is now widely used in the manufac-

Table 2: Semiconductor Devices

name of device	symbol	material	physical phenomena	application
Rectifier power diodes		germanium; silicon	unilateral conduction	power conversion and control, wave shaping and instrumentation; receiver detectors and mixers; switching and logic circuits

ture of field-effect transistors (transistors in which control is effected by application of an electric field) and integrated circuits (*q.v.*).

SEMICONDUCTOR DEVICES AND THEIR APPLICATIONS

Two-terminal pn-junction devices. The unilateral conduction properties of the p-n junction are the basis of the operation of the solid-state junction diode that is mainly used for signal and power rectification. The p-n junction, however, exhibits a number of other useful phenomena that can be used in many practical applications; for example, the p-z junction exhibits variations in the depletion layer depth with voltage. It also exhibits avalanche breakdown characteristics; *i.e.*, nondestructive breakdown caused by the cumulative multiplication of carriers through field-induced impact ionization in the reverse direction. Such other phenomena as the controlled guidance of energy levels, the nonrectification at microwave frequencies (one gigahertz [10^9 hertz] and above), the peculiarities of charge storage (the ability to retain an electrical charge), and the light-emitting capabilities are only a few of the properties that the p-n junction possesses and are the basis of many useful p-n junction devices. Table 2 gives a summary of these semiconductor devices, symbols, the fundamental physical properties in their operation, and the basic areas of application.

Junction diode. The semiconductor diode is a p-n-junction device with unilateral conduction properties. In power rectification, one or several devices are used in different configurations to convert alternating currents into direct currents. The same is done at lower power levels in instrumentation applications. The basic diode parameters (threshold voltage, leakage current, and breakdown voltage) are temperature sensitive. This characteristic is exploited to advantage to stabilize and compensate for temperature instabilities in the operation of solid-state amplifiers and oscillators. Especially constructed diodes, with small depletion capacitance (the capacitance of its depletion layer), are also used as detectors to separate audio frequency from intermediate frequency in radio-receiver circuits. Very low power diodes with idealized unilateral characteristics are used in switching, logic circuits of computer hardware, and digital communications systems.

Zener diode. This diode is a p-n-junction device using closely controlled impurity concentration to provide very sharp and well-defined breakdown voltage over a wide range (a few hundred millivolts to several hundred volts). Operation of the device in the reverse direction results in a constant voltage source that is used in many applications; *e.g.*, as a reference voltage in the regulator

section of a regulated power supply. Because of its voltage sensitivity and fast switching action, the Zener diode is also used for protecting electronic and meter circuits against voltage and current transients and for arc suppression in small circuit breakers. The Zener diode is often used together with a forward-biased diode in series to produce a reference voltage unaffected by temperature changes for temperature-compensated amplifiers. The very low resistance of the Zener diode also makes it useful as a coupling element in direct-coupled amplifiers. Zener-diode control circuits are used for light dimming, relay control, ballast control, voltage multiplication, and many other industrial applications.

Varactor diode. The varactor (variable reactor) is a voltage-variable, reverse-biased p-n-junction device whose effective capacitance can be varied by varying the applied voltage. It has a specially graded junction with an impurity profile that is determined by the desired application. Varactor diodes make possible the solid-state tuning of circuits by voltage variation. They are also useful in switching and frequency-multiplier circuits, for limiting and pulse shaping, and also in a special type of amplifier called a parametric amplifier.

Tunnel diode. The tunnel diode, sometimes called the Esaki diode, is a heavily doped semiconductor device with a very narrow depletion region. Under very low forward-bias conditions (300 to 400 millivolts) and low dissipation, the electrons can tunnel or pass directly through the junction from the conduction energy band to an equal level in the valence band, producing a negative-resistance effect. If the forward bias is increased beyond 400 millivolts, the device conducts as a conventional diode. Tunnel diodes, because of inherent low noise, frequency stability, and high efficiency, find many applications in ultrahigh-frequency amplifiers, oscillators, and switching circuits.

Schottky diode. This is a diode with a metal-semiconductor junction instead of the usual p-n junction. The current flow is the result of majority-carrier electrons at a relatively high energy level ("hot carriers") injected at forward bias. Because the mechanism of conduction across the junction involves majority carriers with a very short lifetime and very little recombination noise (noise resulting from the random process of electron-hole generation and recombination in the semiconductor material), the device is especially suitable for ultrahigh-frequency low-noise mixer and switching circuits.

Step-recovery diode. The step-recovery diode is a p-n-junction device with a graded junction whose impurity profile is designed to minimize stored-minority-carrier transit time. The nonlinear-junction capacitance variation is also minimized. The step-recovery diode is use-

Basic diode parameters

Uses of tunnel diodes

ful in microwave-frequency multipliers and microwave switching.

The $p-i-n$ diode. This diode consists of a thin layer of high-resistivity intrinsic semiconductor between a heavily doped p (input) layer and another heavily doped n (output) layer. At microwave frequencies the device is equivalent to a capacitive high-resistance network, and in the forward direction under avalanche condition the i layer becomes flooded with holes, and the diode changes into a conductor. The device is used as a direct-current-controlled microwave switch. It can also be used as a modulator with the modulating signal producing the required variation in the input resistance.

Gunn and Impatt diodes. These devices, useful as microwave oscillators, are the result of recent research in the field of microwave diodes. The Gunn (after J.B. Gunn) diode operates basically like a tunnel diode in a pellet form mounted in a tunable microwave cavity. The Impatt (Impact Ionization Avalanche Transit Time) diode, on the other hand, generates microwave frequencies in the avalanche mode.

Photo diodes. These are $p-n$ -junction devices designed in special packages equipped with light-focussing lenses. In the forward direction the device is photovoltaic (generates electricity when illuminated), while in the reverse direction it is photoconductive (conducts electricity when illuminated). These diodes are used as light sensors in many alarm systems, in control, and in industrial applications.

Light-emissive diodes. These are specially designed $p-n$ -junction devices using gallium arsenide. The device emits infrared radiation under forward-biased conditions. These devices, together with infrared photo diodes, are finding wide applications in the field of opto-electronic control systems and instrumentation and also in electronic surveying systems.

Injection lasers. The semiconductor diode laser is a higher power version of the light-emissive diode described earlier. By careful selection of the bias voltage, the junction cooling, and optical lens system, the coherent light radiation required for the laser can be achieved.

Transistors. Amplifiers. The most significant role of semiconductor devices is in electronic amplifiers. The majority of solid-state amplifiers have two $p-n$ junctions, implying three layers of semiconductor material. The exceptions include the unijunction transistor, the field-effect transistor, and the tunnel diode. In general terms, the amplifying action of a transistor depends on a low-power input circuit controlling a higher power output circuit. In the frequently used common-emitter configuration, where the input impedance is of the order of a few thousand ohms, a small base current gives rise to a much larger collector current flowing out of the high-impedance collector circuit.

Electronic amplifiers are usually classified into five groups: small-signal amplifiers, large-signal (*i.e.*, power) amplifiers, direct-current amplifiers, wide-band and tuned amplifiers, and feedback amplifiers.

The simple audio-frequency amplifier has limited use and can not deliver a worthwhile power output in other frequency ranges. The low-frequency response of transistor amplifiers is limited because of the extremely large values of coupling capacitors (*i.e.*, the capacitors that couple the output of one stage to the input of another stage) that are required. At very low frequencies and for direct-current applications, directly coupled amplifier stages are sometimes used. The inherent disadvantage in this arrangement is that of voltage drift, largely the result of temperature changes. Various compensating circuits have been designed to overcome this problem. A common alternative is to convert the direct-current signals to alternating current by means of a "chopper" circuit at the input to the amplifier. Numerous good-quality operational amplifiers for very low frequency applications, incorporating silicon transistors, are now available.

At the frequencies from about 100 kilohertz and upward, it is common to have the output circuit of the amplifier tuned to the required frequency band. The main considerations in the design of such amplifiers are the

availability of transistors capable of giving useful gain at high frequency, the incorporation of any stray and inherent transistor capacitances into the tuned circuits, and effective compensation for unwanted feedback paths. At high frequencies, internal feedback in the transistor can be particularly troublesome. This factor varies considerably between transistors of different types. Transistors that have an exponential variation in impurity density across the base region, sometimes known as drift transistors, have a much lower feedback capacitance, with a generally better performance at very high frequencies, than transistors with constant base-impurity content.

The power dissipation within the transistor itself is a major consideration in nearly all amplifier applications. The semiconductor chip in a very high frequency transistor may have a volume of about 0.000001 cubic inch, and consequently heat must be conducted away quickly. In transistor amplifiers designed to produce more than 100 milliwatts of output power, the overall efficiency and the power dissipation become vital design considerations. A major aim is to reduce the standing, or quiescent, current to a minimum. Such a reduction is often accomplished in the push-pull type of circuit by using a pair of matched transistors. A major improvement was the advent of complementary $p-n-p$ and $n-p-n$ transistors, making it possible to produce transformerless amplifiers, a technique that greatly reduces the bulk and expense of audio equipment.

Oscillators. If a proportion of the output voltage from a transistor amplifier is fed back to the input and in step with the input, then the feedback reinforces the input and an oscillator circuit can be produced. In particular, a network of passive components can be connected to the transistor to give an output signal at one particular frequency. The losses in this network are made up by the gain of the transistor. The frequency of the electrical oscillation depends to some extent on the characteristics of the transistor, but suitable circuit design can make the output frequency and amplitude almost independent of any changes due to temperature variations from one transistor to another or to aging of the transistor.

In vacuum tubes, the majority of oscillators involve a tuned circuit with an inductance and capacitance. A significant proportion of transistor oscillators designed primarily for use at frequencies less than 100 kilohertz include a resistance-capacitance network to give a proper feedback signal. In this way it is possible to produce low-cost, small-size oscillator circuits that take full advantage of the transistor characteristics.

Digital circuits. Transistors are often used in pulse or switching circuits in such a manner that the transistor is driven from OFF to fully ON without remaining for any appreciable time in the normal, linear region of its operating characteristics. This is, in fact, the most efficient mode of using a transistor. In practice, a small collector current (a few microamperes in a small germanium transistor and a few nanoamperes [10^{-9} ampere] in a silicon device) does flow. In this case, both the junctions are reverse biased. In practice, the transistor is "bottomed"; that is, it is conducting heavily and the current is limited by the external circuit. Under these circumstances base, collector, and emitter are at virtually the same potential.

In these digital circuits the silicon device has the particular advantage of extremely low cut-off current, and the germanium transistor has a low internal voltage drop when fully switched on. These characteristics give rise to high efficiency and well-defined ON and OFF states.

The digital applications of transistors as gates, counters, and pulse amplifiers are really the heart of any digital computer. A vital feature of digital-circuit design is the speed with which a transistor can be switched through the active region of its characteristics. During the switching process a phenomenon known as "charge carrier storage" (which is electron storage in the case of an $n-p-n$ transistor) occurs. In order to obtain transistor action it is necessary to establish and maintain a certain charge of current carriers in the base region. By considering current to be the result of the flow of charge into and out of a base store, a helpful approach to small and large signal

calculations is obtained, which is often used in the design of digital circuits.

Four-layer (p-n-p-n) devices: thyristors. These devices are p-n-p-n four-layer devices, with two, three, or four external terminals. They have either unidirectional or bidirectional characteristics. The silicon-controlled rectifier and the triac are by far the most commonly used of all thyristor devices. The silicon-controlled rectifier is a reverse-blocking (unilateral) triode (three-terminal) thyristor. The triac, on the other hand, is a bidirectional triode thyristor. Physically, thyristors are three-junction p-n-p-n devices fabricated from successive layers, slices, or pellets of especially doped silicon. Examples of different thyristor constructions are shown in Figure 5.

By courtesy of General Electric Semiconductor Products Department, Syracuse, N.Y.

Figure 5: Thyristor constructions.

Silicon-controlled rectifier. In the forward direction with no gate current, the device acts like an open switch until an appropriate gate signal is applied to the gate terminal, at which time it rapidly switches to the conducting state.

Once the silicon-controlled rectifier is turned on, it cannot be turned off by removing the gate current. It is turned off only if its current is reduced externally below the hold current. The silicon-controlled rectifier is thus a switching device that can be turned on by the proper application of sharp gate-current pulses and turned off usually every time its current is reduced below a minimum holding level. Silicon-controlled rectifier switches have the following advantages over power transistors: higher current capabilities, and better forward-blocking characteristics. Silicon-controlled rectifiers are low-frequency devices that are mainly used for power-frequency switching.

Triac. The triac is a p-n-p-n device especially constructed to provide bilateral operation instead of the unilateral action of the silicon-controlled rectifier. It is equivalent to two silicon-controlled rectifiers in inverse parallel connection.

Other thyristors. Other thyristors include the diac (bidirectional diode thyristor), the sus (silicon unilateral switch) and the SBS (silicon bilateral switch). There is also a host of light-activated thyristors that add to the versatility and scope of the application of thyristors. Among these are the LAS (light-activated switch), the LASCR (light-activated SCR), and the LASCS (light-activated silicon-controlled switch). Figure 6 shows the circuit symbols for these and several other thyristors. Thyristors have replaced vacuum tubes and electromechanical devices as solid-state power conversion and control devices in industrial, control, and consumer circuit applications. This trend was prompted by the many attractive features and characteristics that these devices possess; among them are the following: (1) Reliability: using the now

Timing circuits	photo darkroom timer; oven timer; vending machine logic; industrial process control; automatic blender-mixer shutoff; sweep circuits; oscilloscopes
Remote control	armchair TV control; master switching stations for the home; garage door openers; power switch burglar and other alarm systems; touch switch; electric door openers
Alarm and protection systems	low-speed ring counters and shift registers; computer peripheral equipment; power flip-flops; constant current generators; oscillator-tone generators; pulse amplifiers; static switching; relay replacement; solenoid drivers; latching relay replacement; low-power inverters; thyatron tube replacement
Power electronic circuits	voltage (battery charger sensor); current (electronic crowbar); safety circuits (for machine tools, etc.)

nologies used today are thick-film, thin-film, and monolithic integrated circuits (IC).

Film technology usually involves the deposition of a film of passive component patterns on the top of ceramic or other dielectric substrate or base material. Monolithic integrated circuits, on the other hand, are those circuits, like operational amplifiers or digital counters, in which all the components of the circuit, passive and active alike, are built into the same silicon chip. The individual components of the circuit cannot be separated without permanently destroying its intended electronic function. A hybrid microcircuit is a circuit assembly in which the passive components and their interconnection are formed by one of the film techniques. The monolithic active devices in the form of chips are bonded to the passive film base to complete the assembly.

The basic processes used in the fabrication of monolithic integrated circuits are similar to those used in the fabrication of the planar-epitaxial transistor described earlier, except that instead of building one transistor (by the successive application of photolithographic masking and selective diffusion), all the active and passive devices required for the circuit are built simultaneously. Integrated circuits can be classified into linear or digital types. The operational amplifier is the most common type of linear integrated circuit. It is now replacing the discrete small-signal transistor as the main building block in electronic instrumentation, industrial control systems, and consumer products. A typical monolithic operational amplifier will have about 15 transistors and diodes and about 20 resistors built on a 60-mil-square silicon chip, the whole encapsulated in a metal can with ten leads.

Digital integrated circuits form the main bulk of the market today. They are used as switching, logic, and memory elements in the computer field. They are also used in the field of data and digital communications. In a typical integrated-circuit memory, for example, several thousand transistors are packaged together in a three-dimensional array in silicon to form what is known as a large-scale integrated (LSI) memory (see also INTEGRATED CIRCUITRY).

Photo devices. Semiconductor photo-activated or photo-generative devices are an important class of semiconductor devices that play a role in industrial control, information transmission, digital data processing, power generation, and other industrial processes.

A correctly doped p - n junction, when reverse biased between 30 and 50 volts and equipped with a light-focusing lens, will exhibit variation in its background resistance under sufficient illumination. The junction will generate currents in the milliamperage range for germanium and in the ampere range for silicon. A phototransistor amplifies the photoconductive current generated across the reverse-biased base-emitter-base junction. The light applied to the base through a hole-lens assembly in the case is the input signal. The high impedance of a field-effect phototransistor allows the generation of relatively high gate voltages from small photocurrents. This fact, together with the field-effect transistor's inherent amplification, makes it one of the most sensitive photo devices.

SPECIALIZED FABRICATION TECHNIQUES

Construction. The epitaxial-planar transistor construction discussed earlier is the basis of most modern high-performance, silicon bipolar semiconductor devices. It is used for both small-signal and large-signal power devices. It has good stability, low noise, and high-frequency capability, usually up to 200 megahertz. Other specialized construction techniques are used to improve the capabilities of the devices and to enhance some of their parameters for specific applications.

Annular construction. This construction is usually employed to increase the power and breakdown-voltage capabilities of bipolar-junction transistors. For power transistors (Figure 7C), two annular rings are formed; both of the rings are concentric to the centre emitter element. This provides a large base area for better heat dissipation and also a maximum emitter perimeter. To increase the breakdown capabilities of a bipolar transistor, the star

Figure 7: Specialized transistor structures.

configuration (Figure 7B) is sometimes used. In this case, the base (n -type in a p - n - p transistor) is surrounded by an annular protective band of p -type material. This low-resistance barrier effectively shorts the base currents, restricting their passage in the form of leakage. The annular band is also removed from the main emitter-base junction to avoid voltage breakdown.

Overlay. This construction is used to increase the power and frequency capabilities of radio-frequency transistors; e.g., 50 watts at 50 megahertz. An example of this construction is shown in Figure 7A where a large number of emitters are connected in parallel to increase the emitter periphery.

Electron-beam technique. The ion-implantation technique described earlier is an example of a new approach to the manufacturing of semiconductor devices known as electron-ion-beam technology. Fine-focussed electron beams, which initially were employed in diagnostic tests on semiconductor devices, now are being utilized in the laboratory for creating devices and circuits with resolutions considerably higher than the values that can be achieved by photolithography. An electron beam, for example, has a spot size from five to 200 angstroms (an angstrom is 10^{-8} centimetre), as compared with 5,000 angstroms (the wavelength of visible light) used in conventional photolithography. These beams of charged particles are electrically controllable and thus can be programmed in intensity and positioned over wide ranges by electric signals. The high resolution of the beam-written pattern permits device operation at higher frequencies and at high packaging densities.

BIBLIOGRAPHY. The general area of semiconductor materials and physics is thoroughly covered in J.L. MOLL, *Physics of Semiconductors* (1964); M.J. BUEGER, *Crystal-Structure Analysis* (1960); C.A. Semiconductors and Insulators, Theory of

One of the distinguishing characteristics used to differentiate many solid, liquid, and gaseous materials is their ability to transmit an electric current. In contrast to good electric conductors (e.g., metals), through which electric current can flow easily, poor conductors (i.e., semiconductors and insulators) offer more resistance to electric charges moving through them. Moreover, whereas heating reduces the electrical conductivity of good conductors and cooling enhances it, semiconductors and insulators are transformed into better conductors when heated and poorer ones when cooled. To explain these and related properties, which form the basis for the development of solid-state devices, it is first necessary to classify with greater refinement those substances that are electrical conductors.

GENERAL CONSIDERATIONS

Classification of solids by electrical resistivity. Electrical resistance (resistivity) is the opposition to electric current moving under the influence of a given voltage; it is expressed in units of ohms. The basic unit of resistivity is the resistance of a sample one centimetre long and one square centimetre in cross section; it is usually expressed in the units ohm-centimetres (ohm-cm). Because the resistance of a given solid depends on its length and cross-sectional area, electrical resistivity, symbolized by the Greek letter rho (ρ), is a convenient way to classify and compare materials. Electrical conductivity, symbolized by the Greek letter sigma (σ), is the reciprocal of electrical resistivity, $\sigma = 1/\rho$. The electrical resistivity of solids varies over many orders of magnitude, expressed as factors of ten or integral powers of ten (Figure 1).

At one end of the resistivity range are the superconductors (e.g., lead below 7° K), which are extremely high in conductivity because they have no measurable resistance (this class of materials lies beyond the range of Figure 1). Lowest in resistivity on the scale illustrated are the metals (e.g., silver and copper), with resistivities on the order of 10^{-6} ohm-centimetre. The next lowest group is the semi-metals (e.g., bismuth and arsenic), with only slightly higher resistivities. This group of good conductors is followed by two classes of materials, each covering a wide range of resistivities—the semiconductors, of which germanium and silicon are representative examples, and the insulators, such as fused quartz, with resistivities as large as 10^{18} ohm-centimetres and greater. Metal conductors find application in devices that transmit large currents for purposes of heating and lighting, for turning electric motors, to activate chemical reactions, and to achieve other goals that require an efficient flow of electrons. Such currents are controlled by insulators, resistors, capacitors, and, in

Figure 1: Electrical resistivity of materials at room temperature.

general, devices that are rugged enough to block or shunt the massive flow. In contrast, semiconductors transmit relatively weak currents, and the minute flow of electrons can be controlled with great precision by appropriate devices. One important application is the transistor, a semiconductor device that is used almost universally as a substitute for a radio or electronic tube because of its minute size, low power requirement, and cold operation. Another application is the crystal diode, a device that passes current more readily in one direction than another so that it can rectify (that is, change) alternating current into direct current.

General properties of semiconductors and insulators. Characteristic of the electrical resistivity of poor conductors is its great sensitivity to temperature, pressure, and frequency of electromagnetic radiation. It is also sensitive to its own purity and crystal perfection. For example, the resistivity of the insulator cadmium sulfide (CdS) decreases by 13 orders of magnitude (to one part in 10^{13} of the original value, because one order of magnitude is a factor of 10) upon the addition of less than 0.01 percent of a particular element, referred to as a type of impurity atom; the corresponding change in such typical semiconductors as silicon and germanium is six to seven orders of magnitude (Figure 1). On the other hand, the addition of impurities to typical metals produces a very much smaller change in resistivity, less than one order of magnitude, and the change is of the opposite sign; that is, the addition of impurities increases the resistivity.

Of particular interest is the dependence of resistivity on temperature. In fact, this property is used as a criterion for distinguishing semiconductors and insulators from metals. The resistivity of semiconductors and insulators characteristically increases by many orders of magnitude as the temperature is lowered from room temperature to 1° K (approximately -272° C or -458° F). On the other hand, the corresponding change in the resistivity of metals is a decrease of several orders of magnitude. That is, the resistivity of metals decreases with decreasing temperature, while that of semiconductors and insulators increases with decreasing temperature.

The classification of materials according to the magnitude and temperature dependence of their electrical resistivity can be quite different from a classification based on

Visual properties

Good and poor conductors

visual inspection. Such semiconductors as silicon and germanium, for example, exhibit a metallic lustre, while a metal such as rhenium trioxide (ReO_3) is a reddish, almost transparent solid. Metallic lustre is associated with a high reflectivity at visible light frequencies and is usually, though not necessarily, found in materials with high direct-current conductivities. The electrical conductivity of all solids is dependent on the frequency of the electromagnetic radiation: for metals, conductivity tends to decrease with increasing frequency; for semiconductors and insulators, on the other hand, conductivity tends to increase with increasing frequency. Thus, at ultraviolet frequencies (higher than those of visible light, the optical region) the conductivity of all solid materials is about the same order of magnitude.

Although the conductivity at optical and ultraviolet frequencies is similar for the various classes of materials, the effect of light exposure on low-frequency conductivity (*i.e.*, alternating currents in the material of frequencies lower than those of the radiation) is different. For example, the direct-current conductivity of cadmium sulfide can change by eight orders of magnitude (100,000,000 times) upon exposure to visible light. The increase in electrical conductivity exhibited by certain solids when exposed to light is called photoconductivity. This effect is common in insulators and semiconductors, but it is not observed in metals and semimetals; in semiconductors, such as silicon and germanium, photoconduction is produced by infrared as well as by visible light excitation.

HISTORY

The reason solids are classified according to their direct-current resistivities is partly because of a high correlation between this property and other physical properties. There is also a practical reason for doing so: most of the industrial applications of semiconductors and insulators make use of the low-frequency electrical properties. These applications characteristically exploit the great sensitivity of the resistivity of low-conductivity materials to small variations of external parameters. For example, the large photoconductivity of cadmium sulfide makes this an ideal material for an electrical switch triggered by light. Indeed, rectification (one-directional conduction) and other properties of semiconductors are exploited in the modern electronics industry and computer technology. In its infancy the electronics industry employed semiconductors as rectifiers in crystal sets for radio reception. These crystals were soon replaced by the then more reliable and effective vacuum tube, which controlled current by a relatively weak flow of free electrons through a vacuum, and which dominated the electronics industry for four decades until the invention of the transistor in 1948. (A transistor is a device that utilizes a semiconductor to control or to amplify, or both, small electrical currents. In 1956 three Bell Telephone Laboratories scientists, William Shockley, John Bardeen, and Walter Brattain, were awarded the Nobel Prize for Physics for their investigations of semiconductors and for their discovery of the transistor effect.) Because of this invention and the technological development that it inspired, semiconductor components have now mostly replaced vacuum tubes. Their compactness, simplicity, durability, and reliability are all responsible for the general industrial acceptance of solid-state devices for a variety of applications: from the transistor radio in the home to the hardware of giant computers; from solar cells for converting light into electricity to the electronic circuitry of rockets and satellites in the space program.

The discovery of the transistor is considered a milestone not only in the evolution of semiconductor physics but also in the development of solid-state physics in general. The solid-state research that was initiated to produce high-purity crystals and to study the properties of such materials has led to a better understanding of the basic physical properties of all solids, whether metals, semiconductors, or insulators. Such research has also led to the development of a variety of other technologically important devices, such as lasers, tunnel diodes, and Gunn oscillators. Insofar as semiconductors can, under appropriate conditions, exhibit superconducting and magnetic

properties, the field of semiconductor physics does, in fact, make contact with other broad areas of solid-state physics.

MECHANISMS OF CONDUCTION

In order to understand the nature of electronic conduction in semiconductors and insulators, it is necessary to study in some detail the conduction mechanisms appropriate to these materials. Electrical conduction is associated with the flow of charge between two electrodes attached to two points on these materials, from a positively charged anode to a negatively charged cathode or the reverse, and depends upon the concentration (N) of charged particles, or carriers, in the material. Whereas electrons are the dominant current carriers in metals, semimetals, and semiconductors, for some insulators both electrons and the heavier ions (charged atoms) contribute to the conduction of current.

Mobility of charged particles. To transport effectively electric charges from one electrode to another, the particles must resist collision and scattering along the path of the charge. Thus, charged particles in a solid are not accelerated indefinitely by the application of an external electric field (an electric field either pushes or pulls charged particles), because collisions force these particles to achieve some average velocity, called the drift velocity (v_D); each scattering event tends to randomize the velocity achieved in the acceleration process, so that after each such event the charged particle is effectively returned to zero average velocity, and the acceleration process caused by the electric field must begin again. The mobility, symbolized by the Greek letter mu (μ), which measures the effectiveness of the charge transport by a given charged particle in a conductor, semiconductor, or insulator, is thus defined as the drift velocity achieved through application of unit electric field (E), being equal to the drift velocity divided by the electric field; *i.e.*, $\mu = v_D/E$. That is, as the external field is increased, the drift velocity increases proportionately. Because the drift velocity depends on the magnitude of the applied electric field, the mobility of a particle of mass m and electric charge e can be more directly related to the mean time between scattering events, symbolized by the Greek letter tau, τ , through an equation in which mobility equals the product of the charge and the mean time between scattering events divided by the mass, or $\mu = e\tau/m$. In this way mobility is related directly to the interval of time between collisions; that is, to the effectiveness of a charged particle in avoiding collisions.

Electrical conductivity (σ) equals the product of the mobility of each carrier (μ) and the concentration (number per unit volume) of carriers (N) with charge e ; it may be defined as $\sigma = Ne\mu$. This definition of electrical conductivity is particularly useful for semiconductors and insulators because of the independence of the two factors, the carrier density factor (N), which is highly sensitive to such external parameters as temperature, optical excitation, and others, and the mobility factor (μ), which is sensitive to scattering mechanisms within the material.

Mobility in solids. Whereas conduction by ions is generally ineffective because of low mobility, conduction by electrons in metals, semimetals, semiconductors, and insulators is efficient. In fact, because of quantum mechanical principles, an electron travelling through a perfect crystal lattice is not scattered. The present understanding of electronic conduction in solids goes back to the classical Drude theory (1900), so called for Paul Drude, the German physicist who presented it, and according to which it was supposed that a dense gas of free electrons, interacting strongly with each other, existed in a metal. This theory has since been modified to explain why only a fraction of the available electrons participate in conduction and why the electron scattering times are longer than predicted by classical theory.

Electron diffraction. The wavelike nature of electrons gives rise to diffraction (resulting when obstacles interrupt a sequence of waves) rather than to scattering (resulting when a stream of moving particles meets an obstacle), as the wave traverses a crystal lattice (an orderly

Photo-conductivity

Drift velocity

Conductivity formula

arrangement of atoms which act as obstacles). Thus, in certain directions the waves interfere constructively to yield diffraction peaks of intensity, whereas in other directions destructive interference results. From this point of view, although no scattering occurs, electronic conduction in a periodic (repeating) array of atoms is modified by the presence of the lattice. For most crystalline semiconductors and insulators, the effect of the periodic lattice on the conduction process can be described by an equation in which the electron mobility (μ) is equal to the product of the charge and the mean time between scattering events divided by a factor called the effective mass (m^*): $\mu = e\tau/m^*$ (see below Theoretical approximations). In semiconductors the effective mass tends to be considerably lower than the free electron mass (m)—i.e., the mass of an electron at rest—whereas in insulators the effective mass tends to be higher than the free mass.

Electron scattering. The most important room temperature scattering mechanism in solids is usually the scattering of electrons by the thermal (heat) vibrations of the atoms of the lattice. Because of this mechanism, electrical resistivity varies with temperature, a relationship that is generally valid for materials in which the carrier density is independent of temperature. As the temperature is lowered, the thermal lattice vibrations become less important, and scattering is dominated by crystalline imperfections, such as lattice vacancies or interstitial atoms, lattice dislocations, impurity atoms, and crystal boundaries. Thus, electron scattering is increased by the addition of impurity atoms or by destroying the crystalline order of the solid; in fact, for amorphous (noncrystalline) materials, scattering by these imperfection mechanisms is important even at room temperature.

Because of the increasing importance of lattice vibrations with increasing temperature, the mobility of electrons in solids tends to decrease with increasing temperature. Moreover, because the carrier concentration (density) in metals and semimetals is essentially temperature independent, the increased scattering with increasing temperature leads to a characteristic decrease in conductivity with increasing temperature. For semiconductors and insulators the number of carriers is extremely temperature dependent; in fact, the carrier density increases exponentially with increasing temperature. Such a rapid increase in the carrier density completely overshadows the very much slower decrease in the mobility; thus the conductivity of semiconductors and insulators characteristically increases with increasing temperature.

Activation energy. The strong temperature dependence of the carrier density in semiconductors and insulators is intimately connected with an activation energy, or barrier, which restricts carriers to bound, nonconducting states. This barrier can be overcome by thermal excitation of the particles, which has an exponential temperature dependence through the Boltzmann factor that relates the temperature to the energy of the particle. Thus, the carrier density (N) is equal to the product of the density of the available bound carriers (N_0) and the exponential of minus the ratio of the activation energy (E_a) to twice the Boltzmann constant (k) times the absolute (Kelvin) temperature (T), or $N = N_0 \exp(-E_a/2kT)$. The temperature dependence is extremely high, especially in the temperature range below the characteristic temperature T_c , approximately equal to E_g/k . In insulators this region is generally equal to or greater than 10^3 K, and the room temperature conductivity is very small. For pure semiconductors, the characteristic temperature is equal to or greater than $T_c \geq 10^3$ K, and even here the room temperature conductivity is low (Figure 1). Because of the strong temperature dependence of the conductivity in semiconductors, a constant temperature must be maintained for stable operation of semiconductor devices. In such devices it is important to minimize any power flow and power loss that could cause heating effects, because these would greatly increase the number of carriers, ultimately resulting in avalanche breakdown, a phenomenon that is similar to breakdown processes occurring in the air during a thunderstorm to produce lightning.

CONDUCTION IN SEMICONDUCTORS AND INSULATORS

Conductivity in very pure semiconductors is characterized by extremely strong temperature dependence. As impurities are added, however, the temperature dependence of the carrier density becomes weaker; upon heavy doping with impurity atoms, the carrier density becomes essentially temperature independent, thus exhibiting semi-metallic behaviour.

To gain a better understanding of the effect of impurity atoms on electrical conductivity, it is instructive to take a more microscopic view of a solid and to inquire into the nature of chemical bonding. In this way the interactions of single ions with their neighbours can be examined, and the microscopic interactions can be related to the macroscopic properties of the material. Contrasting with this chemical view of matter is the physical approach, whereby the solid is considered as an immobile structure composed of units arranged in a precise geometric pattern that can be repeated in any direction to extend the structure infinitely. Such a structure is periodic, and this periodicity is exploited to describe the electronic behaviour.

Chemical approach. Perhaps the most powerful application of the chemical approach has been directed toward the question of which atoms and crystal structures favour the formation of insulators, semiconductors, and metals. The approach is well illustrated by the important semiconductors silicon and germanium, which are chemically related to the element carbon and the atoms of which have the same chemical bonding as do the carbon atoms in diamond crystal structure.

Each carbon, silicon, or germanium atom has four valence electrons. (By gaining, losing, or sharing valence electrons, atoms can bind with one another.) Because there are about eight valence states of about the same energy the valence shells of carbon, silicon, and germanium are only half filled. To occupy the four remaining empty states and fill up the shell, each atom shares one electron with each of four neighbouring atoms. Thus, silicon and germanium (like carbon) crystallize in the diamond structure, in which each atom is bound to its four nearest neighbours in a tetrahedral arrangement.

Bonding characterized by the sharing of an electron between neighbouring atoms is called covalent bonding. The covalent bonds in diamond are so strong that it is extremely difficult to remove an electron from any bond. It is the strength of covalent bonding between carbon atoms that accounts for the extreme hardness of diamonds. In germanium and silicon, however, the covalent bonds are weaker because the valence electrons are in shells that are farther from the nucleus than the valence shell of the carbon atom. In such cases it is relatively easy to promote an electron from a covalent bond into a conducting state, and much of semiconductor technology is concerned with controlling the number of broken bonds that can contribute electrons to the conduction process. Increasing the temperature provides thermal energy for breaking bonds, thereby freeing electrons for conduction purposes.

Addition of impurities. The periodic table of the elements is an invaluable aid in comparing their properties. In the table, the elements are arranged in a sequence according to increasing numbers of protons in their nuclei and a corresponding increase of electrons around the nuclei. Elements that this system places in the same vertical column, or group, are similar because they have similar electron structures. The elements carbon, silicon, germanium, and tin are in Group IV of the periodic table. Impurities from neighbouring Groups V or III can be introduced substitutionally into the diamond structure of these elements. While the presence of the impurities has little effect on the crystal structure, they profoundly affect electrical conductivity. For example, antimony (Sb), an element in Group V, has five electrons in the valence shell, one electron more than that needed to satisfy the covalent bonding requirement. When antimony is used as an impurity atom in silicon, only a small amount of energy is needed to liberate the extra electron, which is weakly bound to the positively charged antimony ion (Sb^+). Impurities that donate electrons to the conduction pro-

Tempera-
ture
effect

Chemical
bonding

cess are called donors; here, electrical conduction is by negatively charged carriers and the materials are called n-type.

On the other hand, indium (In), an element in Group III, has only three electrons in its valence shell, which means a one-electron deficiency relative to the covalent bonding requirement. Because the covalent bond is so strong when indium is used as an impurity atom in silicon, the electron deficiency in the indium atom can be satisfied by taking an electron from a covalent bond elsewhere in the material. The covalent bond that now lacks an electron is called a hole and acts like a positive charge; it is free to hop from covalent bond to covalent bond in the material. Impurities that receive electrons are called acceptors; thus, an effective positive charge, a p-type, has been introduced into the conduction process.

Because the impurity atoms in semiconductors and insulators tend to be relatively well isolated from each other, the chemical approach is particularly fruitful. For example, the chemical mass-action law (the rate of a chemical reaction depends on the concentrations of the reacting substances) can be applied to determine the degree of ionization of the impurity atoms and hence the carrier density in the semiconductor.

Compound semiconductors. Silicon, germanium, diamond, and gray tin form the Group IV semiconductors, so called because their atomic structure puts them into the fourth group, or column, of the periodic table. (Other forms of carbon and tin, such as graphite and white tin, do not act as semiconductors.) A class of closely related materials is the III-V compound semiconductors, in which one atom of an element from the third group of the periodic table is surrounded by four neighbouring atoms of an element from the fifth group of the periodic table and conversely, so that the number of atoms from each group is equal. By transferring an electron from a fifth-group atom to a third-group atom, each lattice site becomes occupied by an ion surrounded by four oppositely charged ions in a tetrahedral arrangement, with the electronic bonding similar to that of the diamond structure. Actually, however, the crystal structure for the III-V compound semiconductors is the zinc-blende structure, which is like the diamond structure except that nearest-neighbour atoms are of a different species. An example of a III-V semiconductor is gallium arsenide, in which the bonding is mainly covalent, though some ionic bonding, and therefore Coulomb attraction (the electrostatic attraction between oppositely charged particles), exists between the oppositely charged ions. Because covalent bonding dominates these compounds, they have semiconducting properties similar to the Group IV materials.

Hopping process. The chemical structure approach is useful not only for understanding compound semiconductors but also for explaining molecular solids, which include all solids of organic molecules as well as such materials as solid hydrogen, which has a hexagonal arrangement of hydrogen (H_2) molecules. In molecular solids the dominant conduction mechanism is the hopping of a single electron from one molecular complex to another. Because this process typically involves an activation energy, however, it is not an efficient conduction mechanism. Consequently, molecular solids tend to be poor conductors of electricity.

The hopping process is also an important conduction mechanism in ionic crystals. Here, however, the process involves either a lattice vacancy or an interstitial ion, rather than simply an electron. Just as in the case of electron hopping in molecular crystals, the hopping ions in ionic crystals must overcome a potential activation energy barrier by virtue of their thermal motion. The hopping barriers are lower for small ions than they are for larger ions; hence, a solid with small ions (e.g., H^+ ions in ice) will tend to have relatively higher ionic conductivity. The relative sizes of the ions are important in determining the barrier height. In photosensitive materials, such as silver bromide ($AgBr$), the barrier of the smaller positive silver ions (Ag^+) is much less than that of the larger negative ions (Br^-), a difference that is an essential ingredient in the photographic process.

Amorphous solid semiconductors. The chemical approach has also proven to be very effective in dealing with amorphous solids that do not exhibit any long-range periodic structure. Such solids are noted for their durability, their insensitivity to variations of temperature and pressure, and their insensitivity to the introduction of impurities, vacancies, and interstitial atoms. The most common example of an amorphous material is glass, which consists mostly of a random array of silicon dioxide (SiO_2) molecules as well as impurities. The crystalline form of pure silicon dioxide is quartz, a well-ordered structure. When the ordering is destroyed, a glass results, and some of the properties of the material are changed. For example, fused quartz, the amorphous version of quartz, has a much lower conductivity than crystalline quartz; the ultraviolet properties of fused quartz and crystalline quartz, however, are almost identical.

Physical approach. While the chemical approach is advantageous in studying the more complicated materials, such as molecular and amorphous solids, the physical approach is probably more advantageous in dealing with simple, highly ordered crystalline solids, thus leading to an understanding of semiconductors and insulators. A crystalline solid is conceived of as an infinite, perfectly periodic array of atoms. Initially, this point of view may seem more complicated than that of the chemical approach, in which only a few interacting atoms are considered; a great deal of progress can be made, however, by exploiting the symmetry of the periodic structure, especially the translational symmetry (the movement of a configuration to new coordinates without changing its symmetry) of the perfectly periodic array.

Energy bands and gaps. As a direct consequence of translational symmetry, the discrete energy levels of the free atom spread out to form two kinds of energy bands in the solid, valence bands and conduction bands. The valence bands are those occupied by electrons and the conduction bands are normally unoccupied. If the conduction bands of a semiconductor become partly filled by thermal excitation, the solid becomes conducting. For materials in which the electrons are tightly bound to the atoms, the width of the energy bands is sufficiently small for each band of energy levels to be separated from neighbouring bands by an energy gap. Whereas there are no available valence states in the energy gaps, the number of available states in each energy band would be completely filled if each atom would contribute exactly two electrons.

The result for the number of available states is of great consequence because of the Pauli exclusion principle (i.e., only one electron may occupy a particular energy state), and the result does, in fact, imply that every solid with an even number of electrons is an insulator, and every solid with an odd number is a metal.

The situation in actual solids is not quite so simple for several reasons. Band degeneracies (i.e., several levels with the same energy) occur because of rotational point symmetries (the configuration remains unchanged upon performing a rotation) in the crystal structures. Such band degeneracies characteristically are present in the bands associated with the valence electrons of semiconductors that have the diamond and zinc-blende crystal structure. A second complication, prevalent in semimetals and metals, is the overlapping of neighbouring energy bands. Overlapping arises when the energy that binds electrons to their ion cores becomes weaker, causing electrons to move farther away, thus increasing the band widths and, consequently, decreasing the band gaps from a finite value to zero and, finally, to the overlapping condition. A third complication is associated with the complex arrangement of atoms within the solid. For example, the concept of band occupation given above indicates that solid hydrogen should be a metal (a hydrogen atom has only one electron, an odd number), whereas the solid is actually an insulator consisting of a hexagonal lattice of hydrogen (H_2) molecules. There is, however, a high-pressure phase of solid hydrogen that is metallic, because when the distance between interacting molecules is reduced, the crystal structure changes, with a resulting change in the electrical conductivity.

cies

Ionic
crystal
conduction

It is also possible to form, from the same atom, solids with different electrical properties depending on their crystal structure, a striking example being tin. White tin crystallizes in a tetragonal arrangement and is a high-conductivity metal, while gray tin is a covalently bonded semiconductor crystallizing in the diamond structure. In the case of tin, certain partly filled energy levels (p levels) of the free atom become conduction bands for metallic white tin, whereas the greater symmetry of the diamond structure of gray tin results in a splitting of the p bands into filled bonding and empty antibonding states, thus giving rise to semiconducting behaviour.

Theoretical approximations. The physical approach to the electronic properties of solids uses the translation symmetry of the periodic structure to establish the existence of valence and conduction energy bands. The detailed treatment of energy bands, however, is an exceedingly difficult matter and can be carried out only in an approximate way. Much of the theoretical work results in equations that employ only a small number of factors determined by experiment. Among these factors are the energy gap, which separates the occupied valence states from the empty conduction states, and the effective mass, which describes the dynamic motion of electrons in a solid. By introducing the effective mass concept, it is possible to treat the electrons in a solid as free electrons that possess a mass different from the free-electron mass. The effective mass approximation, whereby the effect of the periodic lattice is taken into account by introducing an effective mass, is extremely useful in dealing with many of the physical phenomena in semiconductors and insulators.

Effective
mass of
electrons

The lattice. The lattice, however, cannot be completely ignored. The atoms of the lattice are in a state of constant vibration, and the characteristic, or normal, mode frequencies of these lattice vibrations have been studied extensively for semiconductors and insulators. The number of normal modes of vibration is completely determined by the crystal structure and the number of atoms per unit cell. For example, in the diamond structure there are three acoustic (sound) modes and three optical (light) modes. The characteristic frequencies of lattice vibrations are determined by a variety of experimental techniques.

Lattice vibrations have an important influence on electrical conductivity because they provide the dominant scattering mechanism for solids at room temperature. In the scattering process, the energy of the electrons is either increased or decreased by the characteristic energies of the lattice. The conduction electrons contribute to both the electrical conductivity and the thermal conductivity of solids. Metals are characteristically good conductors of both heat and electricity, whereas electrical insulators are also typically good thermal insulators.

Statistical properties. The physical approach to solids uses the translational symmetry associated with the periodic lattice to establish the characteristic vibrational frequencies for the lattice. The physical view also exploits the statistical properties of a large ensemble of particles to determine such fundamental properties as the carrier densities of solids. Like electrons, ensembles of particles obey the Pauli exclusion principle, and the statistical behaviour of such ensembles is described by the Fermi-Dirac distribution function, $f(E)$, which expresses the probability that a given state of energy E will be occupied at temperature T . This relationship can be expressed by the following equation, in which the Fermi energy, or chemical potential, is symbolized by the Greek letter zeta, ζ , and k is Boltzmann's constant:

$$f(E) = [1 + \exp \{(E - \zeta)/kT\}]^{-1}.$$

The significance of the Fermi energy (ζ) is that, at $T = 0^\circ \text{K}$, all the states up to energy ζ are completely occupied, while those above energy ζ are completely empty. At higher temperatures a fraction of the states above the Fermi energy will be occupied and, consequently, some states below ζ will be empty in accordance with the distribution function $f(E)$. The distribution function can be applied directly to metals to find, at a given tempera-

ture, the number of excited electrons above the Fermi energy; such excited electrons are directly responsible for the electronic contribution to the specific heat of metals and for the electronic Pauli paramagnetism (permanent magnetism) of metals.

In applying the Fermi-Dirac distribution to semiconductors, it is necessary to take into account the presence of an energy gap above the valence bands that is forbidden to electron states. For pure semiconductors, at temperature equal to 0°K (-273°C or -460°F), the states below the energy gap are completely occupied, those above are completely empty, and the Fermi energy lies within the band gap. If the energy gap is small compared with the product of Boltzmann's constant and temperature, kT , then the Fermi-Dirac distribution function implies that the thermal energy will be strongly effective in exciting electrons into conduction states located in the conduction band. For every electron that is excited into a conduction state, an unfilled valence state is created in the valence bands; unfilled states are called holes and, for conduction purposes, behave very much like positive charges with masses comparable to electron masses.

Holes

For typical semiconductors, such as germanium and silicon at room temperature, the energy gap is very much greater than thermal energies, so that only a few thermally excited carriers are present. In this limit, the temperature dependence of the carrier concentration for both electrons and holes is exponential and of the form $N = N_0 \exp(-E_g/2kT)$, as explained above under **Activation energy**. Both the excited electrons and the holes that are left behind contribute to the conduction process, and for a semiconductor of high purity they are the predominant current carriers at room temperature.

Nonconducting states. The physical approach to solids is also useful in treating certain nonconducting excited states in semiconductors that are associated with the attraction of an electron to the hole that it has left behind. Such states, which are commonly called excitons, either lie below the internal ionization energy of the solid or lie within the energy gap, just below the conducting states. An exciton can be transferred from one lattice site to another by a hopping mechanism. Excitons are generally more important in semiconductors and insulators with large band gaps, such as ionic crystals, than in those with small band gaps, although weak exciton effects have been observed in the latter. Because the exciton does not obey Fermi-Dirac statistics whereas the electron does, it is not possible to obtain a filled band of excitons. The Coulomb attraction of the exciton is in many ways suggestive of the attraction of the electron to the hydrogen ion in the hydrogen atom or of the electron to the positron (a negatively charged electron) in positronium (a short-lived system containing an electron and positron that revolve around a common centre). Theoretical treatments of excitons based on models similar to the hydrogen atom or to positronium have been very successful in explaining many of the characteristic properties of excitons.

Excitons

Nonconducting states within the energy gap are also created by the presence of impurities. Because the free charges associated with impurities tend to screen the attraction between the electron and the hole associated with it, however, the exciton levels are generally observed in materials of higher purity than are desirable for the study of impurity levels.

Extrinsic and intrinsic semiconductors. From the physical point of view, shallow impurity levels in a solid (impurities that have a potential not too different from the host atoms) are generally treated by using models based on a hydrogen-like atom with an electron of effective mass. Impurity levels, unlike states within the conduction and valence bands, tend to be sharp, or discrete; in the simplest cases, the discrete donor (excess electron) levels lie just below the conduction band minimum, while the acceptor (deficiency of electrons) levels lie just above the valence band. Because these levels are easily ionized to create electrons or holes in conducting states, impurities provide a ready source of charged carriers for electrical conduction.

When conduction is dominated by impurity mecha-

nisms, the semiconductor is called extrinsic, in contrast with intrinsic semiconductors, in which conductivity is mainly associated with the thermal excitation of carriers. An extrinsic semiconductor is generally classified as n- or p-type, depending on whether the impurity has an excess of negative charge (n-type) or a deficiency of negative charge (p-type). Under some circumstances, an intrinsic semiconductor can also be classified as n-type or p-type, because the mobility of the electrons and holes may be quite different although their carrier densities are closely equal. In such cases the conduction process itself is dominated by the carriers with the highest mobility.

Measurement of conductivity. A direct measurement of the carrier concentration in a semiconductor is obtained from a phenomenon, called the Hall effect after its discoverer, which makes use of the deflection of the electric current by a transverse direct-current magnetic field. The Hall measurement provides both the sign and concentration of the carriers. A separate measurement of the conductivity allows one to calculate the mobility of the carriers. Because these factors are so important for the characterization of semiconductors, conductivity and Hall-effect measurements are routinely carried out at room temperature and at liquid nitrogen temperature (77° K or -196° C, -321° F) when semiconducting crystals are produced. The temperature dependence of carrier density helps to determine whether the semiconductor is intrinsic or extrinsic.

The conductivity or resistivity of a solid is itself dependent on the magnitude and direction of the magnetic field relative to the current flow. This magnetoresistance effect is associated with the curling up of the electron trajectories in the magnetic field, thereby decreasing the mean free path (the average distance that a particle travels between successive collisions) of the carriers. Such experiments yield valuable information on the directional dependence (anisotropy) of the effective masses of the carriers.

The most direct information, however, on the effective mass for electrons and holes in semiconductors is provided by a cyclotron resonance experiment in which the charged particles can be considered to execute closed orbits in a plane perpendicular to the magnetic field. The experiments establish that the electrons in germanium have an effective mass that is approximately ten times smaller than the free-electron mass; even smaller effective masses have been found in other small-gap semiconductors.

Measurement of energy gaps. The other dominant parameter (a constant, in equations, to which any desired value can be given) that characterizes semiconductors and insulators is the band gap separating the valence states from the conduction states. The most direct measurement of this energy gap involves the excitation of an electron in a valence state to a state in the conduction band through the absorption of a photon (a discrete unit of light energy). The process, called the internal photoelectric effect (the action by which a substance emits free electrons as a result of absorbing light energy), is closely related to the photoelectric effect at a metallic surface. The energy gap is determined as the threshold for the onset of the photoelectric process and typically occurs at infrared or optical frequencies. Optical spectral techniques also provide a powerful tool for the study of discrete exciton and impurity states. The optical excitation of carriers is also exploited in a variety of photoconductive detectors, which are characterized by fast response, high sensitivity, and availability over a wide range of infrared and optical frequencies.

PRINCIPLES OF SEMICONDUCTOR APPLICATIONS

Photographic process. Perhaps the most common application of the photoelectric effect is in the photographic process. Although this process has been studied extensively for many years, the detailed mechanism is not yet completely understood. Photographic film contains small crystallites of silver salts, such as silver bromide or silver iodide, which are darkened when exposed to light and subsequently developed. The initial exposure to light sets

the image in the photographic process; it is associated with the following mechanism.

The incident light frees an electron, which becomes trapped at some impurity site (*e.g.*, thallium). The silver ions, which have a relatively high mobility, diffuse through the lattice and migrate to those sites where the electrons have been trapped. At one of these sites the silver ion becomes neutralized, forming a neutral silver atom and thereby restoring the impurity site to its original state. In this way each impurity site can collect several neutral silver atoms, forming a collection of silver particles called the latent image. When the film is developed, the small silver particles in the latent image grow, and finally the silver salts that are in the ionic form are washed out, retaining the colloidal silver particles. In colour photography a separate image is formed for each of the three primary colours, red, green, and blue.

Luminescence. Also occurring in semiconductors and insulators is a process inverse to the photoelectric effect, one in which the recombination of an electron with a hole or with an impurity centre results in the emission of a photon. The effect, which is called luminescence, is essential in many devices using semiconductors and insulators; for example, a laser is a device that emits light by virtue of releasing radiation stored by creating electron and hole pairs.

Luminescence is also basic to the operation of scintillation counters, which are so important in detecting and measuring high-energy particles. In these devices a high-energy gamma ray (photons with frequencies much higher than visible light) is made to produce a larger number of photons in the visible range (photons with much lower frequencies). The mechanism for such photon production is as follows: the high-energy gamma ray generates very energetic electrons and holes that rapidly become degraded by collisions with other electrons; thus, when a highly energetic gamma ray is absorbed by an insulating material, such as sodium iodide (NaI), it effectively produces a large number of excited electrons, which, in turn, can recombine with an impurity centre or a hole by a luminescent process to produce many photons of visible light, which are then detected optically.

Hot-electron effects. Another property of semiconductors and insulators that has great practical significance is the nonlinear response (*i.e.*, nonproportionality) of the current flow to the applied electric field. For small electric fields the current flow is directly proportional to the applied electric field, and the electrical conductivity (the proportionality constant) is independent of the magnitude of the applied field. For sufficiently large electric fields, however, the conductivity itself can become dependent on the field, either increasing with increasing electric field (giving rise to avalanche effects), or decreasing, or even becoming negative. Nonlinear effects in semiconductors and insulators are sometimes called hot-electron effects because they involve a nonlinear dependence of the Fermi-Dirac distribution function on the applied electric field.

Avalanche breakdown, or sparking, is a common hot-electron effect in insulators. In the presence of a sufficiently large electric field, a conduction electron can pick up enough energy in a mean free path to induce ionization in the solid. With this mechanism for the creation of additional carriers, the current flow can increase catastrophically and the concomitant local heating can result in actual physical damage to the material. Similar avalanche processes occur in gases and are responsible for the operation of such devices as Geiger counters.

Practical devices are also based on hot-electron effects that result in a decrease in current flow with increasing applied electric field. Such a nonlinear effect (the Gunn effect) was discovered in gallium arsenide (GaAs) by a British-United States physicist, John B. Gunn, in 1963 and is the basis for the Gunn oscillator, which supplies large quantities of power at microwave frequencies. In such nonlinear semiconductors, small electric fields excite carriers into high-mobility conduction states; but above a certain threshold field, excitation into low-mobility states becomes energetically possible. With increasing electric

Hall
effect

Avalanche
break-
down

fields, the low-mobility states are occupied with increasing probability, and a decrease in conductivity results. This negative conductivity is basic to the operation of the Gunn oscillator.

Junction effects. Solid-state devices can make use of either bulk effects or junction effects. (Some typical examples of bulk-effect devices are Gunn oscillators, photoconductors, and ruby lasers.) Junctions exist between different semiconductors, or between semiconductors and metals, and are particularly important in devices based on a single junction.

When two dissimilar materials (in semiconductor electronics the most common are silicon, germanium, and gallium arsenide) are placed in contact, there will be a net flow of electrons from one material to the other until the Fermi levels or chemical potentials of the two materials are equal. Thus, in equilibrium, it is possible to take an electron across the junction between the two materials without the expenditure of any energy. In equilibrium there is no net current across the junction, and the hole current is equal and opposite to the electron current.

Perhaps the most common junction is the p-n junction, which is formed by contact between n-type and p-type samples of the same material. In the immediate neighbourhood of the junction there is a depletion layer, a region in which the carrier concentration is low, reflecting the fact that there are no allowed conduction states at the Fermi energy in this region of the crystal (see Figure 2B). In the depletion layer the electrons must tunnel (pass through at very high speeds) to overcome the potential barrier associated with the contact potential. For practical applications of p-n junctions it is important that the junctions be kept narrow and that their physical characteristics be carefully controlled.

From S.M. Sze, *Physics of Semiconductor Devices* (1969): John Wiley & Sons, Inc

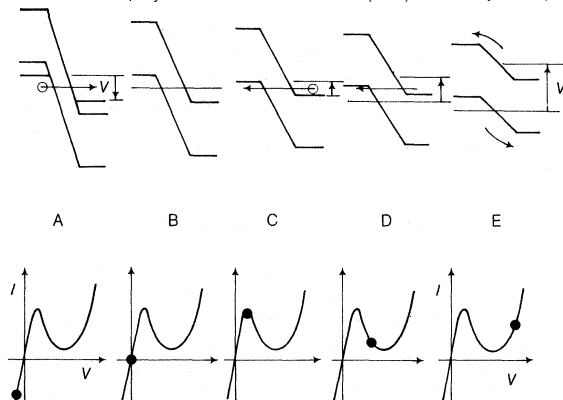

Figure 2: Simplified energy-band diagrams of tunnel diode at: (A) Reverse bias. (B) Thermal equilibrium. (C) Forward bias such that peak current is obtained. (D) Forward bias such that the valley current is approached. (E) Forward bias with thermal current flowing (see text).

The properties of the junction can be altered by superimposing a voltage across it or by modifying the junction characteristics (for example, the width). The effect of an external bias on a p-n junction is illustrated in Figure 2. Application of a reverse bias (Figure 2A) produces a large reverse current, which is illustrated by the dot directly below the I-V (ampere-voltage) curve. The reverse bias increases the potential of the p-type region relative to the n-type region, and conversely the forward bias increases the potential of the n-type region relative to the p-type region. Application of a forward bias (Figures 2C, 2D, 2E) eventually leads to a dramatic decrease in current or a negative conductivity as the number of available states vanish (Figure 2D). Other mechanisms, for example photon- or phonon-assisted tunnelling, provide some current for biasing voltages. Furthermore, by application of an extremely large forward bias, large currents once again become possible (Figure 2E).

A semiconductor in contact with a metal also forms a barrier with carriers removed, on the semiconductor side of the barrier. These junctions are important as rectifying

contacts and operate in the following manner: because the semiconductor effectively lowers the work function (energy needed to eject an electron) of the metal, electrons can be pulled out of the metal and into conducting states of the semiconductor with the application of reasonably small electrical fields. The reverse bias, however, does not produce currents, because the filled levels of the semiconductor are below the Fermi level of the metal.

In addition to rectifying contacts, it is also possible to produce internal photoemission with a semiconductor-metal junction. The light can be incident on the junction, either through the semiconductor (it must be of low frequency so that bulk absorption does not occur) or directly onto the very thin metal coating that covers the semiconductor. In either arrangement, internal photoemission occurs at a lower threshold than for a metal-vacuum interface. The threshold can also be changed by the application of an external potential across the junction.

The internal photoemission process is basic to the operation of a solar cell, which consists of a p-n junction covering the entire external surface of a semiconductor. Light is absorbed in the p-n junction, creating a potential difference that in turn gives rise to a tunnelling current. Thus, the light is converted directly into electrical energy. The experimental conversion efficiency for the process is about 10 percent. Because solid-state electronics is widely used in space satellites, solar cells provide adequate power for the necessary circuitry.

A p-n junction not only can convert light into electrical energy but can also accomplish the inverse process; that is, convert electrical energy directly into light. The emitted radiation, which is produced by the recombination of holes and electrons that have been injected into the junction region by application of a forward bias, has a frequency characteristic of the energy gap. By polishing crystal faces on either side of a p-n junction, a resonant optical cavity, or Fabry-Perot interferometer, is formed from which the recombination radiation can be emitted coherently—that is, the emitted waves are in phase (in step) with each other—thereby producing laser action. Semiconducting diode lasers are of very small size and typically operate at an infrared frequency between 0.04 and two electron-volts, depending on the material. The tuning of a particular laser frequency is accomplished either by temperature variation or by application of an external magnetic field or mechanical stress.

Pressure effects. Application of pressure results in a lattice deformation, which changes the lattice constant and hence the energy gap of the semiconductor; this mechanism is essentially that behind the pressure tuning of lasers. The same kind of mechanical deformation can also greatly influence the electric conductivity of a solid, and the resulting current flow gives rise to piezoelectric effects, the production of electric charges when certain crystals are deformed by mechanical stress, or, conversely, the deformation of a crystal caused by the application of a voltage. This conversion of mechanical motion into an electric current is exploited in such practical devices as phonograph pickups and sonar detectors. Piezoelectric materials that are used for such applications typically have a strong coupling between the electronic band structure and the characteristic modes for the lattice vibrations. An important class of piezoelectric materials are the ferroelectrics (ionic crystals in which the molecules are aligned with one another), such as barium titanate.

Magnetic effects. Magnetism can occur in both insulators and semiconductors. Salts of nickel, cobalt, and iron, and of other atoms with partly filled d-shells (shells in which ten electrons are allowed) in the free atom, form insulating crystals with a variety of magnetic properties. Furthermore, oxides and sulfides of various rare-earth atoms form magnetic semiconductors. Among the many practical applications of magnetic insulators are magnetic memory cores in computers and magnetic gyrators for microwave devices.

Thermoelectric effects. Semiconductors also have proved to be among the most useful materials for the production of devices based on thermoelectric power

Semiconductor and metal junctions

The p-n junction

conversion. The **Seebeck** effect, discovered in 1821, represents a means of converting heat energy directly into electrical energy, whereas the **Peltier** effect (1834) represents a means of using electrical energy for refrigeration. Practical devices based on these two effects make use of a junction between two dissimilar conductors. For thermoelectric generation (**Seebeck** effect), a potential difference is set up across a junction when it is heated. In thermoelectric refrigeration (**Peltier** effect), cooling of a junction results when a current is passed through it. A current passing down a wire or through a junction represents the transport of both charge (electric current) and kinetic energy (heat current). **Lattice-thermal** conduction provides a mechanism for curtailing the temperature difference established by the flow of kinetic energy. The presence of p- and n-type materials on either side of a p-n junction provides high-mobility carriers of opposite sign, which act to enhance thermoelectric generation. The p-n junctions in the semiconductors lead telluride (**PbTe**) and bismuth telluride (**Bi₂Te) have been found to be among the best materials for thermoelectric refrigeration. Although these devices have not replaced mechanical refrigerators for economic reasons, they can be effectively applied in situations that exploit their small size and weight, such as outer-space travel.**

Sammelweis, Ignaz Philipp

Sammelweis, who has been called "the saviour of mothers" for his discovery of the cause of puerperal fever, also introduced antiseptic prophylaxis and thus opened a new era in medical science.

BY courtesy of the Semmelweis Medical Historical Museum and Library, Budapest

Sammelweis, detail of an oil painting by A. Canzi, 1857. In the Semmelweis Medical Historical Museum and Library, Budapest.

He was born in Buda, Hungary, on July 1, 1818. Educated at the Universities of Pest and Vienna, he received his doctor's degree from Vienna in 1844 and was appointed assistant at the obstetric clinic in Vienna. He soon

became involved in the problem of childbed fever, or puerperal infection, the scourge of maternity hospitals throughout Europe. Although most women delivered at home, those who had to seek hospitalization because of poverty, illegitimacy, or obstetrical complications faced mortality rates ranging as high as 25–30 percent. Some thought that the infection was induced by overcrowding, poor ventilation, the onset of lactation, or "miasma." Semmelweis proceeded to investigate its cause over the strong objections of his chief, who, like other continental physicians, had reconciled himself to the idea that the disease was unpreventable.

Sammelweis observed that among women in the first division of the clinic, the death rate from childbed fever was two or three times as high as among those in the second division, although the two divisions were identical with the exception that students were taught in the first and midwives in the second. He put forward the thesis that perhaps the students carried something to the patients they examined during labour. The death of a friend from a wound infection incurred during the examination of a woman who died of puerperal infection and the similarity of the findings in the two cases gave support to his reasoning. He concluded that students who came directly from the dissecting room to the maternity ward carried the infection from mothers who had died of the disease to healthy mothers. He ordered the students to wash their hands in a solution of chlorinated lime before each examination.

Under these procedures, the mortality rates in the first division dropped from 18.27 percent to 1.27 percent, and in March and August of 1848 no woman died in childbirth in his division. The younger medical men in Vienna recognized the significance of Semmelweis' discovery and gave him all possible assistance. His superior, on the other hand, was critical—not because he wanted to oppose him but because he failed to understand him.

In the year 1848 a liberal political revolution swept Europe, and Semmelweis took part in the events in Vienna. After the revolution had been put down, Semmelweis found that his political activities had increased the obstacles to his professional work. In 1849 he was dropped from his post at the clinic. He then applied for a teaching post at the university in midwifery but was turned down. Soon after that, he gave a successful lecture at the Medical Society of Vienna entitled "The Origin of Puerperal Fever." At the same time, he applied once more for the teaching post, but although he received it, there were restrictions attached to it that he considered humiliating. He left Vienna and returned to Pest in 1850.

He worked for the next six years at the St. Rochus Hospital in Pest. An epidemic of puerperal fever had broken out in the obstetrics department, and at his request, Semmelweis was put in charge of the department. His measures promptly reduced the mortality rate, and in his years there it averaged only 0.85 percent. In Prague and Vienna, meantime, the rate was still from 10 to 15 percent.

In 1855 he was appointed professor of obstetrics at the University of Pest. He married, had five children, and developed his private practice. His ideas were accepted in Hungary, and the government addressed a circular to all district authorities ordering the introduction of the prophylactic methods of Semmelweis. In 1857 he declined the chair of obstetrics at the University of Zürich. Vienna still remained hostile toward him, and the editor of the *Wiener Medizinische Wochenschrift* wrote that it was time to stop the nonsense about the chlorine hand wash.

In 1861 Semmelweis published his principal work, *Die Ätiologie, der Begriff und die Prophylaxis des Kindbettfiebers*. He sent it to all the prominent obstetricians and medical societies abroad, but the general reaction was adverse. The weight of authority stood against his teachings. He addressed several open letters to professors of medicine in other countries, but to little effect. At a conference of German physicians and natural scientists, most of the speakers—including the pathologist Rudolf Virchow—rejected his doctrine. The years of controversy gradually undermined his spirit. In 1865 he suffered a

Early interest in childbed fever

Publication of his major work

breakdown and was taken to a mental hospital, where he died on August 13, 1865. Ironically, his illness and death were caused by the infection of a wound on his right hand, apparently the result of an operation he had performed before being taken ill. He died of the same disease against which he had struggled all his professional life.

Semmelweis' doctrine was subsequently accepted by medical science. His influence on the development of knowledge and control of infection was hailed by Joseph Lister, the father of modern antisepsis: "I think with the greatest admiration of him and his achievement and it fills me with joy that at last he is given the respect due to him."

BIBLIOGRAPHY. The first comprehensive biography of Semmelweis was SCHUERER VON WALDHEIM, *Ignaz Philipp Semmelweis* (1905). A recent work by G. GORTVAY and I. ZOLTÁN, *Semmelweis élete és munkássága* (1966; Eng. trans., *Semmelweis: His Life and Work*, 1968), is critical of some of the romantic legends that have grown up around him.

(I.Z.)

Seneca

Lucius Annaeus Seneca, orator, tragedian, stylist, philosopher, statesman, and multimillionaire, was the leading intellectual figure in Rome in the middle of the 1st century AD. In the first phase of Nero's reign (AD 54–62) he and his friends virtually ruled the Roman world, giving a period of (relatively) good government. In his 40 surviving books the thoughts of a versatile but unoriginal mind are expressed and amplified by the resources of an individual style, brief, pointed, rhetorical, and epigrammatic. Their influence on later European culture has been pervasive but subject to fluctuation. So has Seneca's reputation; scholars have been and are divided on his merits as a writer and as a man.

By courtesy of the Staatliche Museen zu Berlin

Seneca, marble bust, 3rd century, after an original bust of the 1st century. In the Staatliche Museen, Berlin.

The problem of reconciling the gap between moral principles and political conduct is unrealistic. Seneca's thought evolved; Nero's autocracy degenerated. Seneca could justly say, at the end of his life, "I point out to others the right way, which I have learned late, and tired out with wandering." As tutor and adviser of princes, his record appears to be better, on a larger scale, than that of Plato or Aristotle. On the other hand, his wealth is not easily condoned by his plea that neither poverty nor opulence affect the philosopher, for it derived from estates (property in Rome, vineyards in Campania, an estate in Egypt, doubtless others), whose profits went into usury. A story that his action in recalling his loans precipitated the rebellion of Boudicca in Britain is first found in the *Roman History* of Dio Cassius, written in the 3rd century.

Seneca, second son of a wealthy family, was born about 4 BC at Corduba in the romanized province of Baetica. The father Lucius Annaeus Seneca (Seneca the Elder) had been famous in Rome as a teacher of rhetoric: the

mother Helvia was of excellent character and education: the older brother was Gallio, met by St. Paul in Achaia in AD 52: the younger brother was the father of the poet Lucan. An aunt took Lucius as a boy to Rome; there he was trained as an orator and educated in philosophy in the school of the Sextii, which blended Stoicism with an ascetic neo-Pythagoreanism. Seneca's health suffered, and he went to recuperate in Egypt, where his aunt was now the wife of the prefect, Gaius Galerius. Returning to Rome about the year 31, he began a career in politics and law. Soon he fell foul of the emperor Caligula, who was deterred from killing him only by the argument that his life was sure to be short.

In 41 the emperor Claudius banished him to Corsica on a charge of adultery with the princess Julia Livilla, the emperor's niece. In that uncongenial milieu he studied natural science and philosophy and wrote the three treatises entitled *Consolationes*. The influence of Agrippina, the emperor's wife, had him recalled to Rome in 49. He became praetor in AD 50, married Pompeia Paulina, a wealthy woman, built up a powerful group of friends, including the new prefect of the guard Sextus Afranius Burrus, and became tutor to the future emperor Nero.

The murder of Claudius in 54 pushed Seneca and Burrus to the top. Their friends held the great army commands on the German and Parthian frontiers. Nero's first public speech, drafted by Seneca, promised liberty for the Senate and an end to the influence of freedmen and women. Agrippina, Nero's mother, was resolved that her influence should continue; and there were other powerful enemies. But Seneca and Burrus, provincials from Spain and Gaul, understood the problems of the Roman world. They introduced fiscal and judicial reforms and fostered a more humane attitude toward slaves. Their nominee Corbulo defeated the Parthians; in Britain a more enlightened administration followed the quashing of Boudicca's rebellion. But as Tacitus, the historian (c. 56–117), says, "Nothing in human affairs is more unstable and precarious than power unsupported by its own strength." Seneca and Burrus were a tyrant's favourites. In 59 they had to condone—or to contrive—the murder of Agrippina. When Burrus died in 62 Seneca knew that he could not go on. He received permission to retire, and in his remaining years he wrote some of his best philosophical works. In 65, Seneca's enemies denounced him as having been a party to the conspiracy of Piso. Ordered to commit suicide, he met death with fortitude and composure.

The *Apocolocyntosis divi Claudii* (*The Pumpkinification of the Divine Claudius*) stands apart from the rest of Seneca's surviving works. A political skit, witty and unscrupulous, its theme is the deification—or "pumpkinification"—of Claudius. The rest divide into philosophical works and the tragedies. The former expound an eclectic version of "Middle" Stoicism, adapted for the Roman market by Panaetius of Rhodes (2nd century BC), and developed by his compatriot Poseidonius in the 1st century BC. Poseidonius lies behind the books on natural science, *Naturales quaestiones*, where lofty generalities on the investigation of nature are offset by a jejune exposition of the facts. Of the *Consolationes*, *Ad Marciam* consoles a lady on the loss of a son; *Ad Helviam matrem*, Seneca's mother on his exile; *Ad Polybium*, the powerful freedman Polybius on the loss of a son but with a sycophantic plea for recall from Corsica. The *De ira* deals at length with the passion of anger, its consequences, and control. The *De clementia*, an exhortatory address to Nero, commends mercy as the sovereign quality for a Roman emperor. *De tranquillitate animi*, *De constantia sapientis*, *De vita beata*, *De otio*, consider various aspects of the life and qualities of the Stoic wise man. *De beneficiis* is a diffuse treatment of benefits as seen by giver and recipient. *De brevitate vitae* demonstrates that our human span is long enough if time is properly employed—which it seldom is. Best written and most compelling are the *Epistulae morales*, addressed to Lucilius. Those 124 brilliant essays treat a range of moral problems not easily reduced to a single formula.

Of the 10 "Senecan" tragedies, *Octavia* is certainly, and *Hercules Oetaeus* is probably, spurious. The others han-

Philosophical works and tragedies

dle familiar Greek tragic themes, with some originality of detail. Attempts to arrange them as a schematic treatment of Stoic "vices" seem too subtle. Intended for playreadings rather than public presentation, the pitch is a high monotone, emphasizing the lurid and the supernatural. There are impressive set speeches and choral passages; but the characters are static, and they rant. The sole representatives of classical tragedy known to the Renaissance world, these plays had a great influence, notably in England. Shakespeare's *Titus Andronicus*, John Webster's *The Duchess of Malfi*, and Cyril Tourneur's *Revenge's Tragedie*, with their ghosts, witches, cruel tyrants, and dominant theme of vengeance, are the progeny of Seneca's tragedies.

Stature
and
influence

Hostile propaganda pursued Seneca's memory. Quintilian, 1st-century rhetorician, criticized his educational influence; Tacitus was ambivalent on Seneca's place in history. But his views on monarchy and its duties contributed to the humane and liberal temper of the age of the Antonines (Antoninus Pius, Marcus Aurelius, and Commodus; AD 138–192). Meanwhile, the spread of Stoicism kept his philosophy alive: new horizons opened when it was found to have Christian affinities. There was a belief that he knew St. Paul, and a spurious collection of letters to substantiate it. Studied by Augustine and Jerome, he consoled Boethius in prison. His thought was a component of the Latin culture of the Middle Ages, often filtered through anthologies. Known to Dante, Chaucer, and Petrarch, his moral treatises were edited by Erasmus; the first complete English translation appeared in 1614. In the 16th to 18th centuries Senecan prose, in content and style, served the vernacular literatures as a model for essays, sermons, and moralizing. Calvin, Montaigne, and Rousseau are instances. As the first of "Spanish" thinkers, his influence in Spain was always powerful. Nineteenth-century specialization brought him under fire from philosophers, scientists, historians, and students of literature. But recent scholarly work and the interest aroused by the bimillenary commemorations of his death in Spain in 1965 suggest that a Senecan revival may be under way.

MAJOR WORKS

PHILOSOPHICAL TREATISES: *Dialogi* (Eng. trans., "Loeb Series," 2 vol., 1917) comprising: *Ad Marciam de consolatione* (AD 40; Consolation to Marcia); *Ad Helviam matrem de consolatione* (c. AD 42; Consolation to Helvia); *Ad Polybium de consolatione* (c. AD 42; Consolation to Polybius); *De providentia* (?AD 41–42; On Providence); *De constantia sapientis* (after AD 47; On the Constancy of the Wise Man); *De ira* (after AD 42; On Anger); *De otio* (?AD 63–65; On Leisure); *De tranquillitate animi* (?AD 63–65; On Tranquillity of Mind); *De brevitate vitae* (?AD 55; On the Shortness of Life); *De clementia* (AD 55–56; On Mercy); *De vita beata* (? c. AD 58–59; On the Happy Life); *De beneficiis* (after AD 56; On Benefits). *Epistulae morales ad Lucilium* (AD 63–65; Eng. trans. by R.M. Gummere, "Loeb Series," 3 vol., 1917–25); *Naturalis quaestiones* (AD 63–65; Eng. trans. by A. Geikie and J. Clarke, 1910).

SATIRE: *Apocolocyntosis divi Claudii* (c. AD 54; The Pumpkinification of Claudius, 1951).

TRAGEDIES: all dates unknown—*Phaedra*; *Troades*; *Thyestes*; *Phoenissae*; *Medea*; *Oedipus*; *Agamemnon*; *Hercules furens*; *Hercules Oetaeus* (? not Senecan); *Octavia* (not Senecan)—Eng. trans. by F.J. Miller, *Seneca's Tragedies*, "Loeb Series," 2 vol., 1917.

BIBLIOGRAPHY

Texts and commentaries: (*Dialogi*): A. BOURGERY and R. WALTZ, 4 vol. (1922–42). (*Epistulae morales*): L.D. REYNOLDS, 2 vol. (1965), an excellent edition. (*Naturalis quaestiones*): P. OLTRAMARE, 2 vol. (1929).

General works: No full-length definitive study of Seneca exists in English. C.W. MENDELL, *Our Seneca* (1941), is good on Seneca the writer. R. WALTZ, *Vie de Sénèque* (1909); and P. GRIMAL, *Sénèque* (1948), are also useful. A.L. MOTTO, *Seneca Sourcebook* (1970), is a guide to Seneca's thought as reflected in his extant prose works; F.L. LUCAS, *Seneca and Elizabethan Tragedy* (1922), is a good introduction to the subject, although written before recent advances in Senecan studies. Comprehensive surveys of recent scholarship include A.L. MOTTO in *Classical World*, 53:13–18, 37–48, 70–71 (1960), addenda, 54:111–112 (1961), and 74:147–158, 177–191 (1971), on the prose works; and M. COFFEY in *Lustrum*, 2:113–186 (1957), on the tragedies.

(D.R.D.)

Senegal

Situated at the western extremity of Africa's tropical zone, the Republic of Senegal (*République du Sénégal*) has an area of 78,684 square miles (203,793 square kilometres), and a population of about 3,755,000 people. It is bounded to the north and to the northeast by the *Sénégal* River, which separates it from Mauritania; to the east by the *Falémé*, a tributary of the *Sénégal* River, which separates it from the Mali; to the south by Guinea and Portuguese Guinea (Guinea Bissau); and to the west by the Atlantic Ocean. The Gambia constitutes a finger of territory 20 miles wide and 200 miles long that thrusts from the coast eastward deep into Senegal.

Senegal—which gained its independence in 1960, first as part of the short-lived Mali Federation and then as a sovereign state in its own right—is among the principal peanut- (groundnut-) producing countries of the world; its light soils and its climate are particularly well suited to this crop. While food crops such as millet are important, the entire economy of Senegal in fact depends literally on its peanut exports. The economy itself is operated in the spirit of "African socialism" of which the Senegalese government is one of the foremost champions; while it is a planned economy, the moderate controls to which it is subjected are applied in an indicative rather than an authoritarian manner. Private investors, whether foreign or Senegalese nationals, are encouraged to establish new enterprises; an investment code grants tax exemptions and permits the withdrawal of profits. Nationalization has been avoided except for the marketing of agricultural products, for which the state has created the Office de Commercialisation Agricole (Agricultural Marketing Board), which conducts marketing operations for the international business companies active in the country. The economic life of Senegal is characterized by its adherence to the franc currency zone, as a result of which the country benefits from French financial support. French is the official language.

Politically, Senegal is a parliamentary democracy, operating under a decentralized presidential regime which in theory permits a multiparty system, but, in fact, encourages the development of a one-party system within which group interests as well as individual interests may find expression. The principal role in political life is played by the president of the republic, in cooperation with a prime minister nominated by him, and a national assembly elected by universal suffrage.

The liberal regime established in Senegal is based on a spirit of participation and of dialogue, associated with a conception of the black African heritage known as *négritude*—a conception which has been expounded by LÉOPOLD SÉDAR SENGHOR (*q.v.*), a Senegalese poet who is president of the republic. Senegal itself has been defined as a land of *négritude*—that is to say, the home of a historic ideology of cultural liberation and of political independence. (For coverage of associated physical features see GAMBIA RIVER; and SENEGAL RIVER; for coverage of the capital city, see DAKAR; for historical aspects, see WEST AFRICA, HISTORY OF.)

THE LANDSCAPE

Relief. Senegal is a flat country, lying in the depression known as the Senegal-Mauritanian Basin. Altitudes of more than about 330 feet are found only at Cap Vert and in the southeast of the country. The country as a whole falls into three structural divisions. These are: first, Cap Vert, which forms the western extremity and consists of a grouping of small plateaus made of hard rock of volcanic origin; second, the southeastern and the eastern parts of the country that consist of the fringes of ancient massifs (mountain masses) contiguous with those buttressing the massif of Fouta Djallon on the Guinea frontier, with the highest point reaching an altitude of 1,640 feet; third, an immense but shallow basin lying between Cap Vert to the west and the edges of the massif to the east.

Washed by the Canary Current, the Atlantic coast of Senegal is sandy and surf beaten. Like the rest of the country, it is low except for the Presqu'île du Cap Vert, which represents the westernmost point of the African

Senghor's
leadership

continent and which shelters Dakar (*q.v.*), the finest port in Africa. To the south of Cap Vert the surf on the coast is less heavy. To the south of the Saloum River mouth, the coast consists of rias (drowned valleys) and is increasingly fringed with mangroves.

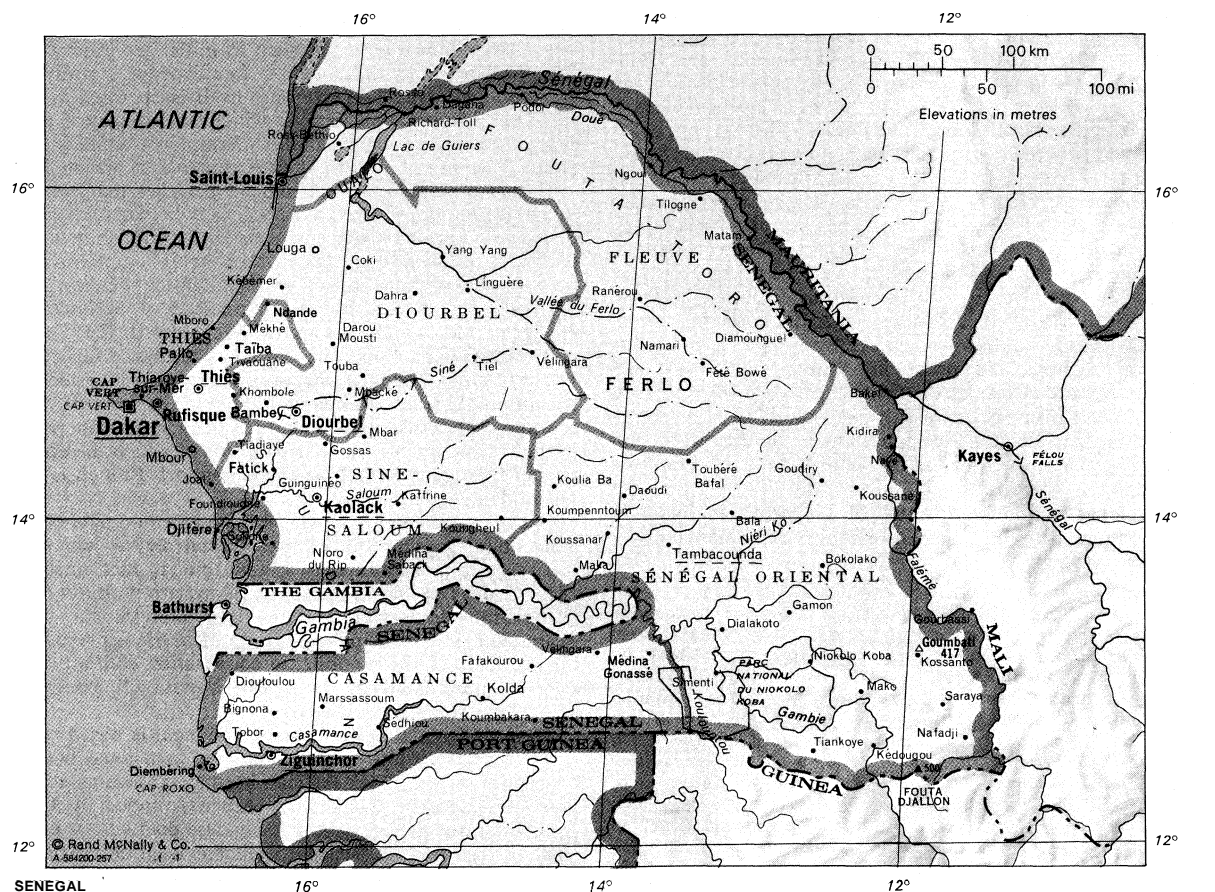

Drainage and soils. The country is drained by the Sénégal, Saloum, Gambie (Gambia), and Casamance rivers, all of which are subjected to a climatic regime characterized by a dry season and a rainy season. Of these rivers, the Sénégal (*q.v.*), which rises in the Fouta Djallon highlands and was for long the main route providing access to the interior, is the most important. After traversing the old massifs over the Guina and Félou waterfalls, the river rapidly drops downward. At Dagana it forms the so-called False Delta, which supplies Lac de Guiers on

the left bank. At the head of the delta is Richard-Toll (the Garden of Richard), named for a 19th-century French nursery gardener. The slope of the land is so gentle on this stretch of the river that at low water, salty seawater flows about 125 miles upstream. The island on which the town of Saint-Louis stands, at the mouth of the river, is situated about 300 yards from the sea in the False Delta whose true mouth lies 10 miles to the south.

Despite its apparent uniformity, Senegal contains a great diversity of soils. These fall generally into two types—the valley soils and those found elsewhere.

The valley soils. The soils of the Sénégal and Saloum river valleys, in their middle courses, are alluvial and consist of sandy limes or clays. Near the river mouths the soils are salty and favourable for grazing. Similar condi-

Physical features and points of interest
Atlantic Ocean...15°00'N 17°00'W

tions are associated with the Gambie and Casamance rivers, except that near their mouths the banks are muddy, while their upper courses have sandy clay soils.

Other soils. Many different types of soils are found in the various regions. In the northwest the soils are ochre-coloured and light, consisting of sands combined with iron oxide. These soils, called "Dior soils," constitute the wealth of Senegal; the dunes they form are highly favourable to peanut cultivation, while the soils between the dunes are suitable for other food crops, such as sorghum. In the southwest the plateau soils are sandy clays, frequently laterized (leached into red residual iron-bearing soils). In the centre and the south the country is covered by a layer of laterite hidden under a thin covering of sand. These soils afford only sparse grazing during the rainy season. In Casamance heavily leached clay soils with a high iron content predominate. Whether they are deep, as in western Casamance, or shallow, as in the southeast of the region, they are suitable for cultivation.

Climate. The Senegalese climate is conditioned by two general factors: first, the tropical latitude and second, the movement of air masses that in turn are governed by anticyclones over the Azores and St. Helena—regions of high pressure over northern Africa and regions of low pressure near the Equator. The prevailing winds fall into two categories—those which are dry and those which bring rains.

The dry winds consist of the trade winds—both from the continent and from the sea—and the harmattan; they bring no rains at all, apart from a very light precipitation which, to the Wolof people of Senegal, is known as the "Heug." The rain-bearing winds blow from the west-northwest, resulting from the high-pressure system centred on St. Helena in the southern Atlantic. In summer these monsoon winds bring rains which become progressively lighter towards the north of the country.

From the combination of these various factors, three principal climates may be distinguished, each of them associated with a characteristic type of vegetation.

The coastal (Canarian) climate. This climate occurs along a coastal strip about ten miles wide running from Saint-Louis to Dakar. Its winters are cool, with minimum temperatures reaching about 63° F (17° C) in January, and maximum temperatures in May not exceeding 81° F (27° C). The rains begin in June, reach their height in August, and cease in October. The average rainfall is about 20 inches.

The Sahelian climate. This occurs in a zone bounded to the north by the Sénégal River and to the south by a line running from Thiès (a town on Cap Vert) to Kayes in the neighbouring country of Mali. The month of January is very cool, especially in the mornings before sunrise, when the temperature drops to about 57° F (14° C); maximum temperatures rise higher than 95° F (35° C). In May, minimum temperatures do not fall below about 72° F (22° C), while maximums often rise above 104° F (40° C). The dry season is quite distinct, and lasts from November to May. Certain places, such as Podor and Matam, are particularly noted for their dryness and for the heat of the sun. Between July and October the rainfall averages about 14 inches, moderating the temperature somewhat. Maximum temperatures at this season amount to about 95° F (35° C).

The Sudanic climate. This occurs in the remainder of Senegal. Regional nuances are in evidence. Thus, from north to south three subdivisions may be recognized, each characterized by the amount of average annual rainfall. First, in the Kaolack-Tambacounda subdivision, rainfall averages between 29 and 39 inches, occurring on about 60 days between June and October. Cultivation without irrigation is possible. Second, in the Gambian region, the rainfall frequently amounts to 50 inches, resulting in the growth of a continuous belt of light forest and patches of herbaceous undergrowth. Third, in the Casamance region, rainfall everywhere exceeds 50 inches, falling on 90 days of the year. The forest is dense and green, and is continuous, without undergrowth. Oil palms, mangroves, and rice fields are characteristic of this climate zone. The Sudanic climate in general is very hot, humid, and un-

comfortable. The town of Kaolack, for example, has a heavy climate that is rendered more oppressive by salt wind.

Animal life. While it is true that large mammals have disappeared from the western part of the country, due to human settlement, such animals as elephants, antelopes, lions, panthers, cheetahs, and jackals may still be encountered in the interior. Herds of warthogs abound in the marshes, especially those of the False Delta. Hares are ubiquitous, and monkeys of all types congregate in noisy bands, above all in the upper Gambia and upper Casamance river valleys. Among the great numbers of birds the quelea, or "millet eater," which is destructive of crops, may particularly be noted, as well as the partridge and the guinea fowl. Reptiles are numerous, and include boa constrictors, pythons, cobras, and venomous snakes. Crocodiles, hippopotamuses, and turtles are to be found in the rivers. The rivers and the coastal waters are rich in fish and crustaceans.

Traditional regions. While such physical factors as geology, soil, climate, and vegetation have resulted in regional differentiation, man has also been a determining factor in the delimitation of different regions, each marked by a traditional type of human settlement. Thus from north to south five principal traditional regions may be distinguished.

The Ferlo region. This is the central region of Senegal; very extensive, it is distinguished by its semidesert aspect and by the poverty of its soils. Vegetation appears only in the south, the north consisting of the Sahelian type of savanna parkland (an intermediate zone between the Sahara and the savanna proper); it affords light grazing for the flocks of nomadic Fulan (Peul) pastoralists.

Fouta-Toro. This region is based upon the Sénégal River, extending approximately from Bakel in the east to Dagana in the north and consisting of a strip of territory that is relatively densely inhabited. Cultivated lands, which are watered by the river and its tributaries in the dry season, are of importance thanks to highly developed agricultural and pastoral use of the soils and vegetation. Most of the region is inhabited by Tukolor people. Fouta-Toro is bounded to the west by the False Delta, also known as the Oualo, which is peopled by the Wolof, who cultivate millet and carry on stock raising, employing Fulani shepherds.

The Dianbour, Cayor, Djolof, and Baol region. This is a diverse area situated between the Ferlo region and the Atlantic, and extending from the Oualo in the north to Cap Vert in the south. The soils are sandy, the winters cool, and peanuts are the primary crop. The population is as diverse as the region itself and includes Wolofs in the north, Serer in the Thiès region, and Lebu on Cap Vert.

The Sudan region. This vast region is bounded by Cap Vert to the northeast, the Ferlo to the north, and the lower Casamance Valley to the southwest. It is composed of the following subregions—The "Little Coast", the Sine-Saloum *région*, Rip, Yacine, Niani, Boundou, Fouladou and the valleys of the Gambia and upper Casamance rivers. In general, the region benefits from ample rainfall which becomes abundant towards the south. The clayey soil is suitable for agriculture, despite the lateritic crust which appears intermittently. The region, as a result, is relatively densely peopled. The estuaries are muddy and salty, with marshy saline depressions known as *tannes* occurring occasionally. The region as a whole is inhabited by a very diverse population composed of all the ethnic groups living in Senegal; the majority are, however, Malinke (Mandingo).

The lower Casamance region. This is a small but strongly characterized region. It is covered by dense vegetation of the Guinean type. Mangroves, oil palms, and raffia palms predominate. The rainy climate favours the cultivation of rice, which has long been a specialty in this part of the country.

Rural settlement. The great majority of the Senegalese population lives in the countryside. There are about 13,000 villages, each with an average population of more than 200 persons. Usually each village has a shaded public gathering place, a mosque, and a water source, whether

Tribal
villages

a well, a spring, or a small stream. The village is administered by a chief who is either traditionally nominated or appointed by the government. Religious life is directed either by a person literate in Arabic, called a marabout, or by a leading sorcerer. Various types of village may be distinguished, according to ethnic characteristics.

The Wolof village. Whether it is situated in the western Ferlo or the Cayor regions, the Wolof village is small, being inhabited by about a hundred farmers. The houses are built of locally obtained materials. Each village may easily be moved from place to place, as the topography provides no natural obstacles to this. Harvests are kept in straw granaries, located far from the compounds for fear of fires. In the eastern Saloum region, the Wolof village is surrounded by three concentric zones of vegetation. The first of these—the inner zone—consists of fields and vegetable gardens and is known as the Tol-keur (literally "kitchen garden"). The second circle consists of land that has been exhausted, except for peanut cultivation, and it is known as the Diate. The third, the farthest from the village, is the Gor, in which cereal crops are cultivated.

The Malinke village. The typical village of the Sudanic region of Casamance consists of a Malinke agglomeration; it is a heritage from the epoch when the Sudanic peoples conquered the region. Each village has between 200 and 300 inhabitants living in enclosed compounds and crowded together in geometrically aligned rectangular huts. Agriculture and stock raising are the principal activities. The chief of each village is generally a marabout, conservative in his ways.

The Serer village. This differs from the Wolof and Malinke village because of its family compounds, called M'Bind, being loosely dispersed; each M'Bind is autonomous. On the islands at the mouth of the Saloum River, the houses of the Serer Niominke people are solidly built and trim. The granary is located in the compound.

The Dyola village. These are substantial rural agglomerations with populations of up to 5,000 people or more. One of the characteristics of this type of village is that it is usually built on the edge of a plateau, or on ground which overlooks the rice fields with which Dyola life is associated. As in the Serer villages, the compounds are not grouped in any distinguishable organization hierarchy. The houses are the best built and the most permanent among the different types of village dwellings to be found. On occasion they constitute veritable fortifications, for example, in the Thionck-Essyl and Ousouye regions; the villages of the Essyl region are often equipped with a rainwater tank. The Dyola and Serer villages have no chiefs with authority or prestige comparable to those of the Wolof or Malinke villages.

Major
towns

Urban settlement. The town of Saint-Louis was founded in 1633, and Dakar in 1857; other towns were, however, more recently founded. All the towns are of colonial origin. Dakar, as was formerly Saint-Louis, is the political and administrative capital. The other towns usually owe their foundation to the peanut trade, for which they were collection points which later developed into urban centres. These towns were often stops along the railroad lines, as at Thiès, Tivaouane, Mékhé, and Louga (between Dakar and Saint-Louis), or Khombole, Bambey, Diourbel, Gossas, Kaffrine, and Koungeul (between Thiès and Kayes, Mali). Certain ports also became towns: among these are Kaolack, Foundiougne, and Fatick (on the Sine-Saloum rivers), and Ziguinchor, Sédhio, and Kolda (on the Casamance River). With the exception of Dakar, Saint-Louis, Rufisque, Thiès, and Kaolack, these towns have not as yet emerged, as it were, from their rural cocoons. Furthermore, all of the towns—including Saint-Louis, Rufisque, and Gorée, all of which had great importance in the past—are today dependent upon Dakar, which has become the focus of attraction for the whole of Senegal.

Apart from the division of the countryside into traditional regions, one may observe that the best lands in Senegal are concentrated in the west and in the river valleys. The remainder of the land becomes increasingly poor and less and less settled as one continues toward the north or toward the east.

PEOPLE AND POPULATION

Linguistic, ethnic, and religious groups. The scientific study of languages in Senegal has not progressed far enough for even a rough type of classification to be attempted. Specialists nevertheless recognize certain imprecise groupings. These are: (a) the Atlantic (West Atlantic) group, including Wolof, Lebu, Serer, Tenda, and Diola; (b) Fulfulde, the Fulani (Peul) language, which also shares some of the characteristics of the Atlantic group; Fulfulde possesses numerous linguistic particularities, and has a complex grammar; and (c) the Mande group, including Bambara, Diula, Malinke, and Soninke (Sarakole). There are seven major ethnic and religious groups, and a number of other less significant groups.

The major groups are located in the Sahel and savanna regions which formerly supported the ancient empires of the western Sudan, such as Ghana, Mali, and Songhai. Until recently the societies composing this grouping were strictly hierarchical in organization, consisting of the princely caste, the nobility, the free men, the lower castes, and finally the slaves. The grouping consists of the following peoples:

The Wolof. Numbering 1,200,000 people, the Wolof represent about one third of the total population. Their language is the most widely used in the republic. The Wolof predominate in the sandy western region. In the Cayor district they are initiates of the Tijānī Muslim brotherhood; the other brotherhood, that of the Murīdīs, is very influential, and its expansion towards the southern part of the country is concurrent with that of peanut cultivation. Members of the Murīdīs brotherhood, strong adherents of Islām, are primarily agriculturalists.

The Serer. Numbering about 600,000, the Serer are densely settled in the western part of the southern Ferlo region. They are experienced farmers, practicing both cultivation and cattle raising. Originally animist by religion, they are now becoming increasingly either Muslim or Catholic.

The Fulani. Also known as the Peuls, Foulah, Fulbe, and Fellata, this group numbers about 500,000; distributed throughout Senegal, the Fulani are particularly found in the Ferlo, the Upper Casamance, and Oualo regions, where their settlements are substantial. Characteristically nomadic pastoralists, many of them have today become settled agriculturalists, above all in the Fouta-Toro region and on the Senegal-Guinea border. They are Muslim.

The Tukolor. Numbering 350,000, the Tukolor (or Toucouleur) are often hard to distinguish from either the Wolof or the Fulani, with both of whom they have often intermarried. The name Tukolor (or Toucouleur) is a distortion of the name of the ancient realm of Tekrou. The Tukolor live primarily in the middle course of the Sénégal River Valley, in the Senegalese part of the Fouta region, and between Bakel and Dagana. They are also found in dispersed groups living on the Gambie and Saloum rivers. They were the first Senegalese people to become Muslim, having accepted Islām probably in the 11th century; many of them are literate in Arabic. Primarily farmers, they are increasingly migrating to the towns, particularly to Dakar and Saint-Louis.

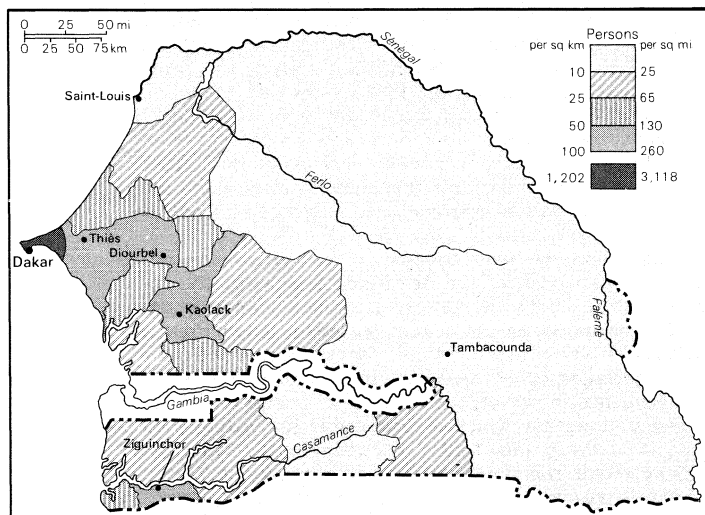

The Dyola. Numbering between 200,000 and 250,000, the Dyola occupy the Lower Casamance Valley and the southwest of the Gambie Valley. They are skilled farmers, specializing in rice growing, but turning more and more to the cultivation of peanuts and millet as the distance from the sea increases. In the Fogni district they are Muslim, but the majority remain animist. Some few have accepted Christianity.

The Malinke. The Malinke (or Mandingo) came originally from the Niger River Valley, and have spread out into various regions of Senegal, especially into the Gambie, Upper Casamance, and Saloum river valleys. Farmers and energetic traders, they number about 200,000; they are Muslim.

The Sarakole, or Soninke. This is a minority group, numbering less than 65,000, and is of Berber descent. They represent an extension into Senegal of the Malinke families of Mali. They are in the process of abandoning

an unfruitful agricultural terrain in order to migrate towards the towns where they often become small traders. They are Muslim.

The numerically less significant Senegalese comprise such peoples as the Maures, who live especially in the north of the country where they are stock raisers or traders; the Lebu of Cap Vert, who are fishermen and often wealthy landowners; and the Bassari, an ancient people who are found in the rocky highlands of Fouta Djallon.

Population density of Senegal.

Demography. The population of Senegal consists of 3,755,000 people with an average population distribution of about 50 people per square mile. The birthrate is 4.6 percent, and the death rate 2.3 percent, giving a rate of increase of 2.4 percent a year.

Migration to the towns as well as to the peanut-growing lands of the west is taking place at a pace that is assuming disturbing proportions. The rural zones which are becoming depopulated by migration are the Fleuve (River) *rkion* in the north, the S n gal Oriental (Eastern Senegal) *rkion* in the southeast, and the Casamance *r gion* in the southwest. The towns and peanut plantations are also attracting migrants from the neighbouring countries of Mali and Guinea, but in numbers that are now becoming insignificant. Other groups of foreigners include Mauritians, Syrians (or Lebanese), and Europeans, who all live in the towns. The pattern of internal migration has resulted in the highest concentration of population occurring in the Cap Vert *rkion*, where it amounts to over 3,000 persons per square mile. In the Thi s *r gion* the concentration is 186 persons per square mile; the proportion drops to about 61 persons per square mile in the Sine-Saloum, Diourbel and Casamance *r gions*, while in the rest of the country the population distribution is 13 persons per square mile. All of this means that about two-thirds of the country's population lives west of a line running north to south from Saint-Louis through Louga to Lingu re and to Koumpentoum near the Gambia frontier, an area comprising about one quarter of Senegal's territory.

The population as a whole is young, with 43 percent being less than 15 years old, 51 percent being between the ages of 15 and 59, and 6 percent being 60 years old or older. The major cause for concern lies in the drift towards the towns, which is creating an increasingly acute administrative problem. In Dakar, for example, the population is increasing at a rate of from 6 to 7 percent a year, which if maintained will result in the population of the city doubling every 12 years.

THE NATIONAL ECONOMY

Resources. The economy is essentially agricultural and, as mentioned, is primarily based upon the peanut crop. The known mineral resources are only of relative importance, consisting of phosphates of lime, located at Ta ba near Tivaouane, about 60 miles north of Dakar,

with reserves estimated at 115,000,000 tons; aluminum phosphates at Palo Dial, near Thi s, with reserves estimated at 100,000,000 tons; titanium-bearing sand deposits at Djifkre, on the shores of Sangomare Bay, which contain ilmenite (the principal ore of titanium, an element used in making steel), zircon (the chief ore of zirconium, also used in steel metallurgy), and rutile (titanium dioxide, used to coat welding rods); salt from the saltworks of Kaolack, which have a considerable potential production. Prospecting for petroleum deposits has so far been without result.

Biological resources include 8,696,064 acres of forest, much of which is located in the Casamance area; these do not, however, yield any commercial products. Production of gum arabic, which is obtained from acacia trees elsewhere in the country, has declined until it is only of secondary significance. The herbaceous vegetation nevertheless permits a relatively important amount of stock raising. By improving the grazing land available, Senegal has the potential to increase the numbers of its cattle herds to a considerable extent.

The waters off Senegal, particularly those at some distance from the shore, are rich in schools of fish, although the coastal waters are also known for their large variety of fish; in this respect Senegal is better endowed than most other tropical countries on the Atlantic seaboard.

The production of cheaper electricity depends on the construction of the Guina hydroelectric project on the S n gal River. In the early 1970s electricity is being produced at thermal generating centres which are located at Dakar.

Sources of national income. *Agriculture.* Agriculture occupies at least 75 percent of the economically active population, and provides the basis for industry as well. Although a certain balance between the raising of livestock and peanut cultivation is maintained, it is the peanut production which earns the foreign exchange that the country needs.

The main problem affecting national agriculture is the dependence upon the peanut crop, and the saying "When peanuts do well we all do well" is still valid. In 1970, when for various reasons production dropped to 600,000 tons, Senegal found itself on the verge of economic catastrophe. About 2,942,000 acres are devoted to peanut cultivation, producing an annual yield of about 1,000,000 tons. Each year the sale of peanut crop results in much economic activity throughout Senegal; the resulting wealth has favoured the development of the smaller towns. The traffic in peanuts has also resulted in the establishment of the river ports of Kaolack, Fouta Djallon, Fatick, S dhiou, and Kolda. Much of the activity at Dakar itself is due to the peanut trade.

Apart from peanuts, which are an export crop, a number of food crops are also grown. About 2,559,000 acres are devoted to sorghum and pennisetum (a genus of Old World grasses), resulting in an annual production of about 630,000 tons of grain. Rice is cultivated both in naturally wet areas and by irrigation. Its large-scale cultivation is restricted to Casamance, to the S n gal River Valley, and to the Sine-Saloum area. About 207,000 acres are used for rice, of which 15,000 acres are used for experimental purposes at Richard-Toll. A further 74,000 acres are being brought into cultivation between Dagana and Saint-Louis. More than 150,000 tons are now produced an-

crop

nually. In addition, about 50,000 tons of maize, 175,000 tons of cassava (manioc), 15,000 tons of beans, and 25,000 tons of sweet potatoes are grown each year.

Livestock. The climate and the savanna type of vegetation encourage the raising of livestock, which is carried on in almost all regions, but is especially characteristic of the north. In 1970 the cattle population was estimated to amount to more than 2,600,000 head. There were also about 2,950,000 sheep and goats, 192,000 horses, 170,000 donkeys, 30,000 camels, and about 93,000 pigs. Stock raising is not a major source of income for the farmer; in addition to the difficulty of improving livestock strains, the fact that stock raising is often conducted for reasons of prestige alone provides an economic drawback.

Fishing. About 20,000 people, possessing about 5,000 canoes, engage in full-time fishing. While many fish are obtained from the rivers, the greater part of the catch is obtained from the sea. Due to the modernization of fishing techniques annual production, which amounted to only about 83,000 tons in 1957, had risen to 189,000 tons by 1970. A fleet of 26 trawlers and more than 60 tuna-fishing boats are now in service.

Mineral production. Of secondary significance in the national economy, mineral production, as already mentioned, consists of phosphate of lime, of which 998,000 tons were obtained in 1970, nine-tenths of which was for export; phosphate of aluminum from Pallo, of which 130,000 tons were produced in 1970; and lesser amounts of ilmenite, zircon, and rutile.

Industry. Industrial production in Senegal is more developed than in most West African countries and accounts for 15 percent of the total national revenue. Both processing and handicraft industries are established. About 90 percent of the processing industry is located in the Cap Vert *région* where six oil processing plants process 500,000 tons of peanuts a year. Two of these plants are established in Dakar, the remaining four being in the towns of Rufisque, Kaolack, Diourbel, and Ziguinchor. In addition, there are six fish canneries, one shoe factory with an output of 500,000 pairs of shoes a year, and one cement manufacturing plant with an output of 240,000 tons of cement a year. Both the shoe factory and the cement plant are located at Rufisque. Other industries, all of which are located in Dakar, include two flour mills, a textile plant, a sugar refinery, a tobacco factory, and a brewery, in addition to a naval shipyard, chemical plants, and an automobile assembly plant.

About 40,000 craftsmen are engaged in traditional handicrafts; the more skilled among them are established at Dakar and Saint-Louis.

There are altogether about 350 industrial enterprises employing 29,000 wage earners. It has been estimated that the value of industrial production rose by 75 percent between 1962 and 1967.

Energy. About 90 percent of energy is produced in Dakar, and is distributed through Saint-Louis via Thiès, Tivaouane, Mékhé, Louga, and other towns along the coastal strip. Kaolack and Mbour are also supplied from Dakar.

Financial services. In finance, Senegal has benefited from the fact that in colonial times it was the principal territory of the administrative grouping known as French West Africa. The Senegalese currency is the franc CFA, the franc issued by the Communauté Financière Africaine. (CFA Fr. 277.71 = \$1.00 U.S.; CFA Fr. 666.50 = £1 sterling, on December 1, 1970.) It has a value of 50 francs CFA to the French franc. Goods entering the country from the franc zone are liable to a simple fiscal tax; those from the Common Market countries enjoy a preferential tariff. There are a considerable number of banks offering financial services. Currency is issued by the Banque Centrale des États de l'Afrique de l'Ouest, which is the agency of the West African Monetary Union to which Senegal belongs, and which includes all French-speaking West African territories with the exception of Guinea. Other financial institutions include the Société Immobilière du Cap Vert (a building society); the Banque Nationale de Développement du Sénégal; the Union Sénégalaise de Banque; and three private banks.

Foreign trade. The value of imports is usually greater than the value of exports. In 1971, for example, imports were valued at \$218,000,000, and exports at \$125,000,000. The principal imports are rice, sugar, petroleum products, machinery, textiles, and chemicals. The principal exports are peanuts and peanut products (representing almost 50 percent of the total), phosphates, leather, and canned fish. About 75 percent of Senegal's exports go to the franc zone, in which France is the principal trading partner. A fraction of exports go to Guinea, Cameroon, the Common Market countries (4 percent of the total), the sterling bloc, the Scandinavian countries, and Japan. Imports are also primarily from the franc zone, with France alone (in 1969) supplying about 40 percent of Senegal's requirements. In 1969 a further 19 percent came from the Common Market, 6 percent from the United States, and 7 percent (primarily rice) from Southeast Asian countries. Other imports came from the sterling zone, while Algeria and Venezuela supplied petroleum products.

Management of the economy. The private sector. Before independence, the economy was virtually entirely in the hands of the private sector. Since it depended primarily on the peanut trade, the large French companies which marketed the peanuts also controlled the importation of European manufactured goods. After independence, however, the Senegalese government created a state agency which is responsible for virtually all aspects of the peanut trade; in consequence, while the private sector remains important in the economy as a whole, it receives its impulse from the state. An investment code is composed of various guarantees and long-term tax concessions, as a result of which investment has been attracted from many quarters.

In 1968 there were almost 3,000 private enterprises in Senegal, of which more than half were in Dakar. These enterprises employed 60,000 persons. Transportation, services, commerce, and industry are in general the responsibility of the private sector.

The public sector. The public sector is of primary importance in a country in which, for historic reasons, a middle class in the western sense has never existed. The intervention of the state, moreover, is not a recent phenomenon; already in existence during the colonial era, it has been given a new form since independence by the creation of the Office de Commercialisation Agricole (Agricultural Marketing Board). Apart from buying and selling peanuts, rice, and millet, the board also sells fertilizer, seed, tools, and equipment, and is thus the primary instrument used by the state in giving form to its policy of "African socialism." Between 30,000 and 40,000 persons are employed by the public sector.

Taxation. As already mentioned, the government encourages investment by granting tax benefits. Most governmental revenue is obtained from indirect taxes, which take the form of local taxes on alcoholic beverages, gasoline, tobacco, firearms, automobiles, and commerce. Direct taxation consists of land taxes, professional licenses, and personal taxes, such as taxes on profits, and income taxes.

Trade unions. Since the end of World War II, Senegalese trade unionism has undergone many mutations. Until 1955 French-speaking African workers in general belonged to the French trade-union movement. In that year, however, they broke away to create the Union Générale des Travailleurs d'Afrique Noire, of which the Senegalese affiliate was the Union Nationale des Travailleurs Sénégalais. This remained the only Senegalese union until the occurrence of disturbances in May and June 1968 which began at the University of Dakar, and in which the Union Nationale des Travailleurs Sénégalais actively participated. As a result, the Senegalese government and the governmental party, the Union Progressiste Sénégalaise, decided to associate trade unionism into the governmental structure; a new union, the Confédération Nationale des Travailleurs Sénégalais, subsequently split away from the Union Nationale des Travailleurs Sénégalais in 1969. The result has been a situation rare in Africa—the coexistence of two trade unions, one governmental, the other

centre

affiliated with the opposition. It would appear that the governmental union draws its strength from the rural areas, while the stronghold of the other remains in Dakar.

Economic policies. Economic life is characterized by two factors. The first is the division of the country into two regions—the western region which is wealthy and dynamic, and the remainder, and larger part, of the country which remains poor and economically stagnant, depending upon a subsistence economy. The second factor is the existence of a single crop economy, which leads to partial unemployment, an insufficient income, and a dependence on an unpredictable climate and the international market. The single crop economy consequently produces a "budget of poverty," resulting in savings so slim as to be virtually nonexistent, and a problematical degree of development that remains primarily dependent upon foreign aid.

In seeking to break this circle, the government introduced its first economic plan in 1958; its primary result was to create a consciousness of the need for further planning. The second plan, which covered the period from 1964 to 1969, sought to diversify agricultural production by encouraging the cultivation of other crops in addition to peanuts. Other steps taken were the creation of the Office de Commercialisation Agricole and the Africanization of personnel in banking and commerce.

Future problems. Among the many problems to be faced, three types may be cited—those relating to neighbouring countries, internal problems, and those related to the future. They may be enumerated as follows: (1) Problems with neighbouring countries: Senegal has experienced some problems with Mali, as well as with Guinea which is attempting to make its way outside the French-speaking community; with Mauritania which is attempting to do without the services of the port of Dakar; and above all with The Gambia, with whom a serious dispute exists. Senegal has experienced disappointment in the failure of the Senegambian Federation that was to have joined the two countries together; furthermore, as a result of this failure, the Senegalese economy has been injured by a great amount of smuggling. (2) Internal problems: The internal situation is still more acute. An inflammatory situation resulted from the abrupt drop in peanut production in the 1970 season, for which the government had forecast a harvest of 1,100,000 tons, whereas barely 600,000 tons were produced. The discrepancy appears to have been caused by the poor performance of the Office de Commercialisation Agricole. Despite a rise in peanut prices on the world market, the price paid to the Senegalese farmer dropped. Thus the 1,700,000 Senegalese peanut cultivators each received an average payment of no more than 134 French francs a head, a circumstance which caused widespread discontent. The situation was not improved by the fact that Senegalese nationalists began to press for the nationalization of the country's entire economic life. (3) The future: Faced with this situation, the government took various measures to safeguard the future. An African banker was appointed to the presidency of the Dakar Chamber of Commerce; the trade union movement was to some extent incorporated in the government with the creation of the Confédération Nationale des Travailleurs Sénégalais; reforms were instituted within the Office de Commercialisation Agricole; and a third four-year plan, covering the period from 1969 to 1973, was published which envisaged an increased agricultural production.

Transportation. *Road transport.* The development of a transport network has taken place primarily in the western part of the country, within the area bounded by Saint-Louis, Kaolack, and Dakar. Despite the fact that the remainder of the country is insufficiently developed, Senegal's transport system nevertheless compares favourably to that of many other West African countries. Most of the 5,800 miles of roads, of which 1,300 miles are paved, are concentrated in western Senegal.

Rail transport. The rail system includes a line from Saint-Louis to Dakar, with a branch line running from Louga inland to Linguère, and the line from Dakar to

the Niger River, at Koulikoro, with two branch lines running from Diourbel to Touba and from Guinguindo to Kaolack. The two main lines meet at the junction of Thiès, which is also the site of railroad repair workshops. The railroad system is suffering from the competition offered by road transport.

Ports. Senegal's four ports are Kaolack, Ziguinchor, Saint-Louis, and Dakar. Only Dakar (*q.v.*) is an international port, the other ports handling only local traffic. In addition to its facilities as a commercial port, Dakar is also in the process of creating a fishing harbor. It is, however, suffering from the competition presented by Nouadibou (Port-Etienne) in Mauritania, and by the port of Las Palmas in the Canary Islands, which is 50 percent cheaper in its port fees. Partly because of these factors, as well as because of the fact that Dakar has been affected by the granting of independence to the former French West African territories of which it was once the administrative capital, its traffic in both passengers and goods has diminished in recent years.

Air transport. The international airport of Dakar-Yoff at Daka is served by a number of airlines. Traffic has diminished slightly in recent years. Domestic services are provided by Air Afrique. There are local airports at Thiès, Saint-Louis, Ziguinchor, Kaolack, Rosso, Podor, Matam, Tambacounda, Kédougou, Sementi, and Kolda.

River transport. Since the end of the 19th century the rivers, of which the Sénégal River has always been the most important, have lost much of their importance. The Sénégal (*q.v.*) is navigable all year round from Saint-Louis to Podor by boats drawing about three feet of water. Other reaches are only navigable in the rainy season; Kayes in Mali, for example, can be reached only at that time. Despite the competition of the railroad, fleets of canoes still provide river transport. Activity on the Saloum River is due to the presence of the peanut port of Kaolack, while traffic on the Casamance is due to the port of Ziguinchor.

ADMINISTRATION AND SOCIAL CONDITIONS

The constitutional framework. Senegal now has its third constitution since independence. It was adopted by referendum on February 22, 1970, by a majority of 99.9 percent of the voters. Like its predecessors, it proclaims its attachment to fundamental human rights, respect for political, trade union, and religious freedoms, and also for individual and collective property rights. The Senegalese state is a social, democratic, and lay (nonecclesiastical) state, with French as its official language.

Government. *The central government.* The most important innovation in the new constitution is the establishment of a decentralized presidential regime. The president of the republic no longer rules directly, as in the past, but through the intermediary of a prime minister whom he nominates and who is responsible to him alone. The president retains special powers concerning justice, foreign policy, and defense. In other spheres his decisions must be approved by the ministers, who thus share the responsibility for presidential decisions. The president is elected for five years, and cannot serve more than two terms in office. Ministers are appointed by the president, who has the right to dissolve the government in case of a vote of censure in the national assembly. Judicial, executive, and legislative powers are separated. Deputies exercise a check on the executive power by means of commissions of inquiry, oral and written questions, and motions of censure.

Regional government. Senegal is divided into seven *régions*, 28 *départements* (provinces), and 94 *arrondissements* (districts). The *régions* and their capitals are the following: Cap Vert (Dakar), Thiès (Thiès), Diourbel (Diourbel), Fleuve (Saint-Louis), Sine-Saloum (Kaolack), Casamance (Ziguinchor), and Sénégal Oriental (Tambacounda). Each *région* is administered by a governor whose role is coordinative; he is assisted by two deputy governors, one dealing with administration, and the other with development. A regional assembly composed of general councillors deals with local taxation. In each *département* the prefect represents the republic,

Dakar's role in international shipping

Relations with The Gambia

The office of the president

as well as the ministers; he sees to the implementation of laws, and supervises the local administrative units. In the *arrondissement* he is assisted by a local official (*chef d'arrondissement*). Several towns operate autonomously with elected municipal councils.

The political process. National Assembly and municipal council elections are held every five years, as also are presidential elections.

Political parties. Due to the fact that Senegalese played a pioneering role in the development of a modern political system in the territories of French West Africa, the political-party system is solidly entrenched, and the concept of a single-party system is generally held to be repugnant. A plethora of parties is not, however, considered desirable. Party political life, therefore, tends to be dominated by the governmental party, the Union Progressiste Sénégalais, which in 1963 succeeded in winning the adherence of two parties of the intellectual elite—the Bloc des Masses Sénégalaises and the Parti du Régroupement Africain, the principal opposition party—which then merged with it. Another party, the Parti Africain d'Indépendance has been outlawed since 1960. The Union Progressiste Sénégalais is committed to the socialization of the economy within the framework of "African socialism," and to the quest for African unity.

The participation of the citizen. At the beginning, political life was of concern only to a very limited élite consisting of the intellectuals, the traditional chiefs, and above all the inhabitants of four communes—Saint-Louis, Dakar, Rufisque, and Gorée—who had been French citizens since 1916. After World War II universal suffrage was introduced by stages, with the electorate increasing from 192,000 voters in 1946 to 890,000 in 1958. The number of voters has since grown larger; by the early 1970s it numbered about 1,500,000. Senegalese citizens today participate in the elections of the president, of the deputies to the national assembly, of regional councillors, and of municipal councillors.

De facto political developments. In addition to participation in political party and trade union activities, other institutions also permit participation in the political process. These include societies for mutual assistance, which are organized both on a regional and on a village basis; youth associations; and religious groupings, which are most influential. The present disinclination of farmers to cooperate economically constitutes, in effect, a method of exerting political pressure on the government.

Justice. Justice is administered in the *départements* by justices of the peace and in the regions by courts of first instance. Criminal cases are judged by assize courts held at Saint-Louis, Kaolack, Ziguinchor, and Dakar. Dakar is the seat of the Court of Appeal.

The Army. The Senegalese army has 7,900 men; 2,000 of these are French (500 sailors, 300 airmen, and 1,200 soldiers) who are maintained in Senegal under a military agreement. The army as a whole includes infantry companies, parachutists, engineers, and communications units, as well as a Garde Républicaine, a constabulary, and naval and air force units. There are 200 officers. Supreme command of the army is vested in the president. Direct command is exercised by a single commander in charge of land, sea, and air forces acting under the orders of the prime minister. The Senegalese army has inherited from the French army a significant armament and a strong organization; it constitutes a fundamental element in Senegalese political life.

Administration. Education. In addition to continuing the educational expansion begun during the colonial period, Senegal has made particular efforts to increase school enrollment in rural areas. In primary education, school enrollment rose from 23 percent of the primary school age population in 1959 to 40 percent in 1969, and it is expected that the proportion will shortly reach 50 percent. There are 138 secondary schools, among which the Lycée Faidherbe at Saint-Louis and the Lycée Van Volenhoven at Dakar are the most renowned and the oldest. Technical education is expanding; technical training is provided by a number of institutions, including l'École Nationale des Travaux Publics and the Lycée Technique

Maurice Delafosse in Dakar, the Lycée Technique Andre Peytavin in Saint-Louis, and the Centre d'Enseignement de Pêche at Thiaroye-sur-Mer.

University education was begun in Dakar in 1957. The University of Dakar, now completed, had an enrollment of 3,380 students in 1970. Following disturbances in 1968, Senegal concluded an agreement with France on higher education by the terms of which the University of Dakar will become oriented to its African context. The Africanization of courses has meant that university degrees, with the exception of those gained in medicine, are no longer equivalent to those obtained in France.

Health services. Although still insufficient, Senegal nevertheless has a considerable range of medical facilities. They include 10 hospitals, 285 clinics, 44 maternity homes, and various services specializing in various diseases, such as tuberculosis, poliomyelitis, syphilis, and leprosy. The Senegalese Red Cross is also active, while environmental studies are conducted by the French Office de la Recherche Scientifique et Technique Outre-Mer in cooperation with the World Health Organization.

Housing. In rural areas dwellings, which are usually well constructed, are roofed with straw, while walls are either made of earth or straw. In more prosperous villages, roofs are sometimes of corrugated iron, and walls are sometimes of cement brick. Houses in the towns are of cement with roofs either of tile or of corrugated iron; many families are usually crowded together. The drift from the countryside and the expansion of town populations has frequently resulted in the proliferation of shanty towns.

Police services. The Ministry of the Interior is responsible for police services, which are under the control of the Director General for Security, who heads the Garde Républicaine, the central city police station, the national constabulary, and some mobile brigades. These forces are officered by a team of magistrates and administrators.

Social welfare. Wages and cost of living. Both wages and the cost of living are highly variable. In rural areas annual income averages between 15,000 and 20,000 francs CFA (between 300 and 400 French francs). In periods of crisis, as for example in 1970, the average rural annual income fell to 13,000 francs CFA (260 French francs). Migrant rural workers who seek temporary employment in towns often raise their wages to an average of 50,000 francs CFA (1,000 French francs) a year. Employees in minor posts in towns—orderlies, cooks, and chauffeurs employed by the administration—enjoy a relatively privileged standard of living, earning wages of between 50,000 and 100,000 francs CFA (1,000 to 2,000 French francs) a year. Those in clerical positions in commerce and industry earn salaries which may amount to 150,000 francs CFA (3,000 French francs). The highest salaries are earned by professors, members of the liberal professions, French expatriates, and international civil servants.

The standard of living in the countryside is low. Manufactured products are more expensive than in the city, which despite often startling social inequalities, may appear to be a kind of paradise in comparison with living conditions in the countryside. About 63 percent of all the wages in the country, for example, are earned in Dakar alone, although only one-eighth of the population lives there. As a result the cost of living in Dakar in 1969, according to United Nations statistics, was the highest of any city in the world.

Health conditions. Thanks to the efforts of doctors during the colonial era, Senegal is rid of the plagues which raged in the early 20th century. If yellow fever, tuberculosis, smallpox, and similar diseases are still to be encountered they at least no longer assume epidemic proportions. In rural areas, however, sanitary conditions leave much to be desired, due to the lack of training and facilities. It must be admitted, however, that this situation is due, above all, to the fact that sanitary facilities are primarily concentrated in Dakar, which recently accounted for three-fifths of the total budgetary expenditure for health. There is one doctor for every 1,000 inhabitants in Dakar, whereas the ratio is one to every 15,000 inhabitants elsewhere in Senegal. Out of 140 midwives, 90 are

The Africanization of university courses

The electorate

Health facilities in Dakar

located in Dakar. The death rate for children between the ages of one and four is five times higher in rural Senegal than it is in Dakar. Life expectancy in the capital is 60 years, whereas in the countryside it is only 38.

Social and economic divisions. As is emphasized by the foregoing, the most marked socioeconomic cleavage in Senegal today is between those living in towns and those living in the country. This division results from the modernizing process which has taken hold in the western fringes of the country.

Country life, in its traditional communal village form, is still followed by 80 percent of Senegalese. The family is extended and lives, under the authority of its most elderly member, in a compound consisting of a group of thatched dwellings, engaging in agriculture for a livelihood. The influence of the marabouts—interpreters of the Qur'an—remains uncontested. Liquid funds are virtually nonexistent, a subsistence economy being followed.

The way of life of the city dwellers stands in contrast to this, since it typifies the modernizing process at work in Senegal. To speak of city life, moreover, is virtually tantamount to speaking of Dakar, since 75 percent of town dwellers live in this one city. The primary factor distinguishing the rural farmer from the town dweller is monetary income, since the inhabitants of the towns earn from 10 to 12 times more than those living elsewhere. Better lodging, better food, better education, and better health conditions are available in the towns. Socially the city dweller, particularly in Dakar, follows a way of life which represents a break with the traditional values of communal village life in its pure form. As worker, clerk, or trader, the town dweller follows a timetable that is governed by the clock instead of by the seasonal rhythms of the countryside. In the towns Tukulor, Wolof, Fulani, Serer, and Dyola tend to define themselves as Senegalese rather than in terms of their community of origin and feel themselves to be a part of the nascent Senegalese nation.

Senegal today, in sum, presents two distinct aspects to the contemporary observer. On the one hand stands Dakar, the capital, with its inhabitants in communication with international society and a universal civilization; on the other stands the remainder of the country, following a provincial pattern of life which has lost its primary impulse and which is growing increasingly stagnant.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. Both the rhythm of life in Senegal and the Senegalese mentality have evolved over a long period of time in a setting which was unacquainted with technology in the Western sense of the word. The attitudes of Senegalese in their relations with nature are consequently different from those of Europeans in general. Fear, magic, and collectivism are dominant in traditional Senegalese life. Writing is absent, or constitutes at best no more than the prerogative of the few. The cultural heritage is preserved in oral tradition of which the guardians have been the most experienced, that is to say the oldest, men. Society thus forms a hierarchy, at the summit of which stand the oldest people.

The state of the arts and popular culture. The traditional Senegalese cultural heritage remains much alive. Rites and initiations are actively practiced in rural areas—for example, by the Bassari of Kédougou. Among Muslims, youths must be circumcised before being accorded the responsibilities of adulthood.

Art, sculpture, music, and dance remain typically Senegalese in expression. Sculpture is characterized by abstraction and by the ideogram; a sculptured gazelle, for example, may be represented solely by its horns and its neck, while an elephant may be represented only by the immense fan formed by its ears and its trunk. The Senegalese artist thus neglects the material aspect in order to give free rein to ideas and to feelings. Similarly, in the absence of written music, the imagination of the musician is released. Without falling into the realm of fantasy, the *griot* (a West African kind of troubadour) recites poems, or tells of warrior deeds, drawing upon his own sources of inspiration. Both dance and music owe much to im-

provisation, which, combined with rhythm, produces an intense effect upon the entire community.

Senegalese literature is incarnated by President Léopold Sédar Senghor. The quality and the importance of his work resulted in his election, in France in 1970, to the Académie des Sciences Morales et Politiques. He is the poet associated with *négritude*, a concept that he has defined as consisting on the one hand of an attitude of defense of the traditional values of black Africa, and on the other of tension towards the modernization of these same values. From this concept Senghor has drawn his political philosophy not only concerning Senegal but the whole of black Africa. Besides Senghor one may also cite the names of Birago Diop, who has revived local legends, as well as of such writers as Ousmane Socé, David Diop, Alioune Diop, Cheikh Anta Diop, Cheikh Amidou Kâne, Abdoulaye Sadj, Abdoulaye Ly, Sembène Ousmane, and Bakary Traoré, all of whom are known for works which combine intelligence with the savour of Senegalese life.

Cultural institutions. Since the World Festival of Negro Arts was organized at Dakar in 1966, a number of existing institutions have been reoriented towards African traditions, while new institutions have also been created. Among the new institutions are the Musée Dynamique, the Théâtre Daniel Sorano, and the Tapestry Factory of Thiès. The existing institutions which have undergone some transformations are the Institut Fondamental d'Afrique Noire, the Maisons de la Jeunesse et de la Culture, and the craft village of Soumbédioune in Dakar, which has become a centre for Senegalese sculpture and goldsmithing.

Press and radio. Senegal was the first of the former French West African territories to have a press. The *Moniteur du Senegal* was founded in 1854, to be succeeded by the *Journal Officiel du Sénégal*. A nonofficial press has also long thrived in Senegal. For a long time the principal independent publication was the daily *Paris-Dakar* which, when Senegal became independent, was renamed *Dakar Matin*. In 1970 both *Dakar Matin* and the publication of the government party, *L'Unité Africaine*, gave way to a new publication *Soleil du Sénégal*. Other important Dakar newspapers are *Afrique Nouvelle* and *Le Moniteur Africain*, while magazines include *Africa* and *Bingo*. Radio Sénégal broadcasts both in French and in English, as well as in several African languages. In 1971 there was no television service.

FUTURE PROSPECTS

In the economic and social sphere, Senegal, of all the West African states of French expression, is the one which has benefitted the most from a modern economic infrastructure. Development was, however, intended to serve colonial ends and envisaged Senegal as playing the leading administrative role among the former French West African territories. It is the reorientation of Senegal towards more restricted national policy goals that is at present causing many problems for the government. Of all the constraints to which Senegal is now subjected, the most serious arise from overdependency upon a single crop economy. Since 1965 the government has been attempting to alter the situation by encouraging crop diversification. This policy has, however, placed the government on the horns of a cruel dilemma: on the one hand the preferential prices accorded by France were ended in 1967, so that it became necessary to increase production in order to compensate for the loss of revenue; on the other hand the necessity of diversifying crops requires a diminution in the proportion of peanuts produced. This situation has become further aggravated by the increasingly serious deficit in the balance of trade. In 1970, finally, serious and dramatic perspectives on the future were opened by the disinclination of the rural population to maintain peanut production as a result of the defective operation of the Agricultural Marketing Board.

It is clear to many that the dominance of peanut production in the national economy must be replaced by diversification, and that this measure should be accompanied by another step—the organization of a West African

The
Organiza-
tion of
Senegalese
Riverain
States

economic grouping. Senegal is already attempting to attain this end by forming—in cooperation with the neighbouring states of Mali, and Mauritania—the Organisation pour la Mise en Valeur du Fleuve SCnCgal (Organization for the Development of the SCnCgal River) for the purpose of achieving the harmonious development of the potentialities of the Senegalese river valley. Senegal argues that it deserves more understanding than it is given by virtue of the originality of the political and economic course that it has been following; that it has chosen to safeguard human values, rather than to sacrifice them for the sake of spectacular economic development—a policy which has placed it in the western camp in the contemporary world. The struggle that it is pursuing to rehabilitate the values of *négritude* when confronted with technical civilization is also proving a rewarding task.

SCnCgal River

The SCnCgal River, 1,015 miles (1,633 kilometres) long, is one of West Africa's longest rivers. Two of its three headstreams rise in the Fouta Djallon plateau, after which it flows northwestward and then westward to drain into the Atlantic Ocean. For 533 miles of its course, it forms the boundary between the Islamic Republic of Mauritania to the north, and the Republic of Senegal to the south. In medieval times, reports of its existence as the "River of Gold" reached European navigators. From the 16th to the 20th centuries, the river formed a route of advance for French colonial influence.

Course of the river. Of the various headstreams of the river, the Falémé and Bafing rise in the Primary sandstones of the Fouta Djallon plateau in Guinea, while the Bakoye rises in western Mali. The Bafing and Bakoye meet at Bafoulabé in the Republic of Mali to form the SCnCgal, 650 miles from its mouth; the stream is then joined by the Falémé near Bakel, below Kayes. From here onward the Senegal–Mauritania boundary lies on the right bank, so that the river belongs to Senegal; nevertheless, a *modus vivendi* (temporary arrangement pending a settlement) permits the use of the river by Mauritania.

From Bakel to Dagana, a distance of 385 miles, the river flows through an alluvial valley as much as 12 miles wide. Floods come in early September at Bakel, reaching Dagana by mid-October. Water level rises 12 feet, the flow is 300 times greater than in the dry season, and the river occupies the entire valley. As the floods retreat, maize (corn), sorghum, sweet potatoes, tomatoes, pulses (plants of the pea family), and cucurbits (plants of the gourd family, such as pumpkins and watermelons) are planted, in that order. The river has many branches, called *marigots*, with meanders, cutoffs (new and shorter channels formed by the water cutting across bends in the river's course), and hollows (depressions in the river's valley), the latter permitting cultivation with sorghum and rice. This is the most populated part of the valley.

Below Dagana, 165 miles from Saint-Louis, the SCnCgal enters its delta. The river floods more widely, and water and soils are saline. The delta is visited by nomads but is sparsely settled. The mouth has been deflected southward by the offshore Canary Current and by trade winds blowing from the north; the result has been the formation of a long sandspit, the Langue de Barbarie. Saint-Louis lies in the river's estuary, which has such a dangerous bar that its port was supplanted by Dakar, 163 miles to the south, after a Dakar to Saint-Louis railway link opened in 1885.

Climate, vegetation, and animal life. The Bafing and Falémé sources receive 80 inches of annual rainfall, mostly from late March to early November; the Bakoye

Basin receives less. The SCnCgal Valley proper receives 10 to 30 inches of rain annually, from late May to mid-October, with mean maximum temperatures of about 105° F (41° C) in April, and mean minimum ones of about 62° F (17° C) in January. Rainfall diminishes downstream, and the climate of Saint-Louis is similar to that of Dakar.

Typical trees of the valley are acacias, notably *Acacia nilotica*, which grows profusely on banks, and *A. senegal*, which provides the gum arabic of commerce, and grows on drier slopes. The grass *Vetiveria nigriflora* grows in tufts in wet depressions. In dry areas near the valley sides *Acacia albida*, *Balanites aegyptiaca* (a shrub with leathery leaves), and grasses are common.

The river is overfished. Nile perch are common. Spoonbills, herons, egrets, and weaver birds are widespread. Among the animals on the river banks hedgehogs, monitor lizards, and warthogs are fairly common.

The riverine peoples. Below Dagana the peoples of the valley are Wolofs; from Dagana they are Tukulors (Toucouleurs) to upstream of Matam, where Soninke (Sarakole) dominate. Throughout the SCnCgal River region small groups of usually nomadic Fulani and Mauri (more commonly Maure or Moors) are found. Villages average about 300 people, who grow millet on the rain-fed lands and use the floodlands for other crops. Both areas provide pasture for the livestock of nomads.

Exploration. French ships entered the estuary at least as early as 1558. From a French fort established in 1638, reconnaissance parties went 160 miles upriver to Podor. In 1659 a larger fort was erected on N'Dar Island in the estuary and named Saint-Louis-du-SCnCgal after the French king Louis IX (St. Louis). This became a base for French exploration of the river and for trade in slaves, gum, gold, skins, ivory, beeswax, and ostrich feathers. André Brûe built a post, Saint-Joseph-de-Galam, 400 miles upstream in 1698, and parties sent by him reached the Félou Falls above Kayes soon after. Some went up the Falémé, where another fort was built. Pierre David penetrated far up that river in 1744.

Resource exploitation. Rice cultivation on lands from which floods have retreated has been locally improved by embankments, with sluices constructed mainly on the Senegalese river bank; diesel pumps are also being tried on the Mauritanian bank. At Richard-Toll, near Dagana, about 14,000 acres are irrigated by means of a dam across the Taoué, a tributary stream up which Sénégal floods penetrate to Lake Guiers. The dam admits this fresh water and retains it by closing the sluices at the end of the flood, thereby preventing the admission of tidal saltwater during the dry season. Rice and, more recently, sugarcane are grown by the use of mechanized equipment and paid labour. Rice yields have been disappointing because of saline soils and the depredations of the quelea bird. In the delta a 50-mile-long embankment controls the entry of floodwater to 78,000 acres, part of which has been prepared for cultivation. This scheme has yet to prove itself. Chinese technicians from Taiwan help with most schemes.

River traffic. Extension of a railway from Kayes to Dakar, completed in 1924, diverted traffic that previously went by river, after which the valley became an economic backwater. Local traffic is carried by boats drawing nine feet or less as far as Podor all year round, and as far as Kayes (566 miles from the river's mouth) from early August to mid-October. Most traffic plies between the river ports of Rosso, Bogué and Kaédi, in Mauritania. Minor ferries exist at Rosso and Kayes; there is a dry season causeway across the river at Kayes.

Prospects for the future. The Organisation des États Riverains du SCnCgal (the Organization of Senegalese Riverain States) comprising Guinea, Mali, Mauritania, and Senegal, promotes cooperation on the river and beyond, but political differences have limited its effectiveness. The construction of one or more dams has been proposed to improve flood control and produce power, but their justification is unclear.

Senghor, Leopold

Equally distinguished as poet, statesman, and advocate of *négritude*—the literary and artistic expression of the black African experience—Leopold Sedar Senghor was born on October 9, 1906, in the picturesque Senegalese town of Joal, the son of a prosperous trader of the Serer tribe. He spent his first seven years in a small village, and his first ambition was to become "a teaching priest to work toward the intellectual emancipation of my race." He therefore attended school at a nearby Catholic mission and a seminary. When he was 20, he realized that the priesthood was not his calling, and he transferred to the lycée (secondary school) in Dakar. Born into a large family, Senghor learned early to get along with people: white and black, Muslim and Christian, and members of both the Serer and the Wolof tribes. Yet, even as a young boy, he was described by an older brother as stubborn. He held tenaciously to certain convictions, one of which was his faith in the importance of African cultural values. As Jean Rous, one of his biographers, relates, when the director of the seminary "denounced [black African] backwardness in civilization," young Senghor retorted "that we, too, had a civilization."

Early life

By courtesy of the United Nations

Senghor, addressing the United Nations General Assembly, 1961.

In 1928 Senghor went to Paris on a partial scholarship and continued his formal studies at the Lycee Louis-le-Grand and at the Sorbonne. There he formed a lifelong friendship with his classmate Georges Pompidou, who later was to become premier and, eventually, president of France. During these years Senghor discovered the unmistakable imprint of African art on modern painting, sculpture, music, and literature, which confirmed his belief in Africa's potential contribution to what he would later call "the civilization of the universal." He learned that distinguished anthropologists, such as Leo Frobenius, had written enthusiastically of the African heritage and character. With the other two originators of the concept of *négritude*, Aime Cesaire of Martinique and Léon G. Damas of French Guiana, he read and discussed works by the black writers of the Harlem Renaissance of the '20s in the United States and translated some of their poetry into French.

Despite his respect for European poetry and Western political thought, he upheld the importance of his African heritage and exhorted his compatriots "to assimilate, not be assimilated."

In 1935 he became the first African agrégé, the highest rank of qualified teacher in the French school system, and began "teaching French to French youngsters" in Tours. Two years later he was transferred to a lycée near Paris. Drafted in 1939, at the beginning of World War II, he was captured in 1940 and spent two years in Nazi concentration camps, where he wrote some of his finest poems. On his release, he joined the French Resistance.

After the war he became a member of the French Constituent Assembly. He was chairman of the subcommittee that passed on the grammatical correctness of the new constitution. In 1946 he was sent as one of Senegal's two deputies to the National Assembly in Paris. Elected on the Socialist (SFIO) ticket, Senghor soon realized that only an African party would accord top priority to African needs. Rejecting the RDA (Rassemblement Démocratique Africain), which in those early years war, affiliated with the Communists, he founded the BDS (Senegalese Democratic Bloc) in 1948 and defeated Lamine Guèye, the SFIO candidate, by a wide margin in the 1951 elections for the French National Assembly. Five years later he became mayor of Thies, Senegal's railroad centre, and was reelected deputy.

When the French Parliament passed (1956) the loi cadre, which gave a large measure of self-government to the African territories, Senghor was one of the first to oppose the act. The loi cadre emphasized territorial rather than federal government, and Senghor realized that this would result in the proliferation of small, unviable states.

To counter the disintegration of West Africa and French Equatorial Africa, he helped to found, and he supported, a series of parties that were dedicated to establishing a federal African unity. But none of these was as successful as the RDA. On the home front he rejoined forces with Lamine Gueye to create the UPS (Senegalese Progressive Union; called after 1976 the Socialist Party [PS]), which by the early 1980s was still the governing party of Senegal. On the broader African scene, he was co-founder of the Convention Africaine in 1957 and the PRA (Party of African Regrouping) in 1958. The alliance of the UPS, the Senegal section of the PRA, and the Union Soudanaise became the PFA (African Federation Party) in 1959; Senghor was co-founder and president. This party led to the creation of what was called the Mali Federation in 1959. Senegal, former French Sudan (now Mali), Dahomey (now Benin), and Upper Volta, all of which had voted against an immediate rupture with France in the September 1958 referendum, were expected to become charter members of the new federation. Dahomey and Upper Volta defected, however, and only Senegal and the French Sudan remained. In December 1959 Senghor made his eloquent, successful appeal to French President Charles de Gaulle for independence. The Mali Federation lasted only until the following August, when the two component states separated. Senegal became a republic, and Senghor was unanimously elected president.

A second major crisis for Senghor occurred in late 1962, when Prime Minister Mamadou Dia, a longtime protégé of Senghor, attempted a coup d'état. The Senegalese again rallied behind Senghor, and Mamadou Dia was sentenced to life imprisonment. A new constitution was ratified, and Senghor was reelected President. He was reelected for three more five-year terms, in 1968, 1973, and 1978. On December 31, 1980, Senghor, 74 years old, resigned and was succeeded by Abdou Diouf.

As the chief executive of a new country with few known resources except peanuts (groundnuts), fish, and phosphates, Senghor tried to modernize Senegal's agriculture, to instill a sense of enlightened citizenship, to combat corruption and inefficiency, to forge closer ties with his African neighbours, to continue cooperation with the French, and to establish peaceful relations with the rest of the world. He advocated an African socialism based on African realities, free of both atheism and excessive materialism. He described the kind of socialism he was seeking

Political career

Assessment

as open, democratic, humanistic socialism that shunned such slogans as "dictatorship of the proletariat." A vigorous spokesman for the Third World, he protested unfair terms of trade that worked to the disadvantage of the agricultural nations.

His concern with political and economic issues strengthened his espousal of *negritude*, which he defined as "the sum total of cultural values of the Negro-African world." The first World Festival of Negro Arts was held in Dakar in April 1966 under the sponsorship of his government, the African Society of Culture, and UNESCO (United Nations Educational, Scientific, and Cultural Organization). For both his literary and his political works, he was awarded honorary doctorates by universities on four continents. In December 1969 he became the first African member of the French Academy of Moral and Political Sciences, filling the vacancy caused by the death of the former German chancellor Konrad Adenauer.

Senghor's career was replete with paradoxes. Although a Catholic and a Serer, he headed a predominantly Muslim, Wolof nation. An outstanding intellectual, he drew his main support from the peasants. A distinguished poet, he was also a professional politician of great skill. The theoretician of *negritude*, Senghor believed, with the French scientist and philosopher Teilhard de Chardin, in the eventual emergence of a planetary civilization.

BIBLIOGRAPHY. The major works of Senghor are: *Poèmes* (1964), containing poems previously published in his *Chants d'ombre* (1945), *Hosties noires* (1948), *Chants pour Nègri* (1949), *Ethiopiennes* (1956), and *Nocturnes* (1961); *Selected Poems*, trans. by JOHN REED and CLIVE WAKE (1964); *Anthologie de la nouvelle poésie nègre et malgache de langue française*, ed. by SENGHOR, with a famous preface by JEAN-PAUL SARTRE (1948); *Liberté*, 2 vol. (1964–71), essays, prefaces, and speeches by Senghor; *Pierre Teilhard de Chardin et la politique africaine* (1962); and *On African Socialism*, trans. by MERCER COOK (1964), three essays.

Works about Senghor include: JEAN ROUS, *Léopold Sédar Senghor: La vie d'un président de l'Afrique nouvelle* (1967), a short biography by a personal friend and political adviser; ARMAND GUBERT, *Léopold Sédar Senghor* (1961), biography, poetry, an interview, and press comments (in French); and I.L. MARKOVITZ, *Léopold Sédar Senghor and the Politics of Negritude* (1969), a scholarly study of the man and of his theory on the evolution of *negritude*.

(W.M.C.)

Sennacherib

Sennacherib (Akkadian, Sin-akhkhe-eriba [the God Sin Has Replaced the Brothers]) was king of Assyria from 704 to 681 BC. He was the son and successor of Sargon II, from whom he inherited an empire that extended from Babylonia to southern Palestine and into Asia Minor, and as king he waged campaigns in Babylonia and rebuilt the city of Nineveh.

Sennacherib leading a military campaign, relief from Nineveh, c. 690 BC. In the British Museum.

Before his accession he served, with ability demonstrated by his extant reports, as a senior administrator and diplomat in the north and northwest of the empire. The main

problem of his reign was in Babylonia, where the growth of the power of the Chaldean and Aramaean tribes seriously disturbed the old urban centres, whose interests in commerce and need for safe trade routes made them usually pro-Assyrian. Political instability was made worse by the interference of Elam (southwestern Iran), so that between 703 and 689 Sennacherib had to undertake six campaigns in that area; his attitude toward the capital city, Babylon, changed from acceptance of native rule to hostility.

The peace was broken in 703 by a tribal insurrection under the Chaldean Merodach-Baladan (Marduk-apal-iddina), with Elamite military assistance. By skillful generalship Sennacherib recovered northern Babylonia and appointed a native Babylonian, Bel-ibni, as ruler. His army devastated the tribal areas in southern Babylonia, though he spared major Babylonian cities, except for a few that had gone over to the tribesmen. Elamite interference in Babylonia probably dictated a campaign in 702 against the petty kingdoms of the Zagros Mountains, vassals of Elam, to forestall a possible Elamite thrust by that route toward eastern Assyria.

In 701 a rebellion, backed by Egypt, though probably instigated by Merodach-Baladan (II Kings 20:12–18; Isa. 39:1–71, broke out in Palestine. Sennacherib reacted firmly, supporting loyal vassals and taking the rebel cities, except for Jerusalem, which, though besieged, was spared on payment of a heavy indemnity (II Kings 18:13–19:36; Isa. 36:1–37:37). The biblical narrative has been interpreted as implying two campaigns against Jerusalem, but this receives no support from Assyrian sources.

Further intrigues by Merodach-Baladan necessitated another Assyrian campaign into the Chaldean area in 700. Merodach-Baladan thereupon took refuge in Elam, where he soon died. Sennacherib's hardening attitude toward Babylon was marked by the introduction of direct Assyrian rule through the replacement of Bel-ibni by Sennacherib's son Ashur-nadin-shum. This gave Babylonia a brief period of stability, during which Sennacherib undertook campaigns in Cilicia and the north. Continuing Elamite support for disaffected Chaldean tribesmen, however, led in 694 to a further attack on southern Babylonia, coupled with a seaborne invasion of Elam across the Persian Gulf. Elam reacted by raiding northern Babylonia, capturing Ashur-nadin-shum, and installing a nominee who ruled for 18 months until removed during a fresh Assyrian attack.

Another Chaldean leader, Mushezib-Marduk, then seized Babylon and, by opening the temple treasuries, bought massive military support from Elam. In 691 the Assyrian and Elamite armies met at Halule on the Diyala, where Sennacherib, though claiming a victory, suffered losses that left him temporarily weakened. In 689 he returned to besiege Babylon, capturing it after nine months. Abandoning attempts to conciliate this great cult centre, Sennacherib systematically sacked Babylon; a text exists that probably represents a theological justification for this impiety.

Sennacherib's most enduring work was the rebuilding of Nineveh, his official residence as crown prince. On his accession he made it his capital, building a splendid new palace, Shanina-la-ishu (Nonesuch). Using prisoners of war for labour, he extended and beautified the city, laying out streets, enlarging squares, restoring and extending public buildings, and erecting a great inner wall, nearly eight miles (13 kilometres) long, which completely encircled the city, and an outer wall; both walls still stand. Around his capital he established plantations of fruit trees and parks of exotic trees and plants; among his introductions was the cotton plant, described as "the wool-bearing tree." To irrigate the plantations, for which at times the Tigris and Khosr rivers fell too low, Sennacherib sought springs and streams in the hills north of Nineveh and led them by six miles (10 kilometres) of canal and a massive stone aqueduct to feed the Khosr. He also undertook building activities in other cities, particularly Ashur.

Sennacherib claimed to be "of clever understanding," a boast supported by his initiatives in technology. He had surveys undertaken for new sources of alabaster and

Campaigns
in
Babylonia

Building
and
techno-
logical
achievements

building stone, and he discovered new stands of giant timber in mountain forests. He devised a new and less laborious method of bronze casting and introduced more convenient equipment for raising water from wells. He showed considerable logistic ability in his seaborne attack on Elam, in which ships built in Nineveh were taken by Phoenician sailors down the Tigris, overland to a canal of the Euphrates, and thence to the Persian Gulf.

Sennacherib died in January 681 by parricide, probably at Nineveh. He was survived by his principal wife Naqia, mother of his heir Esarhaddon, whose non-Assyrian name suggests that she was of either Jewish or Aramaean origin.

Because of his attack on Jerusalem, Sennacherib receives prominence in the Bible. Isaiah regarded Sennacherib as God's instrument (II Kings 19:23–28; Isa. 37:24–29); the prophet did not condemn the King's military activities as such, though punishment was decreed for his arrogance in not acknowledging the divine source of his power.

In *The Story of Ahikar* (a pre-Christian Oriental work), Sennacherib is seen as a king of apparently good repute, under whom the sage Ahikar served; where this same story is alluded to in the book of *Tobit*, however, the King is cast in an evil role. A similar ambivalence is shown in Jewish Talmudic tradition, where Sennacherib, though called an evil man, is also regarded as the ancestor of the teachers of the celebrated Rabbi Hillel.

Classical tradition retained a memory of Sennacherib's activities not only in Babylonia but also in Cilicia, where the building of Tarsus, on the plan of Babylon, was attributed to him. He was also credited with building a temple at Athens. Herodotus' story of an attempted invasion of Egypt frustrated by mice eating the Assyrian bowstrings and quivers may reflect a plague epidemic during Sennacherib's Palestinian campaign; this possibly underlay the story (in II Kings 19:35; Isa. 37:36) of the decimation of the Assyrian army by God's destroying angel, which inspired Lord Byron's poem "The Destruction of Sennacherib."

BIBLIOGRAPHY. D.D. LUCKENBILL (trans.), *The Annals of Sennacherib* (1924), edits all relevant texts then known. This is supplemented by a bibliography and an interesting new text by A.K. GRAYSON, "The Walters Art Gallery Sennacherib Inscription," *Archiv für Orientforschung*, 20:83–96 (1963). T. JACOBSEN and SETON LLOYD, *Sennacherib's Aqueduct at Jerwan* (1935), offer the definitive account of that structure. H.W.F. SAGGS, *The Greatness That Was Babylon*, pp. 118–222 (1962), gives a general account of Sennacherib.

Sensorimotor Skills

Even in the age of automation motor skills must be acquired and utilized. Proficiency in a wide range of activities is dependent upon one's ability to move accurately and within specified time limits. The growing child must master a long list of complex skills as he matures—feeding and dressing himself, riding a bicycle, throwing and catching balls—if he is to be considered successful by his parents and his friends. Social competence hinges to a great extent upon the ability to exhibit proficiency in the contemporary dances; many vocations and professions require abilities to move the fingers, limbs, and body in precise ways. The manual dexterity of the dentist, the ferocious movements of the professional athlete, and the creative efforts of the artisan have in common the necessity to acquire various motor skills and subskills for the assurance of success.

While many modern conveniences have purportedly made life's activities simpler and have apparently reduced the demands upon human beings to learn skills, many other actions demanded of men today require more proficiency. Cars move at higher speeds, requiring quicker and more precise reactions on the part of their operators; the simple radio has been replaced by the colour television set with its multitude of dials; the foxtrot and waltz have been replaced by the more complex dances that require different rhythm patterns to be maintained simultaneously in several parts of the body. Hobbies and recreational pursuits of wide variety are sought by man in an

apparent effort to exercise and to extend his capacities to perform motor skills. Painting and needlework require precision by smaller muscle groups, while tennis, swimming, and the like require the coordination of both large and small muscle groups working in unison.

The term "skill" denotes a movement that is reasonably complex and the execution of which requires at least a minimal amount of practice. Thus skill excludes reflex acts. One does not become skilled at sneezing or at blinking the eyes when an object approaches. At the same time, it has become increasingly apparent to scientists investigating the performance and acquisition of motor acts that the performance of complex skills is closely linked to sensations arising from the things the performer looks at, sensations from the muscles that are involved in the movement itself, as well as stimuli received by other sensory end organs. Thus the term "sensorimotor skill," denoting the close relationship between movement and sensation in the acquisition of complex acts, is found within the research literature with increasing frequency.

Simple components of bodily skills. Most of life's skills are continuous and complex and contain a multitude of integrated components; however, these complex skills may be analyzed by examination of their component parts.

The performance of a skill may be broken down into several time intervals. Initially the performer must be attentive and alert enough to be receptive to some kind of sensory information, which may in turn lead toward some kind of motor act. For this to occur the performer usually becomes aware of some kind of stimulus that is intense or distinctive enough to be perceived as different from other sensory information.

As this cue occurs the performer then must make a decision to act or not to act; and this is generally dependent upon his past experience within similar situations and with similar stimuli, as well as upon his feelings about his personal capabilities. If he decides to act, the next thing that occurs is the selection of an appropriate motor response from the entire "collection" of motor responses that he has acquired.

In the laboratory, a subject's reaction time is the time between the presentation of some kind of stimulus and the performer's initiation of response. The individual's speed of reaction in such situations is dependent upon a number of variables, including the intensity of the stimuli; for example, a person will initiate a movement more quickly to increasingly louder sounds until a limit is reached. If too loud a sound is presented it will delay the onset of the movement and result in a longer reaction time. Similarly, a longer reaction time will be recorded in such experiments if the subject is aware that he will have to initiate a complex movement or if the subject must choose from among a number of stimuli before initiating a movement (e.g., if he must move only if one of a number of various coloured lights is turned on).

The quality of the movement then initiated is dependent upon a number of other factors, the precision of the act required, the past experience of the performer in similar skills, the speed of the movement, the force of the motor act, as well as body part or parts to be moved.

The efficient performance of many types of extremely simple motor skills may be limited by inherent response capacities built into the human nervous system. Finger tapping at more than ten times per second for example is not usually possible. A person's ability to keep a body part relatively steady may be disturbed by natural, regular, and rather predictable oscillation rates of the limbs, fingers, and of the total body (evidenced in measures of body sway).

Individuals vary greatly in their ability to exercise force with various body parts. At the same time, there are limits beyond which it is not realistic to expect humans to go when evidencing strength in various tasks.

Careful experimentation reveals that because of the complexity of the human motor system it is unlikely that an individual ever repeats an apparently similar movement in precisely the same way. Thus the acquisition of skill in a given task involves the performance of a reason-

Definitions

Reception of stimulus and selection and initiation of response

Factors that affect quality of motor response

Basic abilities that contribute to motor skills	<p>ably consistent response pattern, which varies, within limits, from trial to trial.</p> <p>It is a common observation that there seem to be a number of basic motor abilities that may underlie the performance of a number of life's activities. This subject was investigated rather extensively during the 1950s and 1960s. The intercorrelation of performance scores elicited from thousands of young adult subjects who participated in these investigations revealed that there are in fact a number of basic abilities that contribute to the efficient performance of both fine and gross motor skills. Although a detailed examination of these abilities is not possible here, in general it was revealed that there are five components of what might be broadly referred to as "manual dexterity," including fine finger dexterity, arm-wrist speed and aiming ability. Similar research has explored the manner in which performance scores group themselves in skills in which larger muscles are involved. It was found, for example, that there are several kinds of strengths, including static strength (pressure measured in pounds exerted against an immovable object); this is independent of what was termed "dynamic strength" (moving the limbs with force). Muscular flexibility and balancing ability were similarly dissected into several components. Thus discussion of a single quality in human movement is inaccurate. Rather, one should refer to several specific types of ability.</p>	<p>information relative to limb location and object location (if an object is to be dealt with) are employed during the performance of the task to correct the movements of the limb, as when a person reaches toward a glass of water. Thus the direction and speed of the arm are controlled by constant and regular visual monitoring, just as are the initial attempts of a young child to write the letter a.</p> <p>The external stimuli that afforded information concerning the location of the hand and pencil during the writing of the letter a and the position of the arm, hand, and water glass in the first example cited form only part of the regulatory feedback system. There are also internal sources of feedback. The mature performer is aware of the positions of his arm when he cannot see it. Most adults can write their names without watching their hands, or can reach for a glass of water with only a minimum of attention directed toward the location of the vessel they are seeking.</p>	External and internal feedback
Other classifications of motor skills	<p>Motor skills may also be classified by reference to the more general characteristics of the tasks themselves rather than by measuring and intercorrelating the scores elicited by human subjects. It is common, for example, to find the dichotomy "fine" and "gross" motor skill, in which the latter label is applied to acts in which the larger muscles are commonly involved, while the former classification denotes actions of the hands and fingers. One researcher has proposed a three-way classification system, separating human movements into "body transport movements," in which the total body moves in space; limb movements; and manual (hand) actions. In general, however, most skills incorporate precise movements of both larger and smaller muscle groups working in harmony. The basketball player must use his larger skeletal muscles to run and jump but at the same time must employ a fine "touch," evidencing accurate finger control, when dribbling the ball. On the other hand, when a person sits at a desk and writes, the large postural muscles that contribute to the writer's stability are invariably active.</p>	<p>In another experiment the subjects were required to transfer pins from one hole to another with a small pair of pliers. The subjects viewed their performance in a television monitor, which permitted the experimenter to eliminate the subject's view of the pins; the pliers; his own hand; or any combination of pins, pliers, or hand. Improvement in the task was possible under all conditions, and even when all visual information was eliminated the subject learned by apparent reference to the kinesthetic cues arising from the movements of his hands.</p> <p>In addition to information from the performer's own visual and muscular systems, cues from other sources contribute to the execution of sensorimotor skills. This information may consist of some kind of formal instructions prior to attempting the task or may consist of knowledge given at the completion of the task concerning the relative accuracy evidenced.</p> <p>In general it has been found that formal instructions about the mechanics and execution of the task are more effective during the earlier than during the latter stages of skill acquisition. Information relative to task success at the completion of performances is usually more effective if delayed several seconds to give the performer time to integrate the sensory information obtained from his own visual and muscular systems.</p>	The timing of formal instructions
Three phases of learning motor skills	<p>Complex, integrated skills. Most of life's skills are not simple ones. They are rhythmic at times and almost always are composed of several integrated parts. Such skills often are often controlled by the organization of visual information available to the performer, particularly during the early stages of learning. At the same time, the individual's ability to analyze the mechanics of a motor task, his verbal ability, and other intellectual and perceptual attributes may influence his acquisition of a skill.</p> <p>Motor-skill learning has been divided by some authors into three phases. In the first, or cognitive phase, the learner attempts to achieve some understanding of the requirements of the task. Studies of effectiveness of verbal and cognitive pretraining attest to the importance of this initial phase for skilled learning. In the second, or intermediate phase, the learner acquires new response patterns, recognizes the similarity and differences between old and new actions, and gradually eliminates inappropriate motions while instilling the proper ones into the complex skill. In the final phase of skill learning, the skilled act becomes increasingly automatic and less dependent upon external cues. Improvement in performance continues during this final stage but usually at a decreasing rate.</p> <p>Some researchers employ the cybernetic term "feedback" to explain the manner in which a highly complex motor skill is performed. This basic concept generally hypothesizes that the human being is a type of self-correcting servomechanism. And within such a model several types of feedback systems may be used to explain the mechanisms of human skill. During the initial stages of skill acquisition, for example, discrete "bits" of visual</p>	<p>In addition to instructions in the performance of a task offered by another person, it is apparent to many teachers of motor skills and to most experimenters that, as people perform, they silently verbalize instructions to themselves. In one recent experiment it was found that one group of mature college-age youth, left alone in a gymnasium to work out their own unique skill deficiencies, were able to perform badminton skills better than was a second group that was exposed to formal instruction. In general, however, the research indicates that appropriate instructions properly placed within a learning schedule raise final performance levels.</p> <p>Emphasis should be placed, however, upon matching proper instructions to the attributes important during various levels of skill acquisition. In a limited number of tasks it has been demonstrated that perceptual components, knowledge of mechanical principles, and awareness of spatial relations were most important during initial stages of learning; while various motor attributes, reaction time, movement speed, and the like, assumed greater importance during the final stages of skill learning. Final performance was accelerated, in experiments in which these principles were accounted for, by the appropriate placement of instructions just before the emergence of important perceptual, intellectual, and motor factors within a learning schedule.</p> <p>Much attention has been paid to the influence of the duration and placement of practice sessions upon performance and learning. A vast array of practice schedules has been studied, including schedules in which practice sessions were closely spaced in time, those in which a</p>	

prolonged rest was permitted between trials, and various other combinations of spaced and massed practice.

It is usually found that relatively brief practice sessions followed by prolonged rest periods, at least equal in time to the practice sessions, promote the best terminal performance. It is probable that practice sessions should be shorter when less interesting skills or those that are physically taxing are to be acquired, whereas when the task is interesting and not physically fatiguing, performance may be facilitated if the practice sessions are closely spaced in time.

Reasons for plateaus in motor learning curves

When successive performance measures are plotted, a learning curve is obtained that often reveals periods during which no improvement is apparent. These learning "plateaus" often are accounted for by the suggestion that the performer is taking time to build up larger response units from smaller ones. For example, the early studies of this phenomenon utilized the sending rates of telegraphers. It was hypothesized that initially the sender responded to discrete letters, while later he responded to whole words, and finally tapped out phrases. The time taken to integrate letter, word, and phrase responses, during which no apparent improvement occurred, corresponded to plateaus in the learning curve. More recent thinking on this subject, however, suggests other reasons for plateaus in motor learning curves. The hypothesis has been advanced that while response accuracy does not always evidence continual improvement, the intellectual components of the task may be mentally rehearsed by the performer in the absence of measurable progress.

Retention. Good retention is the goal of most people practicing motor skills. The literature indicates that motor skills are more easily retained than are most types of verbal material; however, the differences in retention obtained are often traceable to the relative difficulty and rhythmicity of the task rather than to the fact that one type of act is primarily verbal and the other motor. Easiest to retain is poetry, just as are rhythmic motor skills; more difficult to retain are skills in which there is some kind of irrational pairing of stimuli to response (e.g., moving a lever to a given position when one of ten light cues appears), just as are words having no meaning to the learner.

Factors affecting retention of motor skills

Retention of motor skills depends more upon how well a skill was learned than upon the specific conditions under which performance levels were obtained during initial practice. Overlearning that exceeds a given criterion of success by 50 or 100 percent usually elicits greater retention than if high performance levels have not been achieved initially.

Another factor that governs retention is whether the learner knows in advance that he is to be retested in a given skill. In several recent studies it has been found that groups of subjects who were given instructions that they would be retested for retention, retained more than did other groups who were afforded no similar instructions. If people know they will be held responsible for the reperformance of a skill, they apparently learn the skill with closer attention to the task than those who do not believe that they will later have to perform the skill.

Summary and overview. Skill acquisition involves two major processes. First on the one hand, the performer gains increasing facility in dealing with the sensory information available; he begins to attend to relevant cues, while ignoring information that is extraneous to the performance of the task. Second, the individual smooths his response pattern by dropping out inappropriate components and adopting and integrating relevant movement. Recent research indicates that this process continues for prolonged periods, the final stages of learning being marked by extremely subtle adjustments, involving the finite pairing of eye movements to other movements and the regulation of breathing.

Progress in the understanding of sensorimotor skill will be achieved when an increasing number of tasks within industry, education, and sports are analyzed to determine the general ability traits that contribute to each. Further effectiveness in the instruction of motor skills will occur when more skills are analyzed during the various stages

of their acquisition to determine the ability traits important to each phase. With this information it will be possible to design instructional programs that better match the ability trait structure underlying specific skills, and at the same time to determine at what point during a learning schedule (initial; intermediate, or later stages) various types of instruction should be inserted.

Evaluation of sensorimotor skill. Motor-skill tests may sample relatively simple response capacities, such as simple reaction time to an auditory cue, or more complex and prolonged responses, as when an operator attempts to keep two cursors perpendicular to each other and crossing on a moving dot on a television-type screen.

Some motor-skill tests are found exclusively in a laboratory setting. One of the more common of these is the pursuit rotor task, in which the subject must attempt to hold a flexible stylus and keep its end on a dime-sized circle rotating along the edge of a phonograph-like disk.

Other frequently researched tasks require the subject to coordinate his arms and legs in a device resembling the controls of an airplane, while reacting to some kind of visual display of lights indicative of the position of the "airplane." Motor-skill tests in the laboratory similar to motor skills seen in everyday life may be classified according to the response complexity and/or duration of response elicited from the subject, as well as by the complexity or the sensory information to which the subject is required to respond.

BIBLIOGRAPHY. Standard texts in motor learning include J.B. OXENDINE, *Psychology of Motor Learning* (1968); and B.J. CRATTY, *Movement Behavior and Motor Learning*, 2nd ed. (1967). Books by P.M. FITTS and M.I. POSNER, *Human Performance* (1967); and E.A. BILODEAU (ed.), *Acquisition of Skill* (1966), analyze in detail the sensory components of sensorimotor learning and also the influence of the knowledge of results upon learning. B. KNAPP, *Skill in Sport* (1963), is directed toward understanding the essentials of athletic skills. E. FLEISHMAN, "Human Abilities and Verbal Learning" in R.M. GAGNE (ed.), *Learning and Individual Differences* (1967); and A.W. MELTON (ed.), *Categories of Human Learning* (1964), contain excellent material on motor skill learning, emphasizing individual differences in skilled performance and learning.

(B.J.C.)

Sensory Reception

Sensory reception is the means by which an organism is able to react to changes in its external or internal environment, in particular through the activation of specific parts, which transform the energy change involved into vital processes. In many instances, environmental changes are transmitted from the receptor organ to other parts of the body by specialized cells, but in unicellular organisms such transformations are made by specialized organelles, such as light-sensitive "eye spots" or cilia sensitive to mechanical disturbances. In all higher animals, sensory reception is the special function of sensory neural elements, which "translate" changes into nerve impulses. The biological significance of such a feature is that it allows an organism to make appropriate reactions to changed circumstances; without such provisions it would be in constant danger of injury or death at the slightest environmental alteration. In general, the more highly evolved the organism, the greater the number of environmental changes sensed and the more precisely each is analyzed. Some organisms, however, possess special senses developed for perceiving environmental changes not registered by, nor relevant to, other species.

There are some environmental conditions that are sensed readily by certain animals but only poorly or not at all by man. Man, of course, has taken advantage of the sharpened senses of other animals, as when he uses the acute smell sense of pigs for gathering truffles and of dogs in hunting and more recently for discovering contraband (e.g., marihuana); the keen vision of falcons and hawks in falconry; and the heightened hearing sense of guard dogs.

Classification of sensory systems. According to location of receptors. In general, sense cells, or receptors, located superficially in an organism receive signals from outside the organism and are parts of the exteroceptive

Measurement of motor skills

Specialized senses

system. Receptors located inside the body receive signals from changes taking place inside the body and belong to the interoceptive system. On activation, sense cells cause reactions appropriate to their location; they are said to respond with their local sign. For example, a decapitated frog reacts to stimulation of the skin by precisely directed limb movements aimed at wiping away the stimulus. Local sign in man is expressed by a conscious awareness of the spot being stimulated, as when a person locates a thorn in the skin. This is not true for vision, hearing, and smell, however, the sources of which are localized away from the body surface. Although some authorities believe that projection in space is learned, especially in man, for most animals such ability seems to be innate. In many cases, enteroreceptors stimulate channels that are never brought into consciousness; the presence of a local sign is thus shown only by the appropriateness of the resulting reactions. Internal pain is remarkable in that it is usually "misdirected" (referred) to the body surface in well-established patterns, according to its origin, a considerable help in medical diagnosis.

According to *type of stimulus*. More than one type of energy applied to a sense cell can, if strong enough, generate a nerve impulse, which will be interpreted by the central nervous system (CNS) as a change in the specific energy to which the cell is sensitive and will cause the same results as if the appropriate stimulus were present. Thus, a specific reflex action can be brought about by natural stimulations, such as touch of the skin, as well as by electrical stimulation of the nerve fibres activated by such touch. Each type of sense cell thus causes a specific output reaction and a specific sensation, which is the modality perceived. In other words, if the optic nerve could be functionally connected to the ear and the acoustic nerve to the eye, lightning would be heard and thunder seen (see SENSORY RECEPTION, HUMAN).

Selectivity with regard to specific energy changes comes about in diverse ways, the simplest of which is the localization of the sense cell in such a way that it is protected from unwanted stimuli and by the use of accessory structures that make it extremely sensitive to the wanted one. The sense cells in the eye, for instance, are protected from any but the most severe changes in mechanical pressure; at the same time, the eye's optical properties focus the incoming light on the layer of sense cells constituting the retina. The hair cells of the ear, which are very sensitive to rapid changes in air pressure because of the ear's structure, are also well protected from other mechanical disturbances by shock-absorbing fluid.

Another main factor that differentiates types of sense cells is the presence of specific receptor sites for reacting with the energy to which they are specifically sensitive. Certain cells, for example, can be specifically stimulated by a given substance and no other, at least in the small concentrations required for reaction. Cells with such narrow reaction ranges are rare, however; more often, each cell has a wider spectrum, as is the case of the photoreceptors of the eye with regard to colour. Photoreceptors comprise three types of cell, each with a definite optimum but reactive to well-overlapping band widths, thereby providing for a range of colour vision. In other cases, it is the threshold (the lowest energy level) to any given stimulus that varies in different cells; this variation provides for measurement of the intensity of the stimulus. In many cases, however, intensity is coded by the frequency of the nerve impulses each receptor sends to the central nervous system.

The actual amounts of energy that can be transformed into a nerve impulse are sometimes amazingly small. One or a few photons of light absorbed may suffice not only for reception and transformation into a nerve impulse in several optic fibres but also for visual perception.

Photoreceptors are sensitive to light changes. They contain photopigments for absorption of light. The variety of photopigments in different cells determines the number of colours that can be distinguished. It is interesting to note that in insects, among other animals, colour sensitivity is extended into the ultraviolet range, though it is short in the red range. Cells especially sensitive to in-

frared radiation are found in the remarkable pit organs of vipers, which enable the snake to locate warm-blooded prey from a distance even when it freezes into immobility.

In the skin of warm-blooded animals, nerve endings, with or without accessory structures, are present that react especially to warming or to cooling (see THERMORECEPTION).

Well-known organs of chemical reception are those of smell and of taste. Except in cases in which there is great specificity to one substance, as, for example, the sex attractant in insects, the spectrum of chemoreceptive cells is broad. The sense of taste was long thought to be mediated by narrow, separate fibres for acid, bitter, sweet, and sour sensations; this viewpoint is now being replaced by one in which the spectra are considerably wider. Frogs have been shown to have taste cells that react specifically to distilled water. Chemoreceptors are also present as enteroreceptors, a well-known example being the carotid body in certain vertebrates; this organ monitors oxygen pressure in the carotid artery, which supplies the brain with blood.

Mechanoreceptors are the most widespread type of sense receptor and the most varied with regard to localization, sensitivity, and type of nerve-impulse firing. There are numerous subdivisions of the mechanoreceptive sense, such as touch, pain, sound, gravity, and muscle tone. Examples in humans include the naked nerve endings in the cornea of the eye; the Pacinian corpuscles in the skin, with their multilayered sheathlike covers; and the hair cells in the inner ear. Impulse formation may continue for as long as stimulus lasts, thus giving a continuous (tonic) type of discharge, or be limited and proportional to the rate of change of the stimulus, thus producing an abrupt (phasic) discharge. A remarkable type of mechanoreceptor occurs in the elastic organs of crustacean legs; movement-sensitive cells fire for the time a joint moves in one direction, and others fire for the opposite movement (see MECHANORECEPTION and SOUND RECEPTION).

Electroreception is known only in certain fishes. Electrosensitive cells are accompanied by an organ that sends out small or large voltage changes. The sense cells occur along the long axis of the fish, enabling it both to discover food objects in the surrounding water and to locate other fish. This system is a great aid for navigation in murky water (see BIOELECTRICITY).

Certain animals appear to be able to orient to environmental changes for which no specific sense cells are known. Among these, magnetism is the most outstanding example. In fish, magnetic fields may well be received by electroreceptors. In insects and birds, which seem to perceive magnetic fields, no special sense cells have been implicated. The wide variety of phenomena considered as extrasensory perception in man may be based on direct influence on central-nervous elements, thus bypassing sensory input channels.

Evolution of sensory systems. Specific sensory abilities do not show a clear evolutionary progression, most likely because the development of any type of sense depends on many other factors in the total ecology of a given organism. Vision, for instance, is sometimes poor or absent in a species of a class in which other members have a highly developed visual system: examples include cave-dwelling species, relatives of sighted emergent species.

Mechanical stimuli are effective in all forms of life. Specialized organs, however, appear very early in animal evolution; such organs include gravity and light receptors in jellyfish. In more advanced members of the phyla Mollusca and Arthropoda, greatly developed sense organs occur, some of which show an amazingly close resemblance to vertebrate organs; e.g., *Octopus* eyes and semi-circular canals (for equilibrium). There is always a close relationship between the presence of highly developed sense organs and a region of the central nervous system; the latter is needed to "process" the incoming information in order to abstract the cues of importance to a given animal. The fact that such elaborate systems exist does not exclude the possibility of much shorter and simpler

Taste and smell

Electro-reception

Photo-receptors

pathways, which provide for more localized and quicker reactions; for instance, the blink reflex, caused by the sudden approach of an object to the eye, bypasses the visual cortex of the brain.

Sensory information. Although sensory information must be coded into a flow of nerve impulses for transmittal over distances, interactions between adjacent sense cells and sensory neurons also occur. Nerve cells can influence each other by mutual connections that result in membrane potential changes (electrical differences) in one when the other is stimulated. Similar effects are often caused by nerve impulses. When a number of nerve cells (neurons) with adjacent receptive fields are activated, it is common to find that the ones receiving the strongest stimulation suppress the response of those that are stimulated less. This action leads to a sharper difference at boundaries of stimulated and nonstimulated areas; thus, contrasts can be enhanced by this process, known as lateral inhibition. Certain sense cells have the property of being active, usually at a low rate, when not stimulated. This activity can then be either increased or decreased by appropriate stimuli. It is by such means that neurons indicating visual movements in one direction or sounds changing from one frequency to another obtain their selectivity. Such elaborations can be performed at different levels of the central nervous system. In the higher mammals, for instance, the fibres forming the optic nerve are mainly of two types, with small visual fields, one in which light in the centre of the field excites while light in the surrounding field inhibits, and vice versa. In animals even as highly developed as the rabbit, more complex integration has taken place in the visual periphery, and optic fibres can indicate such features as the movement of oriented lines in specific directions, which in cats and monkeys does not seem to occur before units in the brain have sampled the incoming information.

From this and other information it is clear that the use of the animal makes of its senses is highly correlated with the type of sensory integration taking place in the nervous system. The ways by which a given stimulus is analyzed are varied and as yet only partially understood. It is, however, possible to build models that can be of mutual benefit for engineering and sensory information processing. By feeding back part of the incoming signal to earlier steps in the information processing, stability is greatly enhanced both in organisms and in machines.

(C.A.G.W.)

Sensory Reception, Human

Ancient philosophers called the human senses "the windows of the soul," and Aristotle enumerated at least five senses—sight, hearing, smell, taste, and touch—and his influence has been so enduring that many people still speak of the five senses as if there were no others. Yet, the human skin alone is now regarded as participating in (mediating) a number of different modalities or senses (e.g., hot, cold, pressure, and pain). The modern sensory catalogue also includes a kinesthetic sense (sense organs in muscles, tendons, and joints) and a sense of balance or equilibrium (so-called vestibular organs of the inner ear stimulated by gravity and acceleration). In addition, there are receptors within the circulatory system that are sensitive to carbon dioxide gas in the blood or to changes in blood pressure; and there are receptors in the digestive tract that appear to mediate such experiences as hunger and thirst.

Not all receptors give rise to direct sensory awareness; circulatory (cardiovascular) receptors function largely in reflexes that adjust blood pressure or heart rate without the person being conscious of them. Though perceptible as hunger pangs, feelings of hunger are not exclusively

mediated by the gastric (stomach) receptors. Some brain cells may also participate as "hunger" receptors. This is especially true of cells in the lower parts of the brain (such as the hypothalamus) where some cells have been found to be sensitive to changes in blood chemistry (water and other products of digestion) and even to changes in temperature within the brain itself.

CLASSIFICATION OF THE SENSES AND GENERAL CONSIDERATIONS OF SENSATION

Basic features. One way to classify sensory structures is by the stimuli to which they normally respond; thus, there are photoreceptors (for light), mechanoreceptors (for distortion or bending), thermoreceptors (for heat), chemoreceptors (e.g., for chemical odours), and nociceptors (for painful stimuli). This classification is useful because it makes clear that various sense organs can share common features in the way they convert (transduce) stimulus energy into nerve impulses. Thus, auditory cells and vestibular (balance) receptors in the ear and some receptors in the skin all respond similarly to mechanical displacement (distortion). Because many of the same principles apply to other animals, their receptors can be studied as models of the human senses. In addition, many animals are endowed with specialized receptors that permit them to detect stimuli that man cannot sense. A snake (the pit viper) boasts a receptor of exquisite sensitivity to "invisible" infrared light; some insects have receptors for ultraviolet light and for pheromones (chemical sex attractants and aphrodisiacs unique to their own species) thereby also exceeding human sensory capabilities.

Regardless of their specific anatomical form, all sense organs share basic features. (1) They contain receptor cells which are specifically sensitive to one class of stimulus energies, usually within a restricted range of intensity. Such selectivity means that each receptor can be said to have its own "adequate" or proper or normal stimulus, as, for example, light is the adequate stimulus for visual experience. Nevertheless, other energies ("inadequate" stimuli) can also activate the receptor if they are sufficiently intense. Thus, one may "see" pressure when, for example, the thumb is placed on a closed eye and one experiences a bright spot (phosphene) seen in the visual field at a position opposite the touched place. (2) The sensitive mechanism for each modality is often localized in the body at a receiving membrane or surface (such as the retina of the eye) where transducer neurons (sense cells) are to be found. Often the sensory organ incorporates accessory structures to guide the stimulating energy to the receptor cells; thus, the normally transparent cornea and lens within the eye focus light on the retinal sensory neurons. In some cases, blindness can be cured by surgically removing a lens that has grown opaque from cataract in order to permit light once again to reach the retina. Additional postoperative optical correction in the form of a contact lens or eyeglasses is necessary to compensate for the missing lens. Retinal nerve cells themselves are more or less shielded from nonvisual sources of energy by the surrounding structure of the eye; but mild electrical currents delivered to most sense organs, including the eye, can produce sensory experiences appropriate to the specific organ. The generalized electrical nature of neural function largely accounts for the effectiveness of such currents in evoking a full range of different sensations. (3) The primary transducers or sensory cells in any receptor structure normally connect (synapse) with secondary, ingoing (afferent) nerve cells that carry the nerve impulse along. In some receptors, such as the skin, the individual primary cells possess threadlike structures (axons) that may be yards long, winding from just beneath the skin surface through subcutaneous tissues until they reach the spinal cord. Here each axon from the skin terminates and synapses with the next (second-order) neuron in the chain. By contrast, each primary receptor cell in the eye has a very short axon that is contained entirely in the retina, making synaptic contact with a network of several types of second-order (internuncial) cells, which, in turn, make synaptic contact with third-order neurons called bipolar cells, all still in the retina. The

Classifica-
tion by
stimuli

Lateral
inhibition

Sensory
parts of
the brain

bipolar-cell axons extend afferently beyond the retina, leaving the eyeball to form the optic nerve, which enters the brain to make further synaptic connections. If this visual system is considered as a whole, the retina may be said to be an extended part of the brain on which light can directly fall. (4) From such afferent nerves, still higher order neurons make increasingly complex connections with anatomically separate pathways of the brainstem and deeper parts of the brain (*e.g.*, the thalamus) that eventually end in specific receiving areas in the cerebral cortex (the convoluted outer shell of the brain). Different sensory receiving areas are localized in particular regions of the cortex; *e.g.*, occipital lobes in back for vision, temporal lobes on the sides for hearing, and parietal lobes toward the top of the brain for tactual function.

Approaches to the study of sensing. The science of the human senses is truly interdisciplinary. Philosophers, physicians, anatomists, physical scientists, physiologists, psychologists, and others have all joined in studying sensory activities. Some of their earliest work was anatomical, an approach that continues to be fruitful. Physical scientists, particularly physicists and chemists, made especially important contributions to an understanding of the nature of stimulus energies (*e.g.*, acoustic, photic, thermal, mechanical, chemical); in the process, they also carried out many fundamental measurements of human sensory function. Hermann L.F. von Helmholtz, a 19th century German scientist who was a physicist, physiologist, and psychologist, studied the way in which sound waves and light are received (sensed or detected) and also how they are interpreted (perceived) by people.

Modern studies of sensation have been enhanced by contemporary devices permitting the precise production and control of sensory stimuli. With other kinds of instruments, physiologists have been able to probe the electrical signals generated by sensory cells and afferent nerve fibres to provide a biophysical analysis of sensory mechanisms. Psychophysics embraces the study of the inner (private, subjective) aspects of sensation in terms of outer (public, objective) stimulus energies. One of the oldest and most classical approaches to the study of sensation. psychophysics includes the study of people's reports of their sensations when they are stimulated: of their ability, for example, to match tones of equal loudness, to detect stimulus differences, and to estimate sensory magnitude or intensity under conditions of controlled stimulation. Psychophysical research continues as an active enterprise particularly among modern psychologists.

An old philosophical notion that "mind" is but a clean slate or tablet (*tabula rasa*) until written on by impressions from the senses no longer seems fully tenable; human infants, for example, show inborn (innate) ways of sensing or perceiving at birth. In its modern form, the problem of learned versus innate factors in sensory experience is studied in terms of the extent to which the genetically determined structure and function of sense organs and brain depend upon stimulation and experience for their proper maturation. Poverty of stimulation (sensory deprivation) in an infant's early life increasingly is being documented as detrimental to the full flowering of mature perceptual and intellectual functions. Since this sort of evidence may indeed lend some support to the notion of the *tabula rasa*, modern investigators give credence both to nativistic (based on heredity) and empiricistic (based on learning) interpretations of human sensory function (see also LEARNING, PERCEPTUAL).

A distinction between the discriminatory (epicritic) and emotional (protopathic) features of sensations was made by Sir Henry Head (1861–1940), a British neurologist, who noted, for example, that after a sensory nerve from the skin had been cut, the first sensations to recover as the nerve healed appeared to be diffuse, poorly localized, and extremely unpleasant. He theorized that this initial lack of sharp discrimination associated with unpleasant experience reflected the properties of a primitive protopathic (emotional) neural system which regenerated first. He held that this system subserves pain and the extremes of temperature and pressure sensation usually associated with an affective (emotional) tone. Because recovery of

fine tactual discrimination, sensitivity to lightly graded stimuli, and the ability to localize points touched on the skin returned later, Head posited the existence of another discriminatory system. While later research has not confirmed his theory, the sequence of changes in the recovery following nerve injury is most typical.

Chemical-visceral sensations particularly have hedonic (pleasure–pain) properties. Most people tend to refer to odours and tastes as pleasant or unpleasant; thus, the chemical senses are closely tied to motivation, to preferences, or to aversions. Although reflex licking or sucking is stimulated by tactual stimulation of lips and mouth, newborn infants tend to suck longer and harder when the stimulus has clear hedonic value; *e.g.*, avidly turning their lips toward a nipple to get a sweet taste. (See also EMOTION: MOTIVATION.) Apparently, one's sweet tooth is largely nativistic, in that it requires little prior learning. The craving for salt (especially heightened under conditions of salt deprivation) likewise appears to be widespread throughout the animal kingdom without prior learning. The role of taste and smell as innate factors in behaviour may not be quite so influential in man as in other animals. Man's food habits and preferences are strongly overlaid with custom and tradition; that is, they are learned in large measure.

In the modern era, the language of communication engineering has been found to be useful in describing human senses. Thus, each sensory modality may be described as a channel that receives stimulus information (input), that processes and stores the information, and that retrieves it as needed for the effective behaviour (output) of the individual. In addition, modern engineering has provided devices (*e.g.*, radio, television, radar, the electron microscope) that serve to extend the range and power of man's senses; in the last analysis, however, all such devices convert (transduce) their information back to a form of stimulus energy that is directly perceptible to the unaided senses. Thus a television set is a transducer that converts imperceptible electromagnetic waves into visual and auditory signals. For some special purposes, people may employ alternative sensory channels, as when blind people use Braille or other tactual input as substitutes for the missing visual channels. While the chemical senses have little function in symbolic communication among people, the use of perfumes in romantic signalling is a notable exception. In general, however, the human chemical senses are more directly involved in physiological survival; *e.g.*, warning that a putrid fish is dangerous to eat. One's physical well-being also rests heavily on his proprioceptors (for sensing his own bodily position) and on his sense of balance. These structures, monitoring (feeding back information on) his bodily orientation in space, provide crucial sensory feedback for guiding one's movements (see also PERCEPTION OF MOVEMENT).

CUTANEOUS (SKIN) SENSES

It was observed above that studies of cutaneous (skin) sensitivity yield evidence that man's senses number more than five. There is evidence for two pressure senses (for light and for deep stimulation), for two kinds of temperature sensitivity (warm and cold), and for a pain sense. In the 1880s, experimental findings that the human skin is punctate (selectively sensitive at different points) gave clear indication of a dissociation among functions once lumped together as the sense of touch. Mapping the skin with a fine bristle or with a narrow-tipped (warm or cold) cylinder showed that there were different spots of maximum sensitivity to pressure, warm, and cold. When stimulated between the spots on the skin, people reported no such sensations. Pain-spots also can be located with a finely pointed needle, but the punctate character is less striking since pain seems to be widespread when stimulus intensity is increased. The number of spots is greatest for pain, next for touch, then for cold, and least for warm. Efforts to identify specific receptor cells for each of these sensitive points have been the subject of much debate and still pose a problem that is not completely settled.

Nerve function. Microscopic examination of the skin reveals a variety of nerve terminals; there are free nerve

skinEmotional
aspects of
sensation

endings (which are most common), so-called Ruffini endings, and encapsulated endings, such as the pacinian corpuscle, Meissner's corpuscle, or Krause end bulb, all named for investigators who discovered them (Figure 1).

From E. Gardner, *Fundamentals of Neurology*, 5th ed. (1968); W.B. Saunders Company, Philadelphia

Figure 1: Microscopic view of human skin.

At one time it was thought that each of these specialized structures mediated one of the cutaneous modalities, but efforts to extirpate (surgically remove) the nerve endings under the spots have yielded only questionable data. Further, the cornea of the eye shows only free nerve endings; yet pain, pressure, and some temperature sensations can be elicited by stimulating the corneal surface.

Electrical recordings from the cutaneous nerves of laboratory animals suggest a much wider variety of receptors than are encompassed by the reports people give of their sensations. Some nerve endings seem to respond only to one type of stimulus (*e.g.*, to pressure stimuli of very light weight or to slight temperature changes); others exhibit a broad range of sensitivity. There are some receptors that show combined sensitivity to both temperature and pressure. In some cases only special types of mechanical stimulation (such as rubbing) may be effective. Furthermore, there is an extensive overlap in the areas of skin (receptor fields) for the individual nerve fibres examined, suggesting that there is a neural integration of overlapping afferent inputs of skin nerves. A model of the sensory system that envisages only a single nerve fibre serving one tactual spot is clearly contradicted.

On the other hand, some tactual receptors (*e.g.*, Pacinian corpuscles) respond only to mechanical deformation. This corpuscle is an onion-shaped structure of non-neural (connective) tissue built up around the nerve ending; indeed, the distinctive corpuscle, if anything, reduces the mechanical sensitivity of the nerve terminal itself. If the onion-like capsule is entirely removed, mechanical sensitivity not only remains but is somewhat greater than when the capsule is present.

In addition to the differences in the sensory end structures of the skin, the afferent nerve fibres (axons) from them also show diversity. The nerve fibres range in size from large myelinated (sheathed) axons of 10 to 15 microns diameter down to extremely small unmyelinated fibres measuring only tenths of microns across. Fatter axons tend to conduct nerve impulses more rapidly than do small fibres; when axons of different diameters form a single bundle (a nerve), they constitute a so-called mixed nerve. Thus, electrical records from a mixed nerve show what are labelled A (fast), B (medium), and C (slow) components that reflect the typical speeds at which axons of different diameters conduct. Although such specialized capsules as Pacinian corpuscles tend to be associated with larger diameter axons, and temperature-sensitive endings tend to be associated with medium-size fibres, a unique

relation of each of the skin modalities with one of the A, B, or C fibre groups cannot be supported. All of the cutaneous senses seem to be associated with some fibres of all diameters; furthermore, the C fibres (once thought to be restricted to the pain function) display quite specific sensitivities to nonpainful stimuli applied to the skin.

A major neural pathway for tactual impulses runs along the back (in the dorsal columns) of the spinal cord. Afferent fibres enter the cord from the cutaneous nerves and ascend without synaptic break in one (the ipsilateral) dorsal column. This is a very rapidly conducting pathway shared by fibres that mediate sensations of deep pressure and also kinesthesia. Other tactual, temperature, and pain information crosses the spinal cord close to the level of entry of the sensory fibres and ascends to the brain in contralateral pathways of the cord (the lateral and ventral spinothalamic tracts).

Each of the nerves distributed along the spinal cord contains a sensory bundle that serves a well-defined strip of skin (a dermatome) about an inch or more wide on the body surface. Successive spinal nerves overlap, so that each place on the skin represents two and sometimes three dermatomes; this yields a segmented pattern of strips over the body from head to toe. All dermatomes feed into a single relay centre (the sensory thalamus) deep within the brain, where a precise three-dimensional layout of tactual sensitivity at the body surface can be found. The neurons in this part of the thalamus (the ventral posterolateral nucleus) are specific to particular skin senses (such as pressure) and form small and precise receptor fields. There is a second more diffuse thalamic system (in the posterior thalamic nuclei) where the receptor fields are large, perhaps bilateral, on the left and right sides, perhaps including one whole side of the body. The receptor fields here or the types of stimuli to which they respond are not clearly delineated.

The dissociation of cutaneous senses is dramatically demonstrated in the course of some diseases; for example, in a disorder called syringomyelia, degeneration of the central canal of the spinal cord leads to loss of pain and temperature sensitivity. Nevertheless, the sufferer still can experience pressure. In some instances there may be a complete absence of pain sensitivity with disastrous consequences for the welfare of the afflicted person. Such individuals are bruised and cut and even lose parts of the body because they are unable to sense the dangerous (painful) characteristics of stimuli. Among people born with total absence of the pain sense, there may not be demonstrable anatomic abnormality. Still other instances of dissociation of pain versus pressure occur in surgical procedures (such as tractotomy) in which spinal tracts or parts of the nerves leading into the brainstem are selectively cut. Such operations are designed specifically to relieve pain without unduly diminishing pressure sensitivity.

Pathways from the specific (ventral posterolateral) thalamus end (or project) in a narrow band of brain cortex (the posterior Rolandic cortical sensory area in man) where there is a point-for-point representation of the body surface on the cortical surface. The cortical projection of the more diffuse (posterior) thalamic system is less well charted. There thus appears to be a dissociation between those tactual structures that are highly specific and those that are more generalized.

Tactual psychophysics. The mixture of sensitivities within a given patch of skin provides a ready basis for the concept of adequate stimulation. Sometimes, for example, a cold spot responds to a very warm stimulus, and the person experiences what is called paradoxical cold. The sensation of heat from a hot stimulus presumably arises from the adequate stimulation of warmth receptors combined with the inadequate or inappropriate (albeit effective) stimulation of cold and pain receptors.

Human ability to barely detect pressure (*i.e.*, the human pressure threshold) generally appears when a tension of about 0.85 grams per square millimetre of skin surface is applied on the back of the hand. Thus a force of 85 milligrams applied to a stimulus hair (or bristle) of 0.1 square millimetre is just about enough to elicit the experience of pressure. The energy of impact at pressure thresh-

Variations
in
sensory
nerve
fibres

Paradoxical cold

old is very much greater than that required for hearing or seeing, the skin requiring on the order of 100,000,000 times more energy than the ear and 10,000,000,000 times more energy than the eye. Differential pressure discrimination (the ability to detect just noticeable differences in intensity) requires changes of roughly 14 percent at maximum sensitivity.

Adaptation to pressure is well known; one's awareness of a steadily applied bristle fades and ultimately disappears. As a result people are rarely aware of the steady pressure of their clothing unless movement brings about a change in stimulation. Most dramatic and perhaps best known among tactual experiences is adaptation to thermal stimulation. Continued presentation of a warm or cold stimulus leads to reduction or disappearance of the initial sensation and an increase in threshold values. Total obliteration of thermal sensation through adaptation occurs in the range from about 16° to 42° C (61° to 108° F). If one hand is placed in a bowl of hot (40° C [104° F]) water and adapted to that, and at the same time the other hand is adapted to cold (20° C [68° F]) water, then when both hands are simultaneously placed in lukewarm (30° C [86° F]) water, the previously cooled hand feels warm and the other hand feels cold. This effect was once interpreted as evidence for a single temperature sense, but careful study shows that there are indeed two kinds of temperature receptors, both of which show adaptation. Cold receptors are characterized by an electrical discharge on sudden cooling, normally showing no response to sudden warming; similarly appropriate electrical responses are made by warmth receptors. Both receptors show steady discharges selectively depending on temperature; maximum discharge typically occurs between 38° to 43° C (100° to 109° F) for individual warmth cells and between 15° and 34° C (59° and 93° F) for cold receptors. These temperature receptors show no electrical response to weak mechanical stimulation in either laboratory animals or human subjects.

Pain Pain is least understood among all the human senses. The pattern of stimulation is more crucial in pain than in any other sense. A single brief electric shock to the skin or to an exposed nerve may not elicit the experience of pain; yet it tends to become painful upon repetitive stimulation. Cutaneous pain is often sensed more sharply than is pain associated with deep tissues of the body (e.g., viscera). Certain areas of the body are relatively analgesic (free of pain); for example, the mucous lining of the cheek into which one can bite shallowly without discomfort. The organs of the abdominal cavity are usually insensitive to cutting or burning, but traction or stretching of hollow viscera is painful (as when the stomach is distended by gas). Pain displays sensory adaptation, although the process appears to be more complex than it is for other sensory modalities. Thus, the intensities of headaches, toothaches, and pains from injury often show cyclic fluctuations, possibly from such factors as changes in blood circulation or in degree of inflammation. The visceral pains, those of dental origin, or of diseased tissues can be reduced by analgesic drugs, which tend to be less effective on cutaneous pain. Pain has a strong emotional context (see PAIN, THEORIES OF). In certain cases, after frontal lobotomies (a type of brain surgery) have been performed, a person may report that he still feels the pain of a pin prick or other irritation but that he does not find it as disturbing or emotionally disruptive as he did before the lobotomy. Many phenomena indicate the powerful role of the brain and spinal cord in sensing potentially painful sensory input. Indeed, according to one theory, a so-called gate control system in the spinal cord modulates (increases or decreases) sensory input from the skin to determine whether the input is perceived as painful. This theoretical formulation also may account for moment-to-moment fluctuations in the intensity of perceived pain despite the absence of any stimulus change. Such brain-mediated factors as emotional tension or past psychological experience are held to influence pain perception by acting upon this spinal gate control system.

Itching seems to bear the same relation to pain as tickle

does to pressure. The experience usually lasts long enough to demand attention and (like tickle) normally leads to a response such as rubbing or scratching the affected area. A number of skin disorders are accompanied by itching, presumably from a fairly low level of irritation in the affected area (which also may be produced in undiseased skin). While a single shock by a low-intensity electrical spark normally produces no sensation, a repetitive pattern of such shocks may induce an itch not unlike that produced by an insect bite. Itching also may occur as an aftereffect of the sharp pricking sensation produced by single strong shocks, presumably because the nerves continue to produce a patterned after-discharge following the cessation of the stimulus. Non-painful tactile pattern stimulation is exemplified by vibration. Different frequencies of vibration are readily discriminated and a tactual communication system employing vibrations on the skin has been devised, particularly for people who cannot see or hear. Further research will probably reveal other ways of utilizing the fine discriminatory capacities of the cutaneous senses as substitutes for other sensory avenues of communication.

KINESTHETIC (MOTION) SENSE

It is a common experience that, with the eyes closed, one is aware of the positions of his legs and arms and can perceive the active or passive movement of a limb and its direction. The term kinesthesia (literally "feeling of motion") has been coined for this sensibility.

Nerve function. Four types of sensory structures are widely distributed in muscles, tendons, and joints (Figure 2): (1) the neuromuscular spindle consists of small, fine

From E. Gardner, *Fundamentals of Neurology*, 5th ed. (1968); W.B. Saunders Company, Philadelphia

Figure 2: Sensory structures of muscle, tendon, and joint. Arrows indicate direction of conduction. (Motor nerves and motor nerve endings on contractile muscle fibres not shown.)

muscle fibres around which sensory fibre endings are wrapped; (2) the Golgi tendon organ consists of sensory nerve fibres that terminate in a rich branching encapsulated within the tendon; (3) joint receptors (as in the knee) consist of "spray-type" endings (Ruffini) and Golgi-type and Pacinian corpuscles within the joints; and (4) free nerve endings. All these receptors combine to provide information on active contraction, passive stretch of muscle fibres, and tension whether produced actively or passively. In passive stretch both the muscle-spindle receptors and the tendon receptors send trains of impulses over their sensory (afferent) nerves; in active contraction the spindles show a silent period of neural activity when tension on the parallel fibres is unloaded, while the tendon receptors discharge just as when stretch is passive.

The muscle spindle is contractile in response to its own small-diameter, so-called gamma motor (efferent) fibre. The receptors and the gamma motor fibres of the muscle spindle form a neuromuscular loop that serves to insure that tension on the spindle is maintained within its efficient operating limits. The excitability of the muscle spindle also can be influenced through other neural pathways

that control the general level of excitability of the central nervous system (brain and spinal cord). Activity of the descending reticular formation (a network of cells in the brainstem) may enhance the contraction of the spindle and hence influence its neural discharges.

The knee
jerk

Muscle and tendon receptors combine to play an intimate and crucial role in the regulation of reflex and voluntary movement. Much of this control is automatic (involuntary) and not directly perceptible except in the aftereffects of movement or change of position. The knee jerk that follows a tap just below the kneecap of a freely hanging leg is one such involuntary reflex. Sensory (afferent) impulses from stretching the receptors (*e.g.*, in the muscles) relay to the spinal cord and activate a path to the motor (efferent) nerves leading back to the same muscle. The knee jerk is a purely spinal reflex response (the brain is not required) which is tested usually to determine nerve damage or other interference with the spinal-cord motor mechanisms. Besides producing loss of knee jerk, a disease such as syphilis may lead to locomotor ataxia (a clumsy and stumbling gait) when the germ (called a spirochete) attacks the sensory nerves of the cord's dorsal column. The result is that the sufferer has difficulty sensing the position of his limbs. Another general function of the muscle receptors is the maintenance of muscle tone (or tonus: partial contraction) to permit rapid response (fast reaction time) to stimulation. In normal conditions the muscle has tone and is ready to go; but, when it is without motor stimulation (deafferented), the muscle is flaccid, showing little tone. One's upright posture depends on the tonus of opposing (extensor and flexor) muscles in response to the effects of gravity.

The exact contribution of the muscle receptors to sensation is not entirely understood. It seems clear, however, that they are not essential to the sensation of bodily position. It has been suggested that the appreciation of passive movement of the limbs probably comes largely from the joints, since, after anesthetizing the overlying skin and muscles (*e.g.*, with cocaine), sensibility to the limb movement seems little affected. Evidence also shows that very few of the impulses arising from the muscle receptors themselves reach the cerebral cortex; instead, they ascend in the spinal pathways to another part of the brain (the cerebellum) where they interact in the automatic control of bodily movement. Impulses arising from the joint receptors, on the other hand, have been recorded in both the thalamus and brain cortex, the degree of angular displacement of a joint being reflected systematically in these structures by the frequency of nerve impulses. Symptoms of some diseases also emphasize the importance of joint sensitivity. When bone disease, for example, destroys only the joint receptors the person's ability to appreciate posture and movement is lost.

Cerebellar
disorders

The feedback system. The feedback system leading to muscle tonus is a most delicately balanced mechanism. The gamma loop feeds back information that serves to maintain the muscle tonus and postural adjustments appropriate to the efficient performance of different voluntary actions. The afferent input from the muscle spindles via the spinal cord to the brain's cerebellum traverses an extensive circuit involving interactions of excitatory and inhibitory processes, the end result of which helps insure smooth and finely coordinated movements. Disease or other neurological damage in the cerebellum is characterized by distortions of movement and posture. Some sufferers of cerebellar disorders display crude, overactive motor activity (ballistic movement) that overshoots the mark in attempted voluntary coordination. Other victims of cerebellar disease display what resemble a drunken gait, jerkily stumbling and swaying along. By relying on other sensory cues (*e.g.*, visual and tactual), some people are able to compensate for awkward and uncoordinated movements associated with cerebellar damage.

VESTIBULAR SENSE (EQUILIBRIUM)

Function of the inner ear. The human inner ear contains parts (the nonauditory labyrinth or vestibular organ) that are sensitive to acceleration in space, rotation, and orientation in the gravitational field. Rotation is signalled

by way of the semicircular canals, three bony tubes in each ear that lie embedded in the skull roughly at right angles to each other. These canals are filled with fluid (endolymph); in the ampulla of each canal are receptor cells with fine hairs that project up into the fluid to be displaced as the endolymph lags behind when rotation begins. When rotation is maintained at a steady velocity, the fluid catches up, and stimulation of the hair cells no longer occurs until rotation suddenly stops, again circulating the endolymph. Whenever the hair cells are thus stimulated, one normally experiences a sensation of rotation in space. During rotation one exhibits reflex nystagmus (back-and-forth movement) of the eyes. Slow displacement of the eye occurs against the direction of rotation and serves to maintain the gaze at a fixed point in space; this is followed by a quick return to the initial eye position in the direction of the rotation. Stimulation of the hair cells in the absence of actual rotation tends to produce an apparent swimming of the visual field, often associated with dizziness and nausea; compensatory postural adjustments commonly follow.

Two sacs or enlargements of the vestibule (the saccule and utricle) react to steady (static) pressures; *e.g.*, those of gravitational forces. Hair cells within these structures are covered by a gelatinous cap in which are embedded small granular particles of calcium carbonate (otoliths) that weigh against the hairs. When iron particles are implanted in the same structures of a fish, they may be displaced by externally applied magnets. In this way the fish can be made to assume inverted or other unusual positions in the water. In man, unusual stimulation of the vestibular receptors and semicircular canals also can give rise to sensory distortions in visual and motor activity. The resulting discord between one's visual and motor responses and the external space (as aboard ship in a heaving sea) often leads to nausea and disorientation (*e.g.*, seasickness). In space flight these sensory systems usually are not stimulated except as the weightless astronaut affects them by his own movements. Such abnormal gravitational and acceleratory forces apparently contribute to the nausea or disequilibrium sometimes reported by people in outer space. Training before space flight reduces the likelihood and severity of these symptoms.

Seasick-
ness

Factors affecting equilibrium. In some diseases (*e.g.*, ear infections), irritation of vestibular nerve endings occurs, and the sufferer may be subject to falling as well as to spells of disorientation and vertigo (dizzy confusion). Similar symptoms may be induced by flushing hot and cold water into the outer opening of the ear, since the temperature changes produce currents in the endolymph of the semicircular canals. This caloric (temperature) effect is used in clinical tests for vestibular functions and in physiological experiments. Externally applied electrical currents may also stimulate the nerve endings of the vestibule. When current is applied to the right mastoid bone (just behind the ear), nystagmus to the right tends to occur, associated with a reflex right movement of the head; movement tends to the left for the opposite mastoid. In man, destruction of the labyrinth in only one ear causes vertigo and other vestibular symptoms, such as nystagmus, inaccurate pointing, and tendency to fall. Very often symptoms of sweating and flushing appear, indicating involvement of other (autonomic) parts of the nervous system. Discomfort, disorientation, nausea, and vertigo may gradually subside, and a complete recovery from the one-sided vestibular disability may occur after one or two months. Following complete loss of vestibular function on both sides, the symptoms are much less likely to occur. Some disturbance of equilibrium is present, however; when blindfolded, the person has difficulty in maintaining normal posture or locomotion. This is especially pronounced when he is submerged in water; he tends to become disoriented and is as likely to swim downward as upward in trying to reach the surface (see also EAR AND HEARING, HUMAN).

TASTE (GUSTATORY) SENSE

The sensory structures for taste in man are the taste buds, clusters of cells contained in goblet-shaped structures

Locations
of taste
buds

(papillae) that open by a small pore to the mouth cavity. A single bud contains about 50 to 75 slender cells, all arranged in a banana like cluster pointed toward the gustatory pore (see also CHEMOREPTION). These are the taste receptor cells, which differentiate from the surrounding epithelium, grow to mature form, and then die out to be replaced by new cells in a turnover period as short as seven to ten days. The various types of cells in the taste bud appear to be different stages in this turnover process. Slender nerve fibres entwine among and make contact usually with many cells. In man and other mammals, taste buds are located primarily in fungiform (mushroom-shaped), foliate, and circumvallate (walled-around) papillae of the tongue or in adjacent structures of the palate and throat. Many gustatory receptors in small papillae on the soft palate and back roof of the mouth in human adults are particularly sensitive to sour and bitter, whereas the tongue receptors are relatively more sensitive to sweet and salt. Some loss of taste sensitivity suffered among wearers of false teeth may be traceable to mechanical interference of the denture with taste receptors on the roof of the mouth.

Nerve supply. There is no single sensory nerve for taste in vertebrates. In man, the anterior (front) two-thirds of the tongue is supplied by one nerve (the lingual nerve), the back of the tongue by another (the glossopharyngeal nerve), and the throat and larynx by certain branches of a third (the vagus nerve), all of which subserve touch, temperature, and pain sensitivity in the tongue as well as taste. The gustatory fibres of the anterior tongue leave the lingual nerve to form a slender nerve (the chorda tympani) that traverses the eardrum on the way to the brain stem. When the chorda tympani at one ear is cut or damaged (by injury to the eardrum), taste buds begin to disappear and gustatory sensitivity is lost on the anterior two-thirds of the tongue on the same side. Impulses have been recorded from the human chorda tympani, and good correlations have been found between the reports people give of their sensations of taste and of the occurrence of the afferent nerve discharge. The taste fibres from all the sensory nerves from the mouth come together in the brainstem (medulla oblongata). Here and at all levels of the brain, gustatory fibres run in distinct and separate pathways, lying close to the pathways for other modalities from the tongue and mouth cavity. From the brain's medulla, the gustatory fibres ascend by a pathway to a small cluster of cells in the thalamus and thence to a taste-receiving area in the anterior cerebral cortex.

Physiological basis of taste. No simple relation has been found between chemical composition of stimuli and the quality of gustatory experience except in the case of acids. The taste qualities of inorganic salts (such as potassium bromide, a sedative) are complex; epsom salt (magnesium sulfate) commonly is sensed as bitter, while table salt (sodium chloride) is typical of sodium salts, which usually yield the familiar saline taste. Experiences of sweet and bitter are elicited by many different classes of chemical compound.

Types
of taste
receptors

Theorists of taste sensitivity classically posited only four basic or primary types of human taste receptors, one for each gustatory quality: salty, sour, bitter, and sweet. Yet, recordings of sensory impulses in the taste nerves of laboratory animals show that many individual nerve fibres from the tongue are of mixed sensitivity, responding to more than one of the basic taste stimuli, such as acid plus salt or acid plus salt plus sugar. Other individual nerve fibres respond to stimuli of only one basic gustatory quality. Most numerous, however, are taste fibres subserving two basic taste sensitivities; those subserving one or three qualities are about equal in number and next most frequent; fibres that respond to all four primary stimuli are least common. Mixed sensitivity may be only partly attributed to multiple branches of taste nerve endings. In man, experiences of sugars, synthetic sweeteners, weak salt solutions, and the taste of some unpleasant medicines are blocked by a drug (gymnemic acid) obtained from *Gymnema* bushes native to India. Among some laboratory animals, gymnemic acid blocks only the nerve re-

sponse to sugar, even if the fibre mediates other taste qualities. Such a multiresponsive fibre still can transmit taste impulses (e.g., for salt or sour), so that blockage by the drug can be attributed to chemically specific sites or cells in the taste bud.

In some species of animals (e.g., the cat), specific taste receptors appear to be activated by water; these so-called water receptors are inhibited by weak saline solutions. Water taste might be considered a fifth gustatory quality in addition to the basic four.

The qualities of taste. **Sour.** The hydrogen ions of acids (e.g., hydrochloric acid, HCl) are largely responsible for the sour taste; but, although a stimulus grows more sour as its hydrogen ion (H^+) concentration increases, this factor alone does not determine sourness. Weak organic acids (e.g., the acetic acid in vinegar) taste more sour than would be predicted from their hydrogen ion concentration alone; apparently the rest of the acid molecule affects the efficiency with which hydrogen ions stimulate.

Salt. Although the salty taste is often associated with water-soluble salts, most such compounds (except sodium chloride) have complex tastes such as bitter-salt or sour-salt. Salts of low molecular weight are predominantly salty, while those of higher molecular weight tend to be bitter. The salts of heavy metals such as mercury have a metallic taste, although some of the salts of lead (especially lead acetate) and beryllium are sweet. Both parts of the molecule (e.g., lead and acetate) contribute to taste quality and to stimulating efficiency. In man the following series for degree of saltiness, in decreasing order, is found: ammonium (most salty), potassium, calcium, sodium, lithium, and magnesium salts (least salty). The order appears to vary for other animals.

Sweet. Except for some salts of lead or beryllium, the sweet taste is associated largely with organic compounds (such as alcohols, glycols, sugars, and sugar derivatives). Human sensitivity to synthetic sweeteners (e.g., saccharin) is especially remarkable; the taste of saccharin can be detected in a dilution 700 times weaker than that required for cane sugar. The stereochemical (spatial) arrangement of atoms within a molecule may affect its taste; thus, slight changes within a sweet molecule will make it bitter or tasteless (Figure 3). Several theorists

From R.W. Moncrieff, *Chemical Senses* (1944); Leonard Hill Books

Figure 3: Effects of molecular rearrangement on taste sensation (see text).

have proposed that the common feature for all of the sweet stimuli is the presence in the molecule of a so-called proton acceptor, such as the OH (hydroxyl) components of carbohydrates (e.g., sugars) and many other sweet-tasting compounds. It has also been theorized that such molecules will not taste sweet unless they are of appropriate size.

Bitter. The experience of a bitter taste is elicited by many classes of chemical compounds and often is found in association with sweet and other gustatory qualities. Among the best known bitter substances are such alkaloids (often toxic) as quinine, caffeine, and strychnine. Most of these substances have extremely low taste thresholds and are detectable in very weak concentrations. The size of such molecules is theoretically held to account for whether or not they will taste bitter. An increase in molecular weight of inorganic salts or an increase in length of chains of carbon atoms in organic molecules tends to be associated with increased bitterness.

A substantial minority of people exhibit specific taste blindness, an inability to detect as bitter such chemicals as

Taste
blindness

PTC (phenylthiocarbamide). Taste blindness for PTC and other carbamides appears to be hereditary (as a recessive trait), occurring least frequently among American Indians and Africans, in about a third of Europeans, and in roughly 40 percent of the people in Western India. Evidence for such taste blindness among other animals has been observed only in anthropoid apes; apparently it appeared at a relatively late stage of evolution. Taste blindness for carbamides is not correlated with insensitivity to other bitter stimuli, the reasons for this being poorly understood.

Factors affecting taste sensitivity. Fluids of extreme temperature, especially those that are cold, may produce temporary taste insensitivity. People generally seem to taste most acutely when the stimulus is at or slightly below body temperature. When the tongue and mouth are first adapted to the temperature of a taste solution, sugar sensitivity increases with temperature rise, salt and quinine sensitivity decrease, and acid sensitivity is relatively unchanged. Gustatory adaptation (partial or complete disappearance of taste sensitivity) may occur if a solution is held in the mouth for a period of time. The effect of one adapting stimulus on the person's sensitivity for another one (cross adaptation) is especially common with substances that are chemically similar and that elicit the same taste quality. Adaptation to sodium chloride will reduce one's ability to sense the saltiness of a variety of the inorganic salts but will leave undiminished or even enhance such qualities as bitterness, sweetness, or sourness that were part of the taste of the salt before adaptation. Likewise, adaptation by one acid may reduce sensitivity to the sourness of other acids.

Adaptation studies often are complicated by so-called contrast effects; for example, people say that distilled water tastes sweet following their exposure to a weak acid. Water may take on other taste qualities as well; following one's adaptation to a sour-bitter chemical (urea), water may taste salty. Adaptation tends to diminish or enhance the effect of a subsequent stimulus depending on whether the two stimuli normally elicit the same or a contrasting taste. Thus the adapted sweetness of water and all normally sweet-tasting substances are enhanced after one has tasted acid (sour). The bitterness of tea and coffee or the sourness of lemon are masked or suppressed by sugar or saccharin.

The human gustatory difference threshold (for a just noticeable difference in intensity) is approximately a 20 percent change in concentration. For very weak taste stimuli, however, the threshold sensitivity is poorer.

Food choice. One's ability to taste is intimately concerned in his eating habits or in his rejection of noxious substances. One of the earliest reflex responses of the infant, that of sucking, can be controlled by gustatory stimuli. Sweet solutions are sucked more readily than is plain water; bitter, salty, or sour stimuli tend to stop the sucking reflex.

Among insects, a very specific feeding reaction (proboscis extension) is so automatic that it is widely used as an index of taste stimulation. If a common housefly is held relatively immobile in wax, different parts of the mouth, legs, and body readily may be stimulated by a drop of solution. Sugar solution will make the fly extend its proboscis when a drop is applied to the legs or mouth parts. A fly that has been starved will show a positive response to a weak sugar solution that ordinarily would not affect one that is satiated. Addition of salt or acid to the sugar solution inhibits this response.

Many animals provide clear examples of beneficially selective feeding behaviour. Laboratory rats, when given unhampered choice of carbohydrates, proteins, vitamins, and minerals (each in a separate container), show consistent patterns of self-selection that may be modified by physiological stresses and strains. A rat made salt-deficient by removal of its adrenal glands, for example, will increase its intake of sodium chloride sufficiently to maintain health and growth; normally, such gland removal is fatal in the absence of salt-replacement therapy. Histories of similar effects have been reported in human beings, one dramatic case being that of a child with adrenal

disorder who kept himself alive by satisfying an intense salt craving.

Among human adults, past experience shows a strong influence on eating habits, sometimes to the point that physiological well-being suffers. Food habits and other factors play a significant role in eating behaviour.

Poisonous substances often are unpalatable, but not invariably. Lead acetate, sometimes called sugar of lead, once was used as a sweetening agent with disastrous results before its potentially fatal effects were appreciated. Many palatable substances, including some synthetic sweeteners, are toxic; taste alone is not a reliable guide to safety. A rat poison, alpha-naphthylthiourea (ANTU), was developed in a relatively insoluble and therefore tasteless form; soluble forms of ANTU had all been rejected by the animals. Taste aversions also may be readily established by conditioning, even for substances that have been normally preferred. In one study, a rat tasted saccharin solution three hours before being exposed to enough radiation to become sick. When the animal recovered, it was found to have a strong aversion to the taste of saccharin. Other aversions selectively can be produced by injecting the individual with a nauseating drug following specific taste experience. An unusual finding is that long delays of up to several hours in the time between the presentation of the taste stimulus and the induction of illness do not prevent the conditioning. In most other studies, only brief intervals (perhaps up to minutes in duration) have been found to result in successful conditioning. Bait shyness developed by wild rats that survive poisoning strongly suggests conditioned taste aversion. Positive preferences also are subject to conditioning, as when the tastes of drugs or vitamins become associated with the feelings of well-being they generate.

SMELL (OLFACTORY) SENSE

In mammals the olfactory receptors are located high in the nasal cavity. The yellow-pigmented olfactory membrane in humans covers about 2.5 square centimetres on each side of the inner nose. The olfactory sense receptor is a long thin cell ending in several delicate hairs (cilia) that project into and through the mucus that normally covers the nasal epithelium or lining (Figure 4). Electron microscope photographs show from six to 12 olfactory cilia per cell. The end of each receptor narrows to a fine nerve fibre, which, along with many others, enters the

Olfactory receptors

Contrast effects

olfactory bulb of the brain through a fine channel in the bony roof of the nasal cavity. The olfactory membrane of a young rabbit contains about 100,000,000 ciliated receptor cells that provide as much area as total skin surface of the animal.

Pain endings of the trigeminal nerve fibres are widely distributed throughout the human nasal cavity, including the olfactory region. Relatively mild odorants, such as orange oil, as well as the more obvious irritants, such as ammonia, stimulate such free nerve endings as well as the olfactory receptors.

Odorous molecules may be carried to the olfactory region by slight eddies in the air during quiet breathing, but vigorous sniffing brings a surge into the olfactory region. Odour sensitivity may be impaired by blocking the nasal passages mechanically, as when membranes are congested by infection.

It is generally agreed that the antennae of insects are their principal olfactory sites, but specific mouth parts may also bear endings for smell. The nonliving outer covering (cuticle) of such structures has been shown to be pierced by many ultramicroscopic holes through which odorous molecules enter, presumably to dissolve the fluid underneath. In vertebrates (such as man), olfactory stimulation occurs only after the odour molecule is dissolved in the mucus that covers the olfactory membrane. In spite of the wide biological gap between them, odour sensitivity of man and that of insect display certain similarities of mechanism.

In vertebrates the olfactory nerve fibres enter either of two specialized structures (olfactory bulbs), stemlike projections under the front part of the brain, to end in a microscopic series of intricate basket-like clusters called glomeruli. Each glomerulus receives impulses from about 26,000 receptors and sends them on through other cells, eventually to reach higher olfactory centres at the base of the brain. There are also fibres that cross over from one olfactory bulb to the other. When the olfactory bulbs are removed by surgery, the individual's ability to discriminate odours is lost; details of higher brain centres for smell are still unclear.

Olfactory qualities. The vocabulary of odour is rich with the names of substances that elicit a great variety of olfactory qualities. One of the best known published psychological attempts at classification was in 1916 on the basis of tests of more than 400 different scents on human observers. On the basis of the apparent similarities of perceived odour quality or confusions in naming, it was concluded that there were six main odour qualities: fruity, flowery, resinous, spicy, foul, and burned.

Electrical activity can be detected readily with fine insulated wires inserted into the olfactory bulb. Those portions of the bulb toward the anterior or oral (mouth) region in the rabbit are found to be more sensitive to water-soluble substances, whereas the more posterior or aboral (away from the mouth) parts of the olfactory bulb are more sensitive to fat-soluble substances. In addition, when very fine electrodes are used, individual cells (so-called *mitral* cells) are found to be sensitive to different groups of chemicals. Evidence for the existence of only a few primary receptors, however, does not emerge from such studies; a variety of different combinations of sensitivity has been found. Similarly, recordings from the primary receptor nerve fibres reveal different patterns of sensitivity. Electrical recording of this type also shows that olfactory sensitivity can be enhanced by a painful stimulus, such as a pinch on the foot of an experimental animal. This appears to be a reflex that serves to enhance the detection of dangerous stimuli in the environment. Different parts of the olfactory neural pathways seem to be selectively tuned to discriminate different classes of olfactory information. Thus, the third- and fourth-order olfactory neurons found beyond the olfactory bulb of the rat seem particularly concerned with distinguishing the odour of sexually receptive females. These neurons appear to be especially important in the preference the male rat shows for the smell of urine from a female in heat.

Odorous substances. To be odorous, a substance must be sufficiently volatile for its molecules to be given off

and carried into the nostrils by air currents. The solubility of the substance also seems to play a role; chemicals that are soluble in water or fat tend to be strong odorants, although many of them are inodorous. No unique chemical or physical property that can be said to elicit the experience of odour has yet been defined.

Only seven of the chemical elements are odorous: fluorine, chlorine, bromine, iodine, oxygen (as ozone), phosphorus, and arsenic. Most odorous substances are organic (carbon-containing) compounds in which both the arrangement of atoms within the molecule as well as the particular chemical groups that comprise the molecule influence odour. Stereoisomers (*i.e.*, different spatial arrangements of the same molecular components) may have different odours. On the other hand, a series of different molecules that derive from benzene all have a similar odour. It is of historic interest that the first benzene derivatives studied by chemists were found in pleasant-smelling substances from plants (such as oil of wintergreen or oil of anise), and so the entire class of these compounds was labelled aromatic. Subsequently, other so-called aromatic compounds were identified that have less attractive odours.

The scent of flowers and roots (such as ginger) depends upon the presence of minute quantities of highly odorous essential oils. Although the major odour constituents can be identified by chemical analysis, some botanical essences are so complex that their odours can be duplicated only by adding them in small amounts to synthetic formulations.

Odour sensitivity. In spite of the relative inaccessibility of the human olfactory receptor cells, odour stimuli can be detected at extremely low concentrations. Olfaction is said to be 10,000 times more sensitive than taste. A human threshold value for such a well-known odorant as ethyl mercaptan (found in rotten meat) has been cited in the range of 1/400,000,000th of a milligram per litre of air. A just-noticeable difference in odour intensity may be apparent when there is a 20 percent increase in odorant strength, but at low concentrations as much as 100 percent increase in concentration may be required. Temperature influences the strength of an odour by affecting the volatility and hence the emission of odorous particles from the source; humidity also affects odour for the same reasons. Hunting dogs can follow a spoor (odour trail) most easily when high humidity retards evaporation and dissipation of the odour. Perfumes contain chemicals called fixatives, added to retard evaporation of the more volatile constituents. The temporary anosmia (absence of sense of smell) following colds in the nose may be complete or partial; in the latter case, only the odours of certain substances are affected. Paranosmia (change in perceived odour quality) also may occur during respiratory infections. Changes in sensitivity are reported to occur in women during the menstrual cycle, particularly in regard to certain odorants (steroids) related to sex hormones. Olfactory sensitivity also is said to become more acute during hunger.

Human adaptation to odours is so striking that the stench of a slaughterhouse or chemical laboratory ceases to be a nuisance after a few minutes have passed. Olfactory adaptation, as measured by a rise in threshold, is especially pronounced for stronger odours. Cross adaptation (between different odours) may take place; thus, eucalyptus oil may be difficult to detect after one becomes adapted to camphor. Adaptation long was regarded solely as the result of changes in the olfactory receptor; however, electrical recordings show that the receptor cells in the nose seem to adapt only partially. Rhythmic discharges continue in the olfactory bulb long after the experimenter ceases to detect the odour that is stimulating the experimental animal. Apparently, some olfactory adaptation may occur in the brain as well as in the sense organ.

Odour blending and flavour. The ancient art of perfumery and the modern science of odour control depend on mixing and blending. Two different odours presented together may be readily identifiable. The more they resemble each other, the greater will be the tendency to blend;

Characteristics that impart odour

Olfactory bulbs

Factors affecting odour sensitivity

Flavours
and the
sense of
smell

yet trained workers usually can discriminate the components of a successfully blended perfume. The substantially greater intensity of one odour may mask another. Masking, however, is less effective than chemical conversion or physical collection (removal) as a basis for odour control. Some odorants also may be removed by passing air through activated charcoal.

The distinctive flavours of food are known largely through the sense of smell. Flavour is the composite of experiences from many senses, but the aroma of roast beef and the delicate bouquet of wine are mainly olfactory in origin. Flavour technology has assumed a well-entrenched place in the food industry; it is common practice for manufacturers to use flavour panels of several trained members to judge the flavour of new food products. Using psychophysical methods with adequate statistical control, such panels are very reliable and can detect qualities so subtle that they defy the methods of physics and chemistry. In using large, untrained consumer panels, the emphasis is on acceptability, often an emotional reaction to the product. Such untrained judgments are unstable and may vary among individuals because of idiosyncrasy or differences in experience. The strong cheese odour so palatable to the gourmet can produce revulsion in the uninitiated.

Effects on behaviour. Recognition of friend or foe by social insects may depend upon olfactory cues: certain ants attack their own kind furiously if deprived of the sense of smell by amputation of their antennae; bees entering a strange hive are put to death because the scent of a foreign hive clings to them. Bees also have a specialized organ on the end of the abdomen that deposits a scent on a newly discovered food source to guide other foraging workers. The scents of flowers attest to the evolutionary importance of odour; those flowers that attract insects most efficiently are the likeliest to be pollinated and to reproduce their kind.

The effect of odours on the sexual behaviour of invertebrates is most striking; a female moth, for example, was observed to attract more than 100 males during relatively brief observation periods of about six hours. The physiological basis for the attraction can be traced to specific odour attractants (pheromones), molecules produced by the scent glands of the female. Pheromones also function in defense and as alarms of impending danger. The specific sex attractant of the female silk moth (*Bombyx*) has been identified and synthesized. It has been found that the antennae of the male silk moth contain olfactory receptors specifically sensitive to the female pheromone but that the females have no receptors to detect their own attractiveness.

Mammals in the wild state appear to utilize their odour glands for sexual attraction. Laboratory rats show a preference for the branch of a maze that has been scented with the odour of a sexually receptive female. It is likely that some rudiments of these effects operate in man. The most sexually provocative perfumes have a high proportion of musk or musklike odour. Genuine musk is derived from the sexual glands of the musk deer and is chemically related to human sex hormones; odour sensitivity in humans varies with the menstrual cycle.

Among laboratory animals the secretion of reproductive hormones can be markedly influenced by odour stimulation. This seems to be an innate physiological process rather than the result of learning. A most dramatic effect (pregnancy block) is observed when the odour of a strange male is presented to a recently mated female. The normal hormonal changes following copulation are blocked under these conditions, and the fertilized egg fails to survive. A related study of the periodicity and length of menstrual cycle in women exposed to the normal odours of men suggests there may be similar effects among people. The behaviour of civilized man, molded and shaped by custom and culture though it is, has many of its roots in his basic sensual appetites.

Seoul

Now the capital of the Republic of Korea (South Korea), Seoul (Sŏul-t'ŭkpyŏlsi meaning special city of Seoul) has been the capital of Korea since 1394. The name itself means capital in the Korean language. The city was popularly called Seoul in Korean during the Yi dynasty (1392–1910) and during the period of Japanese rule (1910–45), although the official names in those periods were Hantsung and Kyŏngsŏng respectively. Seoul became the official name of the city after 1945 with the founding of the Republic of Korea. In 1970 it was a fast-growing metropolis of some 5,500,000 people. It is also a rapidly changing city in a transitional stage between traditional and modern urban society.

History. The earliest historical mention of Seoul and the surrounding area dates from the 1st century BC. During the Three Kingdoms period (57 BC–AD 668) of Silla, Koguryŏ, and Paekche, the Seoul area formed a borderland between the three countries and during the early part of the period was most closely associated with the Kingdom of Paekche. According to legend, Paekche's capital, Wiryŏ-sŏng, located at Chiksan, was raided so often that King Ōnjo, the founding king of Paekche, moved back to Pukhan, a place north of the Han-gang (Han River), in about 6 BC. It is believed that Pukhan was at the foot of Tobong-san (Tobong Mountain), in the northeastern section of present-day Seoul.

It was not, however, until King Munjong of Koryŏ built a summer palace in 1068 that a fairly large settlement existed on the present site of the city.

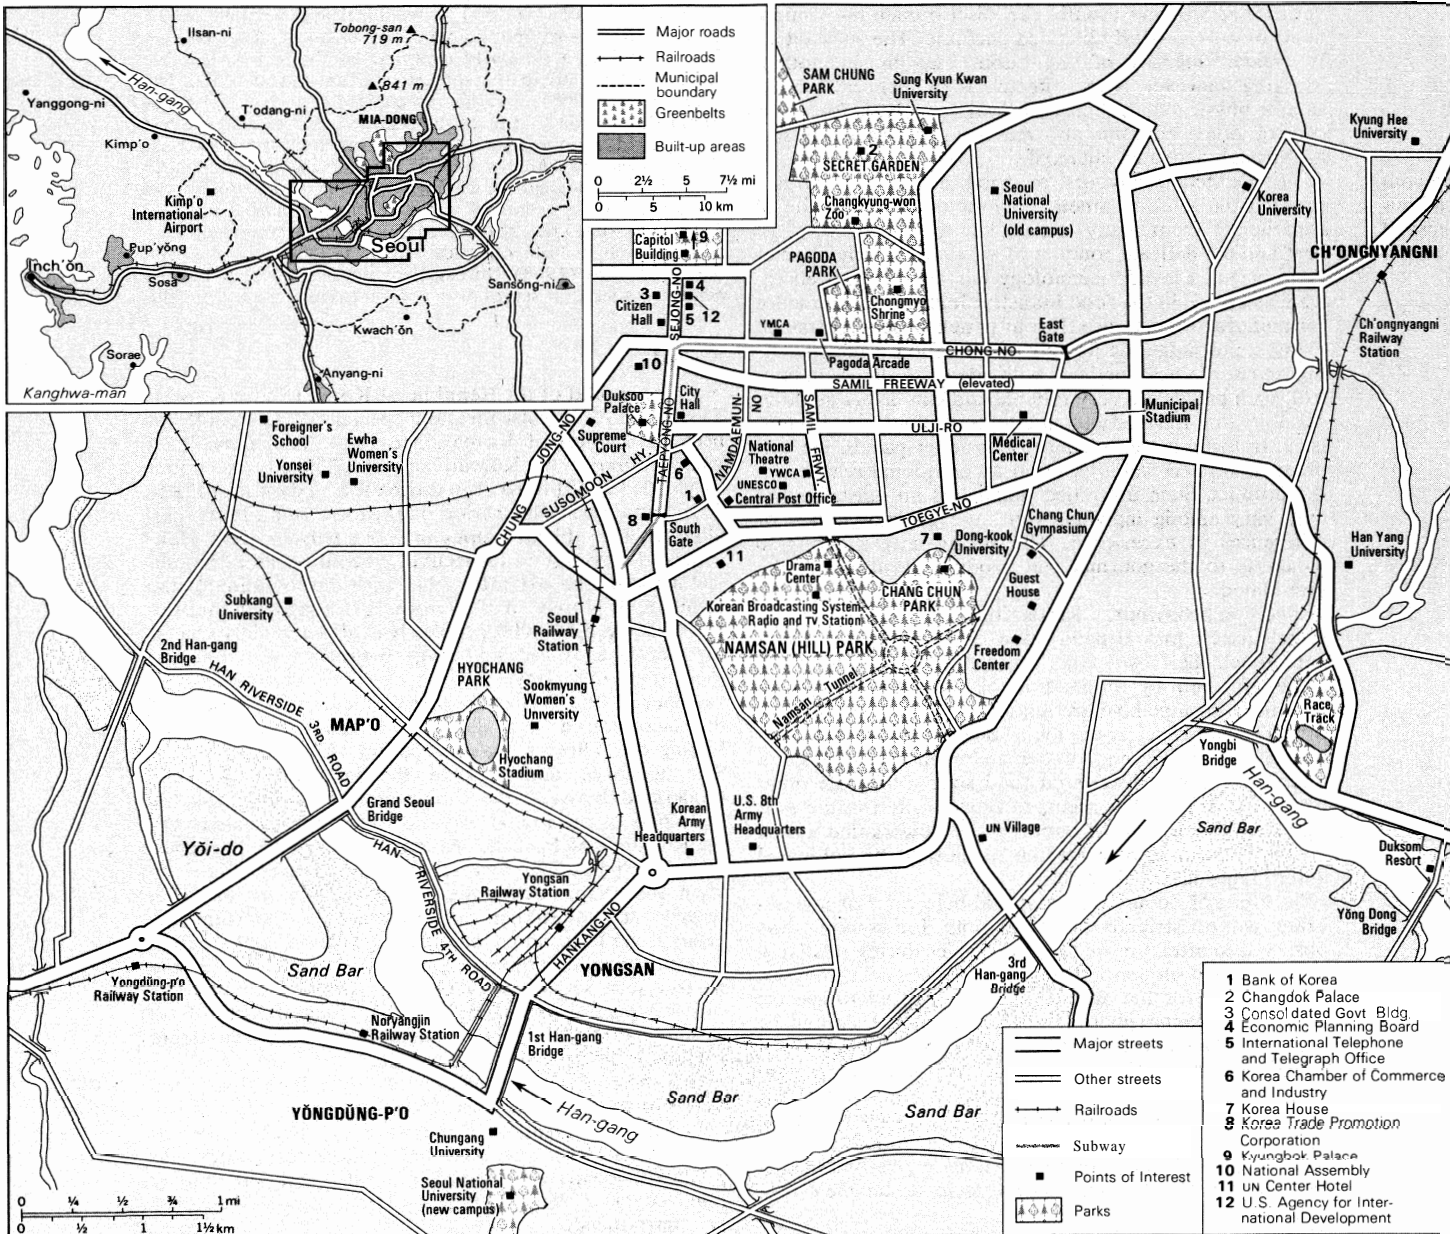

After the annexation of Korea to Japan, the name of the Seoul area was changed to Kyŏng-sŏng in 1911, and minor changes were made in the boundary. Seoul served as the centre of Japanese rule, and modern technology was imported. Roads were paved, old gates and walls partly removed, new Western-style buildings built, and streetcars introduced.

After the end of Japanese control, Seoul came directly under the control of central government instead of under the administration of Kyŏnggi-do (Kyŏnggi Province) in which it lies. In 1962 it was placed directly under the prime minister instead of, as previously, the ministry of home affairs.

The contemporary city. City plan. Seoul was a suitable site for a capital city because of its location at the centre of undivided Korea and on the navigable Han-gang, one of the major rivers flowing into the Yellow Sea. Before the Korean War, small vessels used to navigate the 37 miles up to Seoul. Presently, however, the demilitarized zone that divides Korea into North and South and that runs partly through the mouth of the river has deprived Seoul of its role as a river port.

Central Seoul is located in the lowland of a topographic basin surrounded by low hills of around 1,000 feet. The basin, circled by a wall along the ridges of the hills, is drained by a small tributary of the Han-gang, which is mostly covered by streets or expressways. Main streets and major shopping areas occupy the lower part of the basin. The growth of the city, however, has resulted in buildings spilling out in all directions, firstly out of the four major gates of the old castle toward Yongsan and Yŏngdŭng-p'o to the south, Mia-dong Suyu-dong to the north, Map'o and Hongje-dong to the west, and Ch'ŏngnyangni to the east. The present boundary of Seoul was

Kim Chon-Kil

Current
develop-
ment
plans

airport in Korea and serves also as the centre of the national airline network.

There are several long-term plans to permit Seoul to expand rapidly but in orderly fashion. Establishment of satellite cities, functional centres, dispersal of industry, and urban renewal of the old section are some of the projects under serious consideration. In order to slow the city's growth, a circular zone about three to six miles wide at a distance of about 9.3 miles from the city centre has been established as a green belt. The building of houses and other industrial plants is not allowed in this area, only agriculture and forestry being permitted.

Demography. The population of Seoul has grown very rapidly since 1950, from 1,690,000 to over 5,500,000 in 1970. During the decade 1960–69, the population more than doubled, until its density reached 23,400 persons per square mile, one of the highest in the world. The most densely populated areas were distributed within and outside the old city, while newly developed residential areas in the suburbs had a relatively low density. Koreans constituted nearly all of the population; foreign residents, numbering about 10,000, were mostly Chinese. The sex ratio showed an almost equal proportion, females very slightly outnumbering males.

Housing. Housing shortages have been a chronic problem. Numerous blocks of municipal apartment buildings have been constructed for low-income residents in the old city, and several new residential sections are being prepared. Houses in the lowland and adjacent areas outside the old-city wall are mostly traditional, tile-roofed wooden structures, but new houses in the suburbs are one story and are something akin to Western style. All houses have *ondol* ("heated") floors designed for the cold winter. Coal is used as fuel to warm the *ondol*, but gases extracted from coal are increasingly in demand.

Economic life. Manufacturing (27.9 percent), commerce (34.8 percent), and service industry (20.4 percent) together comprised about 83 percent of all economic activity in 1970. Textiles, machinery, and chemical industries were the most important sectors in manufacturing. Food processing, printing, and publishing were also important. Most of the manufacturing plants are small-scale, and three-quarters of the some 700 textile plants accommodate less than 100 workers.

The two most important shopping centres, located near South and East gates, serve the whole country as well as

Seoul. Banks are not much utilized since checking accounts are unpopular. To encourage savings, high interest rates of more than 17 percent a year are offered by banks, but loans are not easily available because of the shortage of capital in the banks. Accordingly, small companies are highly dependent on private loans.

Social conditions. Because of the rapid expansion of the city, water, sewage disposal, and electricity facilities are inadequate, despite strenuous efforts to keep up with demand. The city has relatively good medical facilities, with 70 hospitals containing over 7,000 beds. There are many smaller medical facilities, including small clinics. There are also many herb doctors. Fires occur frequently during winter and spring because of the cold, dry season and the many wooden structures, placing a heavy demand on the city's fire services.

Education. Compulsory education applies only to the six-year elementary school, but 94 percent of elementary school graduates (1970) go on to the three-year middle school, 89 percent of middle-school graduates (1969) to the three-year high school, and 33 percent of high-school graduates to colleges and universities. There is a serious shortage of elementary-school facilities because of the rapid increase of population, resulting in very crowded classrooms. There are some 38 colleges and universities in Seoul, a total of more than 87,000 students being enrolled in 1970. Major universities are Seoul National, Yonsei, Korea, Ewha Woman's, Sung Kynn Kwan, and Dong-kook universities. The Korea Advanced Institute of Science was established in 1971 to produce natural scientists and was expected to begin receiving students in 1974.

Cultural life and recreation. Important musical organizations in Seoul are the National Classical Music Institute, engaged in preservation of the traditional court music of Korea—and in education of its musicians—and two symphony orchestras, the Korean National Symphony Orchestra and Seoul Symphony Orchestra. There are also a national theatre, over 100 cinemas, Duksookung Art Gallery, national and private museums, and four public libraries.

Main offices of major nationwide daily newspapers, the government newspaper, and two English language newspapers are all located in Seoul. Early in the present decade there were six radio broadcasting stations and three television stations, one of which is owned by the government; most families had at least one radio and there was

News-
papers
and
broad-
casting

Principal
employers

approximately one television set for every four families.

Surrounded by hills, Seoul has numerous large and small parks within easy reach. Changkyong-won, which is an old palace containing in its grounds a modern zoo and a botanical garden, attracts a large number of citizens and tourists throughout the season from spring to autumn. Seoul Athletic Field has a main stadium that can accommodate 57,500 people and smaller attached areas for baseball, tennis, volleyball, and swimming. One large open athletic ground has a capacity of 25,000. Many national games are also held in Hyochang Athletic Ground and Chang Chun Gymnasium, both of which have a large capacity.

BIBLIOGRAPHY. ALLEN D. and DONALD N. CLARK, *Seoul: Past and Present* (1969), is a well written and comprehensive guidebook. EDWARD B. ADAMS, *Through Gates of Seoul*, 2 vol. (1970-71), is a more extensive work, well prepared and containing numerous pictures and maps, some in colour. The *Statistical Yearbook of Seoul* (annual), provides official statistics, with a brief history of Seoul in Korean and English.

(C.Le.)

Sergipe

Sergipe is a state (*estado*) of Brazil located on the southern coast of that country's northeastern bulge into the Atlantic. It is bounded on the east by the Atlantic, on the south and west by the State of Bahia, and on the north by the State of Alagoas, from which it is separated by the São Francisco River. The state has limited agricultural and other natural resources, and the per capita income in the state is 50 percent below the national average. The second smallest Brazilian state, it has an area of 8,492 square miles (21,994 square kilometres). Its population in the early 1970s was over 900,000. The state capital is Aracaju. Sergipe is named after Serigy, a gallant native chief.

History

Located between the captaincies of Pernambuco and Bahia (the latter being at the time the seat of d'el the general government) in the 16th century, Sergipe Rei, as it was then called, was conquered and settled by cattlemen and sugar planters from Bahia. The aborigines were easily subdued by the superior firearms of Cristóvão de Barros, who founded the city of São Cristóvão, the first capital, in 1590. In 1820 Sergipe became an independent captaincy. It became a province of the empire in 1824 and a state of the republic in 1889.

The natural environment. The state is divided into two major geographic regions, a narrow, low, heavily forested coastal region, and a higher zone of rough open country, including tablelands rising to mountainous areas in the west. The northern part of the state drains into the São Francisco River, the southern part into the Atlantic. Small rivers, that are frequently dry in their upper reaches, include the Japarutuba, the Sergipe, the Cotinguiba, the Vasa Barris, the Piaui, and the Real.

Sergipe's climate is typical of the northeastern region of Brazil. The coastal area is hot, with adequate rainfall extending into the São Francisco Valley; the interior is hot and dry and subject to both flood and drought. There are two well-defined seasons, winter (May to September) and summer (October to April). The annual mean temperature is 78° F (26° C). The warmest month, January, has an average of 80° F (27° C) and the coldest month, August, has an average of 75° F (24° C) at Aracaju. The average annual rainfall is 49 inches (1,250 millimetres) at Aracaju.

Vegetation is distributed as follows: 34 percent tropical forests, 50 percent thorny deciduous scrub woodland, known as *caatinga*, and 16 percent coastal vegetation. The forests of the coastal zone have been practically devastated. Only palms and cashew trees still abound. Bird life includes varieties of tinamou and there are some mammals such as deer and caviés and armadilloes.

Population. Sergipe has a population of over 900,000. Population density is 107 persons per square mile (41 per square kilometre), with the heaviest concentrations in the coastal and central regions. Forty-six percent of the population is urban. The most populous cities are Aracaju, the capital (almost 180,000), Estância (over 20,000),

Propriá (over 18,000), and Itabaiana, Lagarto, and São Cristóvão (each over 10,000). About three-fourths of the people are of mixed racial origin. The state is experiencing the processes of gradual ethnic amalgamation that are characteristic of all Brazilian states. The language is Portuguese. The predominant religion is Roman Catholicism.

Administration and social conditions. The governor of the state and the members of the state legislature are elected in accordance with the state constitution and laws. The auxiliary organs of the state government at Aracaju include the State Economic Development Council; the Industrial Company of Sergipe, which is charged with the development of research, plans, and projects; the Sergipe State Bank; the Welfare Institute; and the Superintendency of Public Works.

There are 25 hospitals in the state with five located in the capital and 41 in the interior. There are 4.9 hospital beds per 1,000 inhabitants in the capital and 2 per 1,000 in the interior.

Primary education is compulsory. About 100,000 pupils attend primary schools, with about 20,000 in the capital and 80,000 in the interior. At the intermediate level there are about 23,000 pupils, with 16,000 of these in Aracaju and 7,000 in the interior. There has been an increase in public intermediate education facilities, which have a capacity for 7,000 students, as well as in those for primary education. Higher education is furnished by the Universidade Federal de Sergipe, founded in 1967, in Aracaju. The university has a capacity for 1,000 students.

Eighteen cities, or about one-fourth of those in the state, have operating water systems, and systems for 12 more cities have been planned. Seventy-one of the 74 county seats and 30 villages have electricity. A program of rural electrification is underway; 12 projects are in the starting phase and others being developed.

Economy. The economy is predominately agricultural. Ninety percent of the industrial sector is made up of traditional industries: sugarcane, textiles, and small food-processing enterprises (manioc meal, rice, coconut meal, and milk). The Aracaju Industrial District, an area of 314 acres, was developed in 1960 to attract new industries.

Eight products---cotton, rice, sugarcane, coconut, beans, tobacco, manioc (cassava), and maize (corn)---represented 52 percent of the agricultural production in 1967. Agriculture is concentrated on the lower, fertile lands, the higher interior being devoted primarily to raising livestock. Livestock includes about 825,000 cattle, as well as hogs, sheep, and goats. Horses, mules, and asses also are raised. Sergipe's petroleum reserves are being increasingly exploited, with production surpassing 30,000 barrels of oil a day in 1970 as compared with 9,000 in 1966. The reserves are located principally in the northeast and on the Aracaju maritime platform. There are also reserves of 140,000,000 tons of rock salt, 14,600,000 tons of potassium, and reserves of potter's clay, kaolin, gypsum, limestone, and manganese.

Transportation and communications. Sergipe has 3,165 miles of roads, 757 miles of which are state, 2,159 miles municipal, and 199 miles federal; about 140 miles are asphalted. The Viação Férrea Federal Leste Brasileira (Brazilian East Federal Railway Transit System) covers 183 miles in the state. Construction of a railway bridge over the São Francisco River to link Sergipe (Propriá) to Alagoas (Pôrto Real do Colégio), began in 1971. Although maritime transport has been insignificant, projects have been initiated to improve the harbour of the Rio Sergipe. River transportation on the São Francisco and other rivers is also being developed. The Aeroporto de Santa Maria has a paved runway 6,600 feet long. The Brazilian Mail and Telegraph Enterprise is responsible for communication in Sergipe as a whole. The capital is linked to the system of the Brazilian Telecommunications Enterprise.

Cultural life and institutions. Sergipe's past is rich in outstanding national literary figures, such as Tobias Barreto, Sílvio Romero, Fausto Cardoso, João Ribeiro, and Hermes Fontes. Sergipe has half a dozen newspapers and

Education

Agricultural products

some magazines. Its principal cultural institutions are the Academia Sergipana de Letras, the Instituto Histórico e Geográfico de Sergipe, the Galeria de Artes Alvaro Santos, the Biblioteca Pública do Estado de Sergipe, and the Museu São Cristóvão, which is quite rich in colonial art.

Two popular forms of merrymaking are notable, the *Chegança*, of Iberian origin, and the *bumba-meu-boi*, created by the caboclos (or backwoodsmen, Indians or Portuguese-Indian half-breeds), both of which are danced and sung. Traditional festivals are the June carnivals; the Festa da Laranja (Feast of the Orange), in Buquim; the Festa de Nossa Senhora de Conceição (Feast of Our Lady of the Immaculate Conception), the patron of Aracaju; the Feirinha de Natal, a Christmas festivity in Aracaju; and the Festa de Bom Jesus dos Navegantes (Feast of Good Jesus of the Navigators), a river procession held on January 1 since 1857.

BIBLIOGRAPHY. IVO DO PRADO, *A Capitania de Sergipe* (1919), is a documented account of the founding of Sergipe that also deals with the question of the border with Bahia. FELISBELLO FREIRE, *História de Sergipe* (1855), covers the period 1525–1855. See also J. PIRES WYNNE, *História de Sergipe, 1575–1930*, vol. 1 (1970).

Serpentes

The reptile suborder Serpentes, one of three suborders of the order Squamata, includes only the snakes, a widely known and much misunderstood group of animals. The closest relatives of the snakes are the lizards (suborder Sauria) and the wormlike amphisbaenians (suborder Amphisbaenia).

Arms and legs gone, no ears, only one functional lung, voiceless, eyelids missing—a human being in such condition would be institutionalized and under constant care. Snakes have not only survived these losses but have become highly successful in a great variety of ecological roles. Fearless, independent, and usually solitary, the snake has capitalized upon these apparent deficiencies to become an efficient second- and third-level predator, focussing perhaps 70 percent of its existence on tracking down, catching, and digesting its living prey. The elongate, limbless body of the snake permits it to be soundless in motion, invisible at rest, and almost unlimited in its access to hiding places, such as nests, tree holes, crevices, brier patches, gopher tunnels, and other shelters where small vertebrated animals seem to feel themselves safe from their enemies. Most of the remainder of the snake's existence is dedicated to continued survival in an antagonistic world that is usually either too hot or too cold and is full of other organisms challenging the snake's right to live. With its body temperature almost totally dependent upon the surroundings, the snake must seek out both nightly and seasonal resting places where rising temperatures eventually can be relied upon to rekindle its abilities to move, to sense, and to reproduce. Reproduction demands only a few percent of the male snake's existence, for it consists of little more than a sudden burst of highly seasonal activity followed by an immediate return to the more pressing activities of food search. The female devotes slightly more time to reproductive activities, because she must eventually seek out a suitable place to deposit the eggs or to give birth to a usually good-sized brood. This, too, however, is an act of short duration, followed immediately by return to the continuing problems of daily existence.

Snakes are found around the world in practically every kind of habitat and in all regions except near the poles. They are not successful competitors with man, and only a few diminutive species with very secretive habits find it possible to share living space with humans. When man moves in, practically all reptiles share the fate of large mammals and predatory birds—they must move out or die, because man is not and never has been a particularly good coexisting species except with those organisms that he bends to his will, such as corn or horses, or with those capable of capitalizing upon his presence, such as pigeons and rats. Of the reptiles, the snake is the most distasteful to man, and snake species are quickly wiped out. In rural

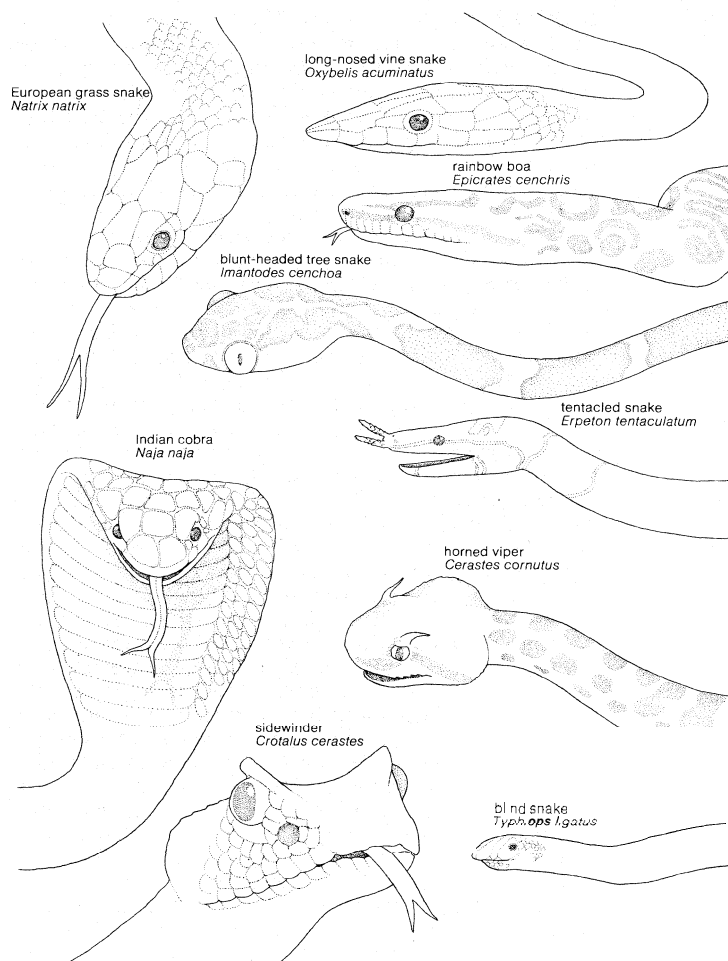

Figure 1: Variation of snake head shapes.
Drawing by M. Moran

areas, man pays the penalty for this eradication in an inevitable increase in the natural prey of the snakes, including rats, mice, and other rodents.

Importance to man

After the unfortunate episode in the Garden of Eden, perhaps the first relationship between man and snakes that one thinks of is envenomation from poisonous snakebite. The likelihood of any individual human encountering a venomous snake during his lifetime has been reduced to almost zero as a result of the tremendously increased world population, the concentration of humans in cities, where poisonous snakes cannot survive, and the reduction in overall numbers of snakes as a consequence of the invasion and destruction of their habitats by man. At the same time, the likelihood of any one poisonous snake, sometime during its life, finding itself in a position in which it must bite a human in self-defense increases geometrically, as a consequence of the enormously inflated human population, man's ever-increasing mobility, and the increased utilization of remote areas for recreation purposes of all sorts. One of these likelihoods is offset by the other, and the overall number of bites per year by venomous snakes around the world remains rather constant, at about 1,000,000 per year. Of this 1,000,000, perhaps 30,000 to 40,000 result in death, with most of the deaths occurring in areas such as tropical Africa and Asia because of the inadequate medical facilities for proper treatment. It has been estimated that in the United States about 1,000 bites occur each year, with approximately 15 resulting in death. Records for bites by the viper in England indicate that only seven deaths occurred between 1899 and 1945 and only one death between 1945 and 1960, with the latter a consequence of treatment rather than of the bite. A large percentage of the bites in the United States occur when the snakes are

Snakebite

handled for various reasons. These reasons include care in zoos, the extraction of venoms, exhibition by showmen in carnivals and sideshows, the maintenance of snakes as pets or curiosities, and their inclusion in religious ceremonies by various sects. Practically all of the time-honoured remedies or first-aid measures for snakebite treatment are more dangerous in the hands of the inexperienced than is the bite itself. If any kind of medical care is available within an hour or less, nothing more than a light tourniquet is needed as emergency treatment.

No snake has ever regularly hunted man, but man continues to engage in seeking out the snake. The uses that man finds for snakes are not extensive, but each of them results in the decimation of wild populations. Snakes are collected as a source of rare and exceedingly expensive leather for belts, pocketbooks, shoes, and gloves. There is a phenomenal traffic in live snakes for purposes of display or as pets, including the flow to zoos, circuses, carnivals, or roadside "snake farms," as well as to the amateur snake fancier with a large collection in his basement. There are perhaps 40–50 research laboratories and antivenin institutes around the world, in which either snakes or snake venoms are used, and live snakes are needed in fairly large numbers for the work. An indication of the numbers of animals involved in this kind of traffic is given by data from the United States Department of the Interior on importations, taken from customs reports. During 1968 and 1969, more than 3,344,000 specimens of living reptiles (including snakes) were brought into the United States. It is difficult to determine how many of these reptiles were snakes, but perhaps a quarter to a third of the total would be a reasonable estimate, which would mean that almost 1,000,000 snakes were shipped into the United States in those two years. The mortality rate among such snakes is high, but those that survive bring prices from about \$5 to as much as \$1,500, and, therefore, this is a multimillion-dollar business. The snake roundup, or snake rodeo, has become recognized as a tourist attraction in the United States, and such events take place in about a dozen different cities each year. The emphasis is on capturing and killing rattlesnakes or copperheads, but usually any snake will do, and the slaughter is always extensive. This phenomenon will die out as the number of available snakes decreases. Distaste for snakes has often led legislatures or monarchs to promise bounties for those killed in areas under their jurisdiction, and such bounties invariably result in the importation of animals from many miles away. In a single year, 1889, 578,415 snakes were turned in for bounties in India. Although Western cultures have never developed the taste, in some parts of Asia the snake is considered a choice delicacy and, by some, even as somewhat of an aphrodisiac.

The serpent is a recurrent figure in religious beliefs, ceremonies, activities, and legends. The decidedly unhuman appearance of the snake, its unwinking eye, its reputed ability to deliver unexpected and sudden death, the fear, hatred, and loathing with which it is regarded by many, the folktales and legends that have surrounded it in practically every culture, all have combined to produce religious overtones in many different parts of the world. While in many religions the snake is primarily a symbol, direct worship of the snake as a godlike creature (not as an indirect representation) is not uncommon. Python worshippers are found in Africa, and the cobra cults of India are well known. Quetzalcoatl was the feathered serpent of the Aztecs. The serpent is a symbol for the snake-handling Protestant sects of the United States, the snake dancers of the Hopi Indians, and perhaps the Burmese snake charmers, who end their ceremonies with a kiss on the top of a cobra's head. Handling of snakes is done both as a gesture of belief and faith in the power of the gods and as an act of defiance of the same power. Bites and fatalities are about equally distributed in both cases.

Natural history

INTERACTION WITH THE ENVIRONMENT

While not exactly at the mercy of the environment, the snake is largely dependent upon it and must devote much of its day-to-day existence to coping with the vagaries and

changes taking place in its surroundings. The problem varies with latitude and altitude, for the actions and reactions of a snake in temperate North America are distinct from those of one living in the American tropical lowlands but are similar to those of another living at higher altitudes in the Andes of Ecuador. No matter where they live, snakes are subjected to pressures from the biotic, or living, parts of the environment as well as from the abiotic, the physical, or nonliving, parts. But the amount or degree of challenge to the snake from different segments of the environment changes drastically depending upon the region it inhabits. The individual living in the hot, humid tropics of Africa, with comparatively constant temperatures close to optimum throughout the year and ample moisture from both rainfall and the surroundings, finds that its environmental problems involve competition with other members of its own species for food supply, the challenge of other species of snakes and perhaps other vertebrates for possession of the ecological niche, and the constant pressure of the predator that finds it a tasty morsel. The viper (*Vipera berus*) living within the Arctic Circle of Europe, on the other hand, is the only snake species present in the area and lives practically unchallenged in its niche but is faced permanently with situations in its physical environment that are substandard for survival, so that death from overheating, freezing, or dehydration is a repetitive threat. These differences among animals from different parts of the world are reflected in their life histories, and it is neither possible nor legitimate to speak of the "life history of the snake" unless one speaks only of a single region or, perhaps, of a single species.

In the tropical regions, life continues at approximately the same activity level year after year. The only break in the rhythm comes in the dry season and this only when the dry season is not just a period of slightly less rainfall. Snakes may enter a short period of dormancy at such times, which is, at least in part, a consequence of the effect the dry season has upon their prey. This dormant period is similar to the hibernation in winter by temperate-area snakes, although little is known about the physiological changes that may or may not take place in tropical dormancy. At higher latitudes and altitudes, during periods of maximum stress, which for most snakes are the cold months, the animals must seek out a place where they can be completely inactive and nonreactive, where their inability to respond to the stimulus of danger is compensated for by the absence of danger, and where the surrounding extremes of low temperature and low humidity are mitigated to the point that they remain within the limits of the tolerance capacity of snakes. Such places are few and far between, and good hibernacula (dens used for hibernation) are recognized and utilized year after year, with snakes of several different species often sharing a den. It seems likely that the snakes do not remember the location of a hibernaculum but utilize the simple expedient of following a scent trail left by other snakes randomly seeking a den, with the scent growing more and more strong as successive snakes arrive from greater and greater distances. Many of the changes that occur in the individual snake after arriving at the hibernaculum are direct results of its dependence upon the environment, and, as its body cools, the heartbeat and respiration slow almost to a stop and there is no muscular activity, little digestion, and no defecation. Physiological changes that are not correlated with or responsive to the surroundings also take place, but not to a degree comparable to those occurring in . . . it

there is no "alarm system" to stir the snake into activity if a tolerance limit is passed. In such a case, the snake simply dies. At the end of the cold season, the snake is totally dependent upon the changes in its surroundings to bring it back to activity; it cannot rouse itself. The stimuli are felt by all almost simultaneously, and snakes emerge by the dozens or even by the hundreds from some denning places. In some species, copulation takes place immediately after enough of the sun's rays have been absorbed to permit the development of an interest in the surroundings; in others, copulation is the final act before entering

Hibernation

Snakes as symbols

hibernation, and the sperm lie dormant in the dormant female. Fertilization of the egg can take place immediately after copulation, but in some species at least, the female can store the sperm for several years, using them to fertilize successive batches of eggs.

BEHAVIOUR

Interactions **between** individuals. Snakes in both tropical and temperate regions tend to be solitary in their habits. The denning and mating aggregations are, for the most part, the only social events of the season. Sea snakes differ in this respect, sometimes being seen travelling in large troops, which seems to indicate an urge to aggregate. Female sea snakes (Hydrophiidae) also congregate in large numbers in seawall caves at parturition time, but this may have no social significance, since it seems to be a consequence of availability of a safe place for the young to be born rather than aggregational behaviour per se. There is some tendency for females of certain species in temperate areas to use a single site for egg deposition. Hunting of food is strictly an individual act for snakes; there are no known instances of cooperative hunting, as seen in some mammal and bird species. Hiding places and basking sites are occasionally shared; this again is a consequence of availability, and in the tropics, where hiding places abound, it is rare to find more than one snake at a time under a log or a rock. Except for these few weak instances, there is no development in snake populations of social behaviour. There is no establishment of social hierarchies, no territoriality, and perhaps no dominance. The combat dance engaged in by two males of the same species, where the bodies are entwined anteriorly and raised higher and higher off the ground until finally one snake overthrows the other, certainly establishes a dominant individual, but there is no indication that awareness of this dominance is retained by either snake. A dominance that must be reestablished at every encounter does not contribute to a social structure. It has been suggested that the combat dance is essentially a homosexual encounter, with each male attempting to copulate with the other.

Combat
dances

Reproduction. The occurrence of mating immediately after emergence from hibernation allows snakes to take advantage of the fact that the females are accessible, concentrated, and receptive. The males are equally concentrated, so pair formation and copulation is a simple matter. Males of some species have nuptial tubercles on various parts of the body, used to stroke or massage the female and, presumably, to arouse her sexually. Even when obvious tubercles are absent, the male uses a rubbing technique to stimulate the female, and in some species a muscle ripple moving along the male's body will provide a lateral caress. There are many descriptions in the literature of courtship dances done by snakes, in which the bodies are entwined and as much as one-third lifted off the ground, the coils ebbing and flowing with silent grace. Unfortunately, in many of these reports, the snakes were not captured and sexed, and the observer simply assumed that a male and female were involved. Recent work, where the snakes have been sexed, tends to indicate that the dance often, if not always, involves two males and is of little or no significance in reproduction. In any event, copulation is achieved after a comparatively brief courtship through the insertion of a hemipenis in the female's cloaca (a common urogenital chamber, lying just anterior to the anus). The hemipenis is one of a pair of mirror-image intromittent organs lying in the base of the male's tail, posterior to the anus, and strictly reserved for mating, for the urinary passages empty directly into the cloaca of the male. Either hemipenis can be used in copulation and must be everted, through a process of turning itself inside out. This is achieved primarily by engorgement of the organ with blood. The everted organ is heavily armed with spines, spinules (minute spines), flounces, calyces, and other ornaments, all of which appear to play a role in ensuring that the male is securely attached to the female for the entire period until the sperm have been deposited. The sperm pass along a deep groove in the hemipenis, which, although open along one

margin when examined in a dead snake, clearly forms a tubular passage as a result of the pressures of the engorged margins of the groove. After release, the sperm may immediately move up the oviducts and fertilize eggs just released from the ovary, or they may be stored by the female and released later to achieve fertilization. Once fertilization has occurred, the egg begins to accumulate additional layers from the shell glands in the oviduct. In some species, this continues until a firm yet pliable, leathery shell has been formed, permeable to both gases and liquids but capable of retaining much of its liquid content unless in a very dry place. The female then deposits the entire clutch of eggs in a protected, damp, warm, and usually dark place, often along with clutches from other females of the same species, for the same stimuli that lead snakes to congregate for hibernation also bring them to the same places for egg laying. Many species immediately abandon the eggs, some remain with the clutch and certainly appear to be protecting them from external danger, and a very few actually assume the role of a brood hen, maintaining a body temperature measurably higher than the surroundings, presumably assisting in incubation. In certain species, additional layers of membranous material are deposited around the embryo, but the calcareous (calcium-containing) shell does not form. Instead, the embryo is retained in the oviduct and continues its development there. This is termed *ovoviviparous* development, since it is simply an egg retained in the oviduct, in contrast to *viviparous*, the condition seen in mammals, where the fetus develops in the uterus and establishes a placental connection with the uterine wall to permit exchange of materials with the maternal circulation. But, while an umbilical connection does not develop, there is now considerable evidence of exchange of materials between mother and fetus across their contiguous, highly vascularized membranous surfaces, and the distinction between the two types of development is so blurred in some species as to become specious.

Egg
laying

Regardless of the devices used to provide it with protection, the snake fetus is always brought to term before the onslaught of environmental conditions that could result in its death. The embryonic turtle can sleep away its first winter in the egg and hatch the following spring none the worse for the experience, but there is as yet no evidence that snakes can do the same. The contrast may result from the fact that the female turtle can scoop out a hole deeply enough that freezing temperatures may not affect her brood, but the female snake is restricted, both by her limbliness and by the nature of the egg itself, to egg laying on or near the surface, where below-freezing temperatures are unavoidable. In the tropics, evidence is scanty, but it would appear that there is an endogenous (*i.e.*, controlled from within) rhythm there as well, since young are not produced throughout the year.

EARLY DEVELOPMENT AND GROWTH

The young snake, whether from an egg or born alive, comes equipped with a sharp cutting device on its upper lip, the egg tooth. It slashes its way out of the rubbery eggshell with this tooth or, in the case of the live-born, cuts its way out of the soft membranes and is instantly competent to cope with its surroundings. Almost invariably, the first act of a newborn snake is to extend its tongue and taste the surroundings, conveying to the Jacobson's organ (a sensitive region in the roof of the mouth) chemical information perhaps more significant than the visual cues picked up by the pair of very inexperienced eyes. Young snakes begin to feed immediately after hatching, displaying considerable ability in the capture and consumption of prey. Venomous snakes are born with functional venom glands and fangs and are capable of immediate utilization of their most formidable weapons. Some of the viperid snakes are born with a bright-green tail tip (contrasting strongly with the rest of the body colour), which they are capable of waving and shaking in a way that attracts the attention of possible prey. Within a very short time after birth, the first sloughing of the skin takes place, and the egg tooth is shed at about the same time.

The rate of growth is correlated with availability of

Growth rates

food and temperatures high enough to permit full metabolic activity. When all factors are optimum, snakes grow surprisingly fast. A brood of California rosy boas born on October 26, 1965, more than doubled their lengths by July 26, 1966. In this nine-month period they had reached lengths only a few inches shorter than their mother, an adult close to maximum length for the species. It has been suggested that all snakes grow rapidly until they reach sexual maturity, after which time growth slows but very seldom stops completely. Snakes have indeterminate growth, which means there is no terminal point in time or size for growth in their lifetime, but they can continue to increase in length until they die. Sexual maturity is reached in about two years by many snakes. In the larger species, sexual maturity comes later, after four or five years or more.

MOLT

A regularly recurrent event during the activity period of all snakes is the shedding, or molting, of the skin. Dormant individuals do not shed, but quite often this is one of the first events to take place after the end of dormancy. The integument of all animals represents the primary buffer between internal structures and the environment, and it is constantly subject to wear, tear, and other damage. The first line of defense against damage, especially when the skin is completely broken, is the formation of a blood clot, a scab, cellular reorganization, and scar formation. The second line of defense is the constant production of new cells in the deeper layers of the skin to provide replacement cells on the surface for those lost or worn away. In snakes, the replacement procedure has been modified to a considerable degree. The replacement cells are not constantly produced independently of each other but are all on the same cycle and are cohesive into a complete unit. When this unit is functional, the old skin lying external to it becomes a threat to continued good health. At this point, the snake's eyes become a milky blue, an indication of a physiological loosening of the skin that forms the eye cap. This loosening is duplicated all over the body, although not so obviously. Shortly, the eyes clear, and the snake rubs loose the skin around the mouth and nose and crawls out of it completely, leaving a new, functional skin resplendent in fresh, bright colours. The rattlesnake sheds its skin in the same fashion as all other snakes, but the process is highly modified at the tail tip, where successive layers of keratinized, hardened epidermis are interlocked, or nested, to form the rattle, a device used to ward off death or injury to the snake caused by large mammals, including man. The use of the rattle is reasonably successful with buffalo, cattle, or horses but spectacularly unsuccessful with man, because, through this advertising, the rattling snake precipitates either its death or capture but seldom its escape.

LOCOMOTION

The snake has overcome the handicap of absence of limbs by developing several different methods of locomotion, some of which are seen in other limbless animals, others being unique. The first method, called serpentine locomotion, is shared with almost all legless animals, such as some lizards, the caecilians, earthworms, and others. This is the way most snakes move and has been seen by any zoo visitor. The body assumes a position of a series of S-shaped horizontal loops, and each loop pushes against any resistance it can find in the environment, rocks, branches, twigs, dust, sand, pebbles, etc. The environment almost always provides sufficient resistance to make movement possible, and many snake species never use any other method of locomotion than this. Such species, when placed on a surface providing no resistance, such as smooth glass, are unable to move, whipping and thrashing around without progress. Other methods of terrestrial movement also involve at least some resistance by the environment but usually less than the first. One of these is known as "concertina" locomotion, because the snake in action resembles the opening and closing of an accordion or concertina. First the tail and the posteriormost part of the body are securely anchored, then the head and the

rest of the body are extended as far forward as possible from that secure base. At the maximum extension, the head and the fore part of the body are anchored and the posterior part drawn up as close as possible in the accordion-like folds. A second cycle follows the first, and the snake progresses. Tree snakes, such as *Imantodes* and *Oxybelis*, modify this technique to move from branch to branch and have a strongly compressed body that permits surprising amounts of the body to be stiffened and extended, using a modified I-beam effect for rigidity. The

San Diego Zoo

Figure 2. In typical method of locomotion, Bahaman boa (*Epicrates striatus*) extending itself to reach branch at right (not shown).

third method is called "caterpillar" or "rectilinear" locomotion, because the body moves in a straight line, using a flow of muscle contractions along the sides that looks like a caterpillar in motion. The body musculature is used for sequential lifting, anchoring, and pushing against individual ventral scales, which results in an inching along. It is used by large, heavy-bodied snakes, such as the boas and some of the vipers. The fourth method is the least dependent on friction with the substrate and, in fact, was developed because of the failure of the substrate to provide sufficient resistance for any of the previously described methods. This method, called sidewinding, characterizes snakes living in the desert, where the sand simply gives way under any kind of push. The sidewinder does not progress forward when in motion but actually goes sideways. The snake, lying extended on the sand, lifts the anterior part of the body, moves it five to six inches to the side, and rests that part on the sand, maintaining a lifted loop to the rest of the body. This lifted loop is then

Side-winding

progressively shifted along the body to the end of the tail at which time the entire snake has moved five to six inches to the side from its previous position. By the time the first loop reaches the end of the tail, a new loop has already lifted the head and started down the body, and the snake looks like a coiled spring rolling across the sand. There is no rolling involved, however, since the ventral surface is always in contact with a substrate and usually leaves its impression behind in the sand, like a footprint. A nonterrestrial method of locomotion is swimming. Most snakes use a somewhat frantic serpentine locomotion in water, and the water provides enough resistance to allow progress, but one would be hard put to say whether snakes are natural swimmers or cannot swim at all but simply take advantage of their natural buoyancy to crawl through the water. The true sea snakes, however, have a morphological adaptation that gives rise to a clearly distinct method of locomotion. The tail is compressed from side to side to form an oar, or paddle, and swimming efficiency is not only improved but raised almost to the level of an art by these snakes.

Form and functionGENERAL FEATURES

The most characteristic aspect of the snake form is the elongate body and tail and the absence of limbs. Fragments of limbs and girdles still survive in a few species of snakes, and in some snakes of the family Boidae the remnant forms a tiny, external spur on either side of the

Body
proportions

body at the anus, which is used by the male during courtship to stimulate the female. There is no snake in which the limb remnants still retain a function in locomotion. The body is usually slender, although there are some very heavily bodied species. The body shape is correlated with activity level, with the slender species moving about all the time and the heavy forms leading a sedentary life. The pit vipers, for example, while not always long snakes, are often big snakes. It seems likely that these snakes evolved in the direction of heaviness only after the development of a heat-sensitive depression, the loreal pit, located between the eye and the nostril, and the venom apparatus, which enabled them to stay in one place and wait for their prey to approach, rather than engaging in a continuous, active search for food. Similarly, some of the largest boid snakes (boas, anacondas, and pythons) have labial pits that function in the same way as the loreal pit of the vipers, so they, too, can be sedentary and grow fat. Arboreal snakes are the most elongated and slender of all, with the tail (the region posterior to the anus) often longer than the body and the body often strongly compressed laterally, which permits greater rigidity of the body frame while crawling from branch to branch. Burrowing snakes are seldom large, and the true burrowers, the Typhlopidae and Leptotyphlopidae, living all their lives like earthworms, are the tiniest snakes of all. The burrowers have almost no tail, although some of them retain a spiny tail tip, which probably serves the animal as an anchoring point when crawling through the soil. The tail in the sea snakes is flattened to form an oar, used to scull through the water. Sea snakes are almost totally helpless on land, locomoting only with the utmost of difficulty.

The skin. The entire body and tail in snakes are covered with scales, which are cornified folds in the epidermal layers of the skin. These scales are usually arranged in longitudinal rows, the numbers and arrangement of which are characteristic of the species. The scales may be large and shield shaped, in which case the number of rows is low, from 8 to 29 or 30, or they may be very small, rounded, and occasionally with the centre raised, in which case the number of rows can be as high as 90 or 100. A single scale may be very smooth and shiny (as in the rainbow snakes), it may have a raised ridge (keel) along its centre, it can be heavily striated, or it may even have a raised spine in the centre, as in the Javanese wart snake. The scales in some species have sensory structures on the posterior margins called apical pits, and all scales have various micro-ornamentations, consisting of hair-like projections, holes, spinules (small spines), and other specializations visible only through an electron microscope. The scales on the ventral surface of the body are modified into broad plates in the majority of species and are used in locomotion. The sea snakes and the blind snakes lack such ventrals, the scales being small, as on the dorsal surface, and there are several other species, such as the anaconda, in which the ventrals are very reduced in size. This appears to be a secondary loss of the enlarged ventrals, correlated with life in an environment where locomotion is achieved in other ways, such as swimming or movement in burrows.

Coloration. The colours and colour patterns seen in snakes are often bright, occasionally spectacular, and in some species even beautiful. Snake colours are produced in two ways, either by pigment deposited in the skin or by differential diffraction of light as a consequence of the physical properties of the skin itself. When seen on a unicolour or uniform background, most snakes are obvious, and their colour patterns seem bold and prominent. When the animals are placed in their natural habitat, however, the significance of the colour patterns becomes obvious. The many lines running at sharp angles to the elongated lines of the body, the triangles or rectangles of colour, the blotches, spots, bands, or lozenges, all become highly disruptive to the eye, and the snake disappears into its surroundings. Blotched or spotted snakes tend to be sedentary and heavy bodied, while striped and the occasional unicolour snakes are usually active species. In both cases, the coloration is protective, since a coiled,

sedentary snake has its body outline completely obscured by the overlapping patterns, while the stripes on a crawling snake eliminate the sensation of motion until they suddenly narrow at the tip of the tail and the snake disappears.

Although in most snakes the colours are such that they help the animal to hide, there are some species that seem to be advertising their presence rather than trying to hide it. Their patterns are aposematic, or warning, in nature, and let a possible enemy or predator know that he runs some risk in an encounter with the snake. The warning is effective, of course, only if the intruder is knowledgeable concerning its significance and can take heed. This implies a teaching and learning sequence, with the dangerous snake as "teacher" and the predator as "student." For this reason, it has been suggested that the bright colours of the highly (and often fatally) venomous coral snakes did not evolve as warnings of the snakes' own poison but as mimics of some other venomous species, less dangerous, but still able to teach the predator the significance of the warning coloration. There is no evidence that avoidance of aposematic species is instinctive; on the contrary, naïve predators readily attempt to take aposematic forms. A predator that dies in its first encounter with a dangerous species cannot act as a selective force favouring the coloration of that species. There are quite a few mildly poisonous rear-fanged snakes, brightly banded in red, black, and yellow (colours found in the coral snakes), that can make a predator suffer a sufficiently painful lesson that it will avoid contact with all similarly coloured snakes, including the fatally venomous coral snakes and the completely harmless milk snakes (*Lampropeltis*). (For a complete discussion of the evolution of mimicry, see MIMICRY.)

Skull and sense organs. Snakes rely on several senses to inform them of their surroundings. The pits, found in the region between the nostril and the eye in the pit vipers (the viperid subfamily Crotalinae) and in the scales of the lip line in some boids, are sensitive to very slight changes in temperature in their surroundings. These snakes feed almost exclusively on animals, such as birds and mammals, that maintain a constant body temperature and can therefore be located by the snake through the reception of the heat of the warm body. The heat lost by even a small rodent is sufficient to alert a waiting viper and enable it to direct a fast strike at the animal as it passes by. Death follows rapidly, and the snake follows the dying animal at a leisurely pace, perhaps in full awareness that it will not go far. The boids use the same technique for detecting warm prey, but after striking they retain the grip, killing by constriction.

The eye of the snake is lidless and covered by a transparent cap of epidermis, which is shed with the rest of the skin at each molt. Animals active during the day usually have round pupils, while the nocturnal species have a vertical or slit pupil that opens up in the dark, as does that of a cat, but closes more effectively in bright light, protecting the sensitive, dark-adapted retina. The eye has been almost completely lost in the burrowing families, in which it is visible only as a black spot buried under the flesh and bone of the head. Arboreal snakes often have a bulging, laterally placed eye, permitting them to see activities directly below as well as above and around them. The structure of the eye in snakes indicates that their lizard ancestor was probably a burrower and that all aboveground activity by snakes is a secondary invasion from an ancestral life underground.

The reception of sound is entirely by bone conduction within the skull. The snake has no external ear, but it still retains a few of the vestiges of the internal ear, which are connected to other skull bones in such a way as to permit transmission of some earth-borne sound waves.

The skull of snakes is characterized by mobility. It is light, with a reduced number of bones, and there are hinge joints at several levels that permit slight rotation or movement of one segment upon another. The only compact unit is the central braincase, with all other skull bones little more than attachments to it. The flexibility of the skull and the jawbones attached to it is a major com-

Warning
coloration

Temperature
detection

pensatory factor to balance the loss of limbs. The snake replaces manipulation of digits with manoeuvrability of skull bones.

The jaws of snakes are highly mobile and are usually heavily armed with teeth. The upper jaw can move to and fro on hinged joints and can also rotate slightly. In most snakes, the upper jaw is connected to the lower jaw by a joint that acts as a pivot point, and, in eating, all toothed bones on one side of the mouth move forward as a unit. In some tree snakes (the colubrid subfamilies Dipsadinae and Pareinae), the connection between the upper jaw and the quadrate is lost, and there are four independent units rather than two. These snakes feed exclusively on small, slippery prey, such as slugs and snails, and this jaw modification permits them to hold their food with three jaws while the fourth is advanced. The maxillary bone (the main bone of the upper jaw) of most snakes is elongated, with many teeth, but in the Viperidae (Old World vipers, New World rattlesnakes, and other pit vipers) only one functional fang remains, on a short, blunt, rotatable maxillary. The position usually occupied by the maxillary has been taken by the pterygoid bone. In the Elapidae (cobras and relatives) the maxillary bears a single fang in a fixed position, sometimes followed by a few smaller, solid teeth. In several different evolutionary lines of snakes, the posterior one or two teeth on the maxillary have enlarged and changed, usually in the direction of developing a groove or canal on the anterior edge to conduct a flow of venom. These are the rear-fanged snakes, usually (although not always) nonlethal to man. Snake teeth are usually long, slightly recurved, and needle-sharp. This facilitates swallowing and prevents loss of food, because the only direction in which a food item, which may be alive when swallowed, can go to escape the teeth is down the throat. Modifications in food habits have often been accompanied by changes in tooth structure or the loss of

Drawing by M. Moran

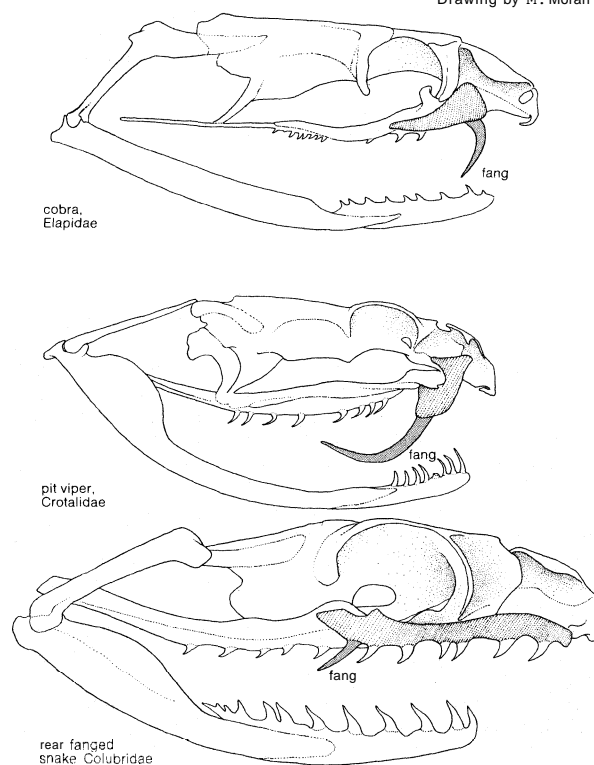

Figure 3: Skulls of representative poisonous snakes,

teeth. The egg-eating snakes, for example, have only a few peglike teeth left. The burrowing blind snakes have very reduced dentition and have often lost the teeth of one jaw entirely.

The vertebral column of snakes is highly elongated and includes many more vertebrae than almost any other kind of vertebrate animal. Since there are no limb girdles

associated with the skeleton, there are no good delimiters of regions, and snakes are generally regarded as having only two kinds of vertebrae, precaudal and caudal. A pair of ribs is associated with each precaudal vertebra except for a few immediately behind the head, but, by definition, there are no ribs on caudal vertebrae. Each vertebra articulates with its neighbours at five different points: first, at the contact point between the centra (the main, central bodies of the bones), which is a ball-and-socket joint; then two points at the zygapophyses (projections from the centra), with articulating surfaces that lie dorsally and ventrally; and finally the zygosphenes and zygantra, found almost exclusively in snakes, the zygosphenes being a projecting shelf on the neural arch (the upper part of the vertebra) and the zygantrum, a pocket into which the zygosphenes fits and within which it can swivel. These five points permit lateral and vertical rotation while preventing almost entirely any twisting of the vertebral column, thus achieving both flexibility and rigidity. The vertebra may bear on its ventral surface a long, posteriorly directed projection called a hypapophysis. The presence or absence of this structure on the vertebrae of the posterior third of the body has been of considerable importance in snake classification, because large groups of species show this as a common characteristic. In the egg-eating snakes (members of the colubrid subfamily Dasypeltinae), the hypapophyses of a series of vertebrae a short distance behind the head have developed anteriorly directed tips that have a distinct coating of enamel-like substance. These serve as eggshell breakers, projecting through a gap in the dorsal intestinal wall, where they can rip into an egg when the snake constricts the muscles of the body as it passes the hypapophyseal points. The crushed shell is regurgitated, and the contents of the egg pass on to the stomach. The vertebrae of the tail tip in the rattlesnake are highly modified to form a "shaker" for the rattle.

Urogenital system. The urogenital system in snakes is not very distinctive from that of other vertebrates. The testes and ovaries tend to be staggered as a consequence of the elongation of the body, with the right usually lying anterior to the left. Snakes do not have a urinary bladder, and kidney wastes are excreted in a solid state as uric acid. As mentioned above, the male snake has two separate intromittent organs, the hemipenes. This structure is not homologous with the penis of mammals but seems to represent a completely different solution to the problem of internal fertilization. It is a saclike structure that must be turned inside out to be inserted in the cloaca of the female and can be removed only by turning it back to inside in, because to draw it out directly would damage the female considerably. The hemipenis is extremely variable in its overall appearance and structure; the cloaca of the female is often similarly constructed, thus preventing cross-fertilization by males of related species.

SPECIALIZATIONS FOR SECURING FOOD

The most essential and time-consuming activity for a snake during nondormant periods, regardless of its habitat, is the pursuit, capture, and digestion of food. There are many morphological and behavioural modifications to be observed in snakes that facilitate food gathering. Some of these changes are widespread and found in practically every kind of snake. Jacobson's organ, for example, is located in the roof of the mouth and is capable of detecting minute quantities of various chemical substances when they are picked up externally on the delicate, double-tipped tongue and thrust into the organ for analysis. It is so significant and useful that it has never been lost by any snake species. While important primarily in trailing and recognition of prey, the Jacobson's organ is also used in detection of enemies, in trailing other snakes of the same species, and in courtship.

Some snakes have specialized salivary glands that elaborate a potent poison, along with either grooved or tubular teeth to permit internal injection of the venom. This device for rapid immobilization of prey has proven successful whenever it has occurred, and several different lines of evolution can be detected both in the type of injector

The

Carl Gans

Types of
venom

tooth and in the chemical composition or mode of action of the venoms. The types of injector tooth include the long, tubular fang of the viperids; the short, hollow fang on a fixed maxillary seen in the elapids; and the several kinds of grooved tooth on the posterior end of the maxillary. In the latter case, there is little doubt but that the development of grooving has taken place several different times in different places. As for the venoms, it is true that the terms neurotoxic, hemotoxic, and cardiotoxic, once used to describe the different effects, are clearly misleading and are too simple for accurate statements concerning venom composition, but it is still accurate to say that some of the components of venoms cause changes in the red blood cells, coagulation defects, and blood-vessel injury, while others produce deleterious changes in sensory and motor functions and in respiration, and still others have a direct effect on the heart. Some venoms kill very rapidly, such as that of *Bothrops insularis* of Queimada Island, off the Brazilian coast, which would lose as prey most of the birds it bites if they could fly very far away. Other venoms kill more slowly, and the snake bites, retreats, and waits, finally trailing the bitten prey, using the tongue and the Jacobson's organ until it finds the already stiffening body. Some snakes, in particular the rear-fanged species, bite, chew, and hold on, eventually bringing the hindmost maxillary teeth into play, which permits the injection of toxins.

Constriction

Other feeding specializations are not so widespread among species, and some are restricted to a single group. Many of the boids and some of the colubrids utilize a constriction method for killing their food. The prey is struck and held by the teeth, and a series of body coils are rapidly thrown around it. These coils tighten until respiration is impossible and suffocation results, but very seldom are bones crushed or broken. The snail-eating snakes have a series of modifications of the teeth, the toothed bones, and the lower jaw that permit the insertion of the lower jaw into a shell to pull out the snail's body. One genus of sea snakes, *Microcephalophis*, has a tiny head and a long neck with the same diameter as the head, which can be inserted deeply into very narrow holes inhabited by its prey. An Asiatic water snake, *Erpeton*, has a pair of elongate tentacles on its snout that appear to function as sighting devices to guide the strange, stiff-bodied strike at a passing fish. There is a great correlation between the difficulty in catching a particular kind of prey and the development of morphological and behavioural devices to help solve the problem. The blind snake living in a termite nest needs no more than its tongue and

Jacobson's organ to permit it to recognize the soft-bodied, defenseless termites, and its eyes and most of its teeth have been lost. But the rattlesnake, seeking the most elusive prey of all in the agile, aware, sensorily acute small mammal, has a full armament of equipment, including the facial pit, the venom gland, the rotatable maxillary bone, the tubular fang, and two functional eyes.

Evolution and classification

EVOLUTIONARY ORIGINS

The oldest fossil definitely identifiable as a snake is *Dinilysia*, from the Upper Cretaceous (about 80,000,000 years ago) of Argentina, considered to be most closely related to the aniliids and others in the superfamily Booidea. Some fossils from earlier deposits have been called snakes, but American paleontologist Alfred S. Romer has tentatively regarded them as lizards. Snake bones are delicate and do not tend to fossilize well. Most snakes are small, and fossil hunters in the past tended to concentrate on larger, more spectacular specimens. Modern techniques have begun to turn up a wealth of material, much of very small size, including snake skull bones and vertebrae. Much of this material is from Pliocene, Pleistocene, and older Recent deposits, and it often either is identifiable with modern genera or else shows close resemblance to them.

Snakes are, thus, a comparatively young group of animals. They arose from a lizard ancestor probably very similar to the modern varanids (monitor lizards). *Dinilysia* shows certain characters very similar to those found in the Bornean lizard *Lanthanotus*, a platynotan lizard related to the Varanidae. Several theories have been proposed as to the habitat preference of the snake ancestor, including aquatic, terrestrial in savanna-like situations, or burrowing. Strong support for the burrowing hypothesis has come from study of the eye. Losses (such as the movable eyelid) caused by ancestral adaptation to burrowing were not regained by the descendant nonburrowing snakes, and other devices to cope with vision problems were developed and refined.

The phenomenal adaptive radiation that produced the many different species of colubrid snakes (a category that includes the vast majority of familiar snakes), now found in practically every kind of habitat and efficiently capitalizing upon almost every kind of terrestrial animal as food, was a very recent event. It probably took place entirely within the Tertiary (from about 65,000,000 to 2,500,000 years ago), and represents a triumph over the handicap of limb loss, which is often a blind alley in evolution. The development of over 2,000 species of snakes occupying practically all available niches is an achievement equivalent to the concomitant emergence and differentiation of the birds or perhaps even that of the mammals.

DISTINGUISHING TAXONOMIC FEATURES

Herpetologists have used a variety of characteristics in the recognition of higher taxonomic units within the snakes, but one tendency has characterized most of the classifications set up by different authors over the years. This has been to base the classification on contrasting conditions of a very few characteristics, occasionally only one. Characteristics used either by themselves or in combinations with one or two others have included the following: the manifold variations in the structure of the hemipenis; the presence or absence of various projections, knobs, folds, shelves, and other modifications of the individual vertebrae; the different types of maxillary teeth and their arrangement on the bone; arrangement and relationships of bones in the skull; presence or absence, location, origin, and insertion of muscles, primarily cranial, but occasionally those of the body; and the type of retina in the eye. If any one of these is emphasized over most others in a classification, that classification will be very different from other systems, because these characteristics are not closely associated genetically and do not tend to group themselves together but vary quite independently. Taxa at the lower levels of classification (genera and species) are usually recognized on the basis

Relation
lizards

of external characteristics that permit easy identification, even though these cannot be used to indicate phylogenetic relationships. These characteristics include the shape, presence or absence, fusion, division, and relationships of the plates of the head; the numbers of rows of dorsal scales and their ornamentation with keels, striae, pits, etc.; the size, number, and condition of ventral, anal, and subcaudal scales; shape of body or head or both; and, in some cases, coloration.

ANNOTATED CLASSIFICATION

The classification presented here represents a conservative summary of the views expressed by G. Underwood, H.W. Parker, H.G. Dowling, A.S. Romer, A. Bellairs, and other prominent herpetologists in the recent literature. Careful analysis of the classifications offered by these authors shows that the major differences are in the level of taxonomic recognition given to a particular group rather than in the allocation of a group with regard to phylogenetic position.

SUBORDER SERPENTES

Reptiles without limbs and with the body greatly elongated; with a very high number of vertebrae in both body and tail, each individual vertebra with zygosphenes and zygantrum and almost all those of the body with a pair of attached ribs. Pectoral girdle completely absent; pelvic girdle usually absent, but present as a vestige in primitive species. Outer ear and tympanum lacking, sound reception entirely by bone conduction. Bones of both jaws usually flexible, loosely attached to the skull and to each other, plentifully supplied with teeth in most species, forming poison fangs in some. The braincase is platytatic.

Superfamily Typhlopoidea (or Scolecophidia)

Diminutive, wormlike snakes that usually retain vestiges of the pelvic girdle and 2 common carotid arteries. Skull compact, with the bones solidly united, which facilitates burrowing; dentition very reduced, with no teeth on the pterygoid, premaxillary, or palatine bones. Intercostal arteries to almost all body segments.

Family Typhlopidae (blind snakes or worm snakes)

Maxillary bone bears teeth arranged transversely and can be rotated slightly on its attachment to the skull; dentary bone usually lacks teeth (present in anomalepine species). Either there is a single pelvic bone or the girdle is absent entirely. Circumtropical in distribution; practically no fossils are known, except for a few specimens from the Tertiary of Europe.

Fanzily Leptotyphlopidae (slender blind snakes)

Maxillary bone bears no teeth and is quite firmly united with the skull; teeth are always present on the dentary. The pelvic girdle made of 3 bones. Tropics of Latin America to southwestern United States, Africa, and southwestern Asia. No fossils are known.

Superfamily Booidea (or Henophidia)

Moderate-sized to very large snakes. Often with vestiges of the pelvis and associated bones, sometimes visible externally as a rudimentary hind limb. There are two common carotid arteries. The coronoid bone of skull usually present; parasphenoid bone does not form part of the optic foramen; supraorbital bone absent in all except some members of the Boidae. Dentition well developed on all jawbones, usually including the premaxillary. Intercostal arteries running to almost all body segments are present.

Family Aniliidae

The femur present as an anal spur in males, and pelvis made up of a single bone. No hypapophyses on the body vertebrae. Ventral scales only slightly larger than dorsal scales, not extending across the full width of the belly. Premaxillary bone with teeth; forms a suture (tight seam) with the maxillary; dentary immovable. One genus, *Anilius*; known only from the Recent of South America; a brightly coloured snake, with red, black, and yellow rings around the body.

Family Xenopeltidae (sunbeam snakes)

Femur absent; no trace of the pelvic girdle. Hypapophyses on the anterior vertebrae. The ventral scales enlarged. Premaxillary bone toothed; forms a suture with the maxillary. Dentary hinged on the surangular bone and movable. One genus, *Xenopeltis*, burrowing snakes from India and elsewhere in Asia. No fossils known.

Family Uropeltidae (shieldtail snakes)

Femur absent; there may or may not be pelvic rudiments. No hypapophyses on the vertebrae. Ventral scales usually not

more than twice as broad as the neighbouring dorsal scales. No teeth on the premaxillary, which forms a suture with the maxillary. Dentary fixed on the surangular and, thus, immovable. A family of burrowing snakes, found only in southern Asia. No fossils known.

Family Boidae (pythons, boas, and wood snakes)

Femur often present; pelvic vestiges occurring in all but a few genera. Hypapophyses present on vertebrae. Ventral scales broad, extending across the entire belly, except in a very few groups. Premaxillary may or may not bear teeth; does not form a suture with the maxillary. Circumtropical; it includes all of the giant snakes as well as several genera of small, secretive snakes. Bones from apparent boids have been found in Tertiary deposits around the world. The family is divided into subfamilies in different ways by different authors. The subfamilies Boinae, for the large New World constrictors, and the Pythoninae, for the Old World pythons, are almost universally recognized.

Fanzily Acrochordidae (wart snakes)

Femur and all pelvic vestiges absent; hypapophyses present throughout the vertebral column. Ventral scales cannot be differentiated from dorsals. Premaxillary bone toothless and free of maxillary bone; dentary not hinged or any part of it free. One genus, *Acrochordus*; aquatic snakes found in Australia, the East Indies, and southeastern Asia. No fossils known.

Superfamily Colubroidea (or Caenophidia)

This superfamily includes the major number of snakes, which have in common the complete absence of any vestiges of the limb girdles and have only the left common carotid artery. Skull quite flexible, with several joints and sutures that permit movement of one part on another. Coronoid bone absent. No teeth on the premaxillary; characteristically, maxillary, palatine, pterygoid, and dentary bones all are toothed; some groups have a fang, or grooved tooth, at the posterior end of the maxillary. Intercostal arteries occur at intervals of several body segments.

Family Colubridae

Maxillary bone comparatively fixed in position, cannot be rotated; usually elongate and armed with teeth throughout its length. Posterior-most maxillary teeth grooved or hollow in some groups, but these fangs are preceded by a series of normal teeth in practically every instance. Hypapophyses may be present on vertebrae throughout the body or may be absent posteriorly, and this character has been used to divide the family into smaller groups. Tail usually long and ending in a point. Found all over the world where snakes occur; species make up the majority of snakes everywhere except Australia. Most of the following subfamilies are recognized by herpetologists, and some authors raise several of them to familiar status.

Subfamily *Dasypeltinae* (egg-eating snakes). Perforated esophagus and a series of elongated, enamel-tipped vertebral hypapophyses, which pass through the perforations and can crush eggshells. Teeth extremely reduced and peglike. Two genera, found in Africa and Asia.

Subfamilies *Pareinae* and *Dipsadinae*. Two small subfamilies of arboreal snakes, specialized for snail eating. These adaptations, including specially modified lower jaw, have evolved separately in the Asian *Pareinae* and the South American *Dipsadinae*.

Subfamily *Xenodonta*. Large, bladelike posterior maxillary teeth, a large adrenal gland, and several other characters. Two of the genera, *Lystrophis* and *Heterodon*, have pointed, recurved, digging snouts not seen in *Xenodon*.

Subfamily *Homalopsinae*. Aquatic, fish-eating snakes, lacking grooved teeth. Stout body with a short tail. Southeast Asia, the East Indies, and Australia.

Subfamily *Colubrinae*. Widespread and often abundant group; contains most of the familiar harmless snakes of Europe and North America. Highly variable in coloration, size, and structure. Many nonpoisonous; some rear-fanged (but rarely dangerous to man); many kill by constriction. About 1,500 species.

Family Viperidae (vipers, rattlesnakes, moccasins, and relatives)

The maxillary bone rides on a hinged joint and is armed with a long, sharp tooth with a canal through it for injection of poison; no other teeth on the maxillary except for replacement fangs. Hypapophyses present on the vertebrae throughout the body.

Subfamily *Viperinae* (Old World vipers). No heat-sensitive pit or excavation in the maxillary bone. Found throughout Europe, Asia, and Africa but not in Australia. Fossils from Miocene of Europe.

Subfamily Crotalinae (pit vipers). Heat- or infrared-sensitive pit present on the side of the head between the nostril and the eye; maxillary bone with deep excavation in its outer surface to accommodate the pit organ. Widely distributed in the New World; one of the larger groups includes rattlesnakes. A few species also known from Asia. Fossils from Pliocene and Pleistocene of North America.

Family Elapidae (cobras, mambas, coral snakes and relatives)

Maxillary bone is shortened, fixed in position; cannot be rotated. Anteriormost tooth on the maxillary a short, fixed, hollow poison fang, usually but not always followed by a few other teeth. Hypapophyses are present on all body vertebrae. Tail rounded and normal, ending in a narrow tip. Elapids are also found abundantly in Asia, Africa, Central America, and South America; especially numerous in Australia, comprising, with sea snakes, more than two-thirds of snake species; rarely enter the United States; do not occur in Europe except as possible fossils.

Family Hydrophiidae (sea snakes)

The maxillary bone much like that of the elapids. Hypapophyses are present on the vertebrae throughout the body. The tail and part of the body compressed vertically into a large, oarlike swimming device. Found in the tropical western Pacific and Indian oceans; only one genus proven to have reached the Pacific coast of the New World.

CRITICAL APPRAISAL

The classification of snakes cannot yet be considered to have achieved the relative stability that characterizes bird and mammal classification. Authorities continue to disagree both on the taxonomic rank to be accorded certain groups and on the relationships of many groups. Romer, for example, recognizes the Xenopeltinae and Loxoceminae as subfamilies of the Aniliidae. Underwood, on the other hand, treats the first as a family, Xenopeltidae, and considers the Loxoceminae to be a subfamily of the Boidae. The Anomalepinae are regarded by some authors as sufficiently distinct from the Typhlopinae to warrant family status.

Emphasis on one characteristic, such as the presence or absence of a pelvis, profoundly affects the classification. Some authorities remove from the Uropeltidae all genera with pelvic remnants, placing them in the Aniliidae. Others have excluded from the Boidae all genera that lack pelvic remnants.

The family Colubridae has troubled taxonomists for nearly two centuries, many attempts having been made to break it into workable groups other than those currently recognized. The conservative view still recognizes only a few small, distinct subfamilies and several large grab-bag subfamilies. Many groups have been separated from the Colubrinae as subfamilies within the Colubridae or even as distinct families.

In older classifications, the pit vipers have sometimes been separated from the Old World vipers as the family Crotalidae.

BIBLIOGRAPHY. BOULENGER, *Catalogue of the Snakes in the British Museum, Natural History*, 3 vol. (1893-96), a classic work, the only attempt ever made in the English language to list, describe, and furnish an aid in the identification of all the snakes of the world; GARTH UNDERWOOD, *A Contribution to the Classification of Snakes* (1967), a highly technical discussion of relationships among the various kinds of snakes; JAMES A. PETERS, *Dictionary of Herpetology* (1964), contains extensive information about snakes and other reptiles, in a readily accessible form; ROGER CONANT, *A Field Guide to Reptiles and Amphibians of the United States and Canada East of the 100th Meridian* (1958), and ROBERT C. STEBBINS, *A Field Guide to Western Reptiles and Amphibians* (1966), extensively illustrated manuals for field identification of snakes, as well as other reptiles; CLIFFORD H. POPE, *The Giant Snakes* (1961), an entertaining discussion of the very large snakes, such as the anaconda and boa constrictor, and *Snakes Alive and How They Live* (1937, reprinted 1958), although somewhat outdated, still a readable account of snake natural history; ALBERT H. and ANNA A. WRIGHT, *Handbook of Snakes of the United States and Canada*, 2 vol. (1957), de-

tailed descriptions of all the kinds of snakes known on the North American continent, with many photographs; COLEMAN J. and OLIVE B. GOIN, *Introduction to Herpetology* (1962), a textbook designed for undergraduate classes at the college level; KARL P. SCHMIDT and ROBERT F. INGER, *Living Reptiles of the World*, pp. 175-279 (1957), a popular account, aimed at the general public, profusely illustrated with colour photographs; RAMONA and DESMOND MORRIS, *Men and Snakes* (1965), a thorough review of man's relationships with snakes, including culture, mythology, medicine, and exploitation; H.W. PARKER, *Natural History of Snakes* (1965), one of the handbook guides to the British Museum, and *Snakes* (1963), a factual account of the general biology of snakes; LAURENCE M. KLAUBER, *Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind*, 2 vol. (1956), a thorough summary, not only of rattlesnakes but of all snakes, their biology and relationships with man; HOBART M. SMITH, *Snakes As Pets* (1965), a guide to the care and feeding of snakes in captivity; JAMES A. OLIVER, *Snakes in Fact and Fiction* (1958), a popular account of the snake, with both true and imaginative stories about size, food, numbers, and other bits of natural history; WOLFGANG BUCHERL, E.E. BUCKLEY, and V. DEULOFEU (eds.), *Venomous Animals and Their Venoms*, 2 vol. (1968-71), a discussion of the classification, distribution, and biology of venomous snakes, with detailed discussions of their venoms as well as treatment of snakebite; SHERMAN A. and MADGE R. MINTON, *Venomous Reptiles* (1969), an entertaining and often anecdotal account of venoms, venomous reptiles, their bites and the treatment of bites, and the intricate relationships of snakes with man and his cultures.

(J.A.P.)

Sesshū

Of all the many distinguished painters Japan has produced, Sessha is usually considered to have been the most outstanding. This estimate is based not only on the excellence of his work but on his eminence as a Zen monk and man of learning. The tradition of the Zen-Buddhist-inspired style of ink painting (*sumi-e*) finds its ultimate expression in his art. Although basing his work on Chinese models, he adapted them to Japanese artistic ideals and aesthetic sensibilities, transforming an artistic style imported from China in the 14th century into something characteristically Japanese.

Sesshii was already hailed during his lifetime as the greatest Japanese painter of his time, a verdict ratified by later generations of artists, many of whom imitated his style or were influenced by his work even as late as the

"Winter Landscape" by Sesshū, ink on paper. In the Tokyo National Museum. 46 cm x 29 cm.

19th century. Several painters even used his name; these included the great 16th century master Hasegawa Tbhaku, who proudly signed himself Sesshii of the fifth generation. An entire school of Japanese painting, the Unkoku school, devoted itself to continuing his artistic heritage.

In contrast to many of the masters of Japanese art about whose lives little is known, the biography and artistic career of Sesshii are recorded in detail. He was born in 1420 in the village of Akahama in Okayama Prefecture (formerly called Bitchu Province). His family name was Oda; his original personal name is no longer known. In 1431, at the age of ten, he was enrolled at the local Zen temple, known as Hofuku-ji, where he received the name Tōyō, meaning "willowlike" (perhaps because he was slender and graceful). Zen Buddhist temples were the artistic and cultural centres of the period as well as the centres of spiritual life. As a young novice, therefore, Sesshii undoubtedly received not only religious guidance but also instruction in calligraphy and painting.

Early
career at
Shbkoku-ji

Around 1440, he left his native province for Kyōto, then the capital city and the intellectual and artistic focus of Japan. The young monk lived at Shbkoku-ji, a famous Zen temple adjacent to the Imperial Palace of the Ashikaga shoguns, who were great art patrons. Shiibun, the most famous Japanese painter of the day, was the overseer of the buildings and grounds at Shbkoku-ji. In addition to studying painting under Shiibun, Sesshii studied Buddhism under the famous Zen master Shurin Suto. Although there are no paintings that can be assigned with certainty to this early period of Sesshii's career, it is believed that he must have worked in the style of Shiibun, who was profoundly influenced both in choice of subject matter and style by the Chinese painters of the Sung period (960–1279). Sung masters enjoyed great favour with the Japanese Zen painters, and their work was eagerly collected by Japanese connoisseurs and artists alike. The young Sesshii, therefore, must have had many opportunities to study masterpieces of Chinese painting.

After spending 20 years in Kyōto, Sesshii left the capital for Yamaguchi in the western part of the island of Honshu, a city that had become an important cultural centre under the Ōuchi clan. In Yamaguchi, the artist became the chief priest of the Unkoku-ji, and it was at this time, probably in 1466, that he began to call himself Sesshū ("Snow Boat"). It seems certain that one of the reasons Sesshii chose to move to Yamaguchi was his desire to go to China. Strategically located, this section of Japan was the staging point for many expeditions to the Asian mainland. The duchi lords, in fact, had a trade permit that enabled them to conduct very profitable commercial transactions with China.

Journey
to China

Sesshii succeeded in joining one of these Japanese trading missions as an art expert and landed in 1468 at Ning-po in southern China. He was to act as a "purchaser priest," who would buy Chinese paintings for his patrons and would also study at the Chinese Zen monasteries. Sesshii was disappointed with contemporary Chinese painting, which, under the Ming dynasty (1368–1644), had turned away from the spiritual and aesthetic ideas prevalent during the Sung period. Nevertheless, the magnificent scenery of China, as well as the contact with the Ch'an (Chinese word for Zen) monasteries, was a source of great inspiration to Sesshii, who often referred to these experiences in his later life. As a distinguished visitor from Japan, Sesshii was treated with great respect. He was honoured with the "First Seat" (that is, the seat next to the abbot in the famous Ch'an monastery of Mt. T'ien-t'ung) which led him to sign several of his paintings "Occupant of the First Seat at T'ien-t'ung." He also travelled to the Chinese capital of Peking. A friend who accompanied him on this trip reported that Sesshii was invited to paint the walls of one of the halls of the Ministry of Rites at the Imperial Palace. It is not known whether this story is true or whether it is an exaggeration of some other invitation, but it does indicate in what high esteem this Japanese master was held by his Chinese contemporaries. What Sesshū's painting of this period may have looked like is perhaps best exemplified by a set of four landscape scrolls (Tokyo

National Museum) that are signed "Tōyō, Japanese Zen Priest," a designation hardly necessary if they were painted in Japan.

Having been honoured at the Imperial Court in Peking and at the most celebrated Zen monastery in China, Sesshii was at the height of his career. In 1469 he returned to Japan where his fame had greatly increased. It is believed that he first went back to Yamaguchi but eventually (probably in 1476) built a charming rustic retreat across the strait near Oita in Bungo Province. He called his new house and studio Tenkai Zuga-rō ("heaven created painting pavillion") as a tribute to the peace and beauty of the setting. Sesshii painted some of his most outstanding works here and received many visitors who wished to hear about his trip to China or to study painting under him.

Retreat
near Oita

After many trips through northern Kyushu and other sections of Japan, Sesshii again returned to Yamaguchi in 1486 and rebuilt his studio. It is not certain if he also lived in Iwami, as some sources suggest, nor is it known in what place he died, although the year of his death was 1506. Several temples claim the honour of being his burial site.

A large body of work has been assigned to Sesshii, but the question of authenticity is particularly vexing. Some of the paintings usually attributed to him are accepted without question on the basis of their outstanding quality, provenance, or inscriptions. Many others bearing his seal and signature are merely assigned to him because of their style and may be school pieces produced by his numerous followers. The largest group of authentic Sesshii scrolls are those in the Tokyo National Museum, which, in addition to four early landscapes believed to have been painted in China, has three of the major works of his maturity. Two of them are hanging scrolls (kakemono) representing autumn and winter. The third is a landscape painted in the *haboku*, or splashed-ink technique, and therefore usually referred to as the "Haboku-sansui" scroll. Painted in 1495, this work was given by Sesshii to his pupil Sōen when he returned to Kamakura after studying under the master.

The so-called long landscape scroll, or "Sansui Chbkan" (probably painted in 1486) is generally considered his masterpiece and is often regarded as the greatest Japanese ink painting. Depicting the four seasons, beginning with spring and ending with winter, it extends over 50 feet (15 metres). Though based in both theme and style on Chinese models, it nevertheless is Japanese in character; for heavier lines, sharper contrasts of dark and light tones, and a flatter effect of space are employed than was customary in Sung painting. Almost equally outstanding is another horizontal landscape scroll in the Asano Collection. Believed to be somewhat earlier in date, the inscription says that it was painted in 1474 at the request of his pupil Thtsu. Its style is far freer and more subtle. A very different kind of landscape painting is the "Amano-Hashidate" scroll (c. 1502–05) in the Kyōto National Museum. Much more detailed and realistic, it is almost like a topographic view of a particular place.

Sesshii's
master-
piece

In addition to these landscapes, Sesshii painted a large number of Buddhist pictures that were often directly inspired by Zen teachings. The most famous of these is the scroll dated 1496 showing Bodhidharma and Hui K'o (1496; Sainen-ji, Aichi Prefecture). Painted in heavy, vigorous lines, it reveals how Hui K'o cut off his arm in order to demonstrate his seriousness to Bodhidharma, the founder of Zen Buddhism who is called Daruma in Japan.

Sesshii also painted decorative screens. Perhaps the best of the ones attributed to him is the pair of six-fold screens showing birds and flowers in the Kosaka Collection in Tokyo. Painted in a realistic yet decorative manner, with slight additions of colour, they reveal yet another aspect of the artist's genius. In contrast to the landscapes and Zen pictures that are inspired by the paintings of Sung China, these pictorial compositions are closer to the type of decorative painting that flourished in China during the Ming period.

While his most celebrated works are all in Japan, other pictures attributed to Sesshii are located in the West, es-

pecially in United States collections. The Museum of Fine Arts, Boston, for example, has seven paintings attributed to him, but the only one that is at all likely to be by Sesshii himself is a pair of screens depicting falcons and monkeys, which has Sesshii's seal and signature, as well as an inscription saying it was painted during the artist's 72nd year. Other works that may be authentic are found in the Cleveland Museum of Art and the Seattle Art Museum. The great hulk, however, of the many scrolls traditionally attributed to Sesshii both in Japan and in the West are generally considered to be school pieces or copies inspired by the work of the master.

MAJOR WORKS

There are only a few authenticated works by Sessha, the most important of which are listed below.

"Four Seasons Landscape," four landscape scrolls (c. 1470–90; Tokyo National Museum); "Autumn Landscape," hanging scroll (c. 1470–90; Tokyo National Museum); "Winter Landscape," hanging scroll (c. 1470–90; Tokyo National Museum); "Short Scroll Landscape" (c. 1474–90; Asano Collection, Odawara); "Portrait of Masuda Kanetaka" (1479; Masuda Collection, Tokyo); "Long Scroll Landscape," or "Sansui Chdkan" (c. 1486; Mōri Collection, Yamaguchi); "Haboku-Sansui," scroll (1495; Tokyo National Museum); "Daruma and Hui K'o," scroll (1496; Sainen-ji, Aichi); "Amano-Hashidate," scroll (c. 1502–05; Kyoto National Museum); "Flowers and Birds," pair of 6-fold screens (undated; Kosaka Collection, Tokyo).

Set Theory

Between the years 1874 and 1897, the German mathematician and logician Georg Cantor (*q.v.*) created a theory of abstract sets of entities and made it into a mathematical discipline. This theory grew out of his investigations of certain concrete problems regarding certain types of infinite sets of real numbers (see ANALYSIS, REAL). A set, wrote Cantor, is a collection of definite, distinguishable objects of perception or thought conceived as a whole. The objects are called elements or members of the set. The theory had the revolutionary aspect of treating infinite sets as mathematical objects that are on an equal footing with those that can be constructed in a finite number of steps. From antiquity, a majority of mathematicians had carefully avoided the introduction into their arguments of the actual infinite (*i.e.*, of sets containing an infinity of objects conceived as existing simultaneously, at least in thought). Because this attitude persisted until almost the end of the 19th century, Cantor's work was the subject of much criticism to the effect that it dealt with fictions and, indeed, that it encroached on the domain of philosophers and violated the principles of religion. Once applications to analysis began to be found, however, attitudes began to change, and in the 1890s Cantor's ideas and results were gaining acceptance. By 1900, set theory was recognized as a distinct branch of mathematics.

At just that time, however, the theory received a severe setback through the derivation of several contradictions in its superstructure (see below Cardinality and transfinite numbers). The main purpose of this article is to present an account of one response to such contradictions as these. The purpose of the development here related is to provide an axiomatic basis for the theory of sets analogous to that developed for elementary geometry. The degree of success that has been achieved in this development, as well as the present stature of set theory, has been well expressed in the Bourbaki *Éléments de mathématique*: "Nowadays it is known to be possible, logically speaking, to derive practically the whole of known mathematics from a single source, The Theory of Sets." (R.R.S.)

Introduction to set theory

FUNDAMENTAL SET CONCEPTS

If the elements and sets to be considered are restricted to some fixed class of objects, such as the letters of the

English alphabet, the universal set (or the universe), denoted by U , can then be defined as that which includes all of the elements—the set of all of the 26 letters. Thus, if A is a set, it will be understood that A is a subset of U . Another set may now be defined that includes all of the elements of U that are not elements of A . This set, called the complement of A , is denoted by A' . (Some writers, employing the convention of "difference sets," speak of "the complement of A with respect to C ," which they denote by " $U-A$.")

The empty (also called the void, or null) set, symbolized by " \emptyset ," contains no elements. One description of the empty set is that of all whole numbers that are neither even nor odd.

Operations on sets. The symbol \cup is employed to denote the union of two sets. Thus, the set $A \cup B$ —read " A union B " or "the union (or join) of A and B "—is the set that consists of all elements belonging either to set A or set B . If sets A and B , however, have one or more members in common, their union will not duplicate those members. A committee, for example, consisting of Jones, Blanshard, Smith, and Hixon (Committee A) may for some common purpose sit in joint session with Committee B , consisting of Blanshard, Morton, Hixon, and Peters. Clearly, the union of Committees A and B must then consist of six members rather than eight, viz., Jones, Blanshard, Smith, Morton, Hixon, and Peters.

The intersection operation is denoted by the symbol \cap . $A \cap B$ —read " A intersect B " or "the intersection of A and B "—is defined as that set comprised of all elements that belong to both A and B . Thus the intersection of the two committees in the foregoing example is the set consisting of Blanshard and Hixon.

If the set E denotes all positive even numbers and the set Q denotes all positive odd numbers, then the union of the two yields the entire sequence of positive natural numbers, and their intersection is the empty set. Any two sets the intersection of which is the empty set are said to be disjoint.

A product of two sets A and B , called a Cartesian product, is denoted by $A \times B$. This product is defined in terms of ordered pairs, analogous to the coordinates (or x and y values) of points on a Cartesian grid in analytic geometry. It is conventional to denote such pairs by enclosure in parentheses. If (a, b) and (c, d) are ordered pairs, then $(a, b) = (c, d)$ if and only if $a = c$ and $b = d$. The Cartesian product $A \times B$ may now be defined as the set consisting of all ordered pairs (x, y) for which x is an element of A and y is an element of B . An example is easily constructed: $A = \{x, y\}$, $B = \{3, 6, 9\}$, $A \times B = \{(x, 3), (x, 6), (x, 9), (y, 3), (y, 6), (y, 9)\}$.

Relations involved in set theory. The relations between sets can be of many sorts; *e.g.*, "is a subset of" (\subseteq), "is equivalent to" (\sim), "is a complement of" ($'$), "is in one-to-one correspondence with," and "has the same cardinal number as" (see below). In addition, pairing relations, defined in terms of some specific criterion, can exist between the individual elements of a set. Examples of pairing relations are: "is parallel to" (\parallel), "is equal to" ($=$), "is less than" ($<$), and "is the same colour as." More broadly conceived, pairing can include the relations depicted on charts and graphs, on which, for example, calendar years may be paired with automobile production figures, weeks with Dow-Jones averages, and degrees of angular rotation with the lift accomplished by a cam.

The relation of one-to-one correspondence between two sets can be conceived as one in which each element of a set A is matched with an element of another set B . If $A = \{x, z, w\}$, for example, and $B = \{4, 3, 9\}$, then A is in one-to-one correspondence with B if and only if a matching such as 4 with x , 3 with z , and 9 with w obtains without any element in either set left unmatched as a remainder.

Many relations display identifiable similarities. The relations "is parallel to," "is the same colour as," and "is in one-to-one correspondence with," for example, all bear the stated relation to themselves as well as to other ele-

Empty set

Union, intersection, and Cartesian product

Pairing relations between elements

Controversy over the actual infinite

ments; thus, these relations are said to be reflexive. These same relations share, in addition, the property that, if an element bears the stated relation to a second element, then the second also bears that relation to the first—a property known as symmetry. Relations also have the property that, if two elements bear the stated relation to a third element, then they bear it to one another as well—a property known as transitivity.

Equiva-
lence
classes and
numbers

Those relations that have all three properties—reflexivity, symmetry, and transitivity—are called equivalence relations. In an equivalence relation, all elements related to a particular element are related to each other, thus forming what is called an equivalence class. For the relation "is parallel to," for example, the equivalence class of a particular line ℓ is the set of all lines parallel to ℓ .

For each of the equivalence classes of sets, it is possible to construct an ordered set—for which not only the membership but also the sequence of its elements is significant—that can be used to name the class.

With appropriate qualifications, the cardinal of the empty set \emptyset can be defined as 0; i.e., $n(\emptyset) = 0$. The number 1, then, is assigned to be the cardinal of the set $\{0\}$ that contains only a single element; it is thus called the successor of 0. Similarly, the number 2, the cardinal of $\{0, 1\}$, is called the successor of 1; and 3, the cardinal of $\{0, 1, 2\}$, is the successor of 2. Continuing in this manner, the set \mathfrak{N} of the natural numbers in the proper sequence $\{0, 1, 2, 3, 4, \dots\}$ is obtained, for which the ordering is given by the successor relation.

It is this ordering that is used when one learns to count. The words one, two, three, four, . . . in proper sequence are associated with the elements in the set that are being counted. If this process stops, the set is said to be finite. Otherwise, it is said to be infinite.

There is a technical difference between cardinal and ordinal numbers. The distinction can be seen in the way these numbers are used.

A number used to designate the size of a set—i.e., to answer the question, "How many?"—is used cardinally. Any use that depends on the position of the number in the prescribed sequence is the ordinal use of the number. The number at the top or bottom of the page is an example of the ordinal use of the number. (Jo.Ha.)

ESSENTIAL FEATURES OF CANTORIAN SET THEORY

At best, the foregoing description presents only an intuitive concept of a set. Essential features of the concept as Cantor understood it include: (a) that a set is a group into a single entity of objects of any kind; and (b) that, given an object x and a set A , exactly one of the statements " x is an element of A " (symbolized $x \in A$) and " x is not an element of A " (symbolized $x \notin A$) is true and the other is false. The definite relation that may or may not exist between an object and a set is called the membership relation.

Extension
and
abstrac-
tion

A further intent of this description is conveyed by what is called the principle of extension, viz., that a set is determined by its members: that sets A and B are equal (symbolized $A = B$) if and only if every element in A is also in B and every element in B is in A ; or, in other terms, $x \in A$ implies $x \in B$ and vice versa. There exists, for example, exactly one set the members of which are 2, 5, and 7; and this set will be written by listing its elements in some order (which order is immaterial) between small braces, possibly $\{5, 2, 7\}$.

A set A is finite if for some natural number n there is a pairing of the elements of A with those of the initial segment $0, 1, \dots, n - 1$ of the natural numbers $0, 1, 2, \dots$ in their usual order. This definition amounts to classifying a set as finite if it has a natural number n as its cardinal number (see below Cardinality and transfinite numbers). In principle, the brace notation is adequate for defining all finite sets.

To define infinite (i.e., nonfinite) sets, Cantor used (sentential) formulas. The phrase " x is a professor" is an example of a formula; if the symbol " x " in this phrase is replaced by the name of a person, there results a declarative sentence that is true or false. The notation " $S(x)$ " will be used to represent such a formula. The

phrase " x is a professor at university y and x is a male" is a formula with two variables. If the occurrences of x and y are replaced by names of appropriate, specific objects, the result is a declarative sentence that is true or false. Given any formula $S(x)$ that contains the letter " x " (and possibly others) but not the letter " A ," Cantor's principle of abstraction asserts the existence of a set A such that for each object x , $x \in A$ if and only if $S(x)$ holds. The unique (because of the principle of extension) set A corresponding to $S(x)$ is symbolized by $\{x | S(x)\}$ and read "The set of all objects x such that $S(x)$." For instance, $\{x | x \text{ is blue}\}$ is the set of all blue objects. This illustrates the fact that the principle implies the existence of sets the elements of which are all objects having a certain property. It is actually more comprehensive. For example, it asserts the existence of a set B corresponding to "Either x is an astronaut or x is a natural number." Astronauts have no property in common with numbers (other than both being members of B). The formula " $x \neq x$ " defines the only set without elements. It is called the empty set and symbolized by \emptyset . The empty set is finite, for its members can be paired with those of the initial segment defined by $n = 0$.

Equivalent sets. Cantorian set theory is thus founded on the principles of extension and abstraction. To describe some results based upon these principles the notion of equivalence of sets will be defined. The set A is defined as equivalent to the set B (symbolized $A \sim B$) if and only if there exists a third set the members of which are ordered pairs such that: (a) the first member of each pair is an element of A and the second is an element of B , and (b) each member of A occurs as a first member and each member of B occurs as a second member of exactly one pair. Thus, if A and B are finite and $A \sim B$, then the third set that establishes this fact provides a pairing or matching of the elements of A with those of B . Conversely, if it is possible to match the elements of A with those of B , then $A \sim B$, because a set of pairs meeting requirements (a) and (b) can be formed (if $a \in A$ is matched with $b \in B$, then the ordered pair (a, b) is one member of the set). By thus defining equivalence of sets in terms of the notion of matching, it is formulated independently of finiteness. As an illustration involving infinite sets, % may be taken to denote the set of natural numbers $0, 1, 2, \dots$ (some authors exclude 0 from the natural numbers). Then $\{(n, n^2) | n \in \mathfrak{N}\}$ establishes the equivalence of \mathfrak{N} and the set of the squares of the natural numbers.

A set B is included in, or is a subset of, a set A (symbolized $B \subseteq A$) if every element of B is an element of A . (So defined, a subset may possibly include all of the elements of A , so that A can be a subset of itself.) If, in addition, the converse is false (hence $B \neq A$), then B is said to be properly included in, or is a proper subset of, A (symbolized $B \subset A$). Thus, if $A = \{3, 1, 0, 4, 2\}$, both $\{0, 1, 2\}$ and $\{0, 1, 2, 3, 4\}$ are subsets of A ; but the latter is not a proper subset. A finite set is nonequivalent to each of its proper subsets. This is not so, however, for infinite sets, as is illustrated with the set \mathfrak{N} in the earlier example. (The equivalence of \mathfrak{N} and its proper subset of the even natural numbers was essentially the paradox noted by Galileo in 1638.)

Cardinality and transfinite numbers. The application of the notion of equivalence to infinite sets was first systematically explored by Cantor. His initial significant finding was that the set of all rational numbers (see ANALYSIS, REAL; ARITHMETIC) is equivalent to \mathfrak{N} but that the set of all real numbers is not equivalent to \mathfrak{N} . The existence of nonequivalent infinite sets justified Cantor's introduction of transfinite cardinal numbers as measures of size for such sets. Cantor defined the cardinal of an arbitrary set A as the concept that can be abstracted from A taken together with the totality of other equivalent sets. Gottlob Frege, in 1884, and Bertrand Russell, in 1902, both mathematical logicians, defined the cardinal number \overline{A} of a set A somewhat more explicitly, as the set of all sets that are equivalent to A ; this definition thus provides a place for cardinal numbers as objects of a universe whose only members are sets.

Equiva-
lence and
subsets

Infinite sets
and power
sets

These definitions are consistent with the usage of natural numbers as cardinal numbers. A natural number, 2 for example, is first assigned to the set $\{0, 1\}$ as a measure of its size; then 2 is assigned to every set equivalent to $\{0, 1\}$. Turning matters around, 2 is the concept that can be abstracted from the collection of sets equivalent to $\{0, 1\}$, or 2 may be defined as this collection of sets. Intuitively, a cardinal number, whether finite (*i.e.*, a natural number) or transfinite (*i.e.*, nonfinite), is a measure of the size of a set. Exactly how a cardinal number is defined is unimportant; what is important is that $\bar{A} = \bar{B}$ if and only if $A \sim B$.

To compare cardinal numbers, an ordering relation—denoted by $<$ —may be introduced by means of the definition: $\bar{A} < \bar{B}$ if A is equivalent to a subset of B and B is equivalent to no subset of A . Clearly this relation is irreflexive $\bar{A} \not< \bar{A}$ and transitive $\bar{A} < \bar{B}$ and $\bar{B} < \bar{C}$ imply $\bar{A} < \bar{C}$.

When applied to natural numbers used as cardinals, $<$ coincides with the familiar ordering relation for \mathbb{N} , so that $<$ is an extension of that relation.

The symbol \aleph_0 (aleph null) is standard for the cardinal number of \mathbb{N} (sets of this cardinality are called denumerable) and \aleph (aleph) is usually used for that of the set of real numbers. Then $n < \aleph_0$ for each $n \in \mathbb{N}$ and $\aleph_0 < \aleph$.

This, however, is not the end of the matter. If the power set of a set A —symbolized $P(A)$ —is defined as the set of all subsets of A , then, as Cantor proved, $\bar{A} < \overline{P(A)}$ for every set A —a relation that is known as Cantor's theorem. It implies an unending hierarchy of transfinite cardinals: $\bar{N} = \aleph_0$, $P(N)$, $\overline{P(P(N))}$, ... Cantor proved that $\aleph = \overline{P(N)}$ and was led to the question whether there is a cardinal number between \aleph_0 and \aleph , which is known as the continuum problem. A solution was completed in 1963 (see below).

There is an arithmetic for cardinal numbers based on natural definitions of addition, multiplication, and exponentiation (squaring, cubing, and so on), which deviates, however, from that of the natural numbers when transfinite cardinals are involved. For example, $\aleph_0 + \aleph_0 = \aleph_0$ (because the set of integers is equivalent to \mathbb{N}), $\aleph_0 \cdot \aleph = \aleph$ (because the set of ordered pairs of natural numbers is equivalent to \mathbb{N}), and $c + \aleph_0 = c$ for every transfinite cardinal c (because every infinite set includes a subset equivalent to \mathbb{N}).

The extension of the natural numbers as cardinal numbers to transfinite numbers described earlier is a typical facet of Cantorian set theory.

The so-called Cantor paradox, discovered by Cantor himself in 1899, is the following: By the principle of abstraction, the formula "x is a set" defines a set U . It is the set of all sets. Now $P(U)$ is a set of sets and so $P(U)$ is a subset of U . By the definition of $<$ for cardinals, however, if $A \subseteq B$, then it is not the case that $\bar{B} < \bar{A}$. Hence, by substitution, $\bar{U} < \overline{P(U)}$. But by Cantor's theorem, $\bar{U} < \overline{P(U)}$. This is a contradiction. In 1902, Bertrand Russell devised another paradox of a less technical nature. The formula "x is a set and $(x \notin x)$ " defines a set R of all sets not members of themselves. Using proof by contradiction, however, it is easily shown that $(A) R \in R$. But then by the definition of R it follows that $(B) (R \notin R)$. Together, (A) and (B) form a contradiction.

Axiomatic set theory

The attitude adopted in an axiomatic development of set theory is that it is not necessary to know what the "things" are that are called "sets" nor what the relation of membership means. Of sole concern are the properties assumed about sets and the membership relation. Thus, in an axiomatic theory of sets, the terms set and the membership relation \in are undefined. The assumptions adopted about these notions are called the axioms of the theory. Its theorems are the axioms together with the statements that can be deduced from the axioms using the rules of inference provided by a system of logic.

Criteria for the choice of axioms include: (A) their consistency (*i.e.*, that it should be impossible to derive as theorems both a statement and its negation), (B) their plausibility (*i.e.*, that they should be in accord with intuitive beliefs about sets), and (C) their richness (*i.e.*, that desirable results of Cantorian set theory can be derived as theorems).

These points are elaborated upon below.

POSTULATES OF AXIOMATIC SET THEORY

The Zermelo–Fraenkel axioms: discussion. The first axiomatization of set theory was given in 1908 by Ernst Zermelo, a German mathematician. From his analysis of the paradoxes, he concluded that they are associated with sets that are "too big," such as the set of all sets in Cantor's paradox. Thus, the axioms that Zermelo formulated are restrictive insofar as the asserting or implying of the existence of sets is concerned. As a consequence, there is no apparent way, in his system, to derive the known contradictions from them. On the other hand, the results of classical set theory short of the paradoxes can be derived. Zermelo's axiomatic theory is here discussed in a form that incorporates modifications and improvements suggested by later mathematicians, principally Thoralf Albert Skolem, a pioneer in metalogic, and Abraham Adolf Fraenkel, an Israeli mathematician. In the literature on set theory, it is called Zermelo–Fraenkel set theory (symbolized ZF), though it would seem historically more correct to call it Zermelo–Fraenkel–Skolem set theory. The ten axioms are first discussed and then formally listed (see below The Zermelo–Fraenkel axioms: formal presentation).

Schemas for generating well-formed formulas. In the axioms that follow, "set" and " \in " are undefined terms. Lowercase Latin letters are used for variables; and variables denote sets. Equality (symbolized $=$) is taken as part of the underlying logic.

The first axiom (see axiom 1, below) conveys the idea that, as in classical set theory, a set is determined by its members. It should be noted that this is not merely a logically necessary property of equality but an assumption about the membership relation as well.

The set defined by the second axiom (see 2) is the empty (or null) set \emptyset .

For an understanding of the third axiom (see 3) considerable explanation is required. Zermelo's original system included the assumption (Aussonderung axiom) that, if a formula $S(x)$ is "definite" for all elements of a set s , then there exists a set the elements of which are precisely those elements x of s for which $S(x)$ holds. This is a version of the principle of abstraction, for it provides for the existence of sets corresponding to formulas. It restricts that principle, however, in two ways. Instead of asserting the existence of sets unconditionally, it can be applied only in conjunction with pre-existing sets. Further, only "definite" formulas (for which Zermelo offered only a vague description) may be used. Clarification was given, however, by Skolem (1922) by way of a precise definition of what will be called simply a formula of ZF. Using tools of modern logic, the definition may be made as follows:

a. For any variables x and y , $x \in y$ and $x = y$ are formulas (such formulas are called atomic).

b. If A and B denote formulas and x is any variable, then each of the following is a formula: If A , then B ; A if and only if B ; A and B ; A or B ; not A ; for all x , A ; for some x , B .

Formulas are constructed recursively (in a finite number of systematic steps) beginning with the (atomic) formulas of (a) and proceeding via the constructions permitted in (b). "Not $(x \in y)$," for example, is a formula (which is abbreviated to $x \notin y$), and "There exists an x such that for every y , $y \notin x$ " is a formula. A variable is free in a formula if it occurs at least once in the formula without being introduced by one of the phrases "for some x " or "for all x ." Henceforth, a formula P in which x occurs as a free variable will be called a "condition on x " and symbolized $P(x)$. The formula "For every y , $x \in y$," for example, is a condition on x . It is to be understood that a formula is a formal expression—*i.e.*, a term

Zermelo's
pioneering
work

without meaning. Indeed, a computer could be programmed to generate atomic formulas and build up from them other formulas of ever-increasing complexity using logical connectives ("not," "and," etc.) and operators ("for all" and "for some"). A formula acquires meaning only when an interpretation of the theory is spelled out; *i.e.*, when (A) a nonempty collection (called the domain of the interpretation) is specified as the range of values of the variables (thus the term set is assigned a meaning, *viz.*, an object in the domain), (B) the membership relation is defined for these sets, (C) the logical connectives and operators are interpreted as in everyday language, and (D) the logical relation of equality is taken to be identity among the objects in the domain.

The terminology "a condition on x " for a formula in which x is free is merely suggestive; relative to an interpretation, such a formula does impose a condition on x . Thus, the intuitive interpretation of the third axiom schema is: given a set a and a condition on x , $P(x)$, those elements of a for which the condition holds form a set. It provides for the existence of sets by separating off certain elements of existing sets. Calling the third axiom schema an axiom schema is appropriate, for it is a schema for generating axioms—one for each choice of $P(x)$.

Axioms for compounding sets. Although the third axiom schema has a constructive quality, further means of constructing sets from existing sets must be introduced if some of the desirable features of Cantorian set theory are to be established. Each of the next three axioms is of this sort.

Using five of the axioms (see 2–6), a variety of basic concepts of classical set theory (*e.g.*, the operations of union, intersection, and Cartesian product; the notions of relation, equivalence relation, ordering relation, and function) can be defined with ZF. Further, the standard results about these concepts that were attainable in classical set theory can be proved as theorems of ZF.

Axioms for infinite and ordered sets. If I is an interpretation of an axiomatic theory of sets, the sentence that results from an axiom when a meaning has been assigned to "set" and " \in ," as specified by I , is either true or false. If each axiom is true for I , then I is called a model of the theory (see METALOGIC: Model theory). If the domain of a model is infinite, this fact does not imply that any object of the domain is an "infinite set." An infinite set in the latter sense is an object d of the domain D of I for which there is an infinity of distinct objects d' in D such that $d'E d$ holds (E standing for the interpretation of \in). Though the domain of any model of the theory of which the axioms thus far discussed are axioms is clearly infinite, models in which every set is finite have been devised. For the full development of classical set theory, including the theories of real numbers and of infinite cardinal numbers, the existence of infinite sets is needed; thus the seventh axiom (see 7) is included.

The existence of a (unique) minimal set, ω , having properties expressed in the seventh axiom can be proved; its distinct members are \emptyset , $\{\emptyset\}$, $\{\emptyset, \{\emptyset\}\}$, $\{\emptyset, \{\emptyset, \{\emptyset\}\}\}$, \dots . These elements are denoted by $0, 1, 2, 3, \dots$ and are called natural numbers. Justification for this terminology rests with the fact that the Peano axioms, which can serve as a base for arithmetic, can be proved as theorems. Thereby the way is paved for the construction within ZF of entities that have all the expected properties of the real numbers.

The origin of the next axiom was Cantor's recognition of the importance of being able to well-order arbitrary sets; *i.e.*, to define an ordering relation for a given set such that each nonempty subset has a least element. The virtue of a well-ordering for a set is that it offers a means of proving that a property holds for each of its elements by a process (transfinite induction) similar to mathematical induction. Zermelo (1904) gave the first proof that any set can be well-ordered. His proof employed a set-theoretic principle that he called the axiom of choice, which, shortly thereafter, was shown to be equivalent to the so-called well-ordering theorem. One form of this principle is expressed as an eighth axiom (see 8).

Intuitively, the axiom asserts the possibility of making a simultaneous choice of an element in every nonempty member of any set; this guarantee accounts for its name. The assumption is significant only when the set has infinitely many members. Zermelo was the first to explicitly state the axiom, although it had been used but essentially unnoticed earlier. It soon became the subject of vigorous controversy because of its unconstructive nature. Some mathematicians rejected it totally on this ground. Others accepted it but avoided its use whenever possible. Some changed their minds about it when its equivalence with the well-ordering theorem was proved as well as the assertion that any two cardinal numbers c and d are comparable (*i.e.*, that exactly one of $c \leq d$, $d \leq c$, $c = d$ holds). There are many other equivalent statements, though even today there are a few mathematicians who feel that the use of the axiom of choice is improper. To the vast majority, however, it, or an equivalent assertion, has become an indispensable and commonplace tool.

Schema for transfinite induction and ordinal arithmetic. One more axiom has been added to the list of axioms (with modifications) postulated by Zermelo. When Zermelo's eight were found to be inadequate for a full-blown development of transfinite induction and ordinal arithmetic, Fraenkel and Skolem independently proposed an additional axiom schema to eliminate the difficulty. As modified by John von Neumann, a Hungarian-born U.S. mathematician, it says, intuitively, that if with each element of a set there is associated exactly one set, then the collection of the associated sets is itself a set; *i.e.*, it offers a way to "collect" existing sets to form sets. As an illustration, each of ω , $P(\omega)$, $P(P(\omega))$, \dots is a set in the theory based on the first eight axioms. But there appears to be no way to establish the existence of the set having these sets as its members. An instance of the next schema, however, provides for its existence.

Intuitively, the ninth axiom or schema (see 9) is the assertion that if the domain of a function is a set then so is its range. That this is a powerful schema (in respect to the further inferences that it yields) is suggested by the fact that the third axiom can be derived from it and that, when applied in conjunction with the sixth axiom, the axiom of pairing can be deduced. The ninth axiom has played a significant role in developing a theory of ordinal numbers. In contrast to cardinal numbers, which serve to designate the size of a set, ordinal numbers are used to determine positions within a prescribed sequence. Following an approach conceived independently by Zermelo and von Neumann, if x is a set, the successor x' of x is the set obtained by adjoining x to the elements of x ($x' = x \cup \{x\}$). In terms of this notion the natural numbers, as defined above, are simply the succession $0, 0', 0'', 0''', \dots$; *i.e.*, the natural numbers are the sets obtained starting with \emptyset and iterating the prime operation a finite number of times. The natural numbers are well-ordered by the \in relation, and with this ordering they constitute the finite ordinal numbers. The axiom of infinity secures the existence of the set of natural numbers; and this set, \aleph_0 , is the first infinite ordinal. Greater ordinal numbers are obtained by iterating the prime operation beginning with ω . An instance of the ninth axiom or schema asserts that $\omega, \omega', \omega'', \dots$ form a set. The union of this set and ω is the still greater ordinal that is denoted by ω_2 (employing notation from ordinal arithmetic). A repetition of this process beginning with ω_2 yields the ordinals $(\omega_2)', (\omega_2)'', \dots$; next after all of those of this form is ω_3 . In this way the sequence of ordinals $\omega, \omega_2, \omega_3, \dots$ is generated. An application of the ninth axiom schema then yields the ordinal that follows all of these in the same sense in which ω follows the finite ordinals; using notation from ordinal arithmetic, it is ω^2 . At this point the iteration process can be repeated. In summary, the axiom of replacement makes possible the extension of the counting process as far beyond the natural numbers as one chooses.

In the ZF system, cardinal numbers are defined as certain ordinals. From the well-ordering theorem (a consequence of the axiom of choice), it follows that

Cardinal
and ordinal
numbers

every set a is equivalent to some ordinal number. Also, the totality of ordinals equivalent to a can be shown to form a set. Then a natural choice for the cardinal number of a is the least ordinal to which a is equivalent. This is the motivation for defining a cardinal number as an ordinal that is not equivalent to any smaller ordinal. The arithmetics of both cardinal and ordinal numbers have been fully developed. That of finite cardinals and ordinals coincides with the arithmetic of the natural numbers. For infinite cardinals, the arithmetic is uninteresting since, as a consequence of the eighth axiom, the sum and product of two such cardinals are each equal to the maximum of the two. In contrast the arithmetic of infinite ordinals is interesting and presents a wide assortment of oddities.

In addition to the guidelines already mentioned for the choice of axioms of ZF, another guideline is taken into account by some set theorists. For the purposes of foundational studies of mathematics, it is assumed that mathematics is consistent; for otherwise any foundation would fail. It may thus be reasoned that, if a precise account of the intuitive usages of sets by mathematicians is given, an adequate and correct foundation will result. Traditionally, mathematicians deal with the integers, with real numbers, and with functions. Thus an intuitive hierarchy of sets in which these entities appear should be a model of ZF. It is possible to construct such a hierarchy explicitly from the empty set by iterating the operations of forming power sets and unions in the following way.

The first level of the hierarchy is composed of the sequence of sets $s_0 = \emptyset, s_1, \dots, s_n, \dots$, in which s_{n+1} is the power set of s_n . The second level consists of the sets at the first level together with those sets obtained by iterating the power set operation any finite number of times. The third level has as its members the union of all sets constructed thus far together with those obtainable by iterating the power set operation as before. The hierarchy of sets envisaged, therefore, consists of all sets that can be obtained by proceeding to an arbitrarily large transfinite level. The domain of the intuitive model of ZF is conceived as the union of all sets in the hierarchy. In other words, a set x is in the model if it is an element of some set of the hierarchy.

Axiom for eliminating infinite descending species. From the assumptions that this system is sufficiently comprehensive for mathematics and that it is the model to be "captured" by the axioms of ZF, it may be argued that models of the first nine axioms that differ sharply from this system should be ruled out. The discovery of such a model led to the formulation by von Neumann of the tenth axiom (see 10).

This axiom eliminates from the models of the first nine axioms those in which there exist infinite descending \in -chains (i.e., sequences x_1, x_2, x_3, \dots such that $x_2 \in x_1, x_3 \in x_2, \dots$), a phenomenon that does not appear in the heuristic model described above. (The existence of models having such chains was discovered by D. Mirimanoff in 1917.) It also has other attractive consequences; e.g., a simpler definition of the notion of ordinal number is possible. Yet there is no unanimity among mathematicians whether there are sufficient grounds for adopting it as an additional axiom, since it does not have the immediate plausibility that even the axiom of choice has nor has it ever been shown to have any mathematical applications.

The **Zermelo-Fraenkel** axioms: formal presentation.

(1) *Axiom of extension.* If a and b are sets and if, for all x , $x \in a$ if and only if $x \in b$, then $a = b$.

(2) *Axiom of the empty set.* There exists a set a such that for all x , it is false that $x \in a$.

(3) *Axiom schema of separation.* If a is a set, there exists a set b such that for all x , $x \in b$ if and only if $x \in a$ and $P(x)$. Here, $P(x)$ is any condition on x in which b is not free (it must be bound by a quantifier such as "all" or "some").

(4) *Axiom of pairing.* If a and b are sets, there exists a set (symbolized $\{a, b\}$ and called the unordered pair of a and b) having a and b as its sole members.

(5) *Axiom of union.* If c is a set, there exists a set a such that $x \in a$ if and only if $x \in b$ for some member b of c .

(6) *Axiom of power set.* If a is a set, there exists a set b such that $x \in b$ if and only if $x \subseteq a$.

(7) *Axiom of infinity.* There exists a set a such that $\emptyset \in a$ and, if $x \in a$, then $(x \cup \{x\}) \in a$, in which $x \cup \{x\}$ is the set x with x adjoined as a further member.

(8) *Axiom of choice.* If a is a set the elements of which are nonempty sets, then there exists a function f with domain a such that for member b of a , $f(b) \in b$.

(9) *Axiom schema of replacement.* If a is a set and $B(x, y)$ a formula (in which x and y are free) such that for $x \in a$ there is exactly one y such that $B(x, y)$, then there exists a set b the members of which are the y 's determined by $B(x, y)$ as x ranges over a .

(10) *Axiom of restriction.* Every nonempty set a contains an element b such that $a \cap b = \emptyset$; i.e., a and b have no elements in common.

The **von Neumann-Bernays-Gödel** axioms: discussion. The second axiomatization of set theory originated with von Neumann in the 1920s. His formulation differed considerably from ZF because the notion of function, rather than that of set, was taken as primitive. In a series of papers beginning in 1937, however, the Swiss logician Paul Bernays, a collaborator with the formalist David Hilbert, modified the von Neumann approach in a way that put it in much closer contact with ZF. In 1940, the Czech-born logician Kurt Gödel, known for his undecidability proof, further simplified the theory. This version will be called NBG.

For expository purposes it is convenient to adopt two undefined notions for NBG: class and the binary relation, \in , of membership (though, as is also true in ZF, \in suffices). In the axioms, capital Latin letters are used as variables. For the intended interpretation, variables take classes—the totalities corresponding to certain properties—as values. A class is defined to be a set if it is a member of some class; those classes that are not sets are called proper classes. Lowercase Latin letters are used as special restricted variables for sets. For example, "for all x , $A(x)$ " stands for "for all X , if X is a set, then $A(X)$ "; i.e., the condition holds for all sets. Intuitively, sets are intended to be those classes that are adequate for mathematics, and proper classes are thought of as those collections that are "so big" that, if permitted to be sets, contradictions would follow. In NBG, the classical paradoxes are avoided by proving in each case that the collection on which the paradox is based is a proper class—i.e., is not a set.

Comments about the axioms that follow are limited to features that distinguish them from their counterpart in ZF. The axioms are listed later (see 11–20, below *The von Neumann-Bernays-Gödel axioms: statement*).

The third axiom or schema (see 13) is presented in a form to facilitate a comparison with the third axiom schema of ZF. In a detailed development of NBG, however, there appears, instead, a list of seven axioms (not schemas) that state that for each of certain conditions there exists a corresponding class of all those sets satisfying the condition. From this finite set of axioms, each an instance of the above schema, the schema (in a generalized form) can be obtained as a theorem. When obtained in this way, the third axiom schema of NBG is called the class existence theorem.

In brief, the fourth to eighth axioms of NBG (see 14–18) are axioms of set existence. The same is true of the next axiom, which for technical reasons is usually phrased in a more general form.

Finally there may appear in a formulation of NBG an analogue (see 20) of the last axiom of ZF.

A comparison of the two theories that have been formulated is in order. In contrast to the ninth schema of ZF (see 9), that of NBG (see 19) is not an axiom schema but an axiom. Thus, with the comments above about the third axiom in mind, it follows that NBG has only a finite number of axioms. On the other hand, since the ninth axiom or schema of ZF provides an axiom for each formula, ZF has infinitely many axioms—which is unavoidable because it is known that no finite subset yields the full system of axioms. The finiteness of the axioms for NBG makes the logical study of the system simpler. The relationship between the theories may be

Comparison
of ZF
and NBG
axiomati-
zations

The
intuitive
hierarchy
of sets

summarized by the statement that ZF is essentially the part of NBG that refers only to sets. Indeed, it has been proved that every theorem of ZF is a theorem of NBG and that any theorem of NBG that speaks only about sets is a theorem of ZF. Finally, it has been shown that ZF is consistent if and only if NBG is consistent.

The von Neumann–Bernays–Gödel axioms: statement.

(11) *Axiom of extension.* If A and B are classes and if, for all (sets) x , $x \in A$ if and only if $x \in B$, then $A = B$.

(12) Same as axiom (2).

(13) *Axiom schema for class formation.* If $P(x)$ is a condition on x in which (a) only set variables are introduced by the phrase "for all" or "for some" and (b) B is not free, then there exists a class B such that $x \in B$ if and only if $P(x)$.

(14) *Axiom of pairing.* Same as axiom (4).

(15) *Axiom of union.* Same as axiom (5).

(16) *Axiom of power set.* Same as axiom (6).

(17) *Axiom of infinity.* Same as axiom (7).

(18) *Axiom of choice.* Same as (8).

(19) *Axiom of replacement.* If (the class) X is a function and a is a set, then there exists a set b such that $y \in b$ if and only if for some x , $(x, y) \in X$ and $x \in a$; i.e., the range of the restriction of a function X to a domain that is a set is also a set.

(20) *Axiom of restriction.* Every nonempty class A contains an element b such that $A \cap b = \emptyset$.

LIMITATIONS OF AXIOMATIC SET THEORY

The fact that NBG avoids the classical paradoxes and that there is no apparent way to derive any one of them in ZF does not settle the question of the consistency of either theory. One method for establishing the consistency of an axiomatic theory is to give a model; i.e., an interpretation of the undefined terms in another theory such that the axioms become theorems of the other theory. If this other theory is consistent, then that under investigation must be consistent. Such consistency proofs are thus relative: the theory for which a model is given is consistent if that from which the model is taken is consistent. The method of models, however, offers no hope for proving the consistency of an axiomatic theory of sets. In the case of set theory and, indeed, of axiomatic theories generally, the alternative is a direct approach to the problem.

If T is the theory of which the (absolute) consistency is under investigation, this alternative means that the proposition "There is no sentence of T such that both it and its negation are theorems of T " must be proved. The mathematical theory (developed by the formalists) to cope with proofs about an axiomatic theory T is called proof theory, or metamathematics. It is premised upon the formulation of T as a formal axiomatic theory; i.e., the theory of inference (as well as T) must be axiomatized. It is then possible to present T in a purely symbolic form; i.e., as a formal language based on an alphabet the symbols of which are those for the undefined terms of T and those for the logical operators and connectives. A sentence in this language is a formula composed from the alphabet according to prescribed rules. The hope for metamathematics was that by using only intuitively convincing, weak number-theoretic arguments (called finitary methods), unimpeachable proofs of the consistency of such theories as axiomatic set theory could be given.

That hope suffered a severe blow in 1931 from a theorem proved by Gödel about any formal theory S that includes the usual vocabulary of elementary arithmetic. By coding the formulas of such a theory with natural numbers (now called Gödel numbers) and by talking about these numbers, Gödel was able to make the metamathematics of S to become part of the arithmetic of S and hence to be expressible in S . The theorem in question asserts that the formula of S that expresses (via a coding) " S is consistent" in S is unprovable in S if S is consistent. Thus, if S is consistent, then the consistency of S cannot be proved within S ; rather, methods beyond those that can be expressed or reflected in S must be employed. Because, in both ZF and NBG, elementary arithmetic can be developed, Gödel's theorem applies to these two theories. Although there remains the possibility of a finitary proof of consistency that cannot be reflected in the foregoing systems of set theory, no hopeful, positive results have been obtained.

Gödel's theorem and the consistency of S

Other theorems of Gödel when applied to ZF (and there are corresponding results for NBG) assert that if the system is consistent, then (A) it contains a sentence such that neither it nor its negation is provable (such a sentence is called undecidable), (B) there is no algorithm (or iterative process) for deciding whether a sentence of ZF is a theorem, and (C) these same statements hold for any consistent theory resulting from ZF by the adjunction of further axioms. Apparently ZF can serve as a foundation for all of present-day mathematics because every mathematical theorem can be translated into and proved within ZF, or within extensions obtained by adding suitable axioms. Thus, the existence of undecidable sentences in each such theory (which entails the existence of true sentences of ZF not provable in ZF) points out the hopelessness of any attempt to base all of conceivable mathematics on a single axiomatic theory and hence implies the inadequacy of the axiomatic approach to mathematics, in particular, via axiomatic set theory.

PRESENT STATUS OF AXIOMATIC SET THEORY

The foundations of axiomatic set theory are in a state of significant change as a result of recent discoveries. The situation is analogous to the 19th-century revolution in geometry, set off by the discovery of non-Euclidean geometries. It is difficult to predict the ultimate consequences of these late 20th-century findings for set theory, but already they have had profound effects on attitudes about certain axioms and have forced the realization of a continuous search for additional axioms. These discoveries have focussed attention on the concept of the independence of an axiom. If T is an axiomatic theory and S is a sentence (i.e., a formula) of T that is not an axiom, and if $T + S$ denotes the theory that results from T upon the adjunction of S to T as a further axiom, then S is said to be consistent relative to T if $T + S$ is consistent and independent of T whenever both S and $\sim S$ (the negation of S) are consistent relative to T . Thus, assuming that T is consistent, if S is independent of T , then the addition of S or $\sim S$ to T yields a consistent theory. The role of the axiom of restriction (AR) can be clarified in terms of the notion of independence. If ZF' denotes the theory obtained from ZF by deleting AR and either retaining or deleting the axiom of choice (AC), then it can be proved that if ZF' is consistent, AR is independent of ZF' .

Of far greater significance for the foundations of set theory is the status of AC relative to the other axioms of ZF. The status in ZF of the continuum hypothesis (CH) and its extension, the generalized continuum hypothesis (GCH) are also of profound importance. (If $q(a)$ denotes "There does not exist a set b such that $\overline{a} < \overline{b} < \overline{P(a)}$," then CH is $q(a)$ for $\overline{a} = \aleph_0$ and GCH is $q(a)$ for all infinite sets a .) In the following discussion of these questions, ZF denotes Zermelo–Fraenkel set theory without AC. The first finding was obtained by Gödel in 1938. He proved that AC and GCH are consistent relative to ZF (i.e., if ZF is consistent, then so is $ZF + AC + GCH$), by showing that a contradiction within $ZF + AC + GCH$ can be transformed into a contradiction in ZF. In 1963, Paul J. Cohen, a Stanford mathematician, proved that (1) if ZF is consistent, then so is $ZF + AC + \sim CH$, and (2) if ZF is consistent, then so is $ZF + \sim AC$. Since in $ZF + AC$ it can be demonstrated that GCH implies CH, Gödel's theorem together with Cohen's establishes the independence of AC and CH. For his proofs Cohen introduced a new method (called forcing) of constructing interpretations of $ZF + AC$. The method of forcing is applicable to many problems in set theory, and since 1963 it has been used to give independence proofs for a wide variety of highly technical propositions. Some of these results have opened new avenues for attacks on important foundational questions.

The current unsettled state of axiomatic set theory can be sensed by the responses that have been made to the question of how to regard CH in the light of its independence from $ZF + AC$. Someone who believes that set theory deals only with nonexistent fictions will have no concern about the question. But for most mathematicians sets actually exist; in particular, ω and $P(\omega)$ exist. Fur-

Relations of axiom of choice to continuum hypotheses

Status of the continuum hypothesis

ther, it should be the case that every nondenumerable subset of $P(\omega)$ either is or is not equivalent to $P(\omega)$; i.e., either CH is true or is false. Followers of this faith regard the axioms of set theory as describing some well-defined reality—one in which CH must be either true or false. Thus there is the inescapable conclusion that the present axioms do not provide a complete description of that reality. A search for such axioms is in progress. One who hopes to prove CH as a theorem must look for axioms that restrict the number of sets. There seems to be little hope for this restriction, however, without changing the intuitive notion of the set. Thus the expectations favour the view that CH will be disproved. This disproof requires an axiom that guarantees the existence of more sets; e.g., of sets having cardinalities greater than those that can be proved to exist in $ZF + AC$. So far, none of the axioms that have been proposed that are aimed in this direction (called "generalized axioms of infinity") serves to prove $\sim CH$. Although there is little supporting evidence, the optimists hope that the status of the continuum hypothesis CH will be settled in the near future. (R.R.S.)

Seurat, Georges

In his short life of only 31 years, Georges Seurat earned an illustrious place in the history of 19th-century French painting as the leading exponent of the Neo-Impressionist school. Beginning with the analyses of colour and light of the Impressionists, who immediately preceded him, and elaborating on them through the observations of scientists, he perfected the technique of pointillism, creating huge compositions with tiny, detached strokes of pure colour too small to be distinguished when looking at the entire work but making his works shimmer with brilliance. Working with infinite deliberation, he completed only seven such works, which nonetheless represented a significant new direction in the course of modern art.

Georges-Pierre Seurat was born on December 2, 1859, in Paris, the son of Antoine-Chrisostôme Seurat, a 44-year-old property owner, originally from Champagne, and Ernestine Faivre, a Parisienne. His father, a singular personality who had been a bailiff, spent most of his time in Le Raincy, where he owned a cottage with a garden (in which Seurat often painted). The young Seurat lived primarily in Paris with his mother, his brother Émile, and his sister Marie-Berthe. At the time of the Paris Commune, in 1871, when Paris rebelled against the French state and set up its own government, the prudent family temporarily withdrew to Fontainebleau.

While attending school, Georges began to draw, and, beginning in 1875, he took a course from a sculptor, Justin Lequien. He officially entered the École des Beaux-Arts in 1878, in the class of Henri Lehmann, a disciple of Ingres, who painted portraits and conventional nudes. In the school library Seurat discovered a book that was to inspire him for the rest of his life: the *Essai sur les signes inconditionnels de l'art* (1827; "Essay on the Unmistakable Signs of Art"), by Humbert de Superville, a painter-engraver from Geneva; it dealt with the future course of aesthetics and with the relationship between lines and images. Seurat was also impressed with the

work of another Genevan aesthete, David Sutter, who combined mathematics and musicology. Throughout his brief career, Seurat manifested an unusually strong interest in the intellectual and scientific bases of art.

In November 1879, at the age of 20, Seurat went to Brest to do his military service. There he drew the sea, beaches, and boats. When he returned to Paris the following autumn, he shared a studio with another painter, Édmond-François Aman-Jean, who then joined him in Lehmann's class. But Seurat and Aman-Jean departed from the policies of the École des Beaux-Arts in admiring the warm landscapes of Jean-Baptiste Millet at the Louvre. The two friends often frequented dance halls and cabarets in the evening, and in spring they took the passenger steamer to the island of La Grande Jatte, the setting of Seurat's future paintings. Seurat exhibited at the official Salon—the state-sponsored annual exhibition—for the first time in 1883. He displayed portraits of his mother and of his friend Aman-Jean. The same year he began his studies, sketches, and panels for "Une Baignade, Asnières." When the picture was refused by the jury of the Salon in 1884, Seurat decided to participate in the foundation of the Groupe des Artistes Indépendants, an association "with neither jury nor prizes," where he showed his "Baignade" in June.

During this period, he had seen and been strongly influenced by the monumental symbolic paintings of Puvis de Chavannes. He also met the 100-year-old chemist Michel-Eugène Chevreul and experimented with Chevreul's theories of the chromatic circle of light and studied the effects that could be achieved with the three primary colours, yellow, red, and blue, and their complements. Seurat fell in with Paul Signac, who was to become his chief disciple, and painted many rough sketches on small boards in preparation for his masterpiece, "Sunday Afternoon on the Island of La Grande Jatte." In December 1884 he exhibited the "Baignade" again, with the Société des Artistes Indépendants, which had grown out of the earlier association and was to be of immense influence in the development of modern art.

Seurat spent the winter of 1885 working on the island of La Grande Jatte and the summer at Grandcamp, in Normandy. The Impressionist master Camille Pissarro, who was temporarily converted to the technique of pointillism, was introduced to Seurat by Signac during this period. Seurat finished the painting "La Grande Jatte" and exhibited it from May 15 to June 15, 1886, at an Impressionist group show. This picture demonstration of his technique aroused great interest. Seurat's chief artistic associates at this time, painters also concerned with the effects of light on colour, were Signac and Pissarro. The unexpectedness of his art and the novelty of his conception excited the Belgian poet Émile Verhaeren. The critic Félix Fénéon praised Seurat's method in an avant-garde review. And Seurat's work was exhibited by the eminent dealer Durand-Ruel in Paris and in New York.

In 1887, while he was temporarily living in a garret studio, Seurat began work on "Les Poseuses." This painting was to be the last of his compositions on the grand scale of the "Baignade" and "La Grande Jatte"; he thought about adding a "Place Clichy" to this number but abandoned the idea. In the following year he completed "Les Poseuses" and also "La Parade." In February 1888 he went to Brussels with Signac for a private viewing of the exposition of the Twenty (XX), a small group of independent artists, in which he showed seven canvases, including "La Grande Jatte."

Seurat participated in the 1889 Salon des Indépendants, exhibiting landscapes. He painted Signac's portrait at this time. His residence at this point was in the Pigalle district, where he lived with his mistress, Madeleine Knobloch, a girl of 21. On February 16, 1890, Madeleine presented him with a son, whom he officially acknowledged and entered in the register of births under the name of Pierre-Georges Seurat. During that year Seurat completed the painting "Le Chahut," which he sent to the exhibition of the Twenty (XX) in Brussels. During that period he also painted the "Jeune Femme se poudrant," a portrait of his mistress, though he continued to conceal

Early exhibition at the Salon

Influence of "La Grande Jatte"

Liaison with Madeleine Knobloch

his liaison with her even from his most intimate friends. He spent that summer at Gravelines, near Dunkirk, where he painted several landscapes and planned what was to be his last painting, "Le Cirque."

As if from some sort of premonition of his impending death, Seurat showed the uncompleted "Cirque" at the eighth Salon des Indépendants. As an organizer of the exhibition, he exhausted himself in the presentation and hanging of the works. He caught a chill, developed infectious angina, and, before the exhibition was ended, he died on Easter Sunday, March 29, 1891. On the following day Madeleine Knobloch presented herself at the town hall of her district to identify herself as the mother of Pierre-Georges Seurat. The child, who had contracted his father's contagious illness, died April 13, 1891. Seurat was buried in the family vault at Père Lachaise cemetery. In addition to his seven monumental paintings, he left some 40 smaller paintings and sketches, about 500 drawings, and several sketchbooks. Though a modest output in terms of quantity, they show him to have been among the foremost painters of one of the greatest periods in the history of art.

MAJOR WORKS

PAINTINGS: "Casseurs de pierre, Le Raincy" (c. 1880–81; private collection, Paris); "Maison dans les arbres" (1881; Museum and Art Gallery, Glasgow); "Les Pêcheurs à la ligne" (1883; Pierre Lévy Collection, Troyes, France); "Une Baignade, Asnières" (1883–84; National Gallery, London); "Sunday Afternoon on the Island of La Grande Jatte" (1884–86; Art Institute of Chicago); "Le Bec du Hoc, Grandcamp" (1885; Tate Gallery, London); "The Bridge at Courbevoie" (1886; Courtauld Institute Galleries, London); "The Asylum and the Lighthouse, Honfleur" (1886; Chester Beatty Collection, London); "Les Poseuses" ("The Models"; 1887–88; Barnes Foundation, Merion, Pennsylvania); "La Parade" ("Invitation to the Side-Show"; 1887–88; Metropolitan Museum of Art, New York); "Sunday at Port-en-Bessin" (1888; Rijksmuseum Kroller-Muller Otterlo); "Le Chahut" (1889–90; Rijksmuseum Kroller-Müller Otterlo); "A Young Woman Holding a Powder-puff" (1889–90; Courtauld Institute Galleries, London); "The Channel at Gravelines, Evening" (1890; Museum of Modern Art, New York); "Le Cirque" ("The Circus"; 1890–91; Louvre, Paris).

DRAWINGS: "Le Marchand d'oranges" (1881; Louvre, Paris); "Le Labourage" (1881; Louvre); "Paysans" (1882–83; Louvre); "La Mère de l'artiste" (1882–83; Metropolitan Museum of Art, New York); "Au concert européen" (1886–87; Museum of Modern Art, New York).

BIBLIOGRAPHY. CESAR DE HAUKE (comp.), *Seurat et son oeuvre*, 2 vol. (1961), is a basic work that serves as a general catalog to the works of Seurat and complements HENRI DORRA and JOHN REWALD, *Seurat* (1959). LUCIE COUSTURIER, *Seurat* (1921; 2nd ed., 1926), gives a lively literary portrait (in French) of the man and the painter. This biographical information was enhanced by GUSTAVE COQUIOT, *Seurat* (1924), also in French. Other general studies include DANIEL C. RICH, *Seurat and the Evolution of "La Grande Jatte"* (1935, reprinted 1969); JACQUES DE LAPRADE, *Georges Seurat* (1945, reissued as *Seurat*, 1951); MEYER SCHAPIRO, "New Light on Seurat," *Art News*, 57:22–24, 44–45, 52 (1958); ANTHONY BLUNT, *Seurat*, with an essay by ROGER FRY (1965); JOHN RUSSELL, *Seurat* (1965); and PIERRE COURTHION, *Georges Seurat* (1969). On Seurat's technique and aesthetic theories, JULES CHRISTOPHE, "Georges Seurat," in *Les Hommes d'aujourd'hui*, vol. 8 (1890), is basic. The major works on Seurat's drawings are GUSTAVE KAHN, *Les Dessins de Georges Seurat, 1859–1891*, 2 vol. (1928); GERMAIN SELIGMAN, *The Drawings of Georges Seurat* (1946); and ROBERT L. HERBERT, *Seurat's Drawings* (1962).

(P.Co.)

Seven Years' War

The Seven Years' War is the name history has given to the last great conflict involving all the major powers of Europe, except Turkey, before the French Revolutionary Wars. One aspect of the conflict—the specifically Franco-British aspect—can be understood as an extension of the so-called French and Indian War, a colonial struggle that broke out in North America and in India before 1756 but ended simultaneously with the Seven Years' War. Further, it is possible to regard the French campaigns in the western areas of the Holy Roman Empire, against electoral Hanover (dynastically united with Great Britain)

and its allies, Brunswick and Hesse-Kassel, as well as the Spanish entry and the consequent Portuguese involvement in the last phase of the war, as by-products of the colonial struggle. From such a point of view, then, the **Seven Years' War** properly is the Austro-Prussian War of 1756–63, in which Russia was also deeply committed against Prussia until the beginning of 1762 and in which Sweden likewise played a part against Prussia. On the other hand, a British alliance with Prussia and a French one with Austria, together with the geographical contiguity of Hanover and Prussia, interwove the fortunes and problems of the two sets of belligerents so closely that, for a practical appreciation, the European campaigns at least should be surveyed as factors of a single war, complex although not incoherent. British and European historians, in fact, are often inclined, regardless of chronology, to use the expression **Seven Years' War** to include also the French and Indian War. The present article is concerned mainly with the campaigns involving Prussia in central and eastern Europe; but the European campaigns of the war between Great Britain-Hanover and France, with the naval war on the French coast, are also noted. (For the colonial theatres of the war see UNITED STATES, HISTORY OF THE; CANADA, HISTORY OF; INDIAN SUBCONTINENT, HISTORY OF THE; and BRITAIN AND IRELAND, HISTORY OF.)

The origins of the war. The outbreak of the war in Europe was caused largely by the attempt of the Austrian Habsburgs to win back the rich province of Silesia, which had been wrested from them by Frederick II the Great of Prussia during the War of the Austrian Succession (1740–48). The great Austrian diplomat Graf Wenzel von Kaunitz engineered an alliance that ranged Austria, Saxony, Sweden, Russia, and France against Prussia. Prussia concluded an alliance with Great Britain, which since 1754 had been at war with France in the New World. The alignment of Austria with France, and of Great Britain with Hanover and Prussia, marked a reversal of long-standing enmity between these countries and constitutes what is known as the "Diplomatic Revolution" (see also EUROPEAN DIPLOMACY AND WARS [c. 1500–1914]). By 1756 the major powers of Continental Europe were poised for an attack on Prussia. Frederick the Great, a believer in attacking first, invaded Saxony on August 29 to detach that country from its alliance.

The Prussian advance into Saxony, 1756. Crossing the Saxon frontier with 70,000 Prussians, Frederick entered Dresden, the Saxon capital, on September 10, while the Saxon Army of not more than 20,000 men fell back on Pirna to the southeast. The Elector, Frederick Augustus II (also king of Poland as Augustus III), and his minister, Heinrich von Brihl, were offered assurances of Prussia's good intentions, which they naturally mistrusted. An Austrian force of 32,000, under Maximilian Ulysses von Browne, was moving from Bohemia to unite with the Saxons. To prevent this junction, Frederick advanced southward into Bohemia; and Browne was severely defeated at Lobositz (Lovosice, midway between Dresden and Prague) on October 1. Returning to Saxony, Frederick received the capitulation of the Saxons at Pirna (October 16), whereupon he took nearly all of them into his own service. The Elector and Brihl retired to Poland.

Russia might have sent forces to Austria's help at once but for the problem of the route they would have to take—namely, the route across Poland. Poland was a sphere of French influence that had maintained itself by opposition to Russian designs. For the perfect achievement of an anti-Prussian coalition, it was most desirable, as Kaunitz saw, for Russia and France to come to terms. The Russians, however, saw the new contingency as an occasion for extracting concessions from France with regard not only to Poland but to Sweden and to Turkey as well. The views of the French foreign ministry, ready to admit a swift passage of Russian troops across Polish territory in order to smash Prussia and so to relieve France of the obligation to help Austria, came into conflict with the *secret du roi* (the secret diplomacy of the king), the primary purpose of which had been to exclude the Russians from Poland at any cost.

In Great Britain, the accession of the Elder William Pitt

to office in November 1756 was to have a decisive effect on the development of the war. Pitt (later earl of Chatham) realized the importance of the colonial theatres of the war and devoted his enormous energy to the success of British arms in India and North America.

Alliances against Prussia, 1757. After weeks of negotiation at cross purposes, the French representative in St. Petersburg obtained Russia's accession to the First Treaty of Versailles by signing a secret promise of French help to Russia, in the event of an attack by Turkey, on January 11, 1757 (December 31, 1756, old style). This contradiction of the long-standing Franco-Turkish entente was immediately disavowed by the French government; and a personal letter from Louis XV to Russia's Empress Elizabeth, the first of an important series, finally secured Russian accession to the treaty without the objectionable secret promise (April 19). An Austro-Russian offensive alliance against Prussia was concluded on February 2, 1757, the parties each undertaking to put 80,000 men into the field and forswearing any separate peace, while secret articles provided for a partition of Prussia.

On May 1, 1757, Austria and France signed the Second Treaty of Versailles, an offensive alliance against Prussia, with further provision for territorial adjustments elsewhere. Austria was to recover Silesia but would cede the Austrian Netherlands for partition between Louis XV and his Spanish Bourbon cousin, Philip, duke of Parma, Piacenza, and Guastalla, whose Italian possessions should then revert to Austria. Militarily, France was to maintain 105,000 men in Germany, in addition to the contingent to be supplied to Austria (which was raised from 24,000 to 30,000), and was to grant an annual subsidy of 12,000,000 livres to Austria.

By a large majority of votes in the Council of Princes of the *Reich*, Austria had secured the declaration of a "war of the Empire" against Prussia. Though Hesse-Kassel, Brunswick, and, naturally, Hanover opposed it, some

Protestant states supported Austria, despite Frederick's attempt to pose as the champion of Protestantism against an Austro-French Catholic coalition.

In central Europe the Prussians in April 1757 advanced into Bohemia again. In the Battle of Prague, on May 6, the 66,000 Austrians under Browne and Prince Charles of Lorraine were routed by Frederick's force of 64,000 before they could be reinforced by another Austrian force under Leopold Joseph, Graf von Daun. The Austrians lost more than 14,000 men; 16,000 escaped to join Daun; the rest took refuge in Prague itself, which the Prussians, whose losses were about the same, proceeded to besiege. A month later Daun, with more than 50,000 men, moved forward to relieve Prague; and Frederick went to meet him with 34,000. The Battle of Kolin, on June 18, was a great victory for Daun. Raising the siege of Prague, the Prussians evacuated Bohemia. The retreat fell just short of being a rout.

Prussia meanwhile was exposed to attack from several directions. The French had begun their campaign in the spring by sending 100,000 men against the Hanoverians and their allies, who formed the so-called Army of Observation under William Augustus, duke of Cumberland, a younger son of King George II. Defeated at Hastenbeck, on the Weser southwest of Hanover, on July 26, 1757, Cumberland withdrew to Stade, near the Elbe estuary, abandoning the defense of the electorate and of Brunswick. A few weeks later, on September 8, the duc de Richelieu, to whom the French command had been transferred, forced Cumberland to sign the Convention of Klosterzeven, which stipulated the disbanding of the Army of Observation. Richelieu then advanced on Prussia's western frontier; and at the same time another French army of 24,000, under the Prince de Soubise (Charles de Rohan), was crossing Franconia, to join the Army of the *Reich*, namely Austria's German allies, under Joseph Friedrich of Saxe-Hildburghausen. Furthermore, Sweden,

The
Second
Treaty
of
Versailles

Richelieu
takes
command

having signed an alliance with France and Austria on March 21, invaded Prussian Pomerania in September so as to annex it, whether Russia approved or not.

The main Russian army of 90,000 men crossed into Polish territory in July and entered East Prussia in August; and on August 30, its general, **Stepan** Fyodorovich Apraksin, inflicted a crushing defeat on the Prussians under Hans von Lehwaldt at Gross-Jagersdorf west of Gumbinnen. To the stupefaction of the world, Apraksin then began a retreat. It now appears that his conduct was caused, at least partly, by the fact that the health of the empress Elizabeth, who hated Prussia, was uncertain, while her heir, the future emperor Peter III, was a self-confessed adorer of Frederick and an opponent of the anti-Prussian war. This meant that any general or statesman who did too much harm to Prussia was risking the displeasure of his future master.

Frederick, with Saxony as his main base, decided first to confront the danger from the west, leaving Frederick Francis of Brunswick-Bevern to face the Austrians in Silesia. To prevent Richelieu's joining Soubise and Saxe-Hildburghausen, he marched first toward Halberstadt; but Austrian successes in Silesia, where Brunswick-Bevern was defeated at Moys (Zgorzelec) on September 7, made him turn eastward again, while Ferdinand of Brunswick remained to observe Saxe-Hildburghausen. A daring Austrian raid on Berlin forced a further diversion of Frederick's forces. Finally, hearing that Soubise and Saxe-Hildburghausen were together on the move in Thuringia, Frederick went to meet them.

The Battle of Rossbach followed on November 5, 1757. The combined strength of the French and the Army of the *Reich* was at least 41,000, against the 21,000 Prussians; but the aggressive Saxe-Hildburghausen and the more cautious Soubise were at variance; and when at last they began the engagement for which Frederick had hoped, the greatly superior mobility of the Prussians, with the brilliant cavalry leadership of Friedrich Wilhelm von Seydlitz, won the day. In less than two hours' fighting, the Allies lost 7,000 men, the Prussians only 550.

Encouraged by the news of Rossbach, the British government, on the insistence of Pitt, repudiated Cumberland's Convention of Klosterzeven. It decided to reinforce the Hanoverians and to transfer the command in western Germany to Ferdinand of Brunswick. In September, a British naval expedition against the French base of Rochefort had been a failure.

In Silesia, the Austrians took Schweidnitz (Swidnica) on November 11 and Breslau (Wrocław) on November 22. Frederick arrived from Thuringia to support Brunswick-Bevern. In the Battle of Leuthen (Lutynia), on December 5, 1757, he won the greatest of his victories. With 43,000 men, he attacked the 72,000 under Charles of Lorraine and routed them with an unexpected cavalry charge followed by a heavy artillery bombardment. As against Frederick's losses of rather more than 6,000, Charles lost 22,000 men, including 12,000 taken prisoner. Breslau fell to the Prussians again.

In the course of the winter, Lehwaldt drove the Swedes back into their own part of Pomerania, where they were able to hold the Prussians outside Stralsund. Frederick's spectacular victories, combined with Apraksin's retreat, completely altered the fortune of the war.

The Prussian offensive of **1758**. William Fermor, a Scottish émigré in the Russian service, had taken Apraksin's place in the autumn of 1757. On January 22, 1758, the East Prussian capital, Königsberg (Kaliningrad), surrendered to him. With the onset of spring, however, the thawing of the snows made the northern roads impassable, and Fermor was temporarily immobilized. In Russia itself, the still anti-French Aleksey Bestuzhev-Ryumin was arrested, and power came into the hands of his rival, Mikhail Illarionovich Vorontsov.

Ferdinand of Brunswick, with his Anglo-Hanoverians, launched a successful offensive against the French in Westphalia; and on March 27 he crossed the Rhine at Emmerich, near the Dutch frontier. On June 23, with 40,000 men, he defeated the Comte de Clermont (Louis de Bourbon-Condé), with 70,000, at Krefeld; and the

effect of this victory, which enabled him to hold all north-western Germany, was scarcely offset by subsequent French successes farther to the south, in Hesse and in Thuringia. The British on April 11 signed a new treaty with Prussia, promising an annual subsidy of 4,000,000 talers (£670,000), while both parties undertook not to make a separate peace with any of the belligerents.

Frederick began the year's campaign with an offensive in Silesia, where Schweidnitz fell on April 16. He then advanced into Moravia, to lay siege to Olmütz (Olomouc). In July, however, the Austrians forced him to abandon the siege. In the north, meanwhile, a new Swedish attack on Prussian Pomerania was being fended off by Lehwaldt; but the Russians were on the march again, going southwestward from East Prussia toward the Oder River and Brandenburg.

To evade interception by the Austrians, Frederick had to march first northwestward into Bohemia, then northward across Silesia. Fermor's 52,000 Russians, having reached the Oder, began a siege of Kustrin (Kostrzyn) on August 15, but Frederick was at Frankfurt an der Oder by August 20. He then moved around Fermor's east flank and, with a total of 36,000 men, attacked the Russians at Zorndorf (Sarbinowo) on August 25. In the bloodiest battle of the war, the Russians' casualties were 42,000 (21,000 killed), the Prussians, 13,500.

Leaving Christoph von Dohna to pursue the defeated Russians, Frederick hastened back to Saxony, to save his brother Prince Henry from attack by superior Austrian forces under Daun, outside Dresden. Daun fell back until he found a strong position at Kittlitz, where he decided to stand with his 90,000 men. Frederick, with 37,000, advanced as far as Hochkirch, never thinking that Daun would venture an offensive. Daun's attack, in the early morning of October 14, took the Prussians by surprise; but Daun, who lost 7,500 men (the Prussians 9,500) was unable to interfere with Frederick's retreat into Silesia. Daun advanced on Dresden again, but the news of Frederick's approach through Lusatia caused him to withdraw to Pirna in November.

Hochkirch in any case put new spirit into the French, who after Krefeld and Zorndorf had been inclined to despair of their European war. The duc de Choiseul became foreign minister in December, in the place of the exhausted François-Joachim de Bernis, whose overtures for peace had been scorned by the British government.

French and Russian campaigns in **1759**. The Third Treaty of Versailles, already drafted by the end of December 1758, was signed in March 1759 and ratified in May. By this, the French obligations of direct help to Austria in men and money were considerably reduced, and the plan of 1757 concerning the Austrian Netherlands and Parma was discarded. The French, however, were still to maintain 100,000 men in Germany.

On April 13 Ferdinand of Brunswick, who had advanced against the French in southwestern Germany, was defeated by the duc de Broglie (Victor-François) at Bergen, near Frankfurt am Main; and on July 9 Broglie took Minden on the Weser. When Marshal Louis-Georges-Erasmus de Contades joined Broglie, the French had 60,000 men against Ferdinand's 43,000 Anglo-Hanoverians; but on August 1, in the Battle of Minden, Ferdinand contrived to lure Contades into an engagement that resulted in the complete rout of the French.

Choiseul had relieved France of its heavier commitments to Austria in order to prosecute the war against Great Britain with greater vigour. He planned an invasion, with landings around London and in Scotland. To transport and escort the expeditions, the Mediterranean fleet from Toulon was summoned to join the Atlantic fleet at Brest; but on its way northward the former fleet was attacked and scattered by Admiral Edward Boscawen in the Battle of Lagos (August 19), off the Portuguese coast. Meanwhile, Edward Hawke was blockading Brest. Later, when Hawke withdrew to English waters (November 9), the Brest fleet took to sea. Then Hawke reappeared, and in the Battle of Quiberon Bay (November 20–21) the French suffered a decisive defeat, with damaging losses. Not only had the invasion project to be

dropped but also British naval superiority was established for the rest of the war.

Minden, Lagos, and Quiberon Bay, together with outstanding successes in North America—the capture of Ft. Niagara on July 24–25 and, of far more significance, that of Quebec on September 18—made 1759 the *annus mirabilis*, or "wonderful year," for the British. From its strong position, the government began negotiations for peace with France. But, while on the one hand its terms were too stiff, on the other, its proposals were made in association with its Prussian ally, who at the end of the year was in no situation to expect favourable treatment from its enemies. Furthermore, Austria and Russia strongly objected to France's treating separately with the British.

In May 1759 the Russian command had been transferred from Fermor to Pyotr Semyonovich Saltykov. Advancing across Poland through Poznań into Brandenburg with 70,000 men, Saltykov defeated 26,000 Prussians, under C.H. von Wedel, at Zuilichau (Sulechów), east of Krossen (Krosno), on July 23. He then moved down the Oder toward Frankfurt, while Daun, from Saxony, sent 35,000 Austrians, under Gideon Ernst von Laudon, northward to join forces with him. Frederick, who had been facing Daun, promptly marched northward also, hoping to prevent the Austro-Russian junction; but he failed to do so. Having joined forces with Wedel and Friedrich von Finck, so that he finally disposed of about 50,000 men, Frederick boldly assailed the enemy in their strong position at Kunersdorf (Kunovice), east of Frankfurt, on August 12. The result was a disaster for Frederick, who in six hours lost more than 18,000 men. He wrote despairingly to one of his ministers, "... to tell you the truth, I believe everything is lost." Saltykov, however, made no immediate use of his victory; but Daun, advancing against the diminished Prussian forces in Saxony, took Dresden on September 14.

Attempts at junction between Daun and Saltykov were frustrated by Frederick's skillful movements after Kunersdorf; and when Saltykov was forced by lack of supplies to retire from the scene, Frederick turned on Daun again. Finck, who had been sent with more than 12,000 men to attack Daun's rear, was surprised by 42,000 of Daun's men at Maxen, south of Dresden, and forced to surrender (November 21). The year had been a bad one for Frederick, but by extraordinary exertion he was again able to take the field.

The Silesian campaign of 1760. For the campaign of 1760, Russia and Austria chose Silesia as the main field of operations: Saltykov, from Poznań, was supposed to march southward (instead of westward into Brandenburg) and to join forces with Laudon. The latter, on June 23, destroyed a Prussian force at Landeshut (Kamienna Góra) and, on July 26, captured the stronghold of Glatz (Kłodzko). Frederick, meanwhile, had first moved eastward against Laudon, then had turned back to besiege Dresden (July 12) on hearing that Daun was moving to Laudon's support. When Daun also turned back, Frederick raised his siege and marched through Meissen and Lusatia into Silesia. While 20,000 Russians, under Zakhar Grigorevich Chernyshev, occupied Prince Henry of Prussia in the vicinity of Breslau, the Austrians were converging on Frederick; but on August 15, at Plaffendorf, near Liegnitz (Legnica), Laudon launched a sudden attack on Frederick's columns in the hope of preventing their escape from encirclement but was beaten off with heavy Austrian losses. A ruse of Frederick's tricked Chernyshev into retreating, and the Austro-Russian plan for a decisive victory in Silesia came to nothing.

Most of Saxony remained defenseless against Daun, and Brandenburg was open to the Russians. A detachment under G.G. Tottleben took Berlin in the night of October 8–9 and was able to retire unmolested on October 13, when Frederick was approaching from Silesia. Daun was able to concentrate 64,000 men around Torgau, against which Frederick marched with about 45,000. The Battle of Torgau, Frederick's last major victory, began on November 3. The Austrian artillery devastated his attacking troops, but Frederick sent wave after wave forward until at last the Austrian line was broken; and, on the arrival

of Frederick's general, Hans Joachim von Zieten (who should have appeared earlier), the Austrians gave up the struggle and retreated. Frederick had lost 13,000 men, Daun 11,000 (including 7,000 captured).

In western Germany, Broglie won a victory at Korbach on July 10, 1760, but this was offset by Ferdinand's victory at Warburg on July 31. Hanover was again saved from French invasion, but a subsequent advance of Ferdinand's troops across the Rhine was reversed by Charles-Eugène-Gabriel de Castries at Klosterkamp on October 16.

George II of Great Britain died on October 25. His grandson and successor, George III, was far more attached than he to British, as distinct from Hanoverian, interests and had a strong dislike for William Pitt, earl of Chatham, who was the foremost exponent of the Anglo-Prussian alliance. Without the British subsidies, Prussia could not have fought on.

Disputes within the anti-Prussian coalition, 1761. By March 1761, when George III's favourite, John Stuart, the 3rd earl of Bute, became British secretary of state for the northern department, the members of the anti-Prussian coalition were at variance in their attitudes toward the war: France wanted a negotiated peace with the British; Austria desired a general congress of the powers, at which the retrocession of Silesia might have been obtained from Prussia; and the Russian Empress was still bent on war until Prussia could be carved up. Formal discussions between the French and the British broke down in July because Pitt finally insisted that, whereas the British would go on supporting Prussia, the French should reduce their support of Austria to a minimum and virtually abandon Germany and that the British should keep all their colonial conquests. Choiseul would not submit to this dictation. To counter it, he fell back on a plan that he had long had in mind—the introduction of Spain into France's war against Great Britain. In August a "Family Compact" was concluded between Louis XV of France and Charles III of Spain. Spain would declare war on Great Britain if France had not obtained peace by May 1, 1762, and France would see that Spanish claims against Great Britain were met at the final peacemaking. When the British government refused to declare immediate war on Spain, Pitt resigned office (October 5, 1761).

Meanwhile, the fighting in western Germany went on as usual. Ferdinand advanced southward from Westphalia but was repulsed by Broglie at Grünberg, between Fulda and Marburg (Maribor), on March 21, 1761; and a French counterthrust into Westphalia was checked by Ferdinand at Vellinghausen, in the middle valley of the Lippe River, on July 15. By October the French had made considerable progress eastward. The capture of Belle-fle-en-Mer, off the Breton coast of France, was achieved by a British expedition in April–June.

For Prussia, Frederick's first concern was to prevent the junction, in Silesia, of Laudon's 72,000 Austrians, based on Glatz, with a Russian army of 50,000 under Aleksandr Borisovich Buturlin. He concentrated his available forces around Schweidnitz, but after two months of skirmishing and marching the Allies effected their junction between Liegnitz and Jauer (Jawor) on August 23. Cut off from the north and outnumbered by three to one, Frederick entrenched himself at Bunzelwitz, where his enemy did not dare to attack him. When Buturlin withdrew to the north in September, leaving only 20,000 Russians under Chernyshev in Silesia, Frederick could move toward Brandenburg; but Laudon took Schweidnitz on October 1, so that the Austrians could count on wintering in Silesia. In Saxony, meanwhile, Daun made gradual progress against Prince Henry; and on the Pomeranian coast the fortress and harbour of Kolberg (Kolobrzeg) fell to the Russians under Pyotr Aleksandrovich Rumyantsev on December 16. No longer sure that he could rely on a British subsidy (since Pitt had gone), Frederick saw that only luck could save him from destruction the next year.

The Prusso-Russian alliance of 1762. Frederick's salvation came with the death of the empress Elizabeth on January 5, 1762, bringing the Prussophile Peter III to the Russian throne. On May 5, Peter made peace with Frederick; and on May 22 the Treaty of Hamburg was con-

Entry of
Spain
into the
war

The
Russians
change
sides

cluded between Prussia and Sweden, through Peter's mediation. Next, in June, Peter not only allied himself with Frederick for action against Denmark over his ancestral Holstein but even instructed Chernyshev to help Frederick to expel the Austrians from Silesia. In July, when Peter was deposed and murdered, Catherine II the Great, his widow and successor, countermanded his positive measures against Denmark and Austria; but she did not renew the war against Frederick.

Daun had been given the Austrian command in Silesia in Laudon's place. Before Catherine's recall of Chernyshev had become effective, when Frederick was trying to recapture Schweidnitz, Daun marched to relieve it but was defeated at Burkersdorf (Burkatów) on July 21. His second attempt at relief was similarly defeated, at Reichenbach (Dzierżoniów), on August 16; and on October 9 Schweidnitz again fell to the Prussians.

In Saxony, on October 29, Prince Henry and Seydlitz together won a considerable victory over the Austrians and their German allies at Freiburg. Austria and Prussia signed an armistice on November 24.

In the west, the British government declared war on Spain on January 2, 1762, three months after its rejection of Pitt's advocacy of the same measure and four months ahead of the Family Compact's deadline for Spain's intervention. The Spaniards then attacked Portugal, which the British promptly reinforced. The Portuguese fortress of Almeida fell to the Spaniards on August 25; and overseas they took Colonia del Sacramento, on the estuary of the Río de la Plata, opposite Buenos Aires. These Spanish successes were counterbalanced by the British capture of Havana, in Cuba (August 13), and of Manila, in the Philippines (October 5). In the same year three important West Indian islands had fallen to the British: Martinique and St. Lucia in February, Grenada in March.

In western Germany, Ferdinand of Brunswick won victories over Soubise at Wilhelmsthal (June 24) and over Prince Xavier of Saxony at Lutterberg (July 23) and took Gottingen (August 16). The French had a success at Johannisberg, near Nauheim, August 30, but lost Kassel on November 1.

The end of the war. Russia's defection from the anti-Prussian alliance convinced Austria that nothing was to be gained from prolonging the war. After the removal of Austria's objections, France could soon come to terms with Great Britain, which in turn had no interest in continuing to back Prussia in a quarrel about Silesia with Austria alone. France in October induced the disappointed Spaniards to join in the negotiations with the British; and on November 3, 1762, anticipating the Austro-Prussian armistice by three weeks, Great Britain and France signed preliminaries of peace, at Fontainebleau. By the Treaty of Paris (February 10, 1763), which settled the colonial aspects of the war, Britain won North America and India and became the undisputed leader in overseas colonization. By the Treaty of Hubertusburg (February 15, 1763) Frederick maintained Silesia and thereby elevated Prussia to a major European power.

Several factors account for Prussia's survival and ultimate victory: the inherent weakness of the anti-Prussian coalition, the "dictatorship" of William Pitt, and the last minute defection of Russia. But what served Prussia best was Frederick himself—his courage, his endurance, and his unbreakable will.

BIBLIOGRAPHY. For general accounts of diplomacy and the fighting, largely from the Prussian side, see RICHARD P. WADDINGTON, *La Guerre de sept ans*, 5 vol. (1899–1914), incomplete but still the best account; CURT JANY, *Geschichte der königlich-preussischen Armee bis zum Jahre 1807*, vol. 2 (1928), by a military historian; MAX IMMICH, *Geschichte des europäischen Staatensystems von 1660 bis 1789* (1905), an old but still valuable study of diplomatic developments; WALTER L. DORN, *Competition for Empire, 1740–1763*, ch. 7 (1940), the story mainly from the British and French points of view; JULIAN S. CORBETT, *England in the Seven Years' War*, 2 vol. (1907), particularly good on tactics and strategy; RICHARD LODGE, *Great Britain and Prussia in the Eighteenth Century* (1923); BASIL WILLIAMS, *The Life of William Pitt, Earl of Chatham*, 2 vol. (1913, reprinted 1966), laudatory but very useful; and A. BOURCET, *Etudes sur la politique du duc de Choiseul* (1907). For a critical study of French policy in

Russia, see L.J. OLIVA, *Misalliance* (1964). ZE. RASHED, *The Peace of Paris, 1763* (1951), stresses politics in England as a factor in peacemaking. See also books cited in the articles on the sovereigns, statesmen, and generals mentioned in the text above.

Seville

Seville (Sevilla) is the capital of the Provincia de Sevilla, in the Andalusia region of southern Spain. An inland port, it is the chief city of Andalusia and the fourth largest in Spain. It was important in history as a cultural centre, and it served as a capital for Muslim Spain and later as a centre for Spanish exploration of the New World. In the 1970s it had a population of about 548,000.

Ancient Seville. Its position on the Guadalquivir Estuary and its rich soil enabled Seville, already populated in the Paleolithic Period, to develop greatly in the Neolithic, when floods facilitated a precocious grain agriculture, documented by the presence of many silos. Dolmens left from this period were rich in artifacts, including gold and copper from the Sierra Morena and bell-shaped vessels, indicating European expansion.

At the end of the Bronze Age, a city appeared that may have been Seville and the name of which, Tartessus, was given to a river and a kingdom. Rich from agriculture, stock raising, and mining (copper, gold, and silver from Riotinto), the Tartessians trafficked in tin from the Casiterides (the Scilly Isles or Cornwall, in England). Biblical quotations and Greek historians confirm the existence of treasures, such as that of El Carambolo, near Seville, where Tartessus' material wealth was uncovered. Such riches attracted Greeks, Phoenicians, and Celts.

The fall of Tartessus was brought about by the spread of iron rather than by Carthaginians, as is generally believed. The Carthaginians were resisted by Turdetan princes of the lower Guadalquivir Valley (c. 500 BC). The Second Punic War in 206 BC included a Roman victory at Ilipa Magna, about eight miles north of what is now Seville, and the founding of Italica (about five miles to the northwest), the birthplace of the Roman emperors Trajan and Hadrian. Later excavation there revealed a high level of urbanization, noteworthy inscriptions, sculptures and mosaics, and a huge amphitheatre. But Italica, built on shifting soil, fell in favour of Hispalis (Seville), the walls of which had been built before Caesar and which inherited Italica's population. Seville's prosperity erased the traces of Hispalis; the columns of Calle Mármoles ("Street of Sculptures") and a few inscriptions remain.

Razed by the Vandals and fertilized by the presence of the Byzantines, Seville reached an apogee in the late Visigothic period, personified in the towering figure of St. Isidore (died AD 636), a politician, bibliophile, and historian, whose *Etymologiae*, a synthesis of ancient culture, was the instructional encyclopaedia of Europe's high Middle Ages.

Muslim Seville. Delivered to the Muslims in 711 by its Jewish inhabitants (whom the Visigoths had persecuted), Seville welcomed the first emir, 'Abd al-Aziz. Córdoba's status as a capital, however, kept Seville rebellious, fired by the discontent of its many rich Christians (Mozarabs, or *mozárabes*) and Jews and its Arab nobles. Under 'Abd ar-Rahmān II, the *qādī* 'Umar ibn Adabbas built, with Roman and Visigothic materials, the mosque whose remains are still to be found in El Salvador. In 844, Normans razed Seville but were defeated and lost 30 ships, many of which remained in the swampland around the Guadalquivir. A second wall was built, enclosing a wider area than the Roman one. 'Abd ar-Rahmān III took Seville c. 918 through trickery and constructed an *alcáza-ba*, or fort, the door of which was recently found.

With the caliphate destroyed in 1031, Seville was the principal factional kingdom under the 'Abbāids: Abii al-Qasim Muhammad; al-Mu'tamid (ruled 1042–69), who expanded his kingdom by resisting Ferdinand I of Castile; and al-Mu'tamid (ruled 1069–91), a great poet who fought Alfonso VI and the Berber Almoravids. Seville flourished culturally in a climate of political tension, economic weakness, and religious laxity. The fall of Toledo in 1085 and the pressure of religious enthusiasts forced al-Mu'tamid to call on the Almoravids, who defeated the Christians at az-Zallāqah and dethroned the "party kings" (*mulūk at-tawā'if*). Al-Mu'tamid died an exile in Morocco.

In the 12th century, under both the Almoravids and their successors the Almohads, Seville was the European capital of an African empire to which it lent its cultural achievement and prestige. Ibn-'Abdūn's *hisbah* treatise describes a Seville that had Muslim, Mozarab, and Hebrew communities, a garrison of watchful Bedouins, noisy markets, beautiful mosques, and cemeteries. The high point of Almohad rule saw population growth, a flourishing economy, the rebirth of poetry, and the construction of more representative monuments: new and more extensive walls of undulating design, the new mosque, one of the largest in Islām, with surrounding commercial districts, a new fort, the first boat bridge over the Guadalquivir, the gardens of Bohaira, the fortresses of Iznalfarach and Alcálá de Guadaira, and the Tower of Gold (Torre del Oro, 1220).

Medieval Christian Seville. With the Almohads defeated in the Battle of Las Navas de Tolosa in 1212, Ferdinand III reconquered the valley of the Guadalquivir. Seville fell to the Christians in 1248 and experienced a complete demographic change with the Repartimiento—the exit of Muslims from the city and its repopulation by Christians. Princes, prelates, great lords, and the military orders received extensive gifts of land, so that small Muslim holdings gave way to large landed estates, with the ensuing pre-eminence of the nobility and economic disequilibrium.

Alfonso X chose to live in Seville, thus colouring the city with courtly refinements and intellectual activity. He founded a school for Latin and Arabic and worked on his prodigious encyclopaedia and the *Cántigas de Santa Maria* (a series of poems). The cathedral was placed in the old mosque, but Alfonso introduced Gothic architecture in a palace next to the fort, the church of Santa Ana, and the Tower of Silver (Torre de la Plata), while continuing to respect the Almohad tradition in the arsenals (*atarazanas*).

Between the 13th and the 14th centuries the land became impoverished because of strife among the nobles, the consolidation of the kingdom of Granada, and the pressure of the Marīnids from Morocco in the Strait of Gibraltar. Alfonso XI defeated the Marīnids in 1340; he improved Seville's administration and gave a lift to the economy through olive agriculture, a soap industry, and commerce in oil as far as the Near East. Guilds were organized, and parish churches were rebuilt uniformly in the Mudejar style, a mixture of Muslim and Western elements. Pedro I, beloved by the residents of Seville, built a palace there that is the principal part of the Alcázar and an echo of the Alhambra.

In the 15th century Seville became illustrious. The ca-

thedral (built in 1403–1506) was one of the largest in the world. The Canary Islands and much of the kingdom of Granada were conquered and colonized from Seville. With the peace and good government of the Catholic monarchs Ferdinand and Isabella, the city grew and prospered despite the expulsion of the Jews (1492) and the establishment of the Inquisition (1478). Seville's great opportunity had arrived: to be the centre of the exploration and exploitation of America through the Casa de Contratación (House of Trade), established in 1503 to regulate commerce between Spain and the New World.

Apogee and decadence. Seville was the richest and most populated city of Spain in the 16th century (some 60,000 inhabitants around 1500, more than 100,000 in 1565, and some 150,000 in 1588). Charles V married Isabella of Portugal in the Alcázar; the Magellan–Elcano expedition embarked from Saulúcar de Berrameda, Seville's outpost, on its first trip around the world; and treasures arrived from Mexico and Peru. European bankers and merchants frequented the market of the *gradas* (the steps), and a fever for luxury invaded the city. The University prospered; the town hall was built in the fine, richly ornamented plateresque style; the cathedral received its gigantic main altarpiece, shrine, and sacristy; and Nebrija wrote the first Castilian grammar (*Gramática castellana*).

This brilliance, however, was fleeting and partially ephemeral. No industries were created to supply America. Most banking and commerce was handled by foreigners, who were enriched by the gold and silver coined in the world's most active mint. The Emperor's war debts ruined the treasury and the city. In the 17th century political and economic decadence contrasted with a great flowering of culture: the painters Velázquez, Zurbarán, Murillo, the sculptor Juan Martínez Montañés, and Fernando de Herrera are the glories of Seville and of Spain. The picaresque novel documented the disillusionment, the poverty, and the genius, as did *The Exemplary Novels* (*Novelas ejemplares*) on Sevillian themes by Cervantes, who conceived of *Don Quixote* while confined in Seville's jail.

In the 18th century the Bourbons stimulated an economic revival. The countryside around Seville was filled with enormous villas. The Fábrica de Tabacos (Tobacco Factory) was built, as were the present university and the Maestranza bull ring. Excavations in Italica were initiated, and new settlements were made in the Sierra Morena. In the 19th century the French invasion, revolutions, and civil war halted these developments. In 1847 the April Fair, an annual gala following Easter, was born. The Iberoamerican Exposition of 1929 initiated a new renaissance in Seville; and the swampland was placed under cultivation, an effort that involved important irrigation works and a degree of industrial development. In the mid-20th century the city's area and population more than tripled.

BIBLIOGRAPHY

Topography: Though nearly 70 years old, W.M. GALLICHAN, *The Story of Seville* (1903), is a good general account on which the later A.F. CALVERT, *Seville*, illustrated (1907), occasionally draws. E.A. PEERS, *Royal Seville* (1926), voices personal impressions. A picture book is YVES BRAYER, *Seville* (1959), with notes. A personal account by NINA C. EPTON, *Andalusia* (1968), devotes a chapter to Seville, while RAFAEL LAFFON, *Seville*, 3rd ed. (1958), is a useful short guide.

History and art: A good, brief, general survey is J. HAZANAS, *Historia de Sevilla* (1932), while the early era receives attention in Muslim Seville in IBN SAHIB AL-SALA, *Sevilla bajo los almohades* (1969). J. DE M. CARRIAZO, *Anecdótico Sevillano del siglo XV* (1947); and S. MONTOTO DE SEDAS, *Sevilla en el Imperio* (1938), cover more modern times. On artistic and archaeological aspects, J. GESTOSO Y PEREZ, *Sevilla monumental y artística*, 3 vol. (1889–92), is a general work; see also A. SANCHO CORBACHO, *Arquitectura barroca Sevillana del siglo XVIII* (1952). On economic history, a fundamental work is R. CARANDE THOBAR, *Carlos V y sus banqueros*, 3 vol. (1943–67); works on special aspects of economic history are H. and P. CHALNI, *Séville et l'Atlantique, 1504–1650*, 12 vol. (1955–60); and R. PIKE, *Enterprise and Adventure: The Genoese in Seville and the Opening of the New World* (1966).

Sewage Systems

Sewage systems are physical systems for the collection of waste water and its treatment before discharge back into the environment. Domestic waste water includes the used water of businesses and office buildings as well as dwellings; industrial waste water is that discharged during industrial operations. In addition to waste water, sewage systems also handle the flow of storm water, either separately or, more commonly, as part of a single system.

The volume of waste water discharged by a community is closely related to the volume of water supply required by it, and keeping the two separate has been one of the most critical problems of modern city engineers.

Because of the time required to plan, finance and build sewage disposal facilities, the engineer who designs such facilities is obliged to make an estimate of future population and industrial growth. The type of industry present or foreseen is important owing to the wide range of water-volume use by various industries—up to 50,000 gallons of water may be used to produce a ton of steel, and up to 100,000 to produce a ton of paper.

The complex and still evolving modern metropolitan sewage system has grown out of a long past, including many disastrous experiences with water-borne diseases and, more recently, other environmental problems such as ecological damage.

HISTORY

Ancient systems. Drainage systems may be traced to the early Christian Era and earlier; surviving examples include the city of Pompeii (1st century AD) and the even earlier Minoan sites on the island of Crete. Such ancient communities provided for conveying away roof water and rainwater from the pavements. Clay pipes for drain lines were the counterpart of lead pipe conveying water to certain buildings, though these refinements were chiefly limited to the official or wealthy class. In Rome drain water was conveyed to the Tiber principally by surface drains, but as early as the 6th century BC part of the cloaca maxima, the main sewer, was vaulted; in the 3rd century AD the entire sewer was vaulted. In addition to carrying storm runoff, the Roman system served a major source of waste water, the public baths.

Roman engineers introduced their techniques throughout their vast empire; even today, at such ancient bath-houses as that at Bath, England, may be seen the lead pipes bringing water in and the drains for discharge of used water.

The Middle Ages. The early Middle Ages witnessed few developments in the field of drainage; in the rude garrison towns and frontier outposts of northwest Europe the disposal of human waste was largely in keeping with the injunction contained in the 23rd chapter of Deuteronomy that prescribed withdrawal outside the camp. But in the rapidly growing cities of the high Middle Ages, the first attempts at organized waste removal were made. Privy vaults, usually built to serve several families, were periodically cleaned. The system was none too satisfactory; wealthy families preferred to live adjacent to or over a watercourse, with the "garderobe" (privy) corbelled out over the water; London Bridge was a favourite residence because of its convenience in this respect. A more significant advance introduced in some places was the cess-pool. But throughout the Renaissance wastes were universally dumped in city gutters to be flushed through the drains by floods.

Public health aspects. Not surprisingly, the crude sanitary arrangements of Europe contributed to the spread of epidemics. John Snow, a 19th-century English physician, compiled a list of outbreaks of cholera that he believed had moved westward from India over a period of centuries, reaching London and Paris in 1849. Snow traced a London recurrence of 1854 to a public well, known as the Broad Street Pump, in Golden Square, which he determined was being contaminated by nearby privy vaults. This was a noteworthy epidemiological achievement, especially since it predated by several years the discovery of the role of bacteria in disease transmission.

When the public health dangers became apparent, Londoners first, and soon after other European city dwellers, were ordered to discharge wastes into the drainage system originally provided to carry storm-water runoff only. It might be said that here stream pollution had its birth, as the concentration of such an organic load on a river like the Thames at London was more than the stream could assimilate without nuisance. The resulting stench was such that burlap saturated in chloride of lime was hung in the windows of Parliament House in an attempt to kill the odours. That experience developed into pressure for the treatment of sanitary wastes. Similar treatment demands arose in the large cities of Germany, which had also experienced major waterborne epidemics. Such catastrophes have today been virtually eliminated by vastly improved sanitation of water and modern water-pollution control. In the infectious hepatitis epidemic of 1955–56 in Delhi, India, a laxity in water-treatment techniques was shown to be the cause of the outbreak.

A major contributor to water pollution problems as they reached major intensity first in England during the early 19th century and in the United States and western Europe a little later was the Industrial Revolution, with its combination of concentration of population and industry. Few major industrial users of water, in their early years of development, paid serious attention to waste products that left the plant. Even today, approximately 50 percent of the total wood used in a modern paper mill goes into the industrial waste-water stream and must be removed by treatment of the waste water. Textile mills discharge some waste fibres and also frequently discharge multicoloured dyes.

DEVELOPMENT OF TREATMENT METHODS

Early treatment techniques simulated natural methods of purification. It was observed that moderate amounts of organic wastes discharged into a watercourse eventually went through a natural purification process. In time the receiving water, as well as the waste water itself, regained a status of natural purity. If too much organic matter was imposed upon a watercourse, however, the water was badly degraded and would become a nuisance to sight and smell as well as become uninhabitable for fish and other aquatic life. Because of the absorptive capacity of the soil and the value of organic material as fertilizer an early attempt at disposal was that of sewage farming, the spreading of raw sewage on the land. This met with particular favour in the large cities of Europe and was employed in Berlin and Paris until relatively recent years. This practice was followed in the early years of experimentation in Britain, but soon gave way to methods of treatment in which the final solids removed from the waste water could be used for organic fertilizers or soil conditioners. Such methods included plain sedimentation and, later, chemical precipitation or sedimentation aided by flocculation chemicals.

Development of the trickling filter. Even these methods were insufficient in many cases and further treatment of the waste water was necessary. Again, observing nature, workers sought to expose the waste-water flow to oxygen from the air by various means. An early attempt consisted of filling a large tank with stones from three to eight inches in average diameter and flooding the interstices with the settled waste water. After contact of several hours, the tank was drained and much organic matter remained on the surface of the stones enmeshed in the zoogeal (massive bacterial) growths that occurred, there. Such a treatment scheme required several such tanks so they could be rotated on a fill-and-draw basis. Because of the labour involved with this manipulation and a desire for something better, the next big step was toward a so-called trickling or sprinkling filter. This was not a filter in the usual sense, but a large shallow concrete tank filled with medium-size stones, over whose surface the settled waste water was allowed to trickle, draining from the bottom of the unit. Such filters were operated intermittently so that air had free access to the zoogeal growths that formed on the filter stones and accomplished the oxidization of material from the waste-water flow.

Industry
and water
pollution

Activated-sludge process. During the years 1912–15, the British developed another process that proved to be still more effective in the removal of organic material from the waste water. Recognizing the trickling filter as merely a means of bringing together the organic matter in the waste water and air as a source of oxygen, British engineers reasoned that by releasing compressed air in a tank of waste water they could achieve a greater measure of control, and hence degree of treatment. They also observed that the circulation of some of the sludge gave a vast area for the same biological action that was going on in the trickling filter, by combining the organisms carried by the sludge, oxygen supplied by the incoming air, and new food supplied by the settled waste water entering the aeration tanks. By varying the amount of air and the amount of sludge returned to the process, higher levels of treatment could be obtained. Because the sludge was teeming with bacterial and associated biological life, the sludge was called "activated" and the process called the "activated-sludge process." It proved highly efficient and was rapidly adopted by cities around the world with severe treatment problems.

MODERN TRENDS

A water-pollution control plant has been described as "a river wound up at one point," because a treatment plant accomplishes, within a few hours, what a river requires days or even weeks to do. In the 1970s nearly all communities needed increasing waste-water treatment; in addition to the greater load from growing populations and industrial activity, there has been a significant increase in most parts of the world in both the stringency and level of enforcement of water-pollution control laws. One result of this pressure has been a search for methods to increase the levels of treatment or, specifically, the removal of organic material from the waste water. Practices of the past have employed biological and physical processes because of their economy.

Chemical treatment. With the increased demands for treatment effectiveness, serious consideration is now being given to the return to chemical precipitation methods. These methods were tried briefly in the 19th century; they were given up, however, because of high costs. The increased value placed by the 20th century on stream cleanliness tends to justify such higher costs, and the treatment plant of the immediate future will probably include chemical precipitation in addition to physical and biological processes.

Separate storm and waste-water sewers. Although most sewer systems still combine storm water and domestic waste water, it is generally recognized that separate systems are highly desirable. Where a combined system is used, heavy rainfall overloads treatment plants, with the result that untreated overflow becomes a source of pollution. Furthermore, where the two streams are kept separate, it is possible to handle each in accordance with the level of treatment required. One proposed method of handling storm runoff is that it be piped to holding reservoirs underground and gradually run through treatment plants.

Recycling. Even further, because of the exhaustion or near exhaustion of water supplies in some areas, there has been a major trend, particularly in the arid parts of the world, to treat waste waters to a level that will allow reuse of the water for various purposes. For many years such treated waters have been used for irrigation, industrial cooling, and certain other industrial processes. Studies are proceeding to reclaim water for many other purposes, with a growing likelihood of eventual reclamation and treatment to the level of drinking water. In the United States, the city of Dallas, Texas, is studying the possibilities of reuse because the city has developed virtually all of the freshwater sources within its reach. Many cities with similar problems, in the U.S. and elsewhere, will soon be studying reuse. The United States government has been carrying on an intensive research program in this area for several years. It is clear that the relation between water supply and water-pollution control is growing steadily closer.

A TYPICAL CITY SEWER SYSTEM: WASHINGTON, D.C.

Modern urban sewage treatments can best be described by reference to a specific city. The Washington, D.C., system has many aspects typical of any large modern city, though its early history is not representative of many others. The town's first bathtubs were installed in the White House and the Capitol, for the members of Congress in the 1840s; in 1850 the U.S. Congress authorized the Corps of Engineers of the U.S. Army to develop a city-wide water supply from the Potomac River. At this point Washington caught up with New York, London, and Paris, which were also encountering the problem of disposing of used water along with wastes. Washington's solution was the same as that of other cities; the existing system of culverts and drains, built for street drainage only, was extended and developed into a sewer system for the disposal of domestic waste water from residences, government offices, and businesses. The system followed the drainage pattern of the city street network and in general made a system of pipes with a sewer available to each private property. At the same time, again in common with other cities, street drains were built to empty into the nearest surface watercourse without any thought of degradation of the water quality. This was in spite of the fact that an engineering study and report (1890) recommended that all extensions of the sewer system separate storm runoff from domestic waste water.

With continued growth of the city, the District of Columbia constructed in the first decade of the 20th century a series of intercepting sewers and a pumping station to lift the domestic waste water into an outfall line for discharge into the Potomac River south of the city. At the same time pumping facilities were installed for the lifting of storm water drainage directly into the nearby Anacostia River. It was impossible to keep domestic and storm flow completely separate, but practical separation was attempted.

With the accelerated growth of the 1920s, concern over pollution of the Potomac increased. The Potomac estuary had a remarkable ability to assimilate pollution because of the large "flats" on both sides of the river that were kept in a state of constant circulation by tidal variations, but a study made by the Public Health Service in 1932 revealed that the river was in such a condition that low flow would bring about serious pollution effects. As a result, Congress decided to proceed with the construction of facilities for the treatment of waste water. This again was in line with decisions being made in many U.S. and European cities at the same period.

Treatment plant at Blue Plains, D.C. During 1934–38 a plant was constructed on the left bank of the Potomac at Blue Plains, D.C., to accommodate a flow of 130,000,000 gallons per day and serve a population of 650,000. Initially, with the help of the Federal Emergency Administration of Public Works, money was allowed for construction of a plant that would remove 90 percent of the organic matter from the waste-water flow. That level of treatment was in accordance with the Public Health Service recommendation contained in the 1932 report. Instead of constructing the plant in accordance with that recommendation, the District of Columbia decided to eliminate the second step in the treatment and construct a sedimentation plant, generally known as primary treatment. The plant was able to remove about 36 percent of the organic matter when it went into operation in August 1938, but as the population load increased, accelerated by World War II, the plant was unable to maintain this level and year by year efficiency dropped until it was regularly under 30 percent.

During World War II, initial plans were made for the relief of the treatment burden, and by 1950 the District of Columbia had begun major construction to increase the capacity of the plant and make further plans for inclusion of secondary treatment.

Activated-sludge plant. The activated-sludge process pioneered in Britain had by now been widely tested. Washington constructed a high-rate activated-sludge treatment plant in anticipation of 70 percent removal of

organic matter. While the new plant brought a major improvement in the river, there was no real possibility of keeping up with the pollution burden, even though the plant grew to a capacity of 290,000,000 gallons daily. In the early 1970s the District planned to extend treatment to a much higher level—once more, a decision being forced on many cities of the United States, Europe, and Asia.

Coordination with surrounding areas. One of the awkward problems confronting city engineers of the 20th century in nearly all countries has been the impossibility of isolating a metropolitan area from neighbouring regions. Rivers carry pollution from city to city, even country to country. In Washington the problem was encountered in a relatively mild form; much of the Maryland suburban area drains into Rock Creek and the Anacostia River, which flow through the District of Columbia; to try to keep the two streams as clean as possible the District of Columbia and the Washington Suburban Sanitary Commission (of Maryland) entered into an agreement to handle each other's flow at a reasonable cost. All the domestic waste water of the suburban areas is now connected into District sewers, with payments made to handle the waste waters. As part of the agreement, the Maryland Commission helps to finance both the construction and the operation of the District of Columbia Water Pollution Control Plant.

Other developments. With continued growth and rising pollution control standards of the 1960s and 1970s, Washington like most other major cities has been turning toward additional treatment, including chemical treatment. One proposal calls for achieving so high a level of treatment that the Potomac estuary into which the effluent flows could be used as an emergency water source.

Another direction in which Washington had headed in company with many other modern cities is toward separation of systems. This is a tedious and expensive process, requiring piping changes on private property. Its long-range wisdom, however, is irrefutable. The redevelopment of certain major areas, such as southwest Washington, has given favourable opportunities for large-scale separation.

An important advance in financing improvements has been adopted by Washington: the sewer-service charge on all those served by the drainage system. This system has been followed more and more by drainage systems serving both municipalities and industry.

Since about 1959 the D.C. sewer system has been interconnected with the areas in Maryland that naturally drain through the District via the Potomac River and major areas in Virginia related to the intercepting sewer serving Dulles International Airport near Herndon, Virginia. As a result of this connection the area served increased by 436 square miles in Maryland and 228 square miles in Virginia. The Metropolitan area in Arlington County and much of the Virginia suburban area adjacent to Arlington County are served by other treatment plants.

Present treatment facilities. At the District of Columbia Water Pollution Control Plant (see illustration) the raw waste water enters the plant pumping station and is treated in the following successive steps: grit removal, preliminary sedimentation, aeration, and final sedimentation. In addition, chlorine treatment may be given to the flow prior to preliminary sedimentation or it may be given to the final effluent. With the first application, the effect of chlorine is to minimize odours from the sedimentation tanks. When fed to the final effluent, chlorine has a disinfectant effect.

The purpose of the sedimentation tanks, both preliminary and final, is to separate solids from the waste-water flow; the solids removed must be given further treatment. At the D.C. plant these solids are exposed to anaerobic digestion and dewatering on vacuum filters. The final product is a moist cake with approximately 70 percent water, suitable for land application as a soil conditioner. During the digestion of sludge, a gas consisting of approximately two-thirds methane is produced that is burned for heat for the plant buildings and to provide some power generation. The sludge gas has a heat value of about 600

Basic steps in the sewage disposal process of the District of Columbia Water Pollution Control Plant.

BTU (British thermal units) per cubic foot and the quantity produced is about one cubic foot per person, per day. A sludge gas engine of 1,200 horsepower drives an 800-kilowatt generator for production of electric power. Initially, the power produced supplied about 95 percent of the needs of the plant, but with the growth of the plant, power requirements have increased rapidly and now the gas engine supplies only a minor proportion of the electric power. It supplies, however, through its jacket water-cooling system, a large amount of the heat necessary to maintain active biological digestion in the sludge digestion tanks.

The total cost of the plant exceeds \$25,000,000 and the annual operating costs in the late 1960s approximated \$2,500,000. Over 250 persons are employed in operation and maintenance.

The full extent of the undertaking may be appreciated when the vast waste-water collection system serving property throughout the area is visualized. In the District of Columbia alone, over 1,700 miles of sewers serve this purpose, while 2,700 miles in the Maryland area give similar service to the properties of that jurisdiction. The maintenance of the system is a major activity, as 200 men are engaged in regular maintenance and minor construction related to the sewer system in the District of Columbia alone. Proper maintenance involves regular inspection of the lines and periodic cleaning to avoid difficulties that could cause great inconvenience and possibly property damage to those served by the drainage system.

WORLDWIDE SEWAGE DISPOSAL PROBLEM

Sewage disposal in non-Western areas is progressing at a rapid pace. The growth of cities and industries has made it necessary for such areas to have public water supplies. The full advantages of a public water supply cannot be realized without a proper drainage system that will remove promptly the used waste water along with the wastes contributed by its use. The advanced state of public health protection from persons living in an environment

served by proper water and sewer service is properly credited to the advantage of these services.

Since World War II Japan has been converting from its outdated agricultural utilization of raw sewage to the modern water-carried drainage system. To build such a system in a metropolis like Tokyo with its population exceeding 11,000,000 is truly a herculean task. The traditional communal bathhouses of Tokyo neighbourhoods eventually will be replaced by household plumbing systems. Thailand, India, Pakistan, and many countries on the African continent are following this pattern. Eastern as well as western Europe has its pollution problems; such densely populated countries as Romania, Czechoslovakia, Hungary, and Poland have intensive programs of water-pollution control under way. In areas where water is extremely short, such as Israel and South Africa, reclamation after full waste-water treatment is practiced. In Windhoek, South West Africa, approximately one-third of the waste water is circulated back to the domestic water supply; plans are being made to increase the return to 50 percent. This is accomplished by following the conventional methods of waste-water treatment with more refined techniques to restore the water to a completely satisfactory public-health quality. At the same time the chemical characteristics of the water are improved, and hardness is reduced. The city of Bangkok, Thailand, is pursuing a gigantic program involving complete reconstruction of its water system and its sewer system along the most modern lines, including a high degree of recycling.

Future problems in the field include proper means of financing the construction and operation of sewer systems including such appurtenances as pumping stations and plants for the control of water pollution, but most significantly higher and higher degrees of waste-water treatment. Research in progress in many countries of the world promises to achieve a high degree of reclamation, and even recycling at reasonable cost.

The control of water pollution is not dependent wholly on the civil and environmental engineers who customarily design the facilities for the collection and treatment of waste waters. For the intelligent operation of such structures, the cooperation of chemists, biologists, bacteriologists, and limnologists (freshwater scientists) has been considered essential for many years. Now, with the added emphasis on ecology and environment, the application of the principles of these broad fields of biology must also be included to meet the problems of the growing world population and its demands for a greatly improved environment.

Sex and Sexuality

Sex, sexuality, and reproduction are all closely interwoven into the fabric of living things, both animal and plant. All relate to the propagation of the race and the survival of the species. Yet there can be sex without sexuality, and reproduction need not be sexual, although for most forms of life sexual reproduction is essential both for propagation and long-term survival. (For the process of sex in human beings, see SEXUAL BEHAVIOUR, HUMAN.)

SEXUAL AND NONSEXUAL REPRODUCTION

Since the life-span of all individual forms of life, from microbes to man, is limited, the first concern of any particular population is to produce successors. This is reproduction, pure and simple. Among lower animals and plants it may be accomplished without involving eggs and sperm. Ferns, for example, shed millions of micro-

scopic, nonsexual spores, which are capable of growing into new plants if they settle in a suitable environment. Many higher plants also reproduce by nonsexual means. Bulbs bud off new bulbs from the side. Certain jellyfish, sea anemones, marine worms, and other lowly creatures bud off parts of the body during one season or another, each thereby giving rise to populations of new, though identical, individuals. At the microscopic level, single-celled organisms reproduce continually by growing and dividing successively to give rise to enormous populations of mostly identical descendants. All such reproduction depends on the capacity of cells to grow and divide, which is a basic property of life. In the case of most animals, however, particularly the higher forms, reproduction by nonsexual means is apparently incompatible with the structural complexity and activity of the individual.

Although nonsexual reproduction is exploited by some creatures to produce very large populations under certain circumstances, it is of limited value in the long run. Such so-called vegetative forms of reproduction, whether of animals or plants, result in individuals that are genetically identical with the parent. All have exactly the same genetic, or inherited, traits, for better or worse. If some adverse environmental change should occur, all would be equally affected and none might survive. At the best, therefore, nonsexual reproduction can be a valuable and perhaps an essential means of propagation, but it does not exclude the need for sexual reproduction.

Sexual reproduction not only takes care of the need for replacement of individuals within a population but gives rise to populations better suited to survive under changing circumstances. In effect it is a kind of double assurance that the race or species will persist for an indefinite time. The great difference between the two types of reproduction is that individual organisms resulting from nonsexual reproduction have but a single parent and are essentially alike, whereas those resulting from sexual reproduction have two parents and are never exact replicas of either. Sexual reproduction thus introduces a variability, in addition to its propagative function. Both types of reproduction represent the capacity of individual cells to develop into whole organisms, given suitable circumstances. Sex is therefore something that has been combined with this primary function and is responsible for the capacity of a race to adapt to new environmental conditions.

Sex cells. The term sex is variously employed. In the broad sense it includes everything from the sex cells to sexual behaviour. Primary sex, which is generally all that distinguishes one kind of individual from another in the case of many lower animals, denotes the capacity of the reproductive gland, or gonad, to produce either sperm cells or eggs or both. If only sperm cells are produced, the reproductive gland is a testis, and the primary sex of the tissue and the individual possessing it is male. If only eggs are produced, the reproductive gland is an ovary, and the primary sex is female. If the gland produces both sperm and eggs, either simultaneously or successively, the condition is known as hermaphroditic. An individual, therefore, is male or female or hermaphrodite primarily according to the nature of the gonad.

As a rule, male and female complement each other at all levels of organization: as sex cells; as individuals with either testes or ovaries; and as individuals with anatomical, physiological, and behavioral differences associated with the complementary roles they play during the whole reproductive process. The role of the male individual is to deliver sperm cells in enormous numbers in the right place and at the right time to fertilize eggs of female individuals of the same species. The role of the female individual is to deliver or otherwise offer eggs capable of being fertilized under precise circumstances. In the case of hermaphrodite organisms, animal or plant, various devices are employed to ensure cross-fertilization, or cross-pollination, so that full advantage of double parentage is obtained. The basic requirement of sexual reproduction is that reproductive cells of different parentage come together and fuse in pairs. Such cells will be genetically different to a significant degree, and it is this fea-

Nonsexual
reproduction

Recirculation

ture that is essential to the long-term well-being of the race. The other sexual distinctions, between the two types of sex cell and between two individuals of different sex, are secondary differences connected with ways and means of attaining the end.

Sexuality: complementary mating types. The complementarity of both male and female sex cells and male and female individuals is a form of division of labour. Male sex cells are usually motile cells capable of swimming through liquid, either freshwater, seawater, or body fluids, and they contribute the male cell nucleus but little else to the fertilization process. The female cell also contributes its nucleus, together with a large mass of cell substance necessary for later growth and development following fertilization. The female cell, however, is without any capacity for independent movement.

In other words, small male cells (sperm cells, spermatozoa, or male gametes) are burdened with the task of reaching a female cell (egg, ovum, or female gamete), which is relatively large and awaits fertilization. A full complement of genes is contributed by both nuclei, representing contributions by both parents, but, apart from the nucleus, only the egg is equipped or prepared to undergo development to form a new organism. A comparable division of labour is seen in the distinction between male and female individuals. The male possesses testes and whatever accessory structures may be necessary for spawning or delivery of the sperm, and the female possesses ovaries and what may be needed to facilitate shedding the eggs or to nurture developing young. Accordingly there is the basic sex, which depends on the kind of sex gland present, and sexuality, which depends on the different structures, functions, and activities associated with the sex glands.

THE ADAPTIVE SIGNIFICANCE OF SEX

When two reproductive cells from somewhat unlike parents come together and fuse, the resulting product of development is never exactly the same as either parent. On the other hand, when new individuals, plant or animal, develop from cuttings, buds, or body fragments, they are exactly like their respective parents, as much alike as identical twins. Any major change in environmental circumstances might exterminate a race since all could be equally affected. When eggs and sperm unite, they initiate development and also establish genetic diversity among the population. This diversity is truly the spice of life and one of the secrets of its success; sex is necessary to its accomplishment.

In each union of egg and sperm, a complete set of chromosomes, representing a complete set of genes, is contributed by each cell to the nucleus of the fertilized egg. Consequently, every cell in the body inherits the double set of chromosomes and genes derived from the two parental cells. Every time a cell divides, during the long period of development and growth, each daughter cell receives exact copies of the original two sets of chromosomes. The process is known as mitosis. Accordingly, any fragment of tissue has the same genetic constitution as the body as a whole and therefore inevitably gives rise to an identical individual if it becomes separated and is able to grow and develop. In the case of the tissue that produces the sex cells do cells divide differently, and genetic differences occur as a result.

During the ripening of the sex cells, both male and female, cell divisions occur (known as meiosis) that result in each sperm and egg cell having only a single set of chromosomes. In each case the set of chromosomes is complete—*i.e.*, one chromosome of each kind—but each such set is, in effect, drawn haphazardly from the two sets present in the original cells. In other words, the single set of chromosomes present in the nucleus of any particular sperm or egg, while complete in number and kinds, is a mixture, some chromosomes having come from the set originally contributed by the male parent and some from the female. Each reproductive cell, of either sex, therefore contains a set of chromosomes different in genetic detail from that of every other reproductive cell. When these in turn combine to form fertilized eggs or fertile

seeds, the double set of chromosomes characteristic of tissue cells is re-established, but the genetic constitution of all such cells in the new individual will be the same as that of the fertilized egg—two complete sets of genes, randomly derived from sets contributed by the two different parents. Variation is thus established in two steps. The first is during the ripening of the sex cells, when each sperm or egg receives a single set of chromosomes of mixed ancestry. None of these cells will have exactly the same combination of genes characteristic of the respective parent. The second step occurs at fertilization, when the pair of already genetically unique sex cells fuse together and their nuclei combine, thus compounding the primary variation.

Reproduction and evolution. Sexual reproduction appears to be a process serving two opposing needs. The individuals produced must be almost exactly like their parents if they are to succeed; *i.e.*, to grow and reproduce in turn, under the prevailing circumstances. At the same time they should exhibit a wide range of differences so that some at least can survive under different environmental circumstances. The first business of reproduction is to produce perfect working copies of the parental organism, without any mistakes. The second is to introduce novelties; *i.e.*, new models that make possible other life styles. Extreme conservatism, in either sexual or nonsexual reproduction, may be disastrous to the species in the long run. Extreme variability may also be detrimental, resulting in the production of too high a percentage of misfits. A delicate balance has to be struck. Variability is necessary but must be kept within bounds. Sex is responsible for controlled diversity, without which adaptation and evolution could not take place.

Natural selection operates in two ways on this basic diversity inherent in any particular population or community. In a stable environment, where there is little change during a long period of time, except for the regular changes associated with the seasons and the daily cycle, those individuals most likely to survive and produce offspring are precisely those that are most like their parents at all stages of their existence. The more radical departures from the established types fail either to grow or to compete successfully and consequently do not reproduce. The less radical departures struggle along but leave progeny in proportionately smaller numbers. If, however, a significant long-term change occurs in the environment, the previously established types are likely to suffer, while other types that previously had been weeded out generation by generation now may be favoured. They may become the more successful at surviving and growing and consequently replace themselves more readily than do others. They, in turn, become the establishment, and the older type is jeopardized. A constant interplay persists between a changeable environment and a variable population. This is adaptation. If environmental change continues in the same general direction, adaptation also continues in the initial direction, and eventually significant evolution becomes apparent.

The variability or diversity resulting from sexual reproduction is vital in two ways. It permits the process of natural selection to work and allows a population of organisms to adapt to new conditions. It also serves as a corrective mechanism. During nonsexual reproduction, particularly of single-cell organisms, large populations of virtually identical individuals are readily built up and maintained for a great many generations. Sooner or later, however, more and more abnormalities appear and, usually, a general waning of vigour ensues. When such organisms subsequently fuse together in pairs, equivalent to sexual reproduction, a rejuvenation and re-establishment of health; strains generally follows.

Life cycles adjusted to environmental change. Both sexual and nonsexual reproduction may be exploited or adjusted to meet widely fluctuating environmental conditions, especially those of a regular seasonal character. This phenomenon is particularly striking in the case of the smaller or simpler forms of animal and plant life that have a life-span of a year or less. The seeds of annual plants germinate in the spring, grow and set seed in turn

The role of each sex

Significance of reproduction

during the summer, and die in the fall. Only the sexually produced seeds persist and represent the species during the long winter season. Certain small, though common, freshwater creatures have a similar cycle. The microscopic eggs of *Hydra* and of *Daphnia*, for example, lie at the bottom of ponds throughout the winter, each within a tough protective case. In late winter or early spring, a new generation of hydras develops, each individual becoming attached to a stone or vegetation and feeding on small crustaceans by means of its long slender tentacles. The daphnias, or so-called water fleas, emerge at about the same time and grow rapidly to maturity. In both cases the growing season, usually from spring until fall, is a time for intensive reproduction by whatever means is most effective. Hydras bud off new hydras continually, each new hydra repeating the process, with the size of populations limited only by available food. Only late in the season, when the food supply drops off and the temperature drops, does the riotous splurge of nonsexual reproduction come to an end. Then each individual ceases to bud and produces either minute ovaries or testes, and in some species, both. Eggs become fertilized, encased, drop into the mud, and await the coming of the following spring, while the parental creatures die as living conditions worsen with approaching winter. Such is a general pattern of life, widely seen among creatures whose individual existence is measured in weeks or months but whose race must persist in some form at all times if extinction is to be avoided.

So it is with *Daphnia* and many others. The *Daphnia* also changes according to the times, but it alternates between one form of sexual reproduction and another. Sexually, it is exquisitely adapted to the little world in which it lives. Under ideal conditions every member of a *Daphnia* community is female. All those first hatching out from winter eggs in the spring are females. Each produces a succession of broods during the month or two of its individual existence, all offspring being females. Each such female, generation after generation, during the spring and summer season, produces eggs that develop at once without need or opportunity of being fertilized. No males in fact are present. Every individual is a self-sufficient breeding female. Population explosions occur wherever environmental circumstances are good. Eventually, however, conditions inevitably change for the worse, either because of effects inherent in any population explosion or because every season comes to an end. Food becomes scarce because of too many consumers; space becomes crowded and in some degree polluted; chilly days succeed the warmth of summer. Whatever it is, and well before disaster can strike, the creatures respond in remarkable ways. On the first signal that conditions may be getting less than good, a certain number of the eggs produced by a population of *Daphnia* develop into males, each with testes in place of ovary, together with certain secondary sexual characteristics. A scattering of males through the virgin paradise, however, is only a first step, a preparedness in case conditions go from bad to worse. If there has been a false alarm, the females continue to produce female-producing eggs that develop parthenogenetically—i.e., without benefit of fertilization—and the males die off without performing any sexual function. But if the environmental signal means the beginning of the end of congenial conditions, a cell in the ovary of each female grows to form a larger egg than usual, and it is of a type that must be fertilized. Then mating between the sexes takes place, and these special, fertilized eggs become thickly encased and alone survive the winter season after becoming separated from the parent.

Wherever small aquatic creatures live in bodies of water that may freeze in winter or dry up in summer, similar adaptations are seen in many forms of life besides hydras and water fleas. Certain small fish, known as the annual fishes, have individual life-spans of about six months. The life-span itself is in fact adapted to the period during which active existence is possible in their particular habitat. When the water holes, swamps, and puddles in which they live begin to dry up, mating takes place, and the fertilized eggs drop into the mud. The parents die, and the

eggs remain in a state of suspended development until the next rainy season occurs. The race must go on whatever the circumstances, and all sex is directed toward this end.

THE ORIGIN OF SEX AND SEXUALITY

All sexual reproduction, no matter how large or small the organisms may be, is a performance of single cells. Only at the level of single cells can the essential genetic recombinations be accomplished. So in every generation new life begins with the egg, which is a single cell, however large it may be. Egg and sperm unite at fertilization, but the fertilized egg is as much a single cell as before. When did it all begin? The generally accepted answer is that the fundamental, or molecular, basis of sexuality is an ancient evolutionary development that goes back almost to the beginning of life on earth, several billion years ago, for it is evident among the vast world of single-celled organisms, including bacteria.

In these lowest forms of life, sex and reproduction are distinct happenings. Reproduction is accomplished in most cases entirely by fission, which is simply cell division repeated regularly, as long as the environmental conditions permit. As long as crowding and other adverse changes are avoided, cells divide, and the daughter cells grow and divide again, for weeks or months on end. This process occurs in both plantlike and animal-like single-celled organisms and in bacteria as well. Under certain other conditions, such cell organisms come together and fuse in pairs, a form of sexual behaviour at its primary level and comparable to the fusion of an egg and sperm. In all such cases, a combined cell is produced in which nuclear exchange or recombination has occurred. Pairing off of this sort takes place sooner or later in all forms of unicellular life, even where no outwardly distinguishable differences can be detected between the pairing individuals. The lack of discernible differences between the members of mating pairs, however, does not mean that pairing occurs between identical individuals. In the much investigated *Paramecium* and other protozoan organisms, two separate populations of cells may continue to increase almost indefinitely by ordinary cell division of single individuals, but when two such populations are mixed together, mating generally occurs immediately between individuals from the two different sources. The fusion, or pairing, has essentially the same function as the fusion of the male and female nucleus during the process of fertilization of eggs of higher forms. It is the basis of sex, the essential event in all cases being the genetic or chromosomal recombination.

Individual mating cells (i.e., eggs, sperm, or even whole single-celled organisms) may be called gametes whether or not they are distinguishable from one another. Yet even among the various single-celled organisms, mating commonly occurs between individuals of two different kinds. This kind of mating is seen most often among the single-celled organisms known as flagellates. In some species the gametes may be alike and all are motile, progressing through the water by means of one or more whiplike flagella similar to the tail of a sperm. In other species, all individuals may still be motile, but pairing occurs between individuals of different sizes. In still others, one of the two mating types may be very small and motile, and the other, large, with stored nutritional material, and nonmotile. All degrees of differentiation between male and female gametes can be found, and it is probable that the basic and characteristic distinction between the sex cells of both animal and plant life in general was established very early in the course of evolution, during the immense period of time when virtually all living organisms consisted of single cells.

This division of labour between mating types, male and female, respectively, is nature's way of attaining two ends. These are the bringing together of the gametes so that fusion may take place and the accumulation of reserves so that development of a new organism can be accomplished. The first calls for as many motile cells as possible; the second calls for cells as large as possible. These different requirements are practically impossible to satisfy by a single type of cell. Accordingly, and especial-

Parthenogenesis

Kinds of gametes

ly in multicelled animals of all sorts, male gametes, or spermatozoa, are extremely small, extremely motile, and are produced in enormous numbers. The larger the number, the greater the likelihood that **some** will encounter and fertilize eggs. On the other hand, the female gametes, or ova, individually need to be as large as possible since the larger the size and the more condensed the internal nutritional reserves, the farther along the path of embryonic development the egg can travel before hatching must occur and the new organism must fend for itself. Nevertheless, eggs in general are caught between the desirability of being individually as large as they can be and the persisting need to be produced in reasonably large numbers, so that an assortment of differing individuals is produced from a **single** pair of parents. A large number of offspring ensures that a proportion, at least, will survive the environmental hazards faced by all developing organisms in some degree.

Differentiation of the sexes. Animals and plants, apart from microscopic kinds of life, consist of enormous numbers of cells coordinated in various ways to form a single organism, and each consists of many different kinds of cells specialized for performing different functions. Certain tissues are set aside for the production of sexual reproductive cells, male or female as the case may be. Whether they are testes or ovaries or, as in some animals and plants, both together in the same parental individual, they are typically contained within the body, and therefore the sex cells usually need to be passed to the outside in order to function. Only in certain lowly creatures such as hydras is there a simpler state, for in hydras the testes and ovaries form in the outermost layer of cells of the slender, tubular body, and the sex cells when ripe burst directly from the simple, bulging gonads into the surrounding water. With few other exceptions, in all other creatures the gonads are part of the internal tissues and **some** means of exit is necessary. In **some**, such as most worms, all that is needed are small openings, or precisely placed pores, in the body wall through which sperm or eggs can escape. In most others, more is needed and a tubular sperm duct or an oviduct leads from each testis or ovary, through which the sex cells pass to the exterior. This is minimal equipment, except where none is needed. The gonad and its duct is accordingly comparable to other glands in the body; that is, the gland is generally a more or less compact mass of cells of a particular, specialized kind, together with a duct for **passage** of the product of the tissue to the site of action. Gonads secrete—*i.e.*, produce and transmit—sex cells that usually act outside the body.

Differentiation between the sexes exists, therefore, as the primary difference represented by the distinction between eggs and sperm, by differences represented by nature of the reproductive glands and their associated structures, and lastly by differences, if any, between individuals possessing the male and female reproductive tissues, respectively.

Sex cells, sexual organs, other sexual structures, and sexual distinction between individuals constitute a series of evolutionary advances connected with various changes and persisting needs in the general evolution of animals and, to some degree, of plants as well. In other words, no matter how large or complex a creature may become, it still needs to deliver functional sex cells to the exterior. This condition is almost always the case for sperm cells. Among aquatic animals, particularly marine animals whose external medium, the ocean, is remarkably similar chemically to the internal body fluid medium of all animals, eggs are also in most cases shed to the exterior, where development of the fertilized eggs can proceed readily. Even so, time and place are important. Starfish, sea urchins, and many others, for instance, accumulate mature eggs and sperm in the oviducts and sperm ducts until an appropriate time when all can be shed at once. When one member of a group of such creatures begins to spawn, chemicals included in the discharge stimulate other members to do the same, so that a mass spawning takes place. One might say that the more they are together the more variable their offspring may be. This situation

actually is the crux of the matter for nearly all forms of life, because while it may be possible for a single individual to possess both male and female gonads, producing both **sperm** and eggs, it remains generally desirable, if not essential, that eggs be fertilized by sperm produced by another individual. Cross-fertilization results in a much greater degree of variability than does self-fertilization. The existence of two types of individuals, male and female, is the common means of ensuring that cross-fertilization will be accomplished, since then nothing else is possible. Where **the** sexes are separate, therefore, all that is necessary is that members of the opposite sex get together at a time and place appropriate for the initial development of fertilized eggs. Typically, spawning of this sort is a communal affair, with many individuals of each sex discharging sex cells into the surrounding water. This process is only suitable, however, when eggs are without tough protective cases or **membranes**; that is, only when eggs are readily fertilizable for some time after being shed and while drifting in the sea. In this circumstance there is no need for individuals of the opposite sex to mate in pairs, nor is such mating practiced.

Mating. Mating between two individuals of the opposite sex becomes necessary when eggs must be fertilized at or before the time the eggs are shed. Whenever eggs have a protective envelope of any kind through which sperm cannot penetrate, fertilization must take place before the envelope is formed. The envelope may at first be a gluey liquid, which covers the egg and solidifies as a tough egg case, as in all crustaceans, insects, and related creatures. It may be a thick membrane of protein deposited around the egg, as in fishes generally; or it may be a material that swells up as a mass of jelly surrounding the eggs after the eggs have been shed, as in frogs and salamanders. And finally, it may be a calcified shell, as in birds and reptiles. In all of these organisms the sperm must reach the egg before the protective substance is added, except in those forms in which a small opening or pore persists in the egg membrane through which sperm can enter.

When and how such eggs need to be fertilized depends on the nature of the protective membranes and the time and place of their formation. The jelly surrounding frog and toad eggs, for instance, swells up immediately after the eggs are shed. Mating and fertilization must take place at the time of spawning. Male frogs mount the back of female frogs and each clasps his **mate** firmly around the body, which not only helps press the egg mass downward but brings the cloacal opening of male and female close together. Eggs and sperm are shed simultaneously, and the eggs are fertilized as they leave the female body. Fish eggs are also fertilized as or shortly after they are shed, although fish have no arms and mating generally is usually no more than a coming together of the two sexes side by side, so that **simultaneous** shedding of sperm and eggs can be accomplished. In other creatures the mating procedure may be much more complicated, depending on various circumstances. Crustaceans such as crabs and lobsters, for example, **mate** in somewhat the same manner as frogs, with the male holding on to the female by means of **clawlike** appendages and depositing sperm at the openings of the oviducts, which are typically situated near the middle of the undersurface of the body.

Mating modifications imposed by the land environment. Greater problems arise on land than in water. Eggs produced by truly terrestrial creatures are either retained in **the** parental body during their development or must be fully protected from drying up. Protective membranes must be tough indeed. More importantly, however, sperm cells must still be deposited where they can swim toward the eggs, for they cannot survive or function except in a watery solution of dilute salts. In all terrestrial creatures, except those that return to water to breed, sperm can survive only in the body of the **male** or female organism. All insects, therefore, must **mate** in order for eggs to be fertilized, and all have appendages at the rear of the body that serve as a copulatory device capable of being used even when in flight. Sperm is injected into the female's duct or storage sac, either for immediate fertilization or for later use. The queens of bees,

The value of cross-fertilization

ants, and termites, in fact, mate once and for all during a nuptial flight and thereafter use the stored sperm to fertilize all the eggs they subsequently produce.

The land vertebrates have to cope with much the same breeding circumstances as the insects. Man is more aware of these procedures because they happen mostly in much larger creatures and also because he has some fellow feeling for them. Reptiles, birds, and even the most primitive surviving mammals — namely, the platypus and spiny anteater of Australasia — produce yolk eggs encased in a more or less rigid calcareous shell. Moreover, within the shell, a thick layer of albumen surrounds the egg proper. Both the albumen and the shell are added after the ovum leaves the ovary and during its passage down the oviduct. Fertilization must take place, if at all, as the eggs enter the oviduct, for neither the albumen nor the shell can be penetrated by spermatozoa. Sperm must therefore be introduced into the female and must be able to make their way up to the end of the oviduct, which is a very long journey for so small a cell. An enormous number must begin the journey to make sure that some will reach the goal.

Sexual anatomy. In reptiles and birds of both sexes, as in amphibians and fish, a single opening to the exterior serves jointly for both the intestine and reproductive duct. This is the cloaca, or vestibule. Nevertheless, copulation of a sort occurs in all three groups of terrestrial vertebrates: the reptiles, birds, and mammals. With the exception of man, the male always mounts the female from the rear or back, and in both reptiles and birds the cloacal openings are pressed closely together to form a continuous passage from one individual to the other. With one exception, the archaic tuatara (*Sphenodon*) of New Zealand, all present-day reptiles have an erectile penis, derived from the cloacal wall, that delivers the sperm into the proper duct. One mating may serve for a long time, and there are cases known in which female snakes have laid fertile eggs after months and sometimes years of isolation in captivity. On the other hand, a penis of any sort is lacking in most kinds of birds, and the pressing together of the cloacal apertures seems to serve well enough. The most advanced copulatory procedure is that of mammals. In mammals the cloaca has become replaced by separate openings for the reproductive duct and intestine, respectively. Eggs have become microscopic, devoid of shell, yolk, and virtually all albumen, although they still need to be fertilized as they enter the upper end of the oviduct. A well-developed, erectile penis is always present in the male for the ejaculation of stored sperm well up the reproductive passage of the female. Accordingly, the two sexes have become strikingly differentiated anatomically, with regard to delivery of sperm, compared with the seemingly primitive anatomical equipment of birds.

Courtship. The coming together of two members of the opposite sex is a necessary preliminary to mating. It may be accomplished by two individuals independently of any larger congregation, or it may result from two individuals pairing off within a breeding population that may have assembled even from the ends of the earth. In the one the problem is to find one another; in the other the problem is to find the appropriate place, called the staging area. In both cases timing and some sort of navigation are important. Mass assembly appears to be the more effective, although a local crowd of any kind of animal may be an open invitation to predators, human or otherwise, and may on occasion become disastrous.

The searching out of a solitary individual by another of the opposite sex can be a difficult matter. In the dark depths of the ocean, for instance, where fish and other marine life forms are extremely scarce and scattered, the chance of encounter is rare indeed. The small angler fish (*Photocorynus spiniceps*) that cruise around at great depths are most unlikely to meet a member of the opposite sex at a time or place when the female happens to be ready to shed her eggs. As a form of insurance to this end, however, any small, young male that happens to meet a large female, apparently at any time, immediately fastens on to her head or sides by his jaws and thereafter

lives a totally parasitic existence sustained by the juices of the female body. Sperm thus becomes available at any time the female may produce eggs to be fertilized.

On land this individual procedure of searching out is common among insects and the more predatory mammals. Male crickets and cicadas sound their familiar signals, by night or by day, which attract any females within hearing distance. More remarkable are those insects and other creatures that produce living light, in some cases for no apparent purpose but in others, such as the firefly, for signalling between the sexes in the dark of summer nights. The male individuals, always more dispensable than females, fly freely at considerable risk, flashing their light at regular intervals. The light of the female, perched more safely on some tall grass, winks back as though it were a landing light, and so they come together. Each of the several species of firefly has its own flash code, or rhythm, and any wasteful attempt at interspecies mixing is avoided. On the same principle, female moths send their personal perfume into the night air, and those males that detect the scent fly toward the source, the winner taking all. Mammals also depend mainly on their sense of smell, being generally colour blind, not too attentive to sound, and, apart from the grazing and browsing creatures, mainly active at night. The scented sex appeal of a cat in heat, whether domestic or wild, excites all the males in the neighbourhood and, with or without the sound of voice, male and female come quickly together in the dark. In all of these, courting is mostly uncalled for since only ready-to-mate individuals are involved in this sexual searching in the dark.

Courting is necessary whenever the male is a supplicant. A female may not be ready to mate, and stimulation in the form of dance or song may be required to create the mood; or, as is commonly the case, there is a surplus of available and eager males, and one must be chosen among many. However it may be, courting is most practiced not only when the female is in command of the final outcome but also when the mating procedure presents certain difficulties. A small male spider dances before a larger and ever ravenous female in an effort to induce her sexual interest rather than her hunger. Birds especially, however, depend on courtship as a preliminary to mating. The mating of birds represents copulation in its simplest form, without benefit of significant anatomical devices. Bird wings are a poor substitute for arms in a sexual embrace. Consequently the fullest cooperation between male and female is essential to success. In most birds a long-lasting, often lifetime, bonding becomes established between a male and female, a bonding that is usually reinforced by ritual behaviour at certain intervals, particularly during the onset of each breeding season and on various occasions when the individuals meet after short periods of separation. In some species a new mate may be taken each season or, as in sparrows, a general promiscuity may prevail.

One important aspect of courtship concerns the question of recognition. In gull colonies, for instance, members of the opposite sex look very much alike, and, at least to humans, the various individuals of one sex or the other may appear exactly the same. The advantages, with regard to successful production, incubation, and rearing of eggs and young, of permanent or semipermanent mate selection, however, are as great in gull colonies as elsewhere. The preliminaries to such a mutual selection not only establish a bond, by various posturings, but also establish the many small idiosyncrasies of action that add up to individuality and make one bird distinguishable among many within a colony, at least to its mate.

Many different forms of sex-oriented behaviour have consequently evolved among birds, depending on the character and particular needs of the various species. Penguins apparently not only look alike to human observers but also to themselves. Penguins seemingly have trouble even distinguishing between the sexes. Being unable to dance or sing, though they can make a lot of noise, male penguins can do little more than offer a pebble to a prospective female. If she accepts it as a token contribution to nest making, the match is on. If it is rejected, the

animals

Sexual
attractants

suitor may have picked an unready female or even another male. In the case of most birds, however, the male can either sing, particularly the smaller kinds, or can strut and dance, with wings and feathers displayed, and some species, such as the lyre bird, continue to enchant the female by sight and sound together. In general, the need for physical mating has led to courtship and an emotional bonding between mating pairs throughout much of the animal kingdom at the higher level, particularly among birds and mammals. These are primarily utilitarian functions relating to the survival of the species, but in their fullest expression they represent what seem to man to be among the finest attributes of life.

SEX PATTERNS

Since the great value of sex as distinct from reproduction is the reassortment and recombination of genes every generation, sex cells from two separate parents ordinarily give rise to the greatest variation, unless the parental individuals are themselves too closely related to each other. The presence of male and female individuals, respectively, generally produced in approximately equal numbers, is characteristic of so much of the animal kingdom that it appears to be the natural state. All that is certain, however, is that this condition has evolved as the most effective means to the particular end, and it may have done so independently among the various more or less unrelated groups of animals. The condition of separate sexes is not a universal fact, and two sexes within the same individual is typical of the more sluggish or actually attached kinds of animal life. Earthworms, slugs, land snails, flatworms, tapeworms, barnacles, sea squirts, and some others are all double-sexed individuals, or hermaphrodites. All have ovaries and testes producing mature eggs and sperm at the same time. Nevertheless, cross-fertilization is accomplished, and self-fertilization, even though possible, is generally avoided. Of those kinds of animal life mentioned above, all except the sea squirts have well-encased eggs that need to be fertilized before being laid. Mutual copulation, whereby each member of a mating pair of individuals introduces sperm into the body of the other member, is characteristic of these creatures, with the exception of the sea squirts.

When animals shed sperm and comparatively naked eggs into the surrounding water, as is the case in sea squirts, self-fertilization is difficult to avoid. Most creatures have evolved an effective separation of the sexes between different individuals. Even so, there are more ways than one of accomplishing this. The common means is to produce male and female individuals that are constitutionally different, yet an equally effective procedure is for all individuals to be constitutionally the same but to become mature as male or female at different stages of the growth cycle. The oyster on its rock changes sex from male to female and back again once or twice a year. Certain shrimps also are hermaphrodites. Each young shrimp of this kind grows up to be a male and is fully and functionally a male when about half the size of the females. As the next season approaches, his testes shrink, no more spermatozoa are produced, and ovaries begin to enlarge. As full growth is reached, the shrimp that had been a male becomes a typical female, ready to mate again, but this time with a young male of a newer generation. The system works as well as any other and clearly has its points. In fact the hagfish, not a true fish but a more primitive jawless vertebrate, also changes sex regularly, from year to year.

Sex differences in animals. In many animals, sexual differences are apparent in addition to the primary sex differentiation into males with testes and females with ovaries and apart from the accessory structures and tissues associated with the presence of one kind of sex gland or the other. Secondary sex differentiation in sexually distinct individuals is to be seen in many forms. In humans, for example, the beard and deep voice of the male and the enlarged breasts of the female are features of this sort. The great claw of the fiddler crab, the antlers of a mouse, the great bulk and strength of a harem master in a fur seal colony, the beautiful fan tail of the peacock, and

the bright feathers of other birds, are all distinctively male characteristics, and all are associated with the sexual drive of males. Females, by and large, are of comparatively quiet disposition and relatively drab appearance. Their function is to produce and nurture eggs, as safely and usually as inconspicuously as possible. The male function is to find and fertilize the female, for which both drive and display are generally required.

It is the business of sperm to be active and so find an egg. Similarly it is the business of males to find a female and mate with her if possible. The male drive, or male eagerness, is a consequence of this special function of males. In nature, males possessing a strong eagerness to mate will find more females and leave more progeny than males lacking in sex drive. The progeny moreover will tend to inherit the drive of the parent. Males therefore are generally competitive with other males, with a premium placed on physical strength and sex drive and also on various devices for the attraction and stimulation of the female. The various exclusively male features already listed are all examples of characteristics of this sort, and they are related to the securing of female mates rather than the actual fertilization of eggs or to the problems of survival and adaptation.

Seasonal or periodic sexual cycles. In most animals sexual reproduction is seasonal or rhythmical, and so is sexual behaviour, whether in the form of courtship, drive, or other activities that lead to mating. In the marine fireworm of the West Indies, for instance, individuals of both sexes live in crevices on the sea floor but come out to breed where their fertilized eggs can drift and develop in the water above. But they can only find one another by means of the luminescence they themselves produce, which is an eerie light visible only in complete darkness. Each spring or summer month they emerge and swim to the surface about one-half hour after sunset when all daylight is gone but only before the moon can rise, a situation that confines them to a monthly breeding period of three or four days after the full of the moon. They follow a lunar rhythm. So do the grunion, a common fish along the southern California coast. Here again mating takes place when all is dark and the tide is high. Pairing occurs in the wash of the waves on the sand; fertilized eggs become immediately buried and there develop until the next high spring tides reach and wash the upper level sand nearly two weeks later. The mysterious biological clocks that apparently all living things possess adjust the rhythms of life to the needs of the particular organism. Some of these timing processes call internal signals on a regular day and night basis; others, on a somewhat longer cycle that keeps pace with the moon rather than the sun; and many, especially in the larger animals, run on a seasonal, or annual, cycle. Many activities are brought into line with the regular changes occurring in the environment. Sex and reproduction, however, are adjusted mainly with regard to two functions; namely, safety while mating, which is therefore commonly in the dark, and the launching of the new generation at a time or season when circumstances are most favourable.

Birds lay eggs, and most mammals deliver their young in early spring, when the months ahead are warm and food is plentiful. Sex for the most part is adjusted to this end. Among the mammals, for example, the period of development within the womb varies greatly, from less than three weeks in the smallest to almost a year in the largest and certain others. Yet with few exceptions, the time for birth is in the spring. The time for mating in most cases is accordingly adjusted to this event: the larger the offspring at birth, the earlier the mating must take place. The horse and the great whales mate in spring and deliver in spring; roe deer mate in summer and deliver in spring; goat and sheep mate in the fall and deliver in spring. Even the elephant, which has a 22-month pregnancy, delivers in spring but must mate in early summer two years before. In small creatures, however, such as mice, rats, hamsters, and shrews, where the gestation, or pregnancy, period is about three weeks, reproduction is still seasonal, but there is time during the warmer months for several broods to be conceived and raised. In others,

Hermaphrodites

Biological control of sexual cycles

expediency may prevail, and mating may occur at a time to suit the convenience of the pairing animals. The little brown bat, for instance, mates in the fall, and yet ovulation does not take place until winter has passed; the spermatozoa survive the winter in the uterus and fertilize the eggs when they in turn arrive there five or six months later. In some other creatures mating occurs at a convenient time, eggs are fertilized, but development itself is suspended at an early stage for a time so that hatching or birthing, depending on the kind of animal, takes place when circumstances are suitable.

In all of this, the time of the mating season is clearly regulated, both with regard to the physiological condition of the animal and to the environmental conditions. The urge and capacity to mate depends on the ripeness of the gonads, male or female. In most animals the reproductive glands wax and wane according to the seasons; that is, with an annual rhythm or else with a shorter cycle. Hormones are mainly in control of this rhythm. Sex hormones, male or female, respectively, are produced by the gonads themselves and cause or maintain their growth and at the same time cause the various secondary sexual characteristics of the male or female individual to become enhanced. Male hormone increases masculinity, even when injected into a female. Female canaries injected with male hormone no longer behave as females and shortly begin to sing loud and long and commence the courtship activities of a male. A hen thus injected grows a larger comb, starts to crow, and begins to strut.

The production of these hormones is in turn controlled by hormones of the pituitary gland. Pituitary hormones stimulate ovarian or testicular tissue, which secretes the sex hormones. The sex hormones not only maintain the growth of the sexual tissues generally but inhibit the secretion of pituitary hormones, so that the process does not get out of hand. The pituitary activity, however, is also influenced by external conditions, particularly by stimuli received indirectly from light. The annual growth of ovaries or testes that occurs in late winter and early spring in frogs, reptiles, birds, and mammals is initiated by the steadily increasing period of daylight. In response to this changing day length, female frogs are packed with eggs and male frogs are ready to croak by the time the mating period arrives. The large eggs of reptiles and birds are ready to be fertilized, and the males are showing whatever they may have to display at the proper time. In mammals, the female comes into heat, the uterus undergoes the preparatory changes for taking care of fertilized eggs, and the male usually has but one thought in his mind. But as daylight ceases to lengthen, the sexual drive slowly diminishes.

SEX DETERMINATION

The determination of the sex of an individual, with regard to both the primary sex—*i.e.*, whether the ovaries or the testes develop—and the various secondary sexual characteristics may be rigorously controlled from the start of development or may be subject to later influences of a hormonal or environmental nature. However this may be, in order to appreciate the action of the control systems, the point of departure is that animals were primitively hermaphrodite, that during early stages of evolution every individual probably possessed both male and female gonads. Differentiation into separate sexes, each possessing male or female gonads but not both at the same time, is a device to ensure cross-fertilization of eggs, whether this is accomplished by having the two types of sexual gland mature at different stages of the growth of the individual, as in some shrimp and others, or whether by the production of two distinct types of individuals, as in most species of animals. This point of view is important because the question ceases to be how testes are caused to develop in the male organism and ovaries in the female but how, in a potentially double-sexed organism, the development of one or the other sex is suppressed. That such is the case is seen as clearly as anywhere in the human condition itself. Neither sex is completely male or female. Females have functional, well-developed mammary glands. Males also have mammary glands, undevel-

oped and nonfunctional although equipped with nipples. Males have a penis for delivering sperm, but females have a small, nonfunctional equivalent—the clitoris. These are secondary sexual features, to be sure, but the difference between the sexes is in the degree of their development, not a matter of absolute presence or absence.

The basis for this is seen in the very beginnings of the development of the reproductive system, in frog, mouse, and man alike. In the young embryo a pair of gonads develop that are indifferent or neutral, showing no indication whether they are destined to develop into testes or ovaries. There are also two different duct systems, one of which can develop into the female system of oviducts and related apparatus and the other into the male sperm duct system. As development of the embryo proceeds, either the male or the female reproductive tissue differentiates in the originally neutral gonad of the mammal.

In the frog and other lower vertebrate animals, the picture is even clearer. The original gonad consists of an outer layer of cells and an inner core of cells. If the individual is to be a male, the central tissue grows at the expense of the outer layer. If it is to be a female, the outer tissue grows at the expense of the central core tissue. If both should grow, which is a possibility although a rare occurrence, the individual will be a hermaphrodite. Anything that influences the direction taken therefore may be said to determine sex.

Sex chromosomes. In most species of animals the sex of individuals is determined decisively at the time of fertilization of the egg, by means of chromosomal distribution. This process is the most clear-cut form of sex determination. When any cell in the body divides, except during the formation of the sex cells, each daughter cell receives the full complement of chromosomes; *i.e.*, copies of the two sets of chromosomes derived from the sperm cell and egg, respectively. The two sets are similar except for one pair of chromosomes. These are the so-called sex chromosomes, and the pair may be exactly alike or they may be obviously different, depending on the sex of the individual. The sex chromosomes are of two types, which are designated **X** and **Y**, and the pair of sex chromosomes may consist of two **X** chromosomes or of an **X** and **Y** paired together. In mammals (including man) and flies, the cells of males contain an **XY** pair and the cells of females contain an **XX** pair. On the other hand, in butterflies, fishes, and birds, the cells of females contain an **XY** pair and those of males contain an **XX** pair. In either case the **Y** chromosome is generally smaller than the **X** chromosome and may even be absent. What is most important concerning chromosomal sex determination is whether the cells of the individual contain one **X** chromosome or two **X** chromosomes. Human beings, for example, have cells with 22 pairs of nonsexual chromosomes, or autosomes, together with an **XX** pair or an **XY** pair. The female has a total of 46 functional chromosomes; the male has 45 plus a **Y**, which is mainly inert. Sex determination thus becomes a matter of balance. With one **X** chromosome plus the 44 autosomes in every cell, the whole course of development of primary and secondary sexual characteristics is toward the male; with two **X** chromosomes plus the autosomes in every cell, the whole system is swung over to the female.

The manipulation of this control system is readily accomplished during the special process of cell division that takes place in the gonads to produce sperm and eggs and their subsequent union at fertilization. In mammals, for example, since all cells in the female contain two **X** chromosomes, all the eggs will receive a single **X** chromosome when they are formed. All eggs are accordingly the same in this respect. In contrast, all cells in the male have the **XY** constitution, and therefore, when the double set of chromosomes is reduced to a single set during the formation of the spermatozoa, half of the spermatozoa will receive an **X** and half will receive a **Y**. Consequently, when an egg is fertilized by a sperm, the chances are about equal that the sperm will carry an **X** or will carry a **Y**, since the two types are inevitably produced in equal numbers. If it carries an **X**, the **XX** female constitution results; if a **Y**, then the **XY** male constitution results.

Early development of reproductive systems in young animals

Abnormal chromosome effects. Occasionally, however, the processes of chromosomal reassortment and recombination occurring during sex cell formation and fertilization depart somewhat from the normal course. Sperm and eggs may be produced that are oversupplied or undersupplied with sex chromosomes. Fertilized eggs in humans may, for instance, have abnormal sex chromosome constitutions such as XXX, XXY, or XO. Those with the triple-X chromosome constitution have all the appearance of normal females and are called, in fact, superfemales, although only some will be fertile. Those with the XO (one X, but lacking Y altogether) constitution, a much more common condition, are also feminine in body form and type of reproduction system but remain immature. Individuals with the XXY constitution are outwardly males but have small testes and produce no spermatozoa. Those with the more abnormal and relatively rarer constitutions XXXXY and XXYY are typically mentally defective and in the latter case are hard to manage. Thus abnormal combinations generally result in an infertility on the one hand and an abnormal sexuality in the whole system, for either too little or too much of what is ordinarily good can be disastrous.

Very different kinds of abnormal development resulting from faulty chromosomal distribution are particularly observable in insects. The most common form in flies is an individual that is male on one side, female on the other, with a sharp line of demarcation. In other cases one-quarter of the body may be male and three-quarters female, or the head may be female and the rest of the body, male. These types are known as gynandromorphs, or sexual mosaics, and result from aberration in the distribution of the X chromosomes among the first cells to be formed during the early development of the embryo. This condition is unknown among higher animals.

Parthenogenesis. The unfertilized, ripe egg possesses all the totipotency for full development. The process of fertilization by a spermatozoon introduces the nucleus of the male sex cell into the female egg, a process that increases the difference between parent and offspring and may determine the sex of the new individual and also stimulates the egg to begin development. These two functions are separate. parthenogenetic development, without benefit of sperm, occurs naturally in various kinds of animals besides the waterflea (*Daphnia*), already described. Artificial, or experimental, parthenogenesis is readily brought about in many other species and by a variety of means. Mature, unfertilized eggs of starfish, sea urchins, various worms, and other marine invertebrate animals can be caused to develop by treatment with a weak organic acid. Unfertilized frog eggs can be readily caused to develop by gentle pricking of the egg surface with the tip of a fine glass needle that has been dipped in lymph. In nature the eggs of various creatures can develop with or without the aid of spermatozoa. The sex of parthenogenetically developed individuals, insofar as it depends on the chromosomal constitution of the developing egg, is consequently affected. Frog eggs developing parthenogenetically become males, since only one X chromosome is present in each cell. In nature, where varying conditions call for various responses, the system is usually more complicated, although based on the general relationship that individuals with the XX constitution will be female and those with a single X will be males. A queen honeybee, for instance, begins her reproductive life with a store of sperm received from a male during her nuptial flight. Throughout spring and summer almost all eggs become fertilized and develop into females (either as nonfertile female workers or as new fertile queens, depending on the nature of food received during growth). Toward the end of summer, when the sperm supply runs low, eggs cease to be fertilized and, when laid, develop into drones, ready to mate with a new queen should occasion arise. In other cases, even parthenogenetically developing eggs may become female individuals through a process of chromosome doubling, which takes place in the mature but unfertilized eggs. Thus certain wasps, waterfleas, and others are able to produce many exclusively female generations in succession.

Effects of environment on sex determination. Sex chromosomes, however, do not determine sex directly but do so through their control of such cell activities as metabolism and hormone production. Their determinative influence, indirect though it is, may be complete. On the other hand, environmental conditions may play the dominating role. In the case of *Bonellia*, a unique kind of marine worm, all eggs develop into small larvae of a sexually indifferent kind. Those that settle freely on the sea floor grow into comparatively large females, each of which has a long, broad extension, the proboscis, at its front end. Those larvae that happen to settle on the proboscis of a female, however, fail to grow beyond a certain minute size and become dwarf males, permanently attached to the female body. The sex-determining factor appears to be the environmental carbon dioxide tension, which is relatively high at the surface of living tissue.

Hormones. Because in most developing animals the reproductive gland is essentially neutral to begin with, there is generally some possibility that agents external to the gland, particularly chemical agents—i.e., hormones—circulating in the blood system, may override the sex-determining influence of the sex chromosomes. In the chick, for example, the sex can be controlled experimentally by such means until about four hours after hatching. If a female chick is injected on hatching with the male sex hormone, testosterone, it will develop into a fully functional cock. Even when injected at later stages of growth, the male hormone causes extra early growth of the comb, crowing, and aggressive behaviour after being injected in either male or female chicks. Female sex hormones, such as estrogen, on the other hand, stimulate early growth of the oviduct in the female and feminize the plumage and suppress comb growth when injected in the male.

This susceptibility of the reproductive glands, and sexuality in general, to the influence of sex hormones is particularly acute in mammals, where the egg and embryo, unprotected by any shell, develop in the uterus exposed to various chemicals filtering through from the maternal blood stream. A developing embryo eventually produces its own sex hormones, but they are not manufactured in any quantity until the anatomical sex of the embryo is already well established. One of the curious things about sex hormones, however, is that the reproductive glands are not the only tissues that produce them. The placenta, through which all exchange between fetus and mother takes place, itself produces tremendous amounts of female sex hormone, together with some male hormone, which are excreted by the mother during pregnancy. This condition is true of humans, as well as of mice and rats. As a rule these hormones are produced too late to do any harm, but not always. The female embryo is fairly immune inasmuch as additional female hormone merely causes a child to be more feminine than usual at an early age. Male embryos, however, may be seriously affected if the female hormone catches them at an early stage. Boy babies may be born that are truly males but under the impact of the feminizing hormone appear superficially to be females and are often raised as such. As a rule, even when older, they have more or less sterile, undescended testes; an imperfect penis; well-developed breasts; an unbroken voice; and no beard. One in a thousand may be like this and on occasion may have won in women's Olympic competitions. In other cases, those somewhat less severely affected, during adolescence when the hidden testes begin to secrete their own male hormones in abundance, the falsely female characteristics become suppressed, and the voice, beard, breasts, and sexual interest take on the pattern of the male. What were thought to be girls in their youth change into the men they were meant to be upon reaching maturity.

BULLOUGH, *The Vertebrate Reproductive Cycles*, 2nd ed. (1961), a short, *concise* account of reproduction, particularly in birds and mammals, with emphasis on hormonal and seasonal controls of sexual maturity and reproduction; L.J. and M.J.G. MILNE, *The Mating Instinct* (1954, paperback ed. 1968), very inclusive and detailed descriptions of the courting and mating behaviour of animals, extensively illustrated photographically; G. PINCUS, *The Control of Fertility* (1965), a highly scientific discussion, by a pioneering authority, of the reproductive process in man and other mammals, with emphasis on the action of hormones on sex cell production, on the first stages of development, and on the problems of fertility; H. WENDT, *The Sex Life of Animals* (1965), a very descriptive account of courting and mating, and sexuality generally, throughout the animal kingdom, translated from an earlier German edition; G.C. WILLIAMS, *Adaptation and Natural Selection* (1966), an illuminating and thoughtful discussion of sexual reproduction in relation to the processes of biological evolution and adaptation.

(N.J.B.)

Sexual Behaviour, Human

Sexual behaviour may be defined as any activity—solitary, between two persons, or in a group—that induces sexual arousal. There are two major determinants of sexual behaviour: the inherited sexual response patterns that have evolved as a means of ensuring reproduction and that are a part of each individual's genetic inheritance, and the degree of restraint or other types of influence exerted on the individual by society in the expression of his sexuality. The objective of this article is to describe and explain both sets of factors and their interaction. It begins with an analysis of the range of human sexual behaviour in terms of the number and gender of the participants and goes on to describe the physiological processes involved in such activity and in the life cycle of the individual. Having thus established the physiological determinants involved, the article moves on to an account of the influence of learning and conditioning in the early years of life and the range, development, and therapy of sexual problems that are often directly related to this early conditioning and to other socially induced inhibitions. In the final section human sexuality is discussed in a much broader cultural and historical perspective, describing varying attitudes and degrees of permissiveness in different cultures and historical periods, common means of social control of sexual activity, and the influence of such factors as religion and socio-economic developments, and concluding with legal regulations of sexual activity. (For a discussion of homosexuality and other deviations, see SEXUAL DEVIATIONS.)

It should be noted that taboos in Western culture and the immaturity of the social sciences for a long time impeded research concerning human sexual behaviour, so that by the early 20th century scientific knowledge was largely restricted to individual case histories that had been studied by such European writers as Sigmund Freud, Havelock Ellis, and Richard, Freiherr von Krafft-Ebing. By the 1920s, however, the foundations had been laid for the more extensive statistical studies that were conducted before World War II in the United States. Of the two major organizations for sex study, one, the Institut für Sexualwissenschaft in Berlin (established in 1897), was destroyed by the Nazis in 1933. The other, the Institute for Sex Research, begun in 1938 by the American sexologist Alfred Charles Kinsey at Indiana University, Bloomington, undertook the study of many aspects of human sexual behaviour. Much of the following discussion rests on the findings of the Institute for Sex Research, which comprise the most comprehensive data available. The only other country for which comprehensive data exist is Sweden.

Physiological and psychological aspects

TYPES OF BEHAVIOUR

Human sexual behaviour may conveniently be classified according to the number and gender of the participants. There is solitary behaviour involving only one individual, and there is socio-sexual behaviour involving more than one person. Socio-sexual behaviour is generally divided into heterosexual behaviour (male with female) and homosexual behaviour (male with male or female with female). If three or more individuals are involved it is, of course, possible to have heterosexual and homosexual activity simultaneously.

In both solitary and socio-sexual behaviour there may be activities that are sufficiently unusual to warrant the label deviant behaviour. The term deviant should not be used as a moral judgment but simply as indicating that such activity is not common in a particular society. Since human societies differ in their sexual practices, what is deviant in one society may be normal in another.

Solitary behaviour. Self-masturbation is *self-stimulation* with the intention of causing sexual arousal and, generally, orgasm (sexual climax). Most masturbation is done in private as an end in itself but is sometimes practiced to facilitate a socio-sexual relationship.

Masturbation, generally beginning at or before puberty, is extremely common in males, particularly among young males, but becomes less frequent or is even abandoned when socio-sexual activity is available. Consequently, masturbation is most frequent among the unmarried. Fewer females masturbate; in the United States, roughly one-half to two-thirds have done so, as compared to nine out of ten males. Females also tend to reduce or discontinue masturbation when they develop socio-sexual relationships. There is great individual variation in frequency, so that it is impractical to try to define what range could be considered "normal."

The myth persists, despite scientific proof to the contrary, that masturbation is physically harmful. Neither is there evidence that masturbation is immature behaviour; it is common among adults deprived of socio-sexual opportunities. While solitary masturbation does provide pleasure and relief from the tension of sexual excitement, it does not have the same psychological gratification that interaction with another person provides; thus, extremely few people prefer masturbation to socio-sexual activity. The psychological significance of masturbation lies in how the individual regards it. For some, it is laden with guilt; for others, it is a release from tension with no emotional content; and for others it is simply another source of pleasure to be enjoyed for its own sake.

The majority of males and females have fantasies of some socio-sexual activity while they masturbate. The fantasy not infrequently involves idealized sexual partners and activities that the individual has not experienced and even might avoid in real life.

Since the masturbating person is in sole control of the areas that are stimulated, the degree of pressure, and the rapidity of movement, masturbation is often more effective in producing sexual arousal and orgasm than is socio-sexual activity, during which the stimulation is determined to some degree by one's partner.

Orgasm in sleep evidently occurs only in humans. Its causes are not wholly known. The idea that it results from the pressure of accumulated semen is invalid because not only do nocturnal emissions sometimes occur in males on successive nights, but females experience orgasm in sleep as well. In some cases orgasm in sleep seems a compensatory phenomenon, occurring during times when the individual has been deprived of or abstains from other sexual activity. In other cases it may result from external stimuli, such as sleeping prone or having night clothing caught between one's legs. Most orgasms during sleep are accompanied by erotic dreams.

A great majority of males experience orgasm in sleep. This almost always begins and is most frequent in adolescence, tending to disappear later in life. Fewer females have orgasm in sleep, and, unlike males, they usually begin having such experience when fully adult.

Attitudes
toward
mastur-
bation

Orgasm in sleep is generally infrequent, seldom exceeding a dozen times per year for males and three or four times a year for the average female.

Most sexual arousal does not lead to sexual activity with another individual. Humans are constantly exposed to sexual stimuli when seeing attractive persons and are subjected to sexual themes in advertising and the mass media. Response to such visual and other stimuli is strongest in adolescence and early adult life and usually gradually declines with advancing age. One of the necessary tasks of growing up is learning to cope with one's sexual arousal and to achieve some balance between suppression, which can be injurious, and free expression, which can lead to social difficulties. There is great variation among individuals in the strength of sex drive and responsiveness, so this necessary exercise of restraint is correspondingly difficult or easy.

Socio-sexual behaviour. By far the greatest amount of socio-sexual behaviour is heterosexual behaviour between only one male and one female. Heterosexual behaviour frequently begins in childhood, and, while much of it may be motivated by curiosity, such as showing or examining genitalia, many children engage in sex play because it is pleasurable. The sexual impulse and responsiveness are present in varying degrees in most children and latent in the remainder. With adolescence, sex play is superseded by dating, which is socially encouraged, and dating almost inevitably involves some physical contact resulting in sexual arousal. This contact, labelled necking or petting, is a part of the learning process and ultimately of courtship and the selection of a marriage partner.

Petting
and
foreplay

Petting varies from hugging, kissing, and generalized caresses of the clothed body to techniques involving genital stimulation. Petting may be done for its own sake as an expression of affection and a source of pleasure, and it may occur as a preliminary to coitus. This last form of petting is known as foreplay. In a minority of cases, but a substantial minority, petting leads to orgasm and may be a substitute for coitus. Excluding foreplay, petting is usually very stereotyped, beginning with hugging and kissing and gradually escalating to stimulation of the breasts and genitalia. In most societies petting and its escalation are initiated by the male more often than by the female, who generally rejects or accepts the male's overtures but refrains from playing a more aggressive role. Petting in some form is a near-universal human experience and is valuable not only in mate selection but as a means of learning how to interact with another person sexually.

Coitus, the insertion of the penis into the vagina, is viewed by society quite differently depending upon the marital status of the individuals. The majority of human societies permit premarital coitus, at least under certain circumstances. In more repressive societies, such as modern Western society, it is more likely to be tolerated (but not encouraged) if the individuals intend marriage. Marital coitus is usually regarded as an obligation in most societies. Extramarital coitus, particularly by wives, is generally condemned and, if permitted, is allowed only under exceptional conditions or with specified persons. Societies tend to be more lenient toward males than females regarding extramarital coitus. This double standard of morality is also seen in premarital life. Postmarital coitus (*i.e.*, coitus by separated, divorced or widowed persons) is almost always ignored. Even societies that try to confine coitus to marriage recognize the difficulty of trying to force abstinence upon sexually experienced and usually older persons.

In the United States and much of Europe, there has been, within the last century, a progressive trend toward an increase in premarital coitus. Currently in the United States, at least three-quarters of the males and over half of the females have experienced premarital coitus. The proportions for this experience vary in different groups and socio-economic classes. In Scandinavia, the incidence of premarital coitus is far greater, exceeding the 90 per cent mark in Sweden, where it is now expected behaviour.

Extramarital coitus continues to be openly condemned but is becoming more tolerated secretly, particularly if mitigating circumstances are involved. In some areas,

such as southern Europe and Latin America, extramarital coitus is expected of most husbands and is accepted by society if the behaviour is not too flagrant. The wives do not generally approve but are resigned to what they believe to be a masculine propensity. In the United States, where at least half the husbands and one-quarter of the wives have extramarital coitus at some point in their lives, there have recently developed small organizations or clubs that exist to provide extramarital coitus for married couples. Despite the publicity they have engendered, however, extremely few individuals have belonged to such organizations. Most extramarital coitus is done secretly without the knowledge of the spouse. Most husbands and wives feel very possessive of their spouses and interpret extramarital activity as an aspersion on their own sexual adequacy, as indicating a loss of affection and as being a source of social disgrace.

Human beings are not inherently monogamous but have a natural desire for diversity in their sexuality as in other aspects of life. Some societies have provided a release for these desires by suspending the restraints on extramarital coitus on special occasions or with certain individuals, and in modern Western society a certain amount of extramarital flirtation or mild petting at parties is not considered unusual behaviour.

Discussion of socio-sexual behaviour would be incomplete without some note of the role it has played in ceremony and religion. While the major religions of today are to varying degrees anti-sexual, many religions have incorporated sexual behaviour into their rites and ceremonies. The ancient and continuing interest of man in the fertility of food plants, animals, and himself makes such a connection between sex and religion inevitable, particularly among peoples with uncertain food supplies. In most religions the deities were considered to have active sexual lives and sometimes took a sexual interest in humans. In this regard it is noteworthy that in Christianity sexual behaviour is absent in heaven and sexual proclivities are ascribed only to evil supernatural beings: Satan, devils, incubi, and succubi (spirits or demons who seek out sleeping humans for sexual intercourse).

Sexuality
in
ceremony
and
religion

Whether or not a behaviour is interpreted by society or the individual as erotic (*i.e.*, capable of engendering sexual response) depends chiefly on the context in which the behaviour occurs. A kiss, for example, may express asexual affection (a mother kissing a child or a kiss between relatives), respect (as a French officer kissing a soldier after bestowing a medal on him), reverence (kissing the hand or foot of a pope), or it may be a casual salutation and social amenity. Even something as specific as touching genitalia is not construed as sexual if done for medical reasons. In other words, the apparent motivation of the behaviour determines its interpretation.

Individuals are extremely sensitive in judging motivations: a greeting kiss, if protracted more than a second or two, takes on a sexual connotation, and recent studies show that if an adult male at a party stands closer than the length of his hand and forearm to a female, she generally imputes a sexual motive to his proximity. Nudity is construed as erotic or even as a sexual invitation—unless it occurs in a medical context, in a group consisting of but one gender, or in a nudist camp.

PHYSIOLOGICAL ASPECTS

Sexual response. Sexual response follows a pattern of sequential stages or phases when sexual activity is continued. First, there is the excitement phase marked by increase in pulse and blood pressure, an increase in blood supply to the surface of the body resulting in increased skin temperature, flushing, and swelling of all distensible body parts (particularly noticeable in the penis and female breasts), more rapid breathing, the secretion of genital fluids, vaginal expansion, and a general increase in muscle tension. These symptoms of arousal eventually increase to a near maximal physiological level, the plateau phase, which is generally of brief duration. If stimulation is continued, orgasm usually occurs. Orgasm is marked by a feeling of sudden intense pleasure, an abrupt increase in pulse rate and blood pressure, and spasms of

the pelvic muscles causing vaginal contractions in the female and ejaculation by the male. Involuntary vocalization may also occur. Orgasm lasts for a few seconds (normally not over ten), after which the individual enters the resolution phase, the return to a normal or sub-normal physiological state. Up to the resolution phase, males and females are the same in their response sequence, but, whereas males return to normal even if stimulation continues, continued stimulation can produce additional orgasms in females. In brief, after one orgasm a male becomes unresponsive to sexual stimulation and cannot begin to build up another excitement phase until some period of time has elapsed, but females are physically capable of repeated orgasms without the intervening "rest period required by males.

Genetic and hormonal factors. While all normal individuals are born with the neurophysiology necessary for the sexual-response cycle described above, inheritance determines the intensity of their responses and their basic "sex drive." There is great variation in this regard: some persons have the need for frequent sexual expressions; others require very little; and some persons respond quickly and violently, while others are slower and milder in their reactions. While the genetic basis of these differences is unknown and while such variations are obscured by conditioning, there is no doubt that sexual capacities, like all other physiological capacities, are genetically determined. It is unlikely, however, that genes control the sexual orientation of normal humans in the sense of individuals being predestined to become homosexual or heterosexual. Some severe genetic abnormality can, of course, profoundly affect intelligence, sexual capacity, and physical appearance and hence the entire sexual life.

While the normal female has 44 autosomes plus two X-chromosomes (female) and the normal male 44 autosomes plus one X-chromosome and one Y-chromosome (male), many genetic abnormalities are possible. These are females, for example, with too many X-chromosomes ($44 + XXX$) or too few ($44 + X$) and males with an extra female chromosome ($44 + XXY$) or an extra male chromosome ($44 + XYY$). No $44 + YY$ males exist—an X-chromosome is necessary for survival, even in the womb.

One's genetic makeup determines one's hormonal status and the sensitivity of one's body to these hormones. While a disorder of any part of the endocrine system can adversely affect sexual life, the hormones most directly influencing sexuality are the androgens (male sex hormones), produced chiefly in the testicles, and the estrogens (female sex hormones), produced chiefly in the ovaries. In early embryonic life there are neither testicles nor ovaries but simply two undifferentiated organs (gonads) that can develop either into testicles or ovaries. If the embryo has a Y-chromosome, the gonads become testicles; otherwise, they become ovaries. The testicles of the fetus produce androgens, and these cause the fetus to develop male anatomy. The absence of testicles results in the development of female anatomy. Animal experiments show that, if the testicles of a male fetus are removed, the individual will develop into what seems a female (although lacking ovaries). Consequently, it has been said that humans are basically female.

After birth and until puberty, the ovaries and testicles produce comparatively few hormones, and little girls and boys are much alike in size and appearance. At puberty, however, these organs begin producing in greater abundance, with dramatic results. The androgens produced by boys cause changes in body build, greater muscular development, body and facial hair, and voice change. In girls the estrogens cause breast development, menstruation, and feminine body build. A boy castrated before puberty does not develop masculine physical characteristics and manifests in adult life more of a feminine body build, lack of masculine body and facial hair, less muscular strength, a high voice, and small genitalia. A girl who has her ovaries removed before puberty is less markedly altered but retains a childlike body build, does not develop breasts, and never menstruates. Castrated individuals or persons producing insufficient hormones can be

restored to a normal condition by administration of appropriate hormones.

Beyond their role in developing the secondary sexual characteristics of the body, the hormones continue to play a role in adult life. An androgen deficiency causes a decrease in a man's sexual responsiveness, and an estrogen deficiency adversely affects a woman's fertility and causes atrophy of the genitalia. A loss of energy may also result in both men and women.

Androgen seems linked in both males and females with aggressiveness and strength of sexual drive. When androgen is given to a female in animal experiments, she becomes more aggressive and displays behaviour more typical of males—by mounting other animals, for example. Estrogen increases her sexual responsiveness and intensifies her female behaviour. Androgen given to a male often increases his sexual behaviour, but estrogen diminishes his sex drive.

In humans the picture is more complex, since human sexual behaviour and response is less dependent on hormones once adulthood has been reached. Removing androgen from an adult male reduces his sexual capacity; but this occurs gradually, and sometimes the reduction is small. Giving androgen to a normal human male generally has little or no effect since he is already producing all he can use. Giving him estrogen reduces his sex drive. Administration of androgen to an adult human female often increases her sex drive, enlarges her clitoris, and promotes the growth of facial hair. Giving estrogen to a normal woman before menopausal age generally has no effect whatsoever—probably because human females, unlike other female mammals, do not have hormonally controlled periods of "heat" (estrus).

Hormones have no connection with the sexual orientation of humans. Male homosexuals do not have more estrogens than normal males (who have a little) nor can their preferences be altered by giving them androgen.

Nervous system factors. The nervous system consists of the central nervous system and the peripheral nervous system. The brain and spinal cord constitute the central system, while the peripheral system is composed of (1) the cerebrospinal nerves that go to the spinal cord (afferent nerves), transmitting sensory stimuli and those that come from the cord (efferent nerves) transmitting impulses to activate muscles, and (2) the autonomic system, the primary function of which is the regulation and maintenance of the body processes necessary to life, such as heart rate, breathing, digestion, and temperature control. Sexual response involves the entire nervous system. The autonomic system controls the involuntary responses; the afferent cerebrospinal nerves carry the sensory messages to the brain; the efferent cerebrospinal nerves carry commands from the brain to the muscles; and the spinal cord serves as a great transmission cable. The brain itself is the coordinating and controlling centre, interpreting what sensations are to be perceived as sexual and issuing appropriate "orders" to the rest of the nervous system.

The parts of the brain thought to be most concerned with sexual response are the hypothalamus and the limbic system, but no specialized "sex centre" has been located in the human brain. Animal experiments indicate that each individual has coded in its brain two sexual response patterns, one for mounting (masculine) behaviour and one for mounted (feminine) behaviour. The mounting pattern can be elicited or intensified by male sex hormone and the mounted pattern by female sex hormone. Normally, one response pattern is dominant and the other latent but capable of being called into action when suitable circumstances occur. The degree to which such inherent patterning exists in humans is unknown.

While the brain is normally in charge, there is some reflex (*i.e.*, not brain-controlled) sexual response. Stimulation of the genital and perineal area can cause the "genital reflex": erection and ejaculation in the male, vaginal changes and lubrication in the female. This reflex is mediated by the lower spinal cord, and the brain need not be involved. Of course, the brain can override and suppress such reflex activity—as it does when an individual decides that a sexual response is socially inappropriate.

Role of
androgen
and
estrogen

Genetic
combina-
tions
in the
sexes

Intra-uterine sexual development

Development and changes of the reproductive system. One's anatomy and sexuality change with age. The changes are rapid in intra-uterine life and around puberty but are much slower and gradual in other phases of the life cycle.

The reproductive organs first develop in the same form for both males and females: internally there are two undifferentiated gonads and two pairs of parallel ducts (Wolffian and Müllerian ducts); externally there is a genital protrusion with a groove (urethral groove) below it, the groove being flanked by two folds (urethral folds). On either side of the genital protrusion and groove are two ridgelike swellings (labioscrotal swellings). Around the fourth week of life the gonads differentiate into either testes or ovaries. If testes develop, the hormone they secrete causes the Müllerian duct to degenerate and almost vanish and causes the Wolffian duct to elaborate into the sperm-carrying tubes and related organs (the vas deferens, epididymis, and seminal vesicles, for example). If ovaries develop, the Wolffian duct deteriorates, and the Müllerian duct elaborates to form the fallopian tubes, uterus, and part of the vagina. The external genitalia simultaneously change. The genital protrusion becomes either a penis or clitoris. In the female the groove below the clitoris stays open to form the vulva, and the folds on either side of the groove become the inner lips of the vulva (the labia minora). In the male these folds grow together, converting the groove into the urethral tube of the penis. The ridgelike swellings on either side remain apart in the female and constitute the large labia (labia majora), but in the male they grow together to form the scrotal sac into which the testes subsequently descend.

At the time of birth both male and female have all the neurophysiological equipment necessary for sexual response, although the reproductive system is not at this stage functional. Sexual interests, sexual behaviour, and sexual response are seen with increasing frequency in most children from infancy on. Even newborn males have penile erections, and babies of both sexes seem to find some pleasure in genital stimulation. What appears to be orgasm has been observed in infant boys and girls, and, later in childhood, orgasm definitely can occur in self-masturbation or sex play.

Puberty may be defined as that short period of time (generally two years) during which the reproductive system matures and the secondary sexual characteristics appear. The ovaries and testes begin producing much larger amounts of hormones, pubic hair appears, female breasts develop, the menstrual cycle begins in females, spermatozoa and viable eggs are produced, and males experience voice change and a sudden acceleration in growth. Puberty generally occurs in females around age 12–13 and in males at about 13–14, but there is much individual variation. With puberty there is generally an intensification or the first appearance of sexual interest. Puberty marks the beginning of adolescence.

Adolescence, from a physical viewpoint, is that period between puberty and the attainment of one's maximum height. By the latter point, which occurs around age 16 in females and 18 in males, the individual has adult anatomy and physiology. In late adolescence the majority of individuals are probably at their peak in terms of sexual capacity: the ability to respond quickly and repeatedly. During this period the sex drive is at its maximum in males, although it is difficult to say whether this is also true of females, since female sexuality, in many societies, is frequently suppressed during adolescence.

Following adolescence there are about three decades of adult life during which physiological changes are slow and gradual. While muscular strength increases for a time, the changes may best be described as slow deterioration. This physical decline is not immediately evident in sexual behaviour, which often increases in quantity and quality as the individual develops more social skills and higher socio-economic status and loses some of the inhibitions and uncertainties that often impede adolescent sexuality. Indeed, in the case of the United States female, the deterioration is more than offset by her gradual loss of sexual inhibition, and the effect of age is not clear until

menopausal symptoms begin. In the male, however, there is no such masking of deterioration, and the frequency of sexual activity and the intensity of interest and response slowly, but inexorably, decline.

If one must arbitrarily select an age to mark the beginning of old age, 50 is appropriate. By then, most females have experienced menopausal symptoms, and most males have been forced to recognize their increasing physical limitations. With menopause, the female genitalia gradually begin to atrophy and the amount of vaginal secretion diminishes—this is the direct consequence of the cessation of ovarian function and can be prevented, or the symptoms reversed, by administering estrogen. If a female has had a good sexual adjustment prior to menopause and if she does not believe in the fallacy that it spells the end of sexual life, menopause will have no adverse effect on her sexual and orgasmic ability. There is reason to believe that if a woman remains in good health and genital atrophy is prevented, she could enjoy sexual activity regardless of age. Males in good health are also capable of continuing sexual activity, although with an ever-decreasing frequency, throughout old age. The male has more difficulty in achieving erection, cannot maintain erection as long, and must have longer and longer "rest periods" between sexual acts. The amount of ejaculate becomes less, but most old males are still fertile. The Cowper's gland secretion (called "precoital mucus") diminishes or disappears entirely. According to Kinsey's data, about one-quarter of males are impotent by age 65, one-half by age 75, and three-quarters by age 80. One must remember, however, that some unknown but certainly substantial proportion of this impotence may be attributed to poor health.

In general, the female withstands the onslaughts of age better than the male. The reduction in the frequency of marital intercourse or even its abandonment is more often than not the result of male deterioration.

PSYCHOLOGICAL ASPECTS

Effects of early conditioning. Physiology sets only very broad limits on human sexuality; most of the enormous variation found among humans must be attributed to the psychological factors of learning and conditioning.

The human infant is born simply with the ability to respond sexually to tactile stimulation. It is only later and gradually that the individual learns or is conditioned to respond to other stimuli, to develop a sexual attraction to males or females or both, to interpret some stimuli as sexual and others as nonsexual, and to control in some measure his or her sexual response. In other words, the general and diffuse sexuality of the infant becomes increasingly elaborated, differentiated, and specific.

The early years of life are, therefore, of paramount importance in the development of what ultimately becomes adult sexual orientation. There appears to be a reasonably fixed sequence of development. Before age five, the child develops a sense of gender identity, thinks of himself or herself as a boy or girl, and begins to relate to others differently according to their gender. Through experience the child learns what behaviour is rewarded and what is punished and what sorts of behaviour are expected of him or her. Parents, peers, and society in general teach and condition the child about sex not so much by direct informational statements and admonitions as by indirect and often unconscious communication. The child soon learns, for example, that he can touch any part of his body or someone else's body except the anal-genital region. The child rubbing its genitals finds that this quickly attracts adult attention and admonishment or that adults will divert him or her from this activity. It becomes clear that there is something peculiar and taboo about this area of the body. This "genital taboo" is reinforced by the great concern over the child's excretory behaviour: bladder and bowel control is praised; loss of control is met by disappointment, chiding, and expressions of disgust. Obviously, the anal-genital area is not only a taboo area but a very important one as well. It is almost inevitable that the genitalia become associated with anxiety and shame. It is noteworthy that

Sexual changes in later life

Development of genital taboo

this attitude finds expression in the language of Western civilizations, as in "privates" (something to be kept hidden) and the German word for the genitals, *Scham* ("shame").

While all children in Western civilizations experience this anti-sexual teaching and conditioning, a few have, in addition, atypical sexual experiences, such as witnessing or hearing sexual intercourse or having sexual contact with an older person. The effects of such atypical experiences depend upon how the child interprets them and upon the reaction of adults if the experience comes to their attention. Seeing parental coitus is harmless if the child interprets it as playful wrestling but harmful if he considers it as hostile, assaultive behaviour. Similarly, an experience with an adult may seem merely a curious and pointless game, or it may be a hideous trauma leaving lifelong psychic scars. In many cases the reaction of parents and society determines the child's interpretation of the event. What would have been a trivial and soon-forgotten act becomes traumatic if the mother cries, the father rages, and the police interrogate the child.

Some atypical developments occur through association during the formative years. A child may associate clothing, especially underclothing, stockings, and shoes with gender and sex and thereby establish the basis for later fetishism or transvestism. Others, having been spanked or otherwise punished for self-masturbation or childhood sex play, form an association between punishment, pain, and sex that could escalate later into sadism or masochism. It is not known why some children form such associations whereas others with apparently similar experience do not.

Around the age of puberty, parents and society, who more often than not refuse to recognize that children have sexual responses and capabilities, finally face the inescapable reality and consequently begin inculcating children with their attitudes and standards regarding sex. This campaign by adults is almost wholly negative—the child is told what not to do. While dating may be encouraged, no form of sexual activity is advocated or held up as model behaviour. The message usually is "be popular" (*i.e.*, sexually attractive), but abstain from sexual activity. This anti-sexualism is particularly intense regarding young females and is reinforced by reference to pregnancy, venereal disease, and, most importantly, social disgrace. To this list religious families add the concept of the sinfulness of premarital sexual expression. With young males the double standard of morality still prevails. The youth receives a double message, "don't do it, but we expect that you will." No such loophole in the prohibitions is offered young girls. Meanwhile, the young male's peer group is exerting a prosexual influence, and his social status is enhanced by his sexual exploits or by exaggerated reports thereof.

As a result of this double standard of sexual morality, the relationship between young males and females often becomes a ritualized contest, the male attempting to escalate the sexual activity and the female resisting his efforts. Instead of mutuality and respect, one often has a struggle in which the female is viewed as a reluctant sexual object to be exploited, and the male is viewed as a seducer and aggressor who must succeed in order to maintain his self-image and his status with his peers. This sort of pathological relationship causes a lasting attitude on the part of females: men are not to be trusted; they are interested only in sex; a girl dare not smile or be friendly lest males interpret it as a sign of sexual availability, and so forth. Such an aura of suspicion, hostility, and anxiety is scarcely conducive to the development of warm, trusting relationships between males and females. Fortunately, love or infatuation usually overcomes this negativism with regard to particular males, but the average female still maintains a defensive and skeptical attitude toward men.

Western society is replete with attitudes that impede the development of a healthy attitude toward sex. The free abandon so necessary to a full sexual relationship is, in the eyes of many, an unseemly loss of self-control, and self-control is something one is urged to maintain from infancy onward. Panting, sweating, and involuntary vo-

calization are incompatible with the image of dignity. Worse yet is any substance once it has left the body: it immediately becomes unclean. The male and female genital fluids are generally regarded with disgust—they are not only excretions but sexual excretions. Here again, societal concern over excretion is involved, for sexual organs are also urinary passages and are in close proximity to the "dirtiest" of all places—the anus. Lastly, many individuals in society regard menstrual fluid with disgust and abstain from sexual intercourse during the four to six days of flow. This attitude is formalized in Judaism, in which menstruating females are specifically labelled as ritually unclean.

In view of all of these factors working against a healthy, rational attitude toward sex and in view of the inevitable disappointments, exploitations, and rejections that are involved in human relationships, one might wonder how anyone could reach adulthood without being seriously maladjusted. The sexual impulse, however, is sufficiently strong and persistent and repeated sexual activity gradually erodes the inhibitions and any sense of guilt or shame. Further, all humans have a deep need to be esteemed, wanted, and loved. Sexual activity with another is seen as proof that one is attractive, desired, valued, and possibly loved—a proof very necessary to self-esteem and happiness. Hence, even among the very inhibited or those with weak sex drive, there is this powerful motivation to engage in socio-sexual activity.

Most persons ultimately achieve at least a tolerable sexual adjustment. Some unfortunates: nevertheless, remain permanently handicapped, and very few completely escape the effects of society's anti-sexual conditioning. While certain inhibitions and restraints are socially and psychologically useful—such as deferring gratification until circumstances are appropriate and modifying behaviour out of regard for the feelings of others—most people labour under an additional burden of useless and deleterious attitudes and restrictions.

Sexual problems. Sexual problems may be classified as physiological, psychological, and social in origin. Any given problem may involve all three categories; a physiological problem, for example, will produce psychological effects, and these may result in some social maladjustment.

Physiological problems of a specifically sexual nature are rather few. Only a small minority of people suffer from diseases of or deficient development of the genitalia or that part of the neurophysiology governing sexual response. A large number of persons, however, experience, at some point in life, sexual problems that are by-products of other pathologies or injuries. Vaginal infections, for example, retroverted uteri, prostatitis, adrenal tumours, diabetes, senile changes of the vagina, and cardiovascular conditions may cause disturbance of the sexual life. In brief, anything that seriously interferes with normal bodily functioning generally causes some degree of sexual trouble. Fortunately, the great majority of physiological sexual problems are solved through medication or surgery. Generally, only those problems involving damage to the nervous system defy therapy.

Psychological problems constitute by far the largest category. They are not only the product of socially induced inhibitions, maladaptive attitudes, and ignorance but also of sexual myths held by society. An example of the latter is the idea that good, mature sex must involve rapid erection, protracted coitus, and simultaneous orgasm. Magazines, marriage books, and general sexual folklore reinforce these demanding ideals, which cannot always be met and hence give rise to anxiety, guilt, and feelings of inadequacy.

Premature ejaculation is a common problem, especially for young males. Sometimes this is not the consequence of any psychological problem but the natural result of excessive tension in a male who has been sexually deprived. In such cases, more frequent coitus solves the problem. Premature ejaculation is difficult to define. The best definition is that offered by the American sexologists, William Howell Masters and Virginia Eshelman Johnson, who say that a male suffers from premature ejaculation if

sexual
relations
of the
young

he cannot delay ejaculation long enough to induce orgasm in a sexually normal female at least half the time. This generally means that vaginal penetration with some movement (although not continuous) must be maintained for more than one minute. The average United States male ejaculates in two or three minutes after vaginal penetration, a coital duration sufficient to cause orgasm in most females the majority of the time. Various methods of preventing premature ejaculation have been tried. One is for the male to excite the female more during the foreplay so that she reaches orgasm more rapidly after penetration, but this technique often excites the male as well and defeats its purpose. Another common method is for the male to think of nonsexual matters, which may prove effective but reduces his pleasure. The most effective therapy is that advocated by Masters and Johnson in which the female brings the male nearly to orgasm and then prevents the male's orgasm by briefly compressing the penis between her fingers just below the head of the penis. The couple come to realize that premature ejaculation can thus be easily prevented, their anxiety disappears, and ultimately they can achieve normal coitus without resorting to this squeeze technique.

Erectile impotence is almost always of psychological origin in males under 40; in older males physical causes are more often involved. Fear of being impotent frequently causes impotence, and, in many cases, the afflicted male is simply caught up in a self-perpetuating problem that can only be solved by achieving a successful act of coitus. In other cases, the impotence may be the result of disinterest in the sexual partner, fatigue, distraction because of nonsexual worries, intoxication, or other causes—such occasional impotency is common and requires no therapy. Some males, however, are chronically impotent and require psychotherapy or behaviour therapy. Such impotency is thought to be the result of deep-seated causal factors such as unconscious feelings of hostility, fear, inadequacy, or guilt. Primary impotence, the inability to ever have achieved erection sufficient for coitus, is more difficult to treat than the far more common secondary impotence, which is impotence in a male who was formerly potent.

Ejaculatory impotence, the inability to ejaculate in coitus, is quite rare and is almost always of psychogenic origin. It seems associated with ideas of contamination or with memories of traumatic experiences. Occasional ejaculatory inability may be expected in older men or in any male who has exceeded his sexual capacity and should cause no concern.

Vaginismus is a powerful spasm of the pelvic musculature constricting the vagina so that penetration is painful or impossible. It seems wholly due to anti-sexual conditioning or psychological trauma and serves as an unconscious defense against coitus. It is treated by psychotherapy and by gradually dilating the vagina with increasingly large cylinders.

Dyspareunia, painful coitus, is generally physical rather than psychological. It is mentioned here only because some inexperienced females fear they cannot accommodate a penis without being painfully stretched. This is a needless fear since the vagina is not only highly elastic but enlarges with sexual arousal, so that even a small female can, if aroused, easily receive an exceptionally large penis.

Disparity in sexual desire constitutes the most common sexual problem. It is to some extent inescapable, since differences in the strength of the sexual impulse and the ability to respond are based on neurophysiological differences. Much disparity, however, is the result of inhibition or of one person having been subjected to more sexual stimuli during the day than the other. The husband who has been seeing attractive females periodically during his work day and who may have had an opportunity to relax on his way back from the office or store is naturally more interested in coitus than his harried wife who has remained at home caring for children and doing housework. Another cause of disparity is a difference in viewpoint. Often a male will anticipate coitus as a palliative to compensate for the trials and tribulations of life, whereas

many females are interested in sex only if the preceding hours have been reasonably problem-free and happy. Even in cases of neurophysiological differences in sex drive, the less-motivated partner can be trained to a higher level of interest, since most humans operate well below their sexual capacities.

Psychological fatigue, a growing disinterest in sexual behaviour with a particular partner, sometimes constitutes a problem. Humans are subject to monotony, and coitus may become routine or even a chore. Lessening frequencies of marital coitus are more often the result of this than of age. The solution lies in varying the time, the setting, and in breaking away from habitual techniques and positions.

Preferences for or antipathies toward particular positions, techniques, or times not infrequently cause trouble. One partner may desire mouth-genital contact or anal stimulation that the other partner finds disagreeable or perverse. Some wish to have coitus in the light, others insist upon darkness; some prefer morning, others evening. The possibilities of disagreement are legion. Even if disagreements stemming from needless inhibition are overcome, there still remain disparities in preference, and these should be met by the philosophy that, by giving pleasure to another, one obtains pleasure. Needless to say, no partner should insist upon that which is abhorrent to the other after the latter has made honest attempts to cooperate.

Lack of female orgasm, anorgasm, is a very frequent problem. One should differentiate between females who become sexually aroused but do not reach orgasm and those who do not become aroused. Only the latter merit the label frigid. It is common for females not to achieve orgasm during the first weeks or months of coital activity. It is almost as though many females must learn how to have orgasm, for after having had one, they respond with increasing frequency. In some cases, the female initially has no idea how to copulate effectively and simply lies passive, expecting the male to bring her to orgasm. Other females resist orgasm because the feeling of being swept away and losing control is frightening. In most cases, however, anorgasm is simply the result of years of inhibition—having been trained since childhood to avoid yielding to the sexual impulse, it is difficult to metamorphose into a responsive and orgasmic being. In the final analysis, anorgasm is psychological in origin; few, if any, females lack the neurophysiology necessary for orgasm, and anthropology shows that in sexually permissive societies virtually all females have little difficulty in attaining orgasm in coitus.

Anorgasm is treated by removing inhibitions, teaching coital techniques, and by inducing orgasm through non-coital methods. The effective therapist should also impress upon the female that not reaching orgasm is no sign of failure or inadequacy on her part or her partner's and that sexual activity is very pleasurable to both, even if orgasm does not ensue. Indeed, some females derive great pleasure and satisfaction without orgasm, a fact that should be made known to anxious husbands. Too great a concern over orgasm defeats itself. As Kinsey once pointed out, thinking is the enemy of sexual pleasure, and a female can scarcely have orgasm if she is worrying about whether she will attain it or not and if she senses that her partner is mentally turning the pages of a marriage manual.

Lastly, sexual problems are often perpetuated by the inability of the partners to communicate freely their feelings to one another. There is a curious and unfortunate reticence about informing one's partner as to what does or does not contribute to one's pleasure. The partner must function on a trial and error basis, ever on the alert for signs indicating the efficacy of his or her efforts. This muteness is even more pronounced when it comes to an individual making suggestions to the partner. Many persons feel that a suggestion or request would be interpreted by the partner that he or she had been inept or at least remiss. As with any other problems, sexual problems can be overcome or ameliorated only if the individuals concerned communicate effectively.

Anorgasm and frigidity

Vaginismus and dyspareunia

Social and cultural aspects

The effects of societal value systems on human sexuality are, as has already been mentioned, profound. The U.S. anthropologist G.P. Murdock has summarized the situation, saying:

All societies have faced the problem of reconciling the need of controlling sex with that of giving it adequate expression, and all have solved it by some combination of cultural taboos, permissions, and injunctions. Prohibitory regulations curb the socially more disruptive forms of sexual competition. Permissive regulations allow at least the minimum impulse gratification required for individual well-being. Very commonly, moreover, sex behavior is specifically enjoined by obligatory regulations where it appears directly to subserve the interests of society.

The historical heritage is, of course, the foundation upon which the current situation rests. Western civilizations are basically Greco-Roman in social organization, philosophy, and law, with a powerful admixture of Judaism derived from Christianity. This historical mixture contained incompatible elements: individual freedom was cherished, yet there was a great emphasis on law and proper procedure; the pantheism of the Greeks and Romans clashed with Judeo-Christian monotheism; and the sexual permissiveness of the Greeks met the fanatical anti-sexuality of early Christianity.

In terms of sex, the most important factor was Christianity. While other vital aspects of human life, such as government, property rights, kinship, and economics, were influenced to varying degrees, sexuality was singled out as falling almost entirely within the domain of religion. This development arose from an ascetic concept shared by a number of religions, the concept of the good spiritual world as opposed to the carnal materialistic world, the struggle between the spirit and the flesh. Since sex epitomizes the flesh, it was obviously the enemy of the spirit. While Judaism subscribed to this dichotomous philosophy, it did have the saving grace of largely exempting marriage from its anti-sexuality. This was not the case with early Christianity, in which sex in any form outside of marriage was unmitigated evil and, within marriage, an unfortunate necessity for procreation rather than pleasure. The powerful anti-sexuality of the early Christians (note that neither God nor Christ has a wife and that marriage does not exist in heaven) was in part due to their apocalyptic vision of life: they anticipated that the end of the world and the Last Judgment would soon be upon them. There was no time for a gradual weaning away from the flesh; an immediate and drastic approach was necessary. Indeed, such excessive anti-sexuality developed that the church itself was finally moved to curb some of its more extreme forms.

As it became evident that human existence was going to continue for some unforeseeable length of time and as occasional intelligent theologians made themselves felt, anti-sexuality was ameliorated to some extent but still remained a foundation stone of Christianity for centuries. This attitude was particularly unfortunate for women, to whom most of the sexual guilt was assigned. Women, like the original temptress Eve, continued to attract men to commit sin. They were spiritually weak creatures prone to yield to carnal impulses. This is, of course, a classic example of projecting one's own guilty desires upon someone else.

Ultimately, legal control over sexual behaviour passed from the church to the state, but, in most instances, the latter simply perpetuated the attitudes of the former. Priests and clergymen frequently continued to exert powerful extralegal control: denunciations from the pulpit can be as effective as statute law in some cases. Although religion has weakened as a social control mechanism, even today, liberalization of sex laws and relaxation of censorship have often been successfully opposed by religious leaders. On the whole, however, Christianity has become progressively more permissive, and sexuality has come to be viewed not as sin but as a God-given capacity to be used constructively.

Apart from religion, the state sometimes imposes purely secular restrictions. The more totalitarian a government,

the more likely it is to restrict or direct sexual behaviour. In some instances, this is simply the consequence of a powerful individual (or individuals) being in a position to impose his (or their) ideas upon the public. In other instances, one cannot escape the impression that sex, being a highly personal and individualistic matter, is recognized as antithetical to the whole idea of strict governmental control and supervision of the individual. This may help explain the rigid sexual censorship exerted by most totalitarian regimes. It is as though such a government, being obsessed with power, cannot tolerate the power the sexual impulse exerts on the population.

PERMISSIVENESS AND SOCIAL CONTROL

Societies differ remarkably in what they consider socially desirable and undesirable' in terms of sexual behaviour and consequently differ in what they attempt to prevent or promote. There appear, however, to be four basic sexual controls in the majority of human societies. First, to control endless competition, some form of marriage is necessary. This not only removes both partners from the competitive arena of courtship and assures each of a sexual partner, but it allows them to devote more time and energy to other necessary and useful tasks of life. Despite the beliefs of earlier writers, marriage is not necessary for the care of the young; this can be accomplished in other ways. Second, control of forced sexual relationships is necessary to prevent anger, feuding, and other disruptive retribution. Third, all societies exert control over whom one is eligible to marry or have as a sexual partner. Endogamy, holding the choice within one's group, increases group solidarity but tends to isolate the group and limit its political strength. Exogamy, forcing the individual to marry outside the group, dilutes group loyalty but increases group size and power through new external liaisons. Some combination of endogamy and exogamy is found in most societies. All have incest prohibitions. These are not based on genetic knowledge. Indeed, many incest taboos involve persons not genetically related (father-stepdaughter, for example). The prime reason for incest prohibition seems to be the necessity for preventing society from becoming snarled in its own web: every person has a complex set of duties, rights, obligations, and statuses with regard to other people, and these would become intolerably complicated or even contradictory if incest were freely permitted.

Fourth, there is control through the establishment of some safety-valve system: the formulation of exceptions to the prevailing sexual restrictions. There is the recognition that humans cannot perpetually conform to the social code and that well-defined exceptions must be made. There are three sorts of exceptions to sexual restrictions: (1) Divorce: while all societies encourage marriage, all realize that it is in the interest of society and the individual to terminate marriage under certain conditions. (2) Exceptions based on kinship: many societies permit or encourage sexual activity with certain kin, even after marriage. Most often these kin are a brother's wife or a wife's sister. In addition, sexual "joking relationships" are often expected between brothers-in-law, sisters-in-law, and cousins. While coitus is not involved, there is much explicit sexual banter, teasing, and humorous insult. (3) There are, in addition, exceptions based on special occasions, ranging from sexual activity as a part of religious rites to purely secular ceremonies and celebrations wherein the customary sexual restrictions are temporarily lifted.

Turning to particular forms of sexual behaviour, one learns from anthropology and history that extreme diversity in social attitude is common. Most societies are unconcerned over self-masturbation since it does not entail procreation or the establishment of social bonds, but a few regard it with disapprobation. Sexual dreams cause concern only if they are thought to be the result of the nocturnal visitation of some spirit. Such dreams were once attributed to spirits or demons known as incubi and succubi, who sought out sleeping humans for sexual intercourse.

Petting among most preliterate societies is done only as

control

a prelude to coitus—as foreplay—rather than as an end in itself. In some parts of sub-Saharan Africa, however, petting is used as a premarital substitute for coitus in order to preserve virginity and avoid pregnancy. There is great variation in petting and foreplay techniques. Kissing is by no means universal, as some groups view the mouth as a biting and chewing orifice ill-suited for expressing affection. While some societies emphasize the erotic role of the female breast, others—such as the Chinese—pay little attention to it. Still others regard oral stimulation of the breast unseemly, being too akin to infantile suckling. Although manual stimulation of the *eenitalia* is nearly universal, a few peoples abstain because of revulsion toward genital secretions. Not much information exists on mouth–genital contact, and one can say only that it is common among some peoples and rare among others.

A considerable number of societies manifest scratching and biting in conjunction with sexual activity, and most of this is done by the female. Sadomasochism in any other form, however, is conspicuous by its absence in preliterate societies.

An enumeration of the societies that permit or forbid premarital coitus is complicated not only by the double standard but also by the fact that such prohibition or permission is often qualified. As a rough estimate, however, 40 to 50 percent of preliterate or ancient societies allowed premarital coitus under certain conditions to both males and females. If one were to count as permissive those groups that theoretically disapprove but actually condone such coitus, the percentage would rise to perhaps 70.

In marital coitus, when sexual access is not only permitted but encouraged, one would expect considerable uniformity in frequency of coitus. This expectation is not fulfilled: social conditioning profoundly affects even marital coitus. On one Irish island reported upon by a researcher, for example, marital coitus is best measured in terms of per year, and among the Cayapas of Ecuador, a frequency of twice a week is something to boast of. The coital frequencies of other groups, on the other hand, are nearer to human potential. In one Polynesian group, the usual frequency of marital coitus among individuals in their late 20s was ten to 12 per week, and in their late 40s the frequency had fallen to three to four. The African Bala, according to one researcher, had coitus on the average of once or twice per day from young adulthood into the sixth decade of life.

Marital coitus is not unrestricted. Coitus during menstruation or after a certain stage of pregnancy is generally taboo. After childbirth a lengthy period of time must often elapse before coitus can resume, and some peoples abstain for magical reasons before or during warfare, hunting expeditions, and certain other important events or ceremonies. In modern Western society one finds menstrual, pregnancy, and postpartum taboos perpetuated under an aesthetic or medical guise, and coaches still attempt to force celibacy upon athletes prior to competition.

Extramarital coitus provides a striking example of the double standard: it is expected, or tolerated, in males and generally prohibited for females. Very few societies allow wives sexual freedom. Extramarital coitus with the husband's consent, however, is another matter. Somewhere between two-fifths and three-fifths of preliterate societies permit wife lending or allow the wife to have coitus with certain relatives (generally brothers-in-law) or permit her freedom on special ceremonial occasions. The main concern of preliterate societies is not one of morality, but of more practical considerations: does the act weaken kinship ties and loyalty? Will it damage the husband's social prestige? Will it cause pregnancy and complicate inheritance or cause the wife to neglect her duties and obligations? Most foreign of all to Western thinking is that of those peoples whose marriage ceremony involves the bride having coitus with someone other than the groom, yet it is to be recalled that this practice existed to a limited extent in medieval Europe as *jus primae noctis*, the right of the lord to the bride of one of his subjects.

Sexual deviations and sex offenses are, of course, social definitions rather than natural phenomena. What is normative behaviour in one society may be a deviation or crime in another. One can go through the literature and discover that virtually any sexual act, even child–adult relations or necrophilia, has somewhere at some time been acceptable behaviour. Homosexuality is permitted in perhaps two-thirds of human societies. In some groups it is normative behaviour, whereas in others it is not only absent but beyond imagination. Generally, it is not an activity involving most of the population but exists as an alternative way of life for certain individuals. These special individuals are sometimes transvestites—that is, they dress and behave like the opposite sex. Sometimes they are regarded as curiosities or ridiculed, but more often they are accorded respect and magical powers are attributed to them. It is noteworthy, however, that aside from these transvestites, exclusive homosexuality is quite rare in preliterate societies.

In conclusion, the cardinal lesson of anthropology is that no type of sexual behaviour or attitude has a universal, inherent social or psychological value for good or evil—the whole meaning and value of any expression of sexuality is determined by the social context within which it occurs.

SOCIO-ECONOMIC FACTORS

Differences in sexual behaviour between classes within technologically developed societies are very marked. Civilizations are made up of class hierarchies, and the different subgroups normally develop their own value systems. Most of the knowledge of the sexual behaviour and attitudes of ancient cultures is that of the upper or ruling class; the behaviour and feelings of the slaves and peasants were seldom recorded. There is the impression—probably a correct one—that throughout history the lower socio-economic class was the most permissive. Sex has always been one of the few pleasures of the poor and oppressed. On the other hand, one must not overlook the fact that a fanatical Puritanism can also flourish at the bottom of the social scale, and, hence, one can never assume that low status and sexual permissiveness are inevitably linked.

The Kinsey studies showed considerable social class differences in sexuality in the United States, chiefly in that the lower class was more tolerant of nonmarital coitus. More recent studies indicate that these class differences have rapidly broken down. Increased literacy and the influence of mass media have made the population more homogeneous in sexual attitudes. One can find, moreover, reversals of the previous pattern: a lower class person on the way up the social ladder may be quite conservative in his sexual views, feeling that this facilitates upward mobility, whereas the person secure in his or her high social status often feels that he or she can afford to flout convention. Actually, the most sexually liberal are those at the very bottom, who have nothing to lose, and those at the very top, who are beyond social retribution.

The great middle class remains the bastion of traditionalism, and it is here that the double standard of morality is most prominent. The intellectualized liberalism of the upper level seeps down only slowly, and the pragmatic egalitarianism of the lower level does not penetrate far upward.

Systems of production and distribution have had a growing influence on sexual behaviour since the Industrial Revolution. The old family pattern was inexorably disrupted by the rise of the industrial state. Children were no longer kept at home to share in the work and be economic assets but left for school or for nonfamily employment, and the degree of parental control diminished. The "working wife" employed outside the home, once found only among the impoverished, has gradually become the typical wife. With her enhanced economic power and her greater association with people outside the home, she became less a chattel. As the population left the family farm and tight-knit small communities for anonymous big-city existence, not only parental but societal controls over behaviour were weakened. Society

of marital
coitus

Breakdown
of class
differences
in sexual
behaviour

became increasingly nomadic with improved transportation and job opportunities. Cultural and ethnic subgroups that formerly would have had little contact were thrown together in the same schools, factories, offices, and neighbourhoods.

All of this vast uprooting and rearranging naturally altered sexual attitudes and behaviour. The individual no longer had the option of choosing to conform or depart from a rather clear-cut sexual moral code but instead was faced with a multiplicity of choices of varying degrees of social acceptability. The major sexual change—one still in progress—was the emancipation of women, which brought with it an increasing acceptance of premarital sexual activity, the concept of woman as a human being with her own sexual needs and rights, and the possibility of terminating an unhappy marriage without incurring serious social censure. A second major change was the erosion of simplistic value systems: with increased mobility and social mixing, the individual learned that the values and attitudes he or she had unquestioningly accepted were not necessarily shared by neighbours and co-workers. As a result, life became not only more complex but more permissive. This growing tolerance has in recent decades extended, to a limited extent, to homosexuality. There is no evidence that homosexuality or other deviant behaviour has measurably increased as a result of society's urbanization and technological progress, but one gains the impression of an increase simply because these topics, previously unmentionable, are now openly discussed in the mass media.

While the old monolithic value systems broke down and individuals were accorded a wider variety of choices in terms of sexual life, there developed a paradoxical trend toward homogeneity as a result of mobility, the mass media, and increasing economic parity. Geographical and social-class differences in sexual attitudes and behaviour have steadily lessened. The plumber's family and the banker's family are now indistinguishable in terms of dress; both have automobiles; their offspring attend the same schools; and they share the same newspapers, magazines, and television programs. One might summarize by saying that society is homogeneous in that everyone now has available a wide diversity of sexual attitudes and activities.

LEGAL REGULATION

Sex laws, the origins of which, as mentioned above, are found within the church, are unique in one important respect. Whereas all other laws are basically concerned with the protection of person or property, the majority of sex laws are concerned solely with maintaining morality. The issue of morality is minimal in other laws: one can legitimately evict an impoverished old couple from their mortgaged home or sentence a hungry man for stealing food. Only in the realm of sex is there a consistent body of law upholding morality.

The earliest sex laws of which there is knowledge are from the Near East and date back to the 2nd millennium B.C. They are remarkable in three respects: there are great omissions—certain acts are not mentioned whereas others receive detailed attention; some laws seem almost contradictory; and penalties are often extraordinarily severe. One obtains the distinct impression that these laws were case law—that is, laws formulated upon specific cases as they arose rather than being the result of lengthy judicial deliberation done in advance. These laws influenced Judaic and, hence, Christian thinking, and some were immortalized in the Bible, chiefly in Leviticus.

As mentioned earlier, when secular law replaced religious law, there was rather little change in content. In Europe the Napoleonic Code represented a break with tradition and introduced some measure of sexual tolerance, but in England and the United States there was no such rift with the past. In the latter country, as each new state joined the union, its sex laws simply duplicated, to a great extent, those of pre-existing states; legislators were disinclined to debate sexual issues or to risk losing votes by discarding or weakening sex laws.

Sex laws may be grouped in three categories: (1) Those

concerned with protection of person. These are based on the element of consent. These otherwise logical laws become problematic when society deems that minors, mental retardates, and the insane are incapable of giving consent—hence, coitus with them is rape. (2) Those concerned with preventing offense to public sensibilities. Statutes preclude public sexual activity, exhibitionism, and offensive solicitation. (3) Those concerned with maintaining sexual morality. These constitute the majority of sex laws, covering such items as premarital coitus, extramarital coitus, incest, homosexuality, prostitution, peeping, nudity, animal contact, transvestism, censorship, and even specific sexual techniques—chiefly oral or anal. Laws relating to sexual conduct and morality are generally far more extensive in the United States than in western Europe and most other areas of the world.

In recent years, in Europe and the United States, a number of highly respected legal, medical, and religious organizations have deliberated on the whole issue of the legal control of human sexuality. They have been unanimous in the conclusion that, while the laws protecting person and public sensibilities should be retained, the purely moral laws should be dropped. Specifying what consenting adults do sexually in private, it is argued, should not be subject to legal control.

In the final analysis, sexuality, like any other vital aspect of human life, must be dealt with on an individual or societal level with a combination of rationality, sensitivity, and tolerance if society is to avoid personal and social problems arising from ignorance and misconception.

BIBLIOGRAPHY. An anthropological overview of sex is given in DONALD S. MARSHALL and ROBERT C. SUGGS (eds.), *Human Sexual Behavior: Variations in the Ethnographic Spectrum* (1971); GEORGE P. MURDOCK, *Social Structure* (1949); and CLELLAN S. FORD and FRANK A. BEACH, *Patterns of Sexual Behavior* (1951); the latter also covers mammalian behaviour. Data on sexual behaviour and attitudes in the United States are in ALFRED C. KINSEY *et al.*, *Sexual Behavior in the Human Male* (1948) and *Sexual Behavior in the Human Female* (1953); while IRA L. REISS, *The Social Context of Premarital Sexual Permissiveness* (1967), provides more recent information on attitudes. General information may be found in JAMES L. MCCARY, *Human Sexuality* (1967), a book that also serves as an excellent sex manual. The best single volume on homosexuality is that of DONALD J. WEST, *Homosexuality* (1968). Genetic, hormonal, and gender matters are summarized in two technical volumes: RICHARD GREEN and JOHN MONEY (eds.), *Transsexualism and Sex Reassignment* (1969); and ROBERT J. STOLLER, *Sex and Gender: On the Development of Masculinity and Femininity* (1968). Sexual physiology is comprehensively treated in WILLIAM H. MASTERS and VIRGINIA E. JOHNSON, *Human Sexual Response* (1966), while their second volume, *Human Sexual Inadequacy* (1970), deals with behaviour therapy. The history of Judeo-Christian attitudes toward sex is presented in detail in L.M. EPSTEIN, *Sex Laws and Customs in Judaism* (1968); and DERRICK S. BAILEY, *Sexual Relation in Christian Thought* (1959). Sex laws are covered by three volumes: RALPH SLOVENKO (ed.), *Sexual Behavior and the Law* (1965); EDWARD SAGARIN and DONALD E.J. MACNAMARA, *Problems of Sex Behavior* (1968); and the AMERICAN LAW INSTITUTE, *Model Penal Code*, 2 vol. (1955–57).

(P.H.Ge.)

Sexual Deviations

Sexual deviation is defined here as any pattern of behaviour including a habitual, preferred, compelling need for sexual gratification by any technique other than willing coitus between man and woman and involving actions that directly result in genital excitement. "Preferred" is a key word in the definition because sexual behaviour that is chosen as desirable is thus distinguished from sexual acts that are prescribed by others or that are momentary, casual, or experimental; such acts would be deviant acts, but they may or may not signal deviation. If a pagan ritual required a celebrant to have intercourse with an animal, for instance, the act would not be considered in the pattern of deviation, because the person is simply obeying a societal code and would presumably not prefer animals under ordinary circumstances. Overall, the criterion of definition here is man's evolutionary and biological need to reproduce the species; and there is intended no social or

Early
examples
of sex laws

cultural implication that deviant behaviour is, or is not, unhealthy, immoral, sinful, useless to society, or contrary to natural law. The only exception in this article is the inclusion of incest, which, though culturally and not physiologically defined, is universally tabooed in one form or another.

Statistical frequencies. The first generalization to apply to all sexual deviations concerns the problem of determining prevalence. Despite a century of scientific study, it is not possible to state precisely for any population how many people are involved in any particular deviation. Published statistics have dubious accuracy because of such errors as poor definition; improper sampling techniques; and denial due to guilt, embarrassment, and secrecy that attends sexual deviation in all societies. Even the Institute for Sex Research (Indiana University), founded by Alfred C. Kinsey (1894–1956), which has demonstrated the possibility of determining the rate of deviation in a given population, still admits the imprecision of its findings and the need for further refinement of statistical techniques. Thus, for the time being, one must be satisfied with approximations and such imprecise measures of frequency as "occasionally," "rarely," "extremely," and "very."

Therapies. Second, there are no adequate statistics on results of theory. Although psychoanalysts may point to psychoanalysis as the preferred treatment for sexual deviations, there is not a single published work demonstrating, in significant numbers of cases and with adequate controls, how effective treatment actually is. The same can be said for all other methods of treatment, although the next decade may determine the reliability of behavioral techniques. Such techniques involve "conditioning" a patient to canalize his desires into new directions by associating his acts with rewarding or punishing stimuli. The individual, for instance, may be rewarded for acts progressively like the act to be preferred until that act finally occurs and is rewarded (positive conditioning). Or an act to be abandoned may be accompanied by electric shocks or other punishments until that act is habitually avoided (aversion therapy).

Whatever the future holds, however, one can say now that all sexual deviations are difficult to treat and the outcomes are uncertain. This is true because the pleasure inherent in the behaviour is intense, and the alternatives so much less so. If cure means to give up what is most pleasurable, even the best intentions may not adequately motivate a patient.

Causes. Third, in spite of the immense literature dealing with the causes of deviation—biological, psychological, or a combination of both—there is little sure knowledge. The hypotheses, however, generally fall into one of the following categories:

1. Willful sinning.
2. Atavism, degeneracy, or hereditary taint. These causes imply, along with a connotation of disgust, an inherited biological inferiority.
3. Animal instinct. If some behaviour, such as licking another animal's genitals, occurs in a number of mammalian species, then human beings, being mammals, may be instinctively inclined to practice such behaviour.
4. Neurophysiological causes. If, by subjecting an animal's brain to neurophysiological, biochemical, or microscopic stimuli under laboratory conditions, one can induce an animal to engage in a certain behaviour, then a similar behaviour found in human beings may be due to the functioning or malfunctioning of corresponding brain centres in man.
5. Genetic causes. Studies of chromosomes and genes are insufficiently advanced to determine whether or not they comprise an ultimate biological basis for sexual deviations. Studies of single families, however, have been offered as evidence of hereditary factors when the same deviation is found in two generations or among many members of the same family and when social or psychological influences can be proved to be minimal. (Identical twins raised apart have often been the subject of such research.)
6. Endocrine causes. Variations in the make-up and

amounts of crucial hormones do affect sexual behaviour. Although it may be excessive to say that a person's behaviour is thus genetically "controlled," his behaviour can certainly be said to be "pushed" in certain directions or "influenced." One hypothesis suggests that there is a narrow time period before or after birth when an unusual dose of a sex hormone can permanently alter gender development so that, for instance, a male rat at maturity will act as if it were a female. If this occurs at the critical period in human beings, changes of masculinity and femininity may result, perhaps associated with changes in sexual practices.

7. Environmental imprinting. From birth on, intense and complex interactions between members of a family and other associates will shape (by reward and punishment, conditioning, and identification) the behaviour and sexual choices of the developing individual. In extreme cases, as has been demonstrated in some birds and animals, there is a critical period during which an infant, exposed to the proper environmental (nonbiological) stimuli, can have his behaviour permanently redirected. (A bird, for instance, may forever after seek a human being rather than another bird as an affectionate and erotic object.) Such behaviour may be insusceptible to forgetting or extinction.

8. Intrapsychic causes. In an attempt to deal with the genetically controlled development of his sex drive, a growing child, threatened by the power of his parents to castrate, abandon, or kill, may work out compromises (deviations) in order to preserve himself and his (now disguised) libido.

9. Societal causes. In different societies and eras certain types of sexual behaviour will be encouraged or punished and will be defined as normal or aberrant. These codes govern or influence sexual practices. In addition, certain codes or taboos, such as the forbidding of nudity, may set up tensions, the resolution of which may be sexual deviations.

No proof exists that any of the causative theories listed above is wrong, and thus each has its worthy proponents. There is a growing agreement, however, that, excepting certain rare and specific cases in which biological abnormalities can be demonstrated, almost all sexual deviations are the result of postnatal, psychological (societal and intrapsychic) influences and that future studies of infant and child development, including studies of family dynamics, will reveal the specific causes of deviation.

Popular misconceptions. The fourth generalization to be made about sexual deviations is that popular conceptions should not interfere with a realistic attempt to understand various forms of deviation. There is no relation between practicing a sexual deviation and being "oversexed"; for what is meant by being "oversexed"? The capacity to perform sexually more than the user of the term? The single-mindedness with which satisfaction is pursued? The bizarreness of the sexual act? Such vagueness has no practical value in analyzing deviation. Similarly, despite contrary public opinion, there is generally no progression from a "minor" deviation to "major" one (even if one could define which are minor and which are major). Each deviation is necessary to its possessor, and he would no more get pleasure from a different deviation than would a more normal person. Progressive deviation, however, should not be confused with multiple deviation, which is common. Fetishism, sadomasochism, and homosexuality with a preference for anal intercourse may all be present in the same person.

The dynamics of deviation. A final generalization: the overall force that causes one's sexual drive to bend, detour, or deviate is seemingly psychic aggression, arising from fear or anxiety, especially in childhood when sexual conditions begin to form. The fear may be inspired by the presumed danger of other people and by the attack of one's own conscience because of the incestuous desires of childhood. Later, when the final form of the deviation is evolving, fear may be surmounted by attacking others. Thus, in the deviant act one can always find—disguised or overt, in fantasies that accompany the act or in the act itself—a hostility toward a sexual object. It seems that

one function of sexual deviations is to degrade the opposite sex. Conversely, one element of the deviant act may serve as a defense: protecting oneself against attack. In fetishism, for instance, an inanimate object may replace a human being for sexual pleasure because it never complains, is always willing, and never accuses or fights back.

Understanding of sexual deviations was greatly increased with the work of Sigmund Freud, especially with the publication in 1905 of the *Three Essays on the Theory of Sexuality*. This work single-handedly lifted the subject out of the realm of simple description or vague theorizing and into a much more fruitful search for causes and psychological mechanisms. In particular, it removed sexual deviations from a state of therapeutic hopelessness inspired by the earlier belief that they were the result of untreatable, subtle, biological degeneracy. Although recognizing that sexual desire had biological sources, Freud emphasized the part that psychological events play in developing both normal and abnormal sexual behaviour. From data collected in the psychoanalyses of his patients, he concluded that most sexual deviations are the result of the thwarting of the normal processes of development to heterosexuality, primarily through demands made on the growing child to curb his many libidinal desires. Through an intense and complicated process of threat and approval, a child learns, particularly from his mother (who funnels into him her idiosyncratic version of her society's mores) that his cannibalistic voraciousness, his unlimited joy in dirtying himself with excrements, or his completely selfish genital needs are simply not acceptable. Since these needs are ultimately biological, they cannot be made to disappear but can only be molded, delayed, and disguised—in time, as much disguised from the individual as from the outside world. These disguises take two main forms: sexual deviations and neuroses.

For Freud, crucial for the development of deviations was the castration complex and the Oedipal situation causing it. In a boy the original unlimited love for his mother must be severely modified if he is to develop into an independent individual; additionally, he cannot hope to have his mother exclusively when his father has prior possession. That circumstance—and the threat of his father's strength—makes the little boy fear that his father could punish him for his sexual desires by removing that most intensely pleasurable organ, his penis. On the other hand, said Freud, little girls, discovering early that they do not have a penis, feel that the humiliating and depriving act of castration has already been performed in the forgotten past, making them inferior and envious of males. How to survive these painful relations with parents and to salvage sexual pleasure are for Freud the main tasks of childhood libidinal development; and, depending on what the parents do and how the child reacts to what is done, one gets various degrees of distortion of normal sexual development.

Sexual deviation may result from either or both of two processes. First, there is fixation, whereby a stage in development, because experienced too intensely, is clung to, thus delaying progress to the next stage or distorting it. Excessive concentration on learning bowel control, for instance, can focus the child excessively on anal sensations; and when he enters the stage of genital ascendancy (penile or clitoral), he (or she) may associate seminal or vaginal fluid with excremental filth or poison. The second process is regression, whereby one more or less reaches psychosexual maturity but, under pressure of severe distress, retreats to a more primitive libidinal state. Pedophilia (see below), for instance, sometimes appears for the first time in a man becoming senile.

Although many aspects of Freud's theory have been questioned or modified, no attack has yet demonstrated the falsity of his claims that infants and children have sexual lives, that eroticism is attached not only to the genitals but also to many other parts of the body, that the sexual pleasures of childhood can be maintained relatively intact into adult life, that sexual desire is tamed only with great difficulty in most societies, that the taming does not destroy sexual instincts but merely makes them take

on different appearances, that infants and children have highly charged libidinal relations with their parents that must be resolved for successful living as an adult, that infantile sexuality lives on in both normal sex practices and sexual deviations, and that there are discoverable in early life psychological forces that produce sexual deviations in an adult.

HOMOSEXUALITY

Homosexuality, very generally defined, is a preference for sexual relations with a person of the same sex. Though the most prevalent deviation, its frequency is unknown, largely because its being considered both sinful and illegal in most societies makes people with this preference unlikely to reveal themselves to authorities. It may be the most prevalent deviation because it is closest to heterosexuality in offering the pleasure of being sexually with a willing object recognized as quite human.

The definition of homosexuality would seem easy enough, and yet authorities disagree, primarily because of the difficulty in determining to what degree a person performing a homosexual act prefers it to some other act. Some experts, for instance, believe that much of adolescent homosexuality is due to the social restrictions on overt heterosexuality, making homosexuality a matter of *faute de mieux*: something adopted for the lack of something better. Likewise, men isolated from women during wartime or imprisonment may turn to transient homosexuality. This is called facultative homosexuality.

The issue of who is a homosexual is further complicated by the fact that many people have conscious or unconscious homosexual desires. They may express them in fantasies or in reading or watching films on the subject, or they may even sense excitement in aborted homosexual acts revealed in affectionate gestures. The homosexual interests of many people appear in dreams, in hatred of homosexuals, or in a man's fear of not seeming manly or a woman's fear of not seeming feminine. According to some analysts, even some cases of paranoid psychosis, drug addiction, alcoholism, and myriad other psychiatric conditions are due to fear of homosexual impulses. In the end, if one accepts Freud's statement that all human beings possess undercurrents of homosexuality because they are biologically and thus psychologically bisexual, the task of precise definition would seem impossible.

Nevertheless, there is a growing consensus that a homosexual can be defined at least relatively: although homosexual tendencies can be found under many circumstances, a homosexual is a person who in fantasy or reality habitually prefers sexual relations with a person of the same sex. That being so, one finds that most people are heterosexual, a smaller number can enjoy both sexes (bisexualism), and a still smaller number exclusively prefer people of the same sex.

The character of homosexuality. *The male homosexual*. Male homosexuals have often been classified in a polarizing fashion: active and passive, insertor and insertee, masculine and effeminate, obligatory and facultative. Such dichotomies all presume that there are masculine homosexuals and feminine ones—the latter identifying themselves with women, being quieter, gentler, more effeminate, and more prone to live and work in ways reminiscent of females and especially preferring to assume a woman's receptive role in sexual acts as much as anatomically possible. Too many homosexuals, however, enjoy alternating in masculine and feminine roles to permit such simple classification. The Kinsey seven-point scale avoids the issue by merely rating people from exclusively heterosexual to exclusively homosexual in their choice of sexual partners throughout life.

Male homosexuals can be habitually effeminate, intermittently so, or habitually masculine. The most effeminate restrict their behaviour to their version of a woman's role, not only mimicking nonsexual femininity but also enjoying being seduced and overpowered by their partner, receiving penises into their anus, mouth, or hand and disliking the insertor role.

They dress flamboyantly and effeminately, with a few resorting even to women's clothes, as at "drag balls" and

beauty contests. This cross-dressing is not sexually exciting, as it is for the transvestite, nor does it indicate a desire to be a female, as it does for the transsexual (see below *Transsexualism and Transvestism*). The effeminate homosexual loves his penis and abhors penisless creatures. He is still so identified with the female role, however, that he can appear as a woman for a short time and enjoy being complimented on his feminine appearance. It is understood by the observers and himself that he has a penis under his costume.

Most male homosexuals are less effeminate, revealing their effeminacy only when safely with other homosexuals. They alternate sexually between active and passive roles, and some also can perform heterosexually and not infrequently marry and have children. Finally, there are habitually masculine men, who, with no apparent wish to simulate femaleness, still choose other males exclusively for sexual pleasure, with a few even exaggerating their masculinity in dress and manner.

There is as yet no way to judge accurately the prevalence of homosexuality and all its characteristics. But the growing number of studies and surveys in such countries as the U.S., Great Britain, and Sweden tends to loosen society's attitudes toward sexuality; and changes in attitudes in turn make such studies easier, with homosexuals more willing to reveal themselves.

The female homosexual. Like their male counterparts, female homosexuals can be very masculine ("butch"), alternatively masculine and feminine, or always feminine ("femme"). The "butch" may dress and act like a man, but this is simply mimicry in the reverse manner of the effeminate male homosexual. These women proclaim their dislike of maleness, especially penises, and, in the extreme, state that men have value only as repositories of sperm. In sexual relations they take a masculine role, playing the seducing and active role, sometimes with artificial penile devices. They prefer "femmes" and rarely have sexual relations with other masculine women. Many believe, because men are unnecessary, that women make the best lovers for women and that a "butch" can seduce any woman, including a normal heterosexual. There is thus an apparent paradox that such women may get along well with effeminate men, closely imitate masculinity in sexual and other ways, and yet hate maleness.

Those who consider themselves bisexual can be masculine (though not so much as "butches") or feminine, switching roles at will. The "femmes" are feminine in dress and behaviour and incapable of simulating masculinity. Though appearing normally heterosexual, they need masculine women (*i.e.*, penisless "men"), finding sexual relations with males unappealing. At times in a "butch-femme" relation the "butch" is the man, but she may also perform as a powerful, punishing, and threatening mother: her partner may behave as a daughter. Thus affectionate mother-daughter roles can combine with threatening sadomasochistic ones.

Female homosexual relations are usually more stable than are male relations because more emphasis is placed on non-erotic companionship. Thus long-lasting liaisons are more likely and may even include the raising of children. Either the child is "adopted" nonlegally or one of the women becomes pregnant so that the two can raise their own child (the necessary male of course being discarded soon after conception).

The homosexual subculture. In modern societies in which homosexuality is condemned but still prevalent, homosexuals usually congregate in large cities, where urban anonymity permits them to develop underground communities. After working in the "straight" (heterosexual) world all day, they can lift their disguises in exclusively "gay" (homosexual) bars where they can meet, talk, dance, drink, and otherwise feel free from observation, censure, or arrest. Helping to increase their sense of solidarity as protection against an intolerant majority has been the gradual invention of their own private language, a jargon of such expressions as "gay," "straight," "butch," and "femme." Additionally they may create homosexual organizations for social, scientific, and political action favouring homosexuality.

A "sexual" subculture has also developed. In most cities, in addition to bars, there are parks, beaches, public toilets, and bathhouses known to male homosexuals for finding sex partners. These bars and other meeting places are familiar to the police, but, recognizing their social value, the authorities usually leave them alone so long as the rest of society is not victimized. Only when occasional public pressure is exerted for a "cleanup" do the police act, invariably, however, permitting an expeditious return to normalcy. In business and the professions male homosexuals dominate certain areas of the creative and performing arts, hairdressing, interior decorating, and fashion designing. In such nonsexual settings effeminate men, protected from female anatomy, often find women congenial. Female homosexuals of masculine persuasion often prefer working in masculine professions, in which their strong motivation can be highly effective.

Comparative views of homosexuality. Male homosexuality was highly valued in ancient Greece, but experts disagree over whether the literary praise of homosexuality meant that it was acceptable for society in general or only for the elite. Others disagree whether the idealized Greek homosexual relation between an older, wiser man and his young patron minimized sexuality or was decidedly sexual as well as philosophic. At any rate, many Greek writers represented homosexuality as ennobling and normal. Ancient Greece also exemplifies the more casual or indifferent attitude toward female homosexuality throughout history, women being considered inferior creatures and their homosexuality not worthy of much comment.

The Greek's congeniality for homosexuality is said to have influenced such neighbours as the Persians and to have been transmitted along with other Greek traditions into the Roman Empire. The Greek view, however, contrasts with the Judaic attitude of respecting heterosexuality for its familial function and strongly disapproving of homosexuality, though not until later times, evidenced in the later books of the Old Testament, was it seen as an abomination punishable by death. This scorn was transmitted to early Christianity, fortified with the belief that far better than any sexual relations at all was abstinence. (To the church's discomfort, those most able to abstain from heterosexuality may lean toward homosexuality.)

Data regarding the Orient are so scattered as to warrant only surmises, though homosexuality was known throughout the Orient in ancient and modern times. As with other civilizations over wide stretches of time, it was alternately accepted and condemned in China, Japan, and India and expressed at times in male prostitution. Clellan S. Ford and Frank A. Beach, reporting on 76 preliterate societies, found 28 in which adult homosexual activities were "totally absent, rare, or carried on only in secrecy" and 48 in which homosexuality was "normal and socially acceptable for certain members of the community." What especially catches the eye in such societies is cross-dressing, a mode of behaviour often cited by anthropologists but usually without proof that it goes beyond masquerading or ritual to involve genital acts. Where true homosexuality does exist, natives, when questioned, have simply been amused that it could conceivably be banned. Nevertheless, M.K. Opler has noted:

Actually, no society, save perhaps ancient Greece, pre-Meiji Japan, certain top echelons in Nazi Germany, and the scattered examples of such special status groups as the berdaches, Nata slaves, and one category of Chukchee shamans, has lent sanctions in any real sense to homosexuality.

Among modern countries, homosexuality seems to find least disfavour in such countries as the Scandinavian nations, The Netherlands, and Japan and to be most condemned in authoritarian countries such as the Soviet Union and in some Latin American countries where *machismo* or manliness is strongly dictated by tradition. In the U.S., which seems moving toward more sexual tolerance, Alfred Kinsey and his group estimated in 1948 that 4 percent of American males were exclusively homosexual throughout their lives, and 10 percent during at least three years of their adult lives; 30 percent had at least some incidental homosexual experience. The estimates for females, reported in 1953, were less specific on "exclusive"

Historical
and
cross-
cultural
data

homosexuality but noted that 13 percent had at least a "homosexual experience" reaching orgasm prior to age 45, or 28 percent a "homosexual response." The validity of such estimates, however, has been subject to debate.

Comparative legal aspects. Generally in all countries there are no laws against homosexuality per se but rather against acts evidencing homosexual gratification, such as sodomy, fellatio, or mutual masturbation. Usually there are also general provisions against "conduct outrageous to public decency," used to ensure the imposition of some penalty when overt homosexuality or some serious crime cannot be proved. Almost all countries—even those having repealed laws against homosexual activities between "consenting adults in private"—reserve severe punishment for an adult having homosexual relations with a minor. In Scandinavia, for instance, homosexual relations are punishable only when one of the persons is under 18 years of age or when the person is between 18 and 21 and demonstrably a victim of superior age and experience. In Great Britain the lower age is 18 (since 1970, the age used in definitions of adulthood in all legal matters); and in those states of the U.S. (Illinois and Connecticut) adopting the principle of "consenting adults," the lower age is 21. (Almost all states of the U.S. still outlaw all "unnatural" or homosexual acts, regardless of the age of the participants.) Japan, France, and some other European countries not only prohibit adults taking advantage of minors but also prohibit any person of authority, such as an employer or guardian, taking advantage of an inferior, such as an employee or ward. Although free to engage in acts involving consent and privacy, anyone using intimidation or violence is subject to severe penalty.

The Soviet criminal code takes a traditional conservative approach to homosexual relations. All sexual relations between men are punishable by a prison term of up to five years, and the penalty is severer when force or superior age or position is used. Communist China, on the other hand, though punishing force, fraud, or the misuse of authority, apparently has no legal proscription against homosexuality between consenting adults in private.

Laws regarding homosexuality may not always reflect public conscience on the matter or the degree of enforcement by authorities.

Cross-species data. All vertebrates, including man, have sufficient equipment to indulge in homosexual behaviour. A male stickleback fish, for instance, may push a nesting female aside, perform on the nest as if female, and then be approached by a dominant male as a female; smaller male iguana lizards are regularly sexually engaged by stronger males; male roosters, bending over, may be mounted by other roosters; cows in heat mount other cows; and dogs, cats, horses, rabbits, lions, and many other species mount others of the same sex. In young primates there is much play activity with members of the same sex that is typical of adult sexual behaviour. Two cases have been reported of male monkey pairs who had well-motivated and coordinated anal intercourse.

This great mass of data, however, cannot answer the question whether any of these animals is a homosexual. No adult animals other than human beings are known to prefer orgasmic intercourse regularly with their own sex.

Theories of causation of homosexuality. Genetic theories. Theories that homosexuality can be hereditary have been popular for more than 100 years, but no real evidence exists that aberrations running through generations or among blood relations are not the result of living in similar or identical environments. One study by F.J. Kallmann in 1952 indicated that among identical twins both were homosexual if one was homosexual; among fraternal twins this condition did not necessarily hold true. Kallmann's study, though impressive, has not been confirmed by subsequent research. Other studies have shown that male homosexuals tend to be born of older mothers; but, although genetic abnormality could be involved (as it is in mongolism), the reason may be simpler: older mothers may find their last son more precious and so rear him differently from their other children.

Constitutional and hormonal theories. Recognizing that all human beings are constitutionally bisexual (the hu-

man fetus of either sex having rudimentary reproductive organs of the opposite sex), researchers have conducted various experiments to redirect male or female behaviour. Sex hormones, for instance, once were considered prime movers of masculinity and femininity. Treating effeminate male homosexuals with male hormones, however, has not resulted in more manliness but rather in an intensification of their sexual excitement with the same effeminate behaviour as before. All theories in this class are thus still inconclusive.

Psychoanalytic theories. According to Freudian theory, usually either boys are too fearful of wanting their mothers sexually and thus turn from her and all like her to the safety of those with penises, or they experience intense relations with their mother and so identify with her femaleness that they take the same love objects (males). In some instances, according to Freud, hatred of a brother, in murderous intensity, is covered over with love; such a hate-ridden love seems to underlie the hostility often found in male homosexual pairs. In other instances, a homosexual looks for a youth reminding him of himself at a younger, idealized age, feeling safer with someone more like himself than with a female. Others are said to be homosexual in order to assume the strength or masculinity they lack, much in the manner of cannibals who eat part of another to incorporate prized qualities. In general, psychoanalysts consider homosexuality a result of severe anxiety in childhood, not a variant of normality.

In Freudian theory, the Oedipus complex is crucial to understanding female homosexuality as well. Failing to establish a loving relation with her father, a little girl may turn from hopes of heterosexuality and return to an earlier stage of love with her mother, who is same-sexed. Excessive penis envy may predispose her to this retreat. Wanting to be male makes her reject her vagina and femininity and overemphasize her clitoris as a phallus. Trying to be like a male and, out of envy, revenging herself on males, she turns from heterosexuality, becomes like her father, and takes women for her lovers.

Learning theories. Learning theories differ from Freudian theories in placing greater emphasis on the power of reward and punishment and general environmental conditioning to shape sexual preferences. A high proportion of homosexuals, for instance, come from disturbed home backgrounds, where they experienced difficulty in identifying with the parent of their own sex. In the case of male homosexuals, there may be an overwhelming mother who binds her son too closely to her through a mixture of overprotection and threats and a father who is unreachable because he is passive, often absent, or so punitive that his son can never have a warm relation with him. Such theories of reward and punishment are similar to certain sociological theories that emphasize the cultural forces forming family beliefs. Whether one's society and thus one's family glorifies homosexuality as in Greece, or puts a taboo on it in such a way as surreptitiously to point up its pleasures, the child is conditioned somehow to the attractions of homosexuality. In societies, on the other hand, that tend toward heterosexual permissiveness for children, without severe rewards and punishments—such as the Israeli kibbutzim—homosexuality seems to be rare or nonexistent.

Treatment of homosexuality. The treatment of choice is psychoanalysis and related psychotherapies. Reports of such treatment are consistently optimistic (that is, provided that the treatment is not forced upon the homosexual but is requested because the condition is distressing) and show rates of remission from one-third to one-half of the patients. Success is less likely if the patients at an early age exhibited strong cross-gender behaviour; marked effeminacy as a young boy or tomboyishness as a young girl. No other treatment seems so successful; the only other therapy that is apparently causing remissions is behaviour conditioning (aversion therapy). Nevertheless, although several patients have given up homosexual practices with such treatment, most have not become heterosexual. Treatments involving hormones and other drugs such as tranquilizers, hypnosis, exhortations, imprisonment, and suggestion have all failed.

DEVIATIONS FOCUSSED ON GENDER IDENTITY

Transsexualism. Transsexualism is a condition in which a biologically normal person believes himself (or herself) to be truly a member of the opposite sex, despite anatomical evidence to the contrary. A transsexual does not simply imitate members of the opposite sex in clothing or manner but becomes adept at seeming to be one. In the fantasy life of childhood, expressed in play, the boy, for instance, invariably takes the female role, and his interest in stories is always focussed on women's activities; unlike a transvestite (see below), he dresses in girls' clothes without sexual excitement. This feminine interest never wavers, though it may be somewhat driven underground at school, only to re-emerge in adolescence, when he habitually behaves with extreme femininity and may even pass successfully in the world as a woman. A female transsexual, of course, experiences a similar reversal.

A transsexual may attempt to be surgically and hormonally transformed. In the male, this consists of removal of facial and body hair, the use of estrogens to develop female secondary sex characteristics, especially breasts; the surgical thinning of the larynx; and a genital "sex change" through removal of testes, amputation of the penis, and creation of an artificial vagina from retained penile skin, other skin, or intestinal grafts, and scrotal tissue. In the female, the operation consists of the use of testosterone to create facial and body hair, a lowering of the voice, and clitoral enlargement; the removal of the breasts, ovaries, tubes, and uterus; the closure of the vagina; and, rarely, a skin grafting to produce a nonfunctioning phallus. There are no known cases of adult transsexuals who have lost their desire to change sex through psychotherapy or psychoanalysis. In a few little boys given treatment along with their parents, however, the process of feminization seems to have been reversed.

Biological theories of the causes of transsexualism rest on animal experiments that have revealed a critical prenatal or infantile period during which, for instance, a single dose of opposite-sex hormone, without demonstrable brain damage, will produce permanent change in the development of masculine or feminine behaviour. More reliable, however, are psychological and environmental theories that have shown that transsexuals derive from disturbed families. The mothers of male transsexuals, for example, usually themselves experience powerful transsexual tendencies in childhood but later put on feminine facades—without heterosexual interests, however—and married men who were distant, passive, perhaps not effeminate but unable to assert themselves in a masculine and fatherly manner. Only one son becomes transsexual, usually the youngest and the one to whom the mother is particularly attracted because of a special quality of infantile beauty and grace and whom the mother keeps in excessively close, blissful relations with her for years—often keeping him physically next to her for many hours, day and night, even when as old as four years, and generally making him feel so much a part of her that there is no normal process of separation that children must go through as they develop. With his mother encouraging him and his father either absent or uninterested, the boy develops unimpeded in a feminine manner, his mother becoming concerned only later when talk arises about her very girlish boy. No similar history or etiology of female transsexuals is known, although there is belief that, unlike the males, the females may be more nearly homosexuals of the very masculine variety. Some female transsexuals tell of a close, tender relation in childhood with an inadequate father who either died or left the family; their mothers were generally aggrieved women who encouraged them to assume many characteristics of the sole of father.

Transvestism. Transvestism here refers not to cross-dressing that is momentary, casual, or ritualistic or adopted for theatrical entertainment but rather to the condition in which one habitually develops sexual excitement fetishistically by wearing clothes of the opposite sex. True transvestism apparently exists only in males and begins when an adolescent or man first finds himself in a woman's garment and is struck by the most intense sexual tension, leading to masturbation and powerful orgasm.

One type, whose cross-dressing remains simply fetishistic, concentrates on a single favourite garment, such as shoes or underwear. In a second type, the condition progresses; the man gradually becomes interested in dressing completely as a woman, feeling transiently like a woman, and learning to appear and carry himself so like a woman that he can go out into the world without detection. Although the sexual excitement combines with the sense of being a woman, such men are no more apt to be homosexual than other men and, in spite of their occasional cross-dressing, spend most of their time appearing masculine and choosing masculine professions. They usually marry. They do not wish to become females; they preserve their genitals, finding in them the source of their greatest sexual pleasure.

No evidence exists that transvestism has genetic, anatomic, or hormonal roots; and reports of a higher than predicted incidence of electroencephalographic abnormalities among transvestites still need confirmation. The psychoanalytic theory of causation presumes that the small boy, fearful that sexual desires for his mother will lead to castration by his father, seeks out a "homosexual" solution by fantasizing that donning female clothes permits him to be a phallic, uncastrated woman. A modification of this theory derives from the finding that boys who become transvestites are often first put in female clothes by a woman or girl who despises maleness and relishes humiliating males. Either she openly despises maleness or she assumes a loving, succouring, "motherly" behaviour, unaware of her wish for a weakened (effeminate) male.

Despite a large literature on psychotherapy as treatment for transvestism, no successes are reported, nor are drugs effective. If success in treatment is defined as the removal of the desire for fetishistic cross-dressing, then the only successes reported are those with aversion therapy: patients have had rapid remission, lasting up to several years, when treated over a period to low-voltage but painful electric shocks or to inductions of violent vomiting in the presence of exciting garments.

Intersexuality. Intersexuality is the condition of having both male and female biological characteristics. An intersexual individual may have—the external or internal features of both sexes, the external genitals of one sex and the gonads of the other sex, or any other obvious or covert blend of male and female characteristics. Related terms are gynandromorphism and hermaphroditism.

Such biological abnormalities can lead to deviation behaviour. An infant appearing externally like a normal female but otherwise being entirely male, for instance, will be raised by the unsuspecting parents as a girl, who grows to accept the femaleness without question. In adolescence, however, when the male hormones start their effects, "she" will react in the same way as a biologically normal girl to the hated masculinizing of her body. When the anatomic abnormality is obvious and the parents do not know whether the child is clearly male or female, however, the child can develop a "hermaphroditic identity," believing itself to be different from all other people and feeling emotionally both male and female or neither. Another noteworthy variety of intersexuality is Klinefelter's syndrome, usually marked by the presence of a third sex chromosome (XXY) in males rather than the normal two (XY) and involving markedly defective testes. Appearing to be anatomically normal males at birth, such children are reared unequivocally as boys but nonetheless on occasion become so feminine in childhood that, like transsexuals, they wish to grow up to be women and take on feminine behaviour.

DEVIATIONS FOCUSSED ON SPECIAL SEX OBJECTS

Pedophilia. In pedophilia the object of sexual pleasure is a prepubescent child. Pedophiles are probably always men, whose objects are more often little girls than little boys and whose behaviour rarely involves sadistic attacks (which seem frequent only because of the great publicity attending such acts) and usually involves fondling the child or persuading the child to manipulate his genitals or engage in some degree of oral or anal sodomy.

According to most published case histories, the male pedophile's childhood is disturbed by a broken home (the scene of divorce, separation, or death) and marked by a higher than average incidence of social and sexual activities with girls his own age. Reaching adolescence, however, he becomes shy and fearful of the sexual and bodily maturity of the girls, becomes inhibited, and rather than turning to homosexuality, returns to the variety of safer females—little girls—with whom he was more comfortable and successful as a boy. Pedophiles actually are often married and have children, even though they find little sexual gratification or affection with their wives, and they chronically struggle with overt neurosis or even mild psychosis. One rare type is the senile man, who, because of his waning sexual capacity for adult women and his weakening sense of morality, recalls the sexual pleasures of childhood and takes to fondling little girls.

As for the molested child, whether or not the act is psychologically traumatic depends upon how old and how willing the child is, whether the man is a stranger, whether there is pleasure or pain, and what private fantasies the child assigns to the act. In some instances there are little girls who participate so actively as to be seducers—not because they are "oversexed" or monstrous but because, growing up fearful and unloved in a shattered family, they learn how sex can bring attentiveness appearing like affection or can serve as a medium of taunting revenge.

As with many other deviations, the most hopeful therapy involves increasing the man's insight into the sources of his need by means of psychoanalysis, group therapy, or other psychotherapy. The success of such treatments, however, is still undetermined.

Fetishism. In psychiatric usage, fetishism denotes deriving sexual excitement directly from an inanimate object or a body part (such as hair or hair ribbon, feet or shoes, underclothing) and, though the mode of using these objects varies (kissing, fondling, smelling, and other physical actions), there is usually masturbation. The fetish serves as a substitute for a wanted but too dangerous whole, live person and seems to possess human qualities, despite perhaps its apparent oddness. Some fetishists, for instance, focus on garments that have been worn and contain the odour of the absent owner. Even if new, the clothes usually suggest intimacy, as in the case of garments worn close to the skin. A rather common practice is stealing and then masturbating into the hair cut from a woman.

Fetishism is found mostly in males, rarely in females. According to psychoanalytic theory (involving the Oedipal complex and castration fears), a small boy observes the anatomical differences between the sexes, comes to realize that his prized penis can be lost because there are penisless creatures, and then begins in fantasy to create a "penis" for women by considering some item of clothing or other fetish as the phallus. As the boy grows older, though, his "ego is split": unconsciously the eroticized fetish stands for the female's penis, even though consciously he recognizes the reality of female genitals. The shortcoming of such a theory, however, is its failure so far to show why one boy will be fetishistic and another not or why fetishism should exist in females. Nonpsychoanalytic theorists explain the condition more simply. Some consider the cause to be conditioning: on some occasion a special sexual arousal was associated with a neutral object, and thereafter, through reinforcement, the object developed in importance. Others suggest the process of imprinting: just as an infant chick can erotically fix on a piece of wood if the piece of wood is presented as the first strong external stimulus in its life, so may a neutral object be imprinted in the first few years of a child's life.

When there are multiple fetishes and other sexual deviations involved, the prognosis for treatment is poor, but when there is the problem of a single fetish, the chances of success increase. Such fetishism has been removed by hypnosis, insight psychotherapy (including psychoanalysis), and aversion therapy.

Incest. Incest refers to culturally prohibited sexual relations between certain family members—the exact members being defined differently from society to society, although every society known to history has had some in-

cest taboos. Although prohibitions against incest have been rationalized on the grounds of the alleged dangers of inbreeding (see *CONSANGUINITY*), such defenses are largely modern afterthoughts. Incest taboos have more practical social origins: marrying outside the family assures a wider circle of allies and various economic advantages, and it also preserves the family (with its procreative and childrearing functions) by precluding the disruptive jealousies that incest might arouse among family members. Whatever the origins, however, incest comes to be socially viewed with intense disgust, even when personal fantasies rather than actual incest are involved.

Freud's psychology of human behaviour centred on the incest taboo and the resultant struggle against it, which he called the Oedipal conflict. The struggle results because, in Freud's view, sexual desire, most prominently toward the parent of the opposite sex, is found universally in small children. In other words, although biologically the desire may be unusual, it must be curbed because it is socially "unnatural."

The severest taboo has always been against mother-son sexual relations, which have been so dramatized in mythologies and generally so execrated by mankind that the act almost never occurs outside of fantasies. In those rare cases reported in modern times, the mother's sexual object was not an adult son but rather a child or defenseless adolescent, and the mother was usually nearly or actually psychotic. On the other hand aborted incestuous activity between mother and son, such as genital manipulation or sensual kisses and embraces, is so common as to be considered at the root of many cases of psychiatric disorder.

Intercourse between father and daughter is more common, with countless cases reported every year. Not infrequently the father, usually an ineffectual man with a history of heavy drinking, has sexual relations with more than one daughter, though one is usually favoured. The man's wife hates her sexual "obligations," helping to cause him to turn to their daughter and often even surreptitiously pushing her daughter onto her husband. All the while she blinds herself to the evidence of incest, even accusing the daughter of having a "dirty mind" should the daughter speak up. In any event, the father-daughter incest may proceed for years, eventually to be dissolved by the daughter, at the latest in her 20s. Although such a continuing experience may not arouse much guilt in father or daughter, both sensing the mother's collusion, they may suffer severe conscious anxiety and guilt should the mother indeed interfere at the outset.

Society uses primarily primitive measures for treating the participants in incest, namely, imprisonment and in an earlier day death. Modern psychotherapy, however, may assist a person, particularly a parent, in reducing the intensity of his incestuous wishes and assist the victim in handling his feelings of guilt or rage.

Bestiality. Bestiality is a sexual deviation in which animals are the preferred objects for achieving sexual gratification. Its frequency is overestimated in the public imagination because of the stories of boys or men isolated on farms and ranches and experimentally sex-playing with animals; such males, however, presumably would prefer females if they were available. Bestiality as a pattern of deviation is rare.

The deviation may arise as the result of fear and inadequacy in approaching members of the opposite sex and often also as the result of a strong previous development of bestial patterns (conditioning). Humiliation is avoided with a compliant animal, and revenge is possible: often bestiality in men is accompanied by overt sadism; the man gets excitement simply from inflicting pain upon, or even killing, the animal and, more rarely, from having intercourse with the animal as well. Bestiality in women (less common than in men) is usually a form of masturbation, the animal being used to rub against or lick the woman's genitals. There seems no real sexual desire for animals, but only the fear of rejection and humiliation by men.

Because only a handful of cases have ever been reported to have been treated, no preferred therapy is known.

Necrophilia. Necrophilia involves sexual gratification with a corpse, which may be mutilated after the sexual

Types of
incest

act. It is to be distinguished from extreme forms of sadism, in which a person is murdered and while dying is subjected to intercourse or masturbation. The necrophiliac is not a murderer. The condition apparently occurs only in men, is extremely rare, and is ordinarily associated with overt psychosis.

The essential rationales for the necrophiliac's excitement are, first that the woman, being dead, is absolutely **undangerous** and, second, that he is revenged upon **womankind**, represented by the dead woman. Such people have not been studied adequately, however, to determine what has happened in their lives that specifically directs their needs. There are no reliable reports on treatment.

DEVIATIONS FOCUSING ON SPECIAL PATTERNS OF ACTS

Exhibitionism. Exhibitionism is the deviation in which sexual excitement or gratification is achieved by exposing one's genitals publicly or semipublicly, almost always to members of the opposite sex, adults or children. It is reported only in males and obviously only in societies in which such exposure is looked upon as sinful and indecent.

The typical exhibitionist is a shy, passive male with strong feelings of inadequacy and impotency and with little capacity for developing affectionate or sexual relations with a woman, even though he may be married. The impulse to expose himself usually occurs when he is feeling especially inadequate; he furtively exposes his penis (usually erect), masturbates, and looks for signs that his victim is impressed or shocked—but he does not wish her to respond sexually. That would terrify him. The danger and apprehension surrounding the act contribute to the excitement; both psychiatrists and courts recognize that exhibitionists seem to feel the need to be caught. (Next to homosexuality, exhibitionism is the deviation most frequently dealt with by the courts.)

The act of exposure for an exhibitionist is thus not an act of seduction or anticipation of a sexual relationship as it is among homosexuals or among some women expressing their femininity seductively in loose or revealing dress. Nor is it like the showing-off of prepubescent boys, since the exhibition for them is not itself sexually exciting or like the foreplay of heterosexuals who are trying to create excitement in their partners. Instead the exhibitionist is one who considers himself unmanly, yet prefers women and attempts in the act of exposure to prove to allegedly skeptical women that he indeed does have a penis and is potent. The exposure can also be meant to express the dirtying of women by the penis and its ejaculate.

There is no reason to believe that exhibitionism has biological causes, since it occurs only in societies in which covering the genitals is crucial and especially in societies of a puritanical nature. Usually the exhibitionist has had early childhood relations with a domineering woman, especially his mother, who had puritanical attitudes toward sex. He grows up shy and immature, with no adequate outlet for his sexual tensions. Strongly identifying with females, such as his mother, but also being masculine enough to desire manliness, he must demonstrate that he too is not penisless and that indeed he has a penis capable of impressing or shocking women.

Although there is cautious optimism about treatment, the degree of success is still indeterminate. Individual psychotherapy and aversion therapy have produced few cures, though they occasionally succeed in conditioning a man to frustrate his urge and reduce his need to be caught. Group therapy has been used extensively because of the considerable populations of imprisoned exhibitionists, but such treatment seems similarly effective in producing discretion, not cure.

Voyeurism. Voyeurism is the deviation in which one achieves sexual excitement and gratification through clandestine peeping. Voyeurs, seemingly all males, usually avoid any sexual approach to females and instead concentrate on watching females in the nude or in the act of undressing or on couples in sex play and find release in masturbating in the course of such peeping.

In societies placing restrictions on **nudity**, young men are given to curiosity about sexual activities and females

and to viewing pornographic drawings, photographs, and motion pictures as partial compensation for their sexual needs. Whereas females in such societies are taught from childhood to conceal themselves and prevent their being looked at, males are indoctrinated to the challenge of this modesty and the forbidden excitement of catching a glimpse. Furthermore, visual pleasures are ubiquitous in restrictive societies, as attested by the popularity of nude and seminude pictures and entertainment.

Given these general circumstances, **why** do some males develop a habitual, preferred need for peeping and voyeuristic activities? The answers are unclear. A voyeur is often the youngest child and a child whose sexual curiosity or tension has been heightened by the provocative feminine behaviour of a **mother** or sisters. Like the exhibitionist, he typically feels shy, inadequate, and fearful of the opposite sex, but he achieves his compensatory feelings of potency and superiority in the act of violating unseen the privacy and modesty of the woman being watched. Intensifying the excitement may be the risks and dangers often associated with peeping. Also, fantasies of identifying with a male partner can contribute to a sense of achievement.

Voyeurism seems difficult to treat and, although various forms of psychotherapy have tended to help patients to curb their impulses to peep, few cures are known.

Sadism. Sadism is the condition in which one achieves sexual excitement or gratification through inflicting physical pain. The sex object can be human or animal, adult or child, a person of the opposite or the same sex. The sadistic activity can be whipping, biting, binding, chaining, knifing, slashing, or other more exotic inflictions—or in extreme cases mutilation or murder or both. It can involve stereotyped ritual or vary from victim to victim in kind and intensity. The sadistic activity may itself be sufficiently exciting to induce the sadist's orgasm or may lead up to sexual intercourse or sodomy. The condition is most often found in males. Women who perform sadistic acts during sexual relations are often not sexually excited but have been put to use by masochistic men.

Various possible causes of sadism have been offered. One suggests that sadism grows out of a child's **frustration**, neglect or rejection by others and the consequent desire to prove one's importance and superiority by delivering retribution upon others. **Another** theory relates sadism and masochism (see below Masochism), suggesting that they represent an exaggeration of the active or passive, aggressive or submissive roles that human beings tend to assume. Other approaches tie sadism more closely to the sexual act: a sadist may be one who feels impotent and fears that he might fail sexually in approaching the opposite sex; to preserve his self-esteem and demonstrate his power, he takes the "easier," though more destructive, avenue of sadistic attack. Or the sadist may be one whose puritanical upbringing has led him to consider sexual relations sinful and depraved; the sadistic acts are punishment of others for allegedly having lustful tendencies or engaging in sexual relations. (Extreme sadists of the murderous type, for example, are known to mutilate the genitals or breasts of their victims.)

At different times Freud tended toward various hypotheses: in an early essay he noted that "the history of human civilization shows beyond any doubt that there is an intimate connection between cruelty and the sexual instinct" and that sadism is thus an intensified primary urge (masochism being "a transformation of sadism"); later he pointed to man's "death wish" or ultimate drive to be inanimate (a masochistic tendency) and stated that sadism is a secondary transformation of this self-destructive urge, an attempt to turn the destruction away from oneself and onto the outside world, where it can be better borne. In any event, Freud emphasized that masochism is often hidden behind sadism; the victim is present within the attacker, either overtly, when the sadist for brief moments becomes himself a masochistic object of attack, or covertly, when throughout the activities he identifies with his victim vicariously.

It is uncertain whether or not there is a successful treatment for sexual sadism. There are a few reports of men treated by psychoanalysis or psychotherapy who, after

Freudian conceptions of sadomasochism

treatment, were driven less (or perhaps not at all) to inflict pain upon others; but programs of group therapy, particularly among convicted sadist offenders, have yet to demonstrate their curative or ameliorative effects. Thus far there are not adequate reports of the success of aversion treatment.

Masochism. Masochism is the condition in which sexual pleasure is derived from the sensation of physical pain. The pain may be either self-inflicted or inflicted by others and can involve such activities as flagellation, pin sticking, binding, spanking, or semi-strangulation. Masochistic sexual fantasies are ubiquitous in women, but overt masochistic behaviour to the point of sexual excitement seems more prevalent in men.

The interpretations of masochism often parallel the interpretations of sadism (see above **Sadism**); many authorities consider masochism a mirror image of sadism, with both tendencies found in varying degrees in the same person. Freud related masochism both to the "death instinct" (the wish for one's own dissolution) and to sadism turned round on oneself. Others have suggested that masochism is a means of holding sadistic impulses in check, and there are indeed examples of persons having long experienced masochistic roles, only to explode, turn sadistic, and kill their attackers when their defenses suddenly fail.

Other attempts to explain the causes of masochism are more closely related to childhood experiences. It is suggested, for instance, that masochistic behaviour may arise when one believes that sexual relations are sinful or disgusting. When fantasizing or engaging in sexual pleasures, therefore, the individual must atone or pay for his sin by means of self-torture. Other evidence suggests a relation between masochistic development and a lack of love and affection in childhood. A child who is neglected by his or her parents and who receives attention only when punished may turn repeatedly to punishment to get attention. Later, punishment translates into an assurance of being wanted and loved. Masochism may also be associated with martyrdom, a way of transferring guilt to others.

Persons with a masochistic life style are difficult to treat, particularly when their behaviour is coupled to the sadistic behaviour of a spouse or lover. As in the case of sadism, psychoanalysis and psychotherapy can be used to develop a patient's insight into his non-rational convictions; but the success of such therapies is still indeterminate for this deviation.

Rape. In psychiatric usage, rape is the act of taking sexual relations by force or threat and without the victim's consent. There is no term for the deviation itself (such as "rapism"), the habitual preference for forcible sexual relations. In legal usage the term rape extends to relatively nondeviant acts such as those involved in a man's obtaining consent through fraud or false pretenses, in a woman's submitting willingly and then retaliating with accusations, and in an adult's having nonforcible sexual relations with a minor (statutory rape) or a mentally incompetent. For obvious anatomical reasons, the deviation is found exclusively in males, about half of whom (according to court records) are married and living with their spouses when committing rape upon other women.

Deviational rape is a form of sadism in which the man achieves excitement only in the awareness that he is harming the woman, as evidenced by her struggles or anguish; behind this awareness lies a fantasy of revenge or a feeling that women are inferior and not worthy of decent treatment. Such attitudes often derive from childhood experiences in which the boy was rejected or humiliated by women and subjected to physical punishment excessive for the boy's misbehaviour. Rapists usually come from families in which violence is frequent between parents or between parents and children. In psychoanalytic theory involving the Oedipal complex, deviational rape represents a displaced attempt to force a rejecting mother into sexual relations.

Although psychoanalysis or related psychotherapies should help the motivated patient to discover the sources of his hatred of women and to find more acceptable means of gratifying his needs, there are as yet no reliable reports of successful treatment.

Satyriasis and nymphomania. Satyriasis and nymphomania refer to excessive or exaggerated sexual desire and activity on the part of males and females, respectively. The difficulty in drawing a meaningful line between "normal" and "excessive" sexual desire or activity is obvious. Satyriasis and nymphomania, which are psychologically induced, should be distinguished, however, from hypersexuality, a biological condition caused by brain lesions or hormonal imbalances and marked by extremely intense sexual desires and frequent spontaneous erection of the penis or clitoris.

A person who centres his or her life on sexual pleasures may do so for various reasons: to escape from one's problems, to compensate for the frustrations of life when few other pleasures are available, or to lend support to one's feelings of adequacy as man or woman. Such pleasures may be sought within marriage, in a variety of deviant sexual acts, or in a pattern of promiscuity. The promiscuous satyr and nymphomaniac specifically, the person with an overpowering, tormenting need for sexual relations with a never-ending number of partners—will be dealt with here, since their attributes are more markedly deviational and definable.

In one variety of males and females, the purpose of such promiscuity is not sexual gratification per se but rather conquest and the proof of superiority over the opposite sex. The satyr or Don Juan, for instance, who operates on the fantasied belief that women are domineering and cruel must attempt to humiliate all women endlessly in an insatiable search for his self-esteem. Seduction is his aim, not sexual intercourse, unless such is necessary to hide his real purposes or to fix the woman dependently on him. The nymphomaniac of parallel design is trying to outdo men, who have been hated and envied since early childhood for their social and anatomical power. The nymphomaniacal woman needs to demonstrate repeatedly that she is better than any man and can outperform him in that most prideful competition, sexual intercourse. Such a woman has another device, in addition to changing partners, for humiliating a man: she insists that he have intercourse "one more time." Then, no matter how many times he manages, she needs "one more time" and in this way wins.

In another variety of satyriasis and nymphomania, the never-ending (and thus painful) search for mates is a search for a fantasied ideal man or woman. Genital sensation is secondary or unimportant; the test is not to outdo or outlast one's partner in sexual intercourse but to find some idealized virtue or quality. A woman may be wanting a sense of peace and safety, for which she searches in man after man. A man may be testing for purity but, in successfully seducing a woman, he proves she is not his pure woman ("the perfect mother").

Without treatment, the satyric or nymphomaniacal sufferer tries to cure the incurable with endless liaisons and thus runs the risk of developing a gradual sense of hopelessness as the years pass, sometimes eventuating in acute depression or even suicide. Such hopelessness derives not only from his or her enslavement to seduction (with all the energy that such requires) but also from the process of aging and reduced attractiveness and potency (physiological or psychological), forcing him or her to rely more on wiliness than on youthful prowess.

Because of the often underlying fears of not being manly or feminine enough (*i.e.*, of being homosexual), the patient must get insight into the roots of the condition if he or she is to be freed from its thrall. This requires extensive psychotherapy or psychoanalysis.

OTHER DEVIATIONS

Abstinence. Abstinence is the conscious avoidance of sexual relations. As a mode of self-restraint, it can be distinguished from biological states (such as aging, castrations, genetic disorders, or malnutrition) that prevent sexual activity or desire. There are several modes or degrees of abstinence, among them those involving (1) full masturbation; (2) masturbation short of orgasm; (3) excitement engendered by fantasy, without masturbation and with or without orgasm; (4) disguised sexual excitement;

as in religious **frenzies** containing unacknowledged sexual imagery or in various **kinds** of veiled sadistic or masochistic abuse; and (5) total self-denial, without any detectable sexual excitement or substitution.

There are also various motivations for abstinence, such as extreme commitment to a moral or intellectual purpose (private or institutional) requiring abstinence, or extreme fear of **punishment** from one's conscience. There are also rare persons who, though biologically normal, are effortlessly abstinent. Compared to most other deviations, abstinence is a common pattern in those societies in which religious and ethical systems place a premium upon physical denial. As a test of motivation and as a respectable offering to higher powers, abstinence has been pursued for thousands of years in almost every culture. Its value in focussing sexual energy into other productive channels of behaviour is as strong today as in earlier eras.

Devotional masturbation. Masturbation is self-stimulation of the genitals, commonly to orgasm, using the hand, some other bodily part, or an inanimate instrument. It is the most common cause of orgasm in both males and females prior to marriage. The frequency of the practice depends on the intensity of one's sex drive, emotional **conflicts**, and the availability of other outlets.

Although most psychiatrists and psychologists consider masturbation an expected practice on the path to heterosexual relations, it serves equally to gratify in fantasy many of the sexual deviations discussed above. Additionally, it can be devotional if it persists out of fear of heterosexual relations or if it is so associated with shame or guilt as to cause serious personality disorders of a broader nonsexual nature. Folkways deploring masturbation are common in many societies, causing chronic guilt and sense of inferiority in some young people.

Although masturbation itself may not be sexually deviant in a statistical sense, the fantasies accompanying it usually are. In mild form, these may be simply voyeuristic, but in more involved storytelling, deviation appears. For instance, a person may, while masturbating, fantasy being beaten, raped, or humiliated or taking revenge upon members of the opposite sex. Because such fantasies may appear even in nondevotional heterosexuals, however, they point up the fact that sexual deviation is a relative, not an absolute, state.

Polymorphous-perversepersonality. The term **polymorphous-perverse personality** refers to an individual who is indiscriminate in his object or mode of sexual behaviour. Although the capacity to imagine oneself in almost any deviant act is general, few people can or need to perform such **acts**. Some individuals, however, can enjoy almost any potential inducer of orgasm, whether the sex object be man, woman, child, beast, or inanimate object and whether the method involves the object's genitals or some other body part. This lack of discrimination is thought to result from a person's inability to develop sexually beyond early stages of life. Although the condition is occasionally found in the mentally retarded (who fail to develop well beyond childhood) and in persons disturbed by brain lesions as in senility, most people with a **polymorphous-perverse personality** are either nearly or wholly psychotic persons or **nonpsychotic persons** who, in sexual and nonsexual areas of living, are unable to develop lasting, affectionate relations with others.

Minor deviations. The variety of deviant sexual acts seems limited only by a human being's anatomy and physiology and his capacity for invention and fantasy. Thus there are innumerable other sexual acts and patterns—such as **cunnilingus** (oral stimulation of the vulva or clitoris) and **fellatio** (oral stimulation of the penis); **buggery**, or anal intercourse; acts involving urination or defecation; **frottage**, or rubbing against other persons for sexual **excitement** (as in crowded buses or subways); and **coprolalia**, or using obscene language. Most such **behaviour** would not be defined as **deviant** if the acts are momentary, experimental, for variety, or part of foreplay. These acts would be considered in the realm of sexual deviation if they involved a habitual and preferred practice. Some, of course, are elements of other deviations, such as homosexuality or sadomasochism. It should also

be noted that such conditions as **pyromania** and **kleptomania** may be sexual deviations when they are demonstrably associated with sexual excitement or gratification.

STOLLER, *Sex and Gender* (1968), a study on earliest roots of masculinity and femininity, using highly deviant subjects as "natural experiments" for revealing more normal processes of gender development.

(R.J.S.)

Seychelles

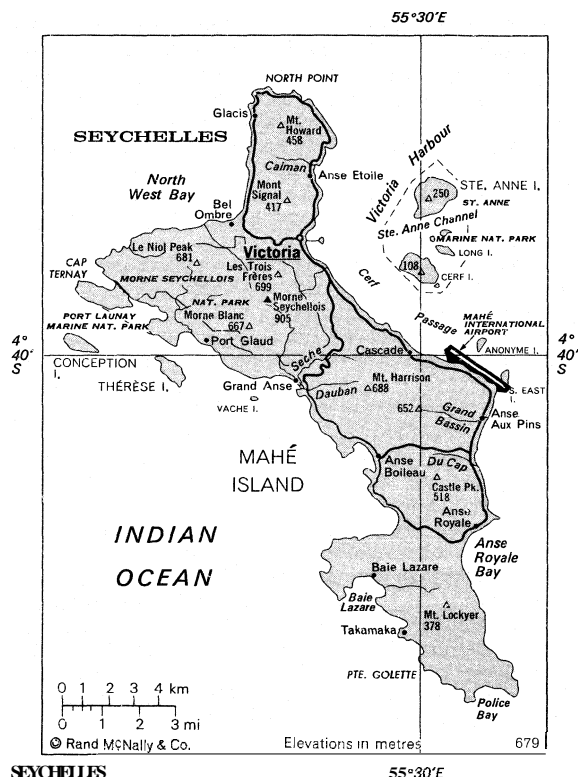

The Republic of Seychelles is an archipelago situated between 4° and 11° south latitude and 46° and 56° east longitude in the Indian Ocean. **Mahé**, the main island, is about 680 miles (1,100 kilometres) northeast of Madagascar. The republic is composed of 40 central, **mountainous**, granitic islands of the **Mahé** group and 60 outer, flat, coralline islands, all spread over an area of some 150,000 square miles (400,000 square kilometres). The archipelago has a land area of 171 square miles (444 square kilometres), of which **Mahé** Island takes up 57 square miles. The capital is Victoria, a town with a population in 1970 of 15,600, on **Mahé**. Seychelles is a member of the United Nations and of the Organization of African Unity.

Physical geography, flora, and fauna. The islands of the **Mahé** group rise from a large, shallow, crescent-shaped submarine plateau to 3,000 feet (900 metres) above sea level in the **Morne Seychellois** on **Mahé**. The overall aspect of these islands, with their lush tropical vegetation, is that of high, hanging gardens overlooking silver-white beaches and clear lagoons. In contrast, the outer, coralline islands rise only a few feet above sea level.

The climate is tropical-oceanic, the average annual temperature varying from 24° C (75° F) to some 30° C (86° F) at sea level. Two monsoons blow over the islands, the southeast ("Svette") from May to November and the northwest ("Vents d'Nord") from November to May. **Rainfall** varies from island to island, tending to decline from the granitic islands to the southernmost coralline islands. On **Mahé**, the annual rainfall at sea level averages 92 inches (2,300 millimetres). The granitic islands have only small streams that run swiftly into the sea, hence, even short droughts produce water shortages.

The only remaining primary forests are of **coco-de-mer** (or sea coconut; *Lodoicea seychellarum*), which grows in protected reserves on Praslin and **Curieuse** islands. **Aldabra** Island is famed for its birdlife. The giant tortoise, once widely distributed, is now almost extinct and is protected. Hunting of the green sea turtle also is regulated. There are few insects and no animals dangerous to man on the islands, though there are sharks in abundance in the seas around.

History. Probably the Arabs were the first to see the Seychelles, but they did not settle there, and the Portuguese sighted the archipelago in the early 16th century. The first recorded landing was made in 1609 by an expedition of the English East India Company, which found the islands uninhabited and abounding in water, fish, birds, and fruits. During the early 18th century they

proved to be ideal hideouts for pirates.

In 1742 Bertrand-François Mahé, comte de La Bourdonnais, the French governor of Mauritius, sent Capt. Lazare Picault to explore the islands. Picault eventually anchored in a bay on the southwest coast of Mahé, which he named. The French, however, made no real attempt to annex Mahé and its surrounding islands till 1756, when a frigate was sent to take possession and forestall the British. The islands were named *Séchelles*, later altered by the British to *Seychelles*. In 1770 the first colonists began to arrive from Reunion. They so depleted the forests and the giant tortoises for exports that in 1789 they were confined to fixed areas and forbidden to trade. By the early 19th century the population had grown to more than 2,000. War between France and Britain did not affect the islands till 1794, when a British squadron appeared and demanded unconditional surrender. The Seychelles were finally ceded to Britain in 1814, by the Treaty of Paris, and were incorporated as a dependency of Mauritius, which by that time the British also had taken from France.

Under British rule the Seychelles entered a long period of peaceful obscurity. The abolition of slavery in the 1830s produced a fundamental change in the agricultural pattern. The settlers, finding themselves without a labour force, changed from raising labour-intensive food crops and cotton to crops that required less labour, such as coconut, vanilla, and cinnamon. In 1903 the Seychelles became a crown colony. Previous constitutional advances had occurred in 1872 with the appointment of a Board of Civil Commissioners and in 1888 with the appointment of the first nominated Legislative and Executive councils. The Seychelles, however, had to wait till 1948 to have their first Legislative Council with elected members. In 1970 they obtained a new constitution, universal adult suffrage, and a governing council with an elected majority.

The year 1364 had seen the formation of the Seychelles People's United Party (SPUP), led by France-Albert René, and the Seychelles Democratic Party (SDP), led by James R. Mancham. The first was leftist, the second centre-conservative, but both came to espouse independence. The elections of November 1970 brought the majority of votes and 10 seats in the Legislative Council to the SDP, and Mancham became chief minister. At the next election (April 1974) the SDP increased its majority.

On October 1, 1975, the archipelago obtained the abso-

lute right of self-government, and at midnight on June 28-29, 1976, Seychelles became independent as the 36th member of the Commonwealth of Nations. At the same time the outer islands Aldabra, Desroches, and Farquhar—which, together with Diego Garcia in the Chagos Archipelago, for military reasons had received in 1965 an exceptional position as the British Indian Ocean Territory—were returned to Seychelles.

In 1975 the two political parties had agreed to form a coalition government, with Mancham as president and René as prime minister. On June 5, 1977, while Mancham was in London, rebels seized control of the police headquarters and other public buildings and invited René to assume the presidency. He did so, announcing that his government, while certainly not Marxist, would develop a form of socialism appropriate for the country.

Source: Official government figures; Rene Moreux et Cie., *Marches tropicaux et méditerranéens*.

The people. The original French colonists on the previously uninhabited islands, and their black slaves, were joined in the 19th century by deportees from France and by a few British. Asians from China, India, and Malaya arrived later in smaller numbers. Widespread intermarriage has resulted in a population of mixed descent.

The census of 1960 put the total population at 41,041, that of 1971 showed that the figure had risen to about 52,400, and that of 1977 showed 61,898. More than 90 percent of the people live on Mahé, a quarter in the capital, Victoria. The coral islands have no permanent population. The large increase of population during the 1970s (17 percent between 1970 and 1977) was for the most part attributable to development on Mahé.

All along the coasts of the main granitic islands are small villages, many of them populated by fishermen and their families, made up of thatched cottages clustered around a church and facing the sea. On the small islands there are only isolated cottages near the beaches.

English and French are the official languages. The mother tongue of most Seychellois, however, is Creole, a patois that is a mixture of clipped French (much of it archaic) with words from African languages and a few mutilated English words. About 90 percent of the population is Roman Catholic.

The economy. The so-called tertiary economic sector (commerce, transport, banking, insurance, tourism, administration, domestic services) is the most important in Seychelles' economic life, followed by agriculture, forestry, fishing, and the building industry. There is almost total absence of industrial plants. Tourism is of growing importance in the economy. About 15,200 visitors came to the islands in 1972, 49,500 in 1976, and the projection for 1981 is 80,000. The traditional export products that brought in foreign currency (cinnamon, copra, guano) are gradually losing importance.

Completion of the road system, the water-supply system, and the internal communications (road and air) system are planned. The harbour of Victoria has been enlarged and modernized. The international airport, near Victoria, was opened in 1971, the first modern hotel in 1972.

Administration and social conditions. The constitution of the Republic of Seychelles (1976) provides for a president of state at the head of the executive branch. He is responsible especially for foreign affairs, defense, and in-

ternal security, and he nominates and dismisses the ministers. The Cabinet consists of the prime minister and 10 other ministers, all of whom must be members of the unicameral National Assembly (25 elected members). There is a Supreme Court and a Court of Appeal for both criminal and civil matters. Since 1977 the regime has been enlarging the country's security forces.

Education standards have been rising steadily, as is shown by the literacy rate of 74 percent among persons aged 15 to 29. Though education is not compulsory, 95 percent of children of primary school age attend school. Six-year primary school is free. Children over 12 may attend secondary grammar school (admission by examination) or junior secondary school followed by technical and vocational courses. There is a teacher-training college, and scholarships are awarded for further education overseas.

Seychelles has few tropical diseases. Tuberculosis, leprosy, and filariasis, once common, are declining. The main islands have adequate hospitals and clinics.

Prospects for the future. The policy of the government is to support fishing and agriculture. The prospects for industry are negligible because the internal market is so small and the islands have no mineral resources apart from guano. An appropriate promotion of tourism and the development of the fishing industry are promising, however. In the foreseeable future, the Republic of Seychelles will be dependent upon foreign aid.

BIBLIOGRAPHY. A more detailed description of these islands may be found in JONATHAN D. SAUER, *Plants and Man on the Seychelles Coast: A Study in Historical Biogeography* (1967); BURTON BENEDICT, *People of the Seychelles* (1966); GUY LONNET, *The Seychelles* (1972); and WILHELM MARQUARDT, *Seychellen, Komoren und Maskarenen: Handbuch der ostafrikanischen Inselwelt* (1976). Sforza, Ludovico

One of the most magnificent of the Renaissance princes, a patron of Leonardo da Vinci and other great artists, Ludovico Sforza was at the same time typical of his time and rank in his ruthless pursuit of power. He won a leading position in Italy by his subtle and unprincipled diplomacy and his trust in himself and his destiny.

Sforza, detail from the Sforzesca altarpiece by the Master of the Pala Sforzesca (1480-1520). In the Brera, Milan.

Ludovico Sforza was born at Vigevano, Pavia, on July 27, 1452, the second son of Francesco Sforza, who had made himself duke of Milan. While still a child, he

received the epithet *il Moro* (the Moor) because of his dark complexion and black hair. Brought up at his father's refined court, he remained, after his father's death in 1466, in the service of the new ruler, his elder brother Galeazzo Maria. When Galeazzo was murdered, however, in 1476, leaving the duchy to his seven-year-old son Gian Galeazzo, Ludovico first revealed his appetite for power, plotting to win the regency from the child's mother, Bona of Savoy. The plot failed, and Ludovico was exiled but eventually, through threats and flattery, won a reconciliation with Bona and brought about the execution of her most influential adviser and chief minister, Cicco Simonetta, in 1480. Shortly afterward, he compelled Bona to leave Milan and assumed the regency for his nephew.

From that moment he entered the arena of "equilibrium politics," by which a precarious balance was maintained among the major Italian states. Taking advantage of the rivalry between these states, he established Milan's supremacy. Distrusting Venice, he remained on good terms with Florence and its Medici ruler, Lorenzo the Magnificent. He secured useful alliances with Ferdinand I, king of Naples, whose granddaughter Isabella was married in 1489 to Gian Galeazzo, and with the Borgia pope Alexander VI, through the influence of Ludovico's brother Ascanio, who was a cardinal. In 1491 Ludovico married Beatrice d'Este, the beautiful and cultured daughter of the Duke of Ferrara. The marriage proved to be unusually harmonious, in spite of Ludovico's mistresses; and Beatrice bore him two sons, Massimiliano and Francesco, both of whom later became dukes of Milan.

With lavish but enlightened patronage of artists and scholars, Ludovico made the court of Milan the most splendid in Europe. Leonardo da Vinci and the architect Donato Bramante were among the many artists, poets, and musicians who gathered in Milan. Ludovico sponsored extensive work in civil and military engineering, such as canals and fortifications. The court and the common people alike rejoiced in Ludovico's magnificent celebrations; the Milanese, however, though enjoying well-being, were increasingly burdened by taxes.

Resentful of the overshadowing splendour of the court of Ludovico and Beatrice, Gian Galeazzo, the rightful ruler of Milan, and his wife, Isabella, left Milan to establish court at Pavia. Isabella was more outraged by Ludovico's flagrant usurpation of the ducal powers than her husband was, and she appealed to her grandfather, Ferdinand I, who intervened in 1492, ordering Ludovico to surrender control of the duchy to Isabella and Gian Galeazzo. Ludovico refused and, fearing a war with Naples, formed an alliance with two foreign sovereigns, the emperor Maximilian I and King Charles VIII of France. For an enormous sum of money Maximilian not only bestowed upon Ludovico the title of duke of Milan in 1494, legitimizing his usurpation, but also married Bianca Maria, Gian Galeazzo's sister. Charles VIII, who was contemplating the seizure of the kingdom of Naples from Ferdinand, received Ludovico's promise of help.

The campaign of Charles VIII to conquer Naples in 1494-95 threw the whole of Italy into confusion and eventually alarmed even Ludovico himself. He joined the league led by Venice, which, in spite of Charles's initial successes, soon expelled him from Italy. Ludovico was the ultimate victor in this affair, achieving for a time maximum safety and almost unlimited power; both Gian Galeazzo and Ferdinand died in 1494, and Charles VIII himself soon became reconciled with him. Ludovico is reported to have said at the time that Pope Alexander was his chaplain, the emperor Maximilian his general, the governing Signoria of Venice his chamberlain, and Charles VIII his courier. The illusion, however, did not last long.

Charles VIII died in 1498 and was succeeded by Louis XII, a descendant of the first duke of Milan. Louis claimed the duchy and, with the support of Venice and a Milanese population oppressed by Ludovico's taxation, quickly conquered it. When the Milanese had in turn tired of Louis's rule, Ludovico, who sought refuge with Maximilian, tried to retake Milan with German and Swiss mercenaries. His Swiss troops, however, refused to fight for him in a crucial battle, and in April 1500 Ludo-

Alliance with Maximilian I and Charles VIII

Ludovico's fall

vico was captured by the French while attempting to escape, disguised as a Swiss. His fall was celebrated all over Italy. He was imprisoned in the castle of Loches in Touraine, from which he tried in vain to escape. He died there, still unresigned, on May 27, 1508.

The memory of Ludovico was clouded for centuries by Machiavelli's accusation that he "invited" Charles VIII to invade Italy, paving the way for subsequent foreign domination. The charge was perpetuated by later historians who espoused the ideal of national independence. More recent historians, however, placing the figure of Ludovico in its Renaissance setting, have re-evaluated his merits as a ruler and given a more equitable assessment of his achievement.

BIBLIOGRAPHY. The personality of Ludovico Sforza is described with full particulars in F. MALAGUZZI-VALERI, *La Corte di Lodovico il Moro*, 4 vol. (1913–23; 2nd ed. of vol. 1 only, 1929); and compendiously in E. VERGA, *Storia della vita milanese* (1909; 2nd ed., 1931). Concise biographies are: S.A. NULLI, *Lodovico il Moro* (1929); and P. PIERI, "Ludovico il Moro," in *Enciclopedia Italiana*, vol. 21 (1934). Biographical information may also be found in the best works on the Sforza Family: C. SANTORO, *Gli Sforza* (1968), an excellent book with an exhaustive bibliography; L. COLLISON MORLEY, *The Story of the Sforzas* (1933); and G. FRANCIOSI, *Gli Sforza* (1932). The politics of Ludovico Sforza and the Renaissance in Milan are dealt with in detail by various authors in TRECCANI'S *Storia di Milano*, vol. 7 (1956) and vol. 8 (1957).

Shaftesbury, Anthony Ashley Cooper, 1st Earl of

Anthony Ashley Cooper, the 1st earl of Shaftesbury, whose political career extended over more than 40 years, is best known as the most prominent and skillful opponent of Charles II's pro-Catholic policies. He was born at Wimborne St. Giles, Dorset, on July 22, 1621. From his maternal grandfather, Sir Anthony Ashley, and his father, Sir John Cooper, he inherited estates in Dorset and Wiltshire, and although some were lost through litigations during his minority, his inheritance was large enough to enable him to contemplate a career in politics at an early age. On February 25, 1639, he married Margaret, the daughter of Lord Coventry, Charles I's Lord Keeper; this marriage ended with her death ten years later. When still only 18, he had been elected to the Short Parliament (April–May) of 1640, but his election to the Long Parliament of the same year was disputed and he was not allowed to take his seat.

Though the Civil War broke out in 1642, Cooper did not take up arms for the King until the summer of 1643, and in February 1644 he went over to the side of Parliament, dissatisfied with the political and religious influences uppermost at the Royalist Court in Oxford (the

king's headquarters) at that time. He took an active part in the operations in Dorset in 1644. There is little evidence of his activities between 1645 and 1652, other than his marriage to Lady Frances Cecil, the Earl of Exeter's sister, in 1650, and that he became a member of a commission to aid a parliamentary committee that was to examine projects for law reform. It may have been this commission membership that secured his nomination to the Barebones Parliament (July–December) of 1653. In December 1653 he helped to persuade the more conservative majority of that Parliament to resign its powers to Oliver Cromwell, the victorious Puritan leader. As a result, he was appointed to the Council of State established by the Instrument of Government that set up the Protectorate—with Cromwell as Lord Protector—and elected to the first Parliament that met under its terms, in 1654. His association with Cromwell ceased at the end of that year, however, probably because he disliked a regime that seemed increasingly more military than parliamentary. In 1655 (his second wife had died in 1654) he married as his third wife, Margaret Spencer, the niece of the earl of Southampton, the leading Cavalier peer remaining in England after Charles's execution, but there is no evidence that he positively favoured a Royalist Restoration until 1660, when every other possible political alternative had proved unsuccessful. On May 8 he was appointed one of the 12 commissioners sent by the House of Commons to Holland to invite Charles II to return, and after Charles had done so, Cooper was admitted to Charles's Privy Council.

From 1660–73 he held office under Charles II, becoming Lord Ashley in 1661 and earl of Shaftesbury in 1672. During this period his intelligence, his capacity for business, and his ability as a speaker in the House of Lords were generally recognized, but because of his equivocal political past he was at first given only the then minor office of chancellor of the exchequer. By the end of the 1660s, however, he had been admitted to the King's "Cabinet Council" and in 1672 he became lord chancellor—the last to preside in Chancery with no formal legal training other than a short spell in Lincoln's Inn (one of the four legal schools and societies). His name has been associated with three particular acts of policy between 1670 and 1673: the Stop of the Exchequer of 1672, which by suspending the repayment of debt for twelve months gave Charles the use of his revenue for naval preparations; the Declaration of Indulgence of the same year; and the third Dutch war of 1672–74. The first of these is now known to have been the responsibility of Sir Thomas Clifford; the second reflected his consistent desire to secure toleration for Dissenters (religious groups that did not belong to the Church of England), though the King and Clifford intended the bill primarily as relief for Catholics; the third was, in Shaftesbury's mind, a natural continuation of the commercial rivalry with the Dutch. Earlier, in 1670, he signed a sham Anglo-French treaty supposedly to reduce the commercial supremacy of the Dutch, but he was unaware that the previous secret Treaty of Dover had provided for Charles to declare himself a Catholic, a prospect he could never have condoned. In 1673 he supported the first Test Act, designed to exclude Catholics from office, and opposed the marriage of the King's brother and heir, James, duke of York, a Catholic, to another Catholic. Later in that same year, Charles, feeling that he could no longer trust his chancellor, dismissed him.

In the years that followed, Shaftesbury gradually became the most formidable politician in the Whig opposition or "Country Party," against the King and his Lord Treasurer, Danby, until, in 1678, a certain Titus Oates gave information about an alleged extensive Catholic plot to kill Charles and put James on the throne. This gave Shaftesbury his first real chance to acquire a wide base of support. Though he had not contrived the tale—nor did he prompt Oates to come forward at first—he realized he could exploit the situation to his own advantage. In the ensuing national panic, Shaftesbury took control of the political chaos, organized an elaborate party network, exercised great control over elections, and acquired a

The
Exclusion
Bill

large following in Parliament. His strategy was primarily aimed at securing the passage of the Exclusion Bill, which would keep Catholic James from the throne, using Charles's illegitimate son, the duke of Monmouth, a puppet of Shaftesbury, as a possible claimant to the throne. Although the bill passed in the Commons, it was rejected by the Lords because of the King's strong opposition. Shaftesbury rode to the next Parliament, at Oxford on March 21, 1681, with an armed following, but Charles dissolved it within a week, leaving him helpless, without a following, and, as the general panic dissolved, without a cause. He was seized on July 2, 1681, and committed to the Tower of London, but he was acquitted of the trumped-up charge of treason by a London grand jury in November. Shortly before the trial the most famous attack on him, John Dryden's satire *Absalom and Achitophel*, appeared. In the absence of another Parliament, Shaftesbury could do little more. After privately discussing the possibility of rising against the government, he fled the country in November 1682, and died in Holland in January 1683.

Shaftesbury was a man of intelligence, charm, and wide and usually enlightened interests, including those related to colonization. In 1663, he was given a grant, along with seven others, of the province of Carolina in North America, and was appointed president of the Council of Trade and Foreign Plantations from 1672 to 1674. The philosopher John Locke, who helped him to draft the *Fundamental Constitutions* of Carolina and superintended the surgical operation that saved his life in 1668, was a member of his household from 1667 to 1675. Recent scholarly work on Locke has stressed the importance of his connection with Shaftesbury and has modified the impression of the earl left by Dryden's partisan satires and other unfavourable, sometimes unjust, evaluations through history.

BIBLIOGRAPHY. The most recent biography is K.H.D. HALEY, *The First Earl of Shaftesbury* (1968), an attempt to demonstrate a consistency of political outlook throughout Shaftesbury's various changes in his career. Earlier biographies are W.D. CHRISTIE, *A Life of Anthony Ashley Cooper, First Earl of Shaftesbury* (1871); and L.F. BROWN, *The First Earl of Shaftesbury* (1933). The best general account of the reign of Charles II is in D. OGG, *England in the Reign of Charles II*, 2 vol., 2nd ed. (1955). ANDREW BROWNING, *Thomas Osborne, Earl of Danby and Duke of Leeds, 1632-1712*, 3 vol. (1944-51), is a biography of Shaftesbury's most important rival. See also M. LEE, *The Cabal* (1965); and J.R. JONES, *The First Whigs* (1961).

(K.H.D.H.)

Shaka

In the first quarter of the 19th century the tribal structure of southern Africa was convulsed by wars generated by Shaka, the ruthless founder of the Zulu Empire. In less than a decade as the paramount chieftain of the Zulu clan, he revolutionized the techniques of tribal warfare and fashioned an efficient and terrifying fighting force that created havoc throughout the area of present-day Natal and beyond.

Shaka was born about 1787, the son of Senzangakona, chieftain of the Zulu, and Nandi, an orphaned princess of the neighbouring Langeni clan. Because his parents belonged to the same clan, their marriage violated Zulu custom, and the stigma of this extended to the child. The couple separated when Shaka was six, and Nandi took her son back to the Langeni, where he passed a fatherless boyhood among a people who despised his mother and made him the butt of endless cruel pranks. In 1802 the Langeni drove Nandi out, and she finally found shelter with the Dletsheni, a subclan of the powerful Mtetwa. When Shaka was 23, Dingiswayo, the Mtetwa paramount chieftain, called up Shaka's Dletsheni age group for military service. For the next six years, he served with brilliance as a warrior of the Mtetwa Empire.

Senzangakona died in 1816, and Dingiswayo released Shaka from service and sent him to take over the Zulu. The eldest son of Senzangakona's Great Wife had already mounted the throne; messengers slew him even before Shaka arrived.

Shaka, lithograph by W. Bagg, 1836.

The Zulu, at this time, probably numbered fewer than 1,500, occupying an area on the White Umfolozi River, perhaps ten miles on a side. They were among the smallest of the more than 800 Eastern Nguni-Bantu clans, but from the day of Shaka's arrival they left forever the ranks of the sleepy upcountry clans and commenced their march to greatness. Shaka ruled with an iron hand from the outset, meting out instant death for the slightest opposition.

His first act was to reorganize the army. Like all the clans, the Zulu were armed with oxhide shields and spin-dly throwing spears. Battles were little more than brief and relatively bloodless clashes in which the outnumbered side prudently gave way before extensive casualties occurred. Shaka first rearmed his men with a long-bladed, short-hafted stabbing assegai, which forced them to fight at close quarters. He then instituted the regimental system based on age groups, quartered at separate kraals (villages) and distinguished by uniform markings on shields and by various combinations of headdress and ornaments. He also developed standard tactics, which the Zulu used in every battle. The available regiments (known collectively as the *impi*) were divided into four groups. The strongest, termed the "chest," closed with the enemy to pin him down, while two "horns" raced out to encircle and attack the foe from behind. A reserve, known as the "loins," was seated nearby, with its back to the battle so as not to become unduly excited, and could be sent to reinforce any part of the ring if the enemy threatened to break out. The battle was supervised by *indunas*, or officers, who used hand signals to direct the regiments. An *impi* consistently covered 50 miles a day, living off grain and cattle requisitioned from the kraals it passed, and accompanied by boys who carried the warriors' sleeping mats and cooking pots.

Shaka fought for extermination, incorporating the remnants of the clans he smashed into the Zulu. He first sopped up the small clans in his vicinity, starting with the Langeni; he sought out the men who had made his boyhood a misery and impaled them on the sharpened stakes of their own kraal fences. In less than a year, the Zulu—and their army—had quadrupled in number. In 1817 Dingiswayo—still Shaka's overlord—was murdered, and the last restraint on Zulu expansion removed. Within two years, Shaka bested the only clans large enough to threaten him, the Ndwandwe and the Qwabe, and in a series

Reorgani-
zation
of the
army

The
Mfecane
of the
1820s

of annual campaigns he then struck at and smashed the complex network of clans living to the south of the Zulu territories. By 1823 present-day Natal was a depopulated ruin of smoking kraals, and the terrified survivors had broken up tribal patterns as far away as the Cape Colony.

Although Shaka's depredations were limited to the coastal area, they led indirectly to the *Mfecane* ("the Crushing") that devastated the inland plateau in the early 1820s. Marauding clans, fleeing the Zulu wrath and searching for land, started a deadly game of musical chairs that broke the clan structure of the interior and left 2,000,000 dead in its wake. The Roer Great Trek of the 1830s passed through this area, succeeding only because virtually no one was left to oppose them.

The first Europeans came to Port Natal (present-day Durban) in 1824. A dozen settlers of the Farewell Trading Company established a post on the landlocked bay and soon made contact with Shaka, whose kraal *Bulawayo* lay 100 miles to the north. Fascinated by their ways and their artifacts, but convinced that his own civilization was much superior, he permitted them to stay. Two of the early settlers, Henry Francis Fynn and Nathaniel Isaacs, became fluent Zulu linguists, and most of what is known of early Nguni history stems from their writings.

In 1827 Nandi died, and with his mother's death Shaka became openly psychotic. About 7,000 Zulus were killed in the initial paroxysm of his grief, and for a year no crops were planted, nor could milk—the basis of the Zulu diet staple—be used. All women found pregnant were slain with their husbands, as were thousands of milch cows, so that even the calves might know what it was to lose a mother.

Early in 1828 Shaka sent the *impi* south in a raid that carried the warriors clear to the borders of the Cape Colony. They had no sooner returned, expecting the usual season's rest, than he sent them off to raid far in the north. It was too much for his associates, and two of his half-brothers, Dingane and Mhlangana, together with an *induna* named Mbopa, murdered him on September 22, 1828.

Shaka—who seems to have had at least a tendency to homosexuality—left no offspring, despite a harem of 1,200 women. (He consistently killed any woman there found pregnant.) He ruled by the sheer force of his personality, building, by scores of daily executions, a fear so profound that he could afford to ignore it. His subjects no more thought of resisting him than a mouse would gain-say an elephant.

Shaka dominates the history of the Eastern Nguni-Bantu, and as the founder of a Zulu Empire he has already passed into legend. He was highly intelligent and, at least on the tactical level, something of a military genius. He, nevertheless, lacked the political sagacity of a Dingiswayo or a Mshweshwe, who founded the Sotho nation from the debris of the *Mfecane*. Shaka's only objective was to destroy all that he encountered, subordinating as much land and as many people as possible to his personal hegemony. In that process, he created an armed nation so monolithic that it survived the mismanagement of two incompetent successors and lasted for 50 years, until the British destroyed it in the Zulu War of 1879.

MALCOLM (eds.), *The Diary of Henry Francis Fynn* (1950), and NATHANIEL ISSACS, *Travels and Adventures in Eastern Africa*, ed. by LOUIS HERRMAN, 2 vol. (1936–37), primary sources by two of the first Europeans to have prolonged contact with Shaka; A.T. BRYANT, *Olden Times in Zululand and Natal* (1929), an extensive history of the Eastern Nguni-Bantu clans during the Shakan era.

(D.R.M.)

Shakespeare, William

Widely regarded as the greatest writer of all time, William Shakespeare occupies a position unique in world literature. Other poets, such as Homer and Dante, and novelists, such as Leo Tolstoy and Charles Dickens, have

transcended national barriers; but no writer's living reputation can seriously compare with that of Shakespeare, whose plays, written in the late 16th and early 17th centuries for a small repertory theatre, are now performed and read more often and in more countries than ever before. The prophecy of his great contemporary, the poet and dramatist Ben Jonson, that Shakespeare "was not of an age, but for all time," has been marvellously fulfilled. It may be audacious even to attempt a definition of his greatness, but it is not so difficult to describe the variety of gifts that enabled him to create imaginative visions of pathos and mirth that, whether read in the book or witnessed in the theatre, fill the mind and linger there. He is a writer of great intellectual rapidity, perceptiveness, and poetic power. Other writers have had these qualities. But with Shakespeare the keenness of mind was applied not to abstruse or remote subjects but to human beings and their complete range of emotions and conflicts. Other writers have applied their keenness of mind in this way. But Shakespeare is astonishingly clever with words and images, so that his mental energy, when applied to intelligible human situations, finds full and memorable expression, convincing and imaginatively stimulating. As if this were not enough, the art form into which his creative energies went was not remote and bookish but involved the vivid stage impersonation of human beings, commanding sympathy and inviting vicarious participation. Thus many of Shakespeare's great merits can survive translation into other languages and into cultures remote from that of Elizabethan England.

I. Shakespeare the man

HIS LIFE

Although the amount of factual knowledge available about Shakespeare is surprisingly large for one of his

station in life, many find it a little disappointing, for it is mostly gleaned from documents of an official character. Dates of baptisms, marriages, deaths, and burials; wills, conveyances, legal processes, and payments by the court—these are the dusty details. There is, however, a fair number of contemporary allusions to him as a writer, and these add a reasonable amount of flesh and blood to the biographical skeleton.

Early life in Stratford. The parish register of Holy Trinity Church, Stratford-on-Avon, Warwickshire, shows that he was baptized there on April 26, 1564; his birthday is traditionally celebrated on April 23. His father, John Shakespeare, was a burgess of the borough, who in 1565 was chosen an alderman and in 1568 bailiff (the position corresponding to mayor, before the grant of a further charter to Stratford in 1664). He was engaged in various kinds of trade and appears to have suffered some fluctuations in prosperity. His wife, Mary Arden, of Wilmcote, Warwickshire, came from an ancient family and was the heiress to some land. (Given the somewhat rigid social distinctions of the 16th century, this marriage must have been a step up the social scale for John Shakespeare.)

Education
at
Stratford's
grammar
school

Stratford enjoyed a grammar school of good quality, and the education there was free, the schoolmaster's salary being paid by the borough. No lists of the pupils who were at the school in the 16th century have survived, but it would be absurd to suppose the bailiff of the town did not send his son there. The boy's education would consist mostly of Latin studies—learning to read, write, and speak the language fairly well and studying some of the classical historians, moralists, and poets. Shakespeare did not go on to the university, and indeed it is unlikely that the tedious round of logic, rhetoric, and other studies then followed there would have interested him.

Instead, at the age of 18 he married. Where and exactly when are not known, but the episcopal registry at Worcester preserves a bond dated November 28, 1582, and executed by two yeomen of Stratford, named Sandells and Richardson, as a security to the bishop for the issue of a license for the marriage of William Shakespeare and "Anne Hathaway of Stratford," upon the consent of her friends and upon once asking of the banns. (Anne died in 1623, seven years after Shakespeare. There is good evidence to associate her with a family of Hathaways who inhabited a beautiful farmhouse, now much visited, two miles from Stratford.) The next date of interest is found in the records of the Stratford church, where a daughter, named Susanna, born to William Shakespeare, was baptized on May 26, 1583. On February 2, 1585, twins were baptized, Hamnet and Judith. (The boy Hamnet, Shakespeare's only son, died 11 years later.)

How Shakespeare spent the next eight years or so, until his name begins to appear in London theatre records, is not known. There are stories—given currency long after his death—of stealing deer and getting into trouble with a local magnate, Sir Thomas Lucy of Charlecote, near Stratford; of earning his living as a schoolmaster in the country; of going to London and gaining entry to the world of theatre by minding the horses of theatregoers; it has also been conjectured that Shakespeare spent some time as a member of a great household and that he was a soldier, perhaps in the Low Countries. In lieu of external evidence, such extrapolations about Shakespeare's life have often been made from the internal "evidence" of his writings. But this method is unsatisfactory: one cannot conclude, for example, from his allusions to the law that Shakespeare was a lawyer; for he was clearly a writer, who without difficulty could get whatever knowledge he needed for the composition of his plays.

Career in the theatre. The first reference to Shakespeare in the literary world of London comes in 1592, when a fellow dramatist, Robert Greene, declared in a pamphlet written on his deathbed:

There is an upstart crow, beautified with our feathers, that with his Tygers heart wrapt in a Players hide supposes he is as well able to bombast out a blank verse as the best of you; and, being an absolute Johannes Factotum, is in his own conceit the only Shake-scene in a country.

Greene's
attack on
the
"upstart"
dramatist

It is difficult to be certain what these words mean; but it is clear that they are insulting and that Shakespeare is the object of the sarcasms. When the book in which they appear (*Greenes, groats-worth of witte, bought with a million of Repentance*, 1592) was published after Greene's death, a mutual acquaintance wrote a preface offering an apology to Shakespeare and testifying to his worth. This preface also indicates that Shakespeare was by then making important friends. For, although the puritanical city of London was generally hostile to the theatre, many of the nobility were good patrons of the drama and friends of actors. Shakespeare seems to have attracted the attention of the young Henry Wriothesley, the 3rd earl of Southampton; and to this nobleman were dedicated his first published poems, *Venus and Adonis* and *The Rape of Lucrece*.

One striking piece of evidence that Shakespeare began to prosper early and tried to retrieve the family fortunes and establish its gentility is the fact that a coat of arms was granted to John Shakespeare in 1596. Rough drafts of this grant have been preserved in the College of Arms, London, though the final document, which must have been handed to the Shakespeares, has not survived. It can scarcely be doubted that it was William who took the initiative and paid the fees. The coat of arms appears on Shakespeare's monument (constructed before 1623) in the Stratford church. Equally interesting as evidence of Shakespeare's worldly success was his purchase in 1597 of New Place, a large house in Stratford, which as a boy he must have passed every day in walking to school.

It is not clear how his career in the theatre began; but from about 1594 onward he was an important member of the Lord Chamberlain's Company of players (called the King's Men after the accession of James I in 1603). They had the best actor, Richard Burbage; they had the best theatre, the Globe; they had the best dramatist, Shakespeare. It is no wonder that the company prospered. Shakespeare became a full-time professional man of his own theatre, sharing in a cooperative enterprise and intimately concerned with the financial success of the plays he wrote.

Unfortunately, written records give little indication of the way in which Shakespeare's professional life molded his marvellous artistry. All that can be deduced is that for 20 years Shakespeare devoted himself assiduously to his art, writing more than a million words of poetic drama of the highest quality.

Privatelife. Shakespeare had little contact with officialdom, apart from walking—dressed in the royal livery as a member of the King's Men—at the coronation of King James I in 1604. He continued to look after his financial interests. He bought properties in London and in Stratford. In 1605 he purchased a share (about one-fifth) of the Stratford tithes—a fact that explains why he was eventually buried in the chancel of its parish church. For some time he lodged with a French Huguenot family called Mountjoy, who lived near St. Olave's Church, Cripplegate, London. The records of a lawsuit in May 1612, due to a Mountjoy family quarrel, show Shakespeare as giving evidence in a genial way (though unable to remember certain important facts that would have decided the case) and as interesting himself generally in the family's affairs.

No letters written by Shakespeare have survived, but a private letter to him happened to get caught up with some official transactions of the town of Stratford and so has been preserved in the borough archives. It was written by one Richard Quiney and addressed by him from the Bell Inn in Carter Lane, London, whither he had gone from Stratford upon business. On one side of the paper is inscribed: "To my loving good friend and countryman, Mr. Wm. Shakespeare, deliver these." Apparently Quiney thought his fellow Stratfordian a person to whom he could apply for the loan of \$30—a large sum in Elizabethan money. Nothing further is known about the transaction, but, because so few opportunities of seeing into Shakespeare's private life present themselves, this begging letter becomes a touching document. It is of some interest, moreover, that 18 years later Quiney's son

Shakespeare's
financial
interests

Thomas became the husband of Judith, Shakespeare's second daughter.

Shakespeare's will (made on March 25, 1616) is a long and detailed document. It entailed his quite ample property on the male heirs of his elder daughter, Susanna. (Both his daughters were then married, one to the aforementioned Thomas Quiney and the other to John Hall, a respected physician of Stratford.) As an afterthought, he bequeathed his "second-best bed" to his wife; but no one can be certain what this notorious legacy means. The testator's signatures to the will are apparently in a shaky hand. Perhaps Shakespeare was already ill. He died on April 23, 1616. No name was inscribed on his gravestone in the chancel of the parish church of Stratford-on-Avon. Instead these lines, possibly his own, appeared:

Good friend, for Jesus' sake forbear
To dig the dust enclosed here.
Blest be the man that spares these stones,
And curst be he that moves my bones.

EARLY POSTHUMOUS DOCUMENTATION

Shakespeare's family or friends, however, were not content with a simple gravestone, and, within a few years, a monument was erected on the chancel wall. It seems to have existed by 1623. Its Latin epitaph, immediately below the bust, attributes to Shakespeare the worldly wisdom of Nestor, the genius of Socrates, and the poetic art of Virgil. This apparently was how his contemporaries in Stratford-on-Avon wished their fellow citizen to be remembered.

The tributes of his colleagues. The memory of Shakespeare survived long in theatrical circles, for his plays remained a major part of the repertory of the King's Men until the closing of the theatres in 1642. The greatest of Shakespeare's great contemporaries in the theatre, Ben Jonson, had a good deal to say about him. To William Drummond of Hawthornden in 1619 he said that Shakespeare "wanted art." But, when he came to write his splendid poem prefixed to the Folio edition of Shakespeare's plays in 1623, he rose to the occasion with stirring words of praise:

Triumph, my Britain, thou hast one to show
To whom all scenes of Europe homage owe.
He was not of an age, but for all time!

Besides almost retracting his earlier gibe about Shakespeare's lack of art, he gives testimony that Shakespeare's personality was to be felt, by those who knew him, in his poetry—that the style was the man. Jonson also reminded his readers of the strong impression the plays had made upon Queen Elizabeth I and King James I at court performances:

Sweet Swan of Avon, what a sight it were
To see thee in our waters yet appear,
And make those flights upon the banks of Thames
That so did take Eliza and our James!

Shakespeare seems to have been on affectionate terms with his theatre colleagues. His fellow actors John Heminge and Henry Condell (who, with Burbage, were remembered in his will) dedicated the First Folio of 1623 to the Earl of Pembroke and the Earl of Montgomery, explaining that they had collected the plays "... without ambition either of self-profit or fame; only to keep the memory of so worthy a friend and fellow alive as was our Shakespeare, . . ."

Anecdotes and documents. Seventeenth-century antiquaries began to collect anecdotes about Shakespeare, but no serious life was written until 1709, when Nicholas Rowe tried to assemble information from all available sources with the aim of producing a connected narrative. There were local traditions at Stratford: witticisms and lampoons of local characters; scandalous stories of drunkenness and sexual escapades. About 1661 the Vicar of Stratford wrote in his diary: "Shakespeare, Drayton, and Ben Jonson had a merry meeting, and it seems drank too hard; for Shakespeare died of a fever there contracted." On the other hand, the antiquary John Aubrey wrote in some notes about Shakespeare: "He was not a company keeper: lived in Shoreditch; wouldn't be debauched, and, if invited to, writ he was in pain." Rich-

ard Davies, archdeacon of Lichfield, reported, "He died a papist." How much trust can be put in such a story is uncertain. In the early 18th century, a story appeared that Queen Elizabeth had obliged Shakespeare "to write a play of Sir John Falstaff in love" and that he had performed the task (*The Merry Wives of Windsor*) in a fortnight. There are other stories, all of uncertain authenticity and some mere fabrications.

When serious scholarship began in the 18th century, it was too late to gain anything from traditions. But documents began to be discovered. Shakespeare's will was found in 1747 and his marriage license, in 1836. The documents relating to the Mountjoy lawsuit already mentioned were found and printed in 1910. It is possible that further documents of a legal nature may yet be discovered, but as time passes the hope becomes more remote. Modern scholarship is more concerned to study Shakespeare in relation to his social environment, both in Stratford and in London. This is not too easy, because the author and actor lived a somewhat detached life: a respected tithe-owning country gentleman in Stratford, perhaps, but a rather rootless artist in London.

Portraits. Curiosity about what Shakespeare looked like has not been adequately satisfied. Two representations have indisputable claims to authenticity: a half-length bust in the Stratford-on-Avon parish church, which was in position within a few years of his death; and an engraving used as a frontispiece to the Folio edition of his plays in 1623. The family must have approved the memorial statue, and presumably his friends must have thought the engraving a reasonable likeness. The bust shows Shakespeare with a pen in his hand; the face is rather round, but the high forehead is striking. The engraving is by Martin Droeshout, a member of a family of Flemish artists resident in London, and it has provided the image by which Shakespeare is now best known. The "Chandos" portrait (so called because the Duke of Chandos once owned it) in the National Portrait Gallery, London, seems to have been owned by Sir William Davenant. It resembles the bust and the engraving to a certain extent and could have been a portrait painted in Shakespeare's lifetime. Many other portraits alleged to be of Shakespeare began to appear in the later 17th century and in the 18th century. These are artists' "creations," fabrications, or downright forgeries.

engraving

II. The poet and dramatist

THE INTELLECTUAL BACKGROUND

Shakespeare lived at a time when ideas and social structures established in the Middle Ages still informed men's thought and behaviour. Queen Elizabeth I was God's deputy on earth, and lords and commons had their due places in society under her, with responsibilities up through her to God and down to those of more humble rank. The order of things, however, did not go unquestioned. Atheism was still considered a challenge to the beliefs and way of life of a majority of Elizabethans, but the Christian faith was no longer single—Rome's authority had been challenged by Martin Luther, John Calvin, and a multitude of small religious sects. Royal prerogative was challenged in Parliament; the economic and social orders were disturbed by the rise of capitalism, by the redistribution of monastic lands under Henry VIII, by the expansion of education, and by the influx of new wealth from discovery of new lands.

An interplay of new and old ideas was typical of the time, when official homilies exhorted the people to obedience, while the Italian political theorist Niccolò Machiavelli expounded a new practical code of politics that caused Englishmen to fear the Italian "Machiavillain" and yet prompted them to ask what men do, rather than what they should do. In Hamlet, disquisitions—on man, belief, a "rotten" state, and times "out of joint"—clearly reflect a growing disquiet and skepticism. The translation of Montaigne's *Essays* in 1603 gave further currency, range, and finesse to such thought, and Shakespeare was one of many who read them, making direct and significant quotations in *The Tempest*. In philosophical inquiry the question "how?" became the impulse for ad-

Popularity
of the
plays

vance, rather than the traditional "why?" of Aristotle. Shakespeare's plays written between 1603 and 1606 unmistakably reflect a new, Jacobean distrust. James I, who, like Elizabeth, claimed divine authority, was far less able than she to maintain the authority of the throne. The so-called Gunpowder Plot (1605) showed a determined challenge by a small minority in the state; James's struggles with the House of Commons in successive Parliaments', in addition to indicating the strength of the "new men," also revealed the inadequacies of the administration.

POETIC CONVENTIONS AND DRAMATIC TRADITIONS

The Latin comedies of Plautus and Terence were familiar in Elizabethan schools and universities, and English translations or adaptations of them were occasionally performed by students. Seneca's rhetorical and sensational tragedies, too, had been translated and often imitated, both in structure and rhetoric. But there was also a strong native dramatic tradition deriving from the medieval miracle plays, which had continued to be performed in various towns until forbidden during Elizabeth's reign. This native drama had been able to assimilate French popular farce, clerically inspired morality plays on abstract themes, and interludes or short entertainments that made use of the "turns" of individual clowns and actors. Although Shakespeare's immediate predecessors were known as "university wits," their plays were seldom structured in the manner of those they had studied at Oxford or Cambridge; instead, they used and developed the more popular narrative forms. Their subplots, for example, amplified the main action and theme with a freedom and awareness of hierarchical correspondences that are medieval rather than classical.

Changes in language. The English language at this time was changing and extending its range. The poet Edmund Spenser led with the restoration of old words, and schoolmasters, poets, sophisticated courtiers, and travellers all brought further contributions from France, Italy, and the Roman classics, as well as from farther afield. Helped by the growing availability of cheaper, printed books, the language began to become standardized in grammar and vocabulary and, more slowly, in spelling. Ambitious for a European and permanent reputation, the essayist and philosopher Francis Bacon wrote in Latin as well as in English; but, if he had lived only a few decades later, even he might have had total confidence in his own tongue.

Shakespeare's literary debts. In Shakespeare's earlier works his debts stand out clearly: to Plautus for the structure of *The Comedy of Errors*; to the poet Ovid and to Seneca for rhetoric and incident in *Titus Andronicus*; to morality drama for a scene in which a father mourns his dead son, and a son his father, in *Henry VI*; to Marlowe for sentiments and characterization in *Richard III* and *The Merchant of Venice*; to the Italian popular tradition of commedia dell'arte for characterization and dramatic style in *The Taming of the Shrew*; and so on. But he did not then reject these influences; rather, he made them his own, so that soon there was no line between their effects and his. In *The Tempest* (which is perhaps the most original of all his plays in form, theme, language, and setting) folk influences may also be traced, together with a newer and more obvious debt to a courtly diversion known as the masque, as developed by Ben Jonson and others at the court of King James.

THEATRICAL CONDITIONS

The Globe and its predecessor, the Theatre, were public playhouses run by the Chamberlain's Men (later the King's Men), a leading theatre company of which Shakespeare was a member. To these playhouses almost all classes of citizens, except the Puritans, came for afternoon entertainment. The players were also summoned to court, to perform before the monarch and assembled nobility. In the summer they toured the provinces, and on occasion they performed at London's Inns of Court (associations of law students), at universities, and in great houses. Popularity led to an insatiable demand for plays:

repertories were always changing, so that early in 1613 the King's Men could present "fourteen several plays." The theatre soon became fashionable too, and in 1608–09 the King's Men started to perform on a regular basis at the Blackfriars, a "private" indoor theatre where high admission charges assured the company a more select and sophisticated audience.

Shakespeare's first associations with the Chamberlain's Men seem to have been as an actor. He is not known to have acted after 1603, and tradition gives him only secondary roles, such as the ghost in *Hamlet* and Adam in *As You Like It*, but his continuous association must have given him direct working knowledge of all aspects of theatre: like Aeschylus, Molière, Bertolt Brecht, or Harold Pinter, Shakespeare was able to work with his plays in rehearsal and performance and to know his actors and his audiences and all the different potentialities of theatres and their equipment. Numerous passages in Shakespeare's plays show conscious concern for theatre arts and audience reactions. Prospero in *The Tempest* speaks of the whole of life as a kind of "revels," or theatrical show, that, like a dream, will soon be over. The Duke of York in *Richard II* is conscious of how

... in a theatre, the eyes of men,
After a well-graced actor leaves the stage
Are idly bent on him that enters next,
Thinking his prattle to be tedious.

And Hamlet gives expert advice to visiting actors in the art of playing.

In Shakespeare's day, there was little time for group rehearsals, and actors were given the words of only their own parts. The crucial scenes in Shakespeare's plays, therefore, are between two or three characters only, or else are played with one character dominating a crowded stage. Female parts were written for young male actors or boys, so Shakespeare did not often write big roles for them or keep them actively engaged on stage for lengthy periods. Writing for the clowns of the company—who were important popular attractions in any play—presented the problem of allowing them to use their comic personalities and tricks and yet have them serve the immediate interests of theme and action.

Theatre is a collaborative art, only occasionally yielding the right conditions for individual genius to flourish and develop, and Shakespeare's achievement must at least in part be due to his continuous association with the Chamberlain's and King's Men, who were as practiced in acting together as he was to become in writing for them.

CHRONOLOGY

Despite much scholarly argument, it is often impossible to date a given play precisely. But there is a general consensus, especially for plays written 1585–1601, 1605–07, and 1609 onward. The following list of first performances is based on external and internal evidence, on general stylistic and thematic considerations, and on the observation that an output of no more than two plays a year seems to have been established in those periods when dating is rather clearer than others.

1589–92	1 <i>Henry VI</i> , 2 <i>Henry VI</i> , 3 <i>Henry VI</i>
1592–93	<i>Richard III</i> , <i>The Comedy of Errors</i>
1593–94	<i>Titus Andronicus</i> , <i>The Taming of the Shrew</i>
1594–95	<i>The Two Gentlemen of Verona</i> , <i>Love's Labour's Lost</i> , <i>Romeo and Juliet</i>
1595–96	<i>Richard II</i> , <i>A Midsummer Night's Dream</i>
1596–97	<i>King John</i> , <i>The Merchant of Venice</i>
1597–98	1 <i>Henry IV</i> , 2 <i>Henry IV</i>
1598–99	<i>Much Ado About Nothing</i> , <i>Henry V</i>
1599–1600	<i>Julius Caesar</i> , <i>As You Like It</i>
1600–01	<i>Hamlet</i> , <i>The Merry Wives of Windsor</i>
1601–02	<i>Twelfth Night</i> , <i>Troilus and Cressida</i>
1602–03	<i>All's Well That Ends Well</i>
1604–05	<i>Measure For Measure</i> , <i>Othello</i>
1605–06	<i>King Lear</i> , <i>Macbeth</i>
1606–07	<i>Antony and Cleopatra</i>
1607–08	<i>Coriolanus</i> , <i>Timon of Athens</i>
1608–09	<i>Pericles</i>
1609–10	<i>Cymbeline</i>
1610–11	<i>Winter's Tale</i>
1611–12	<i>The Tempest</i>
1612–13	<i>Henry VIII</i> , <i>The Two Noble Kinsmen</i>

The

porary
drama of
Shake-
speare's
time

The
Elizabe-
than
playhouse

Shakespeare's two narrative poems, *Venus and Adonis* and *The Rape of Lucrece*, can be dated with certainty to the years when the Plague stopped dramatic performances in London, in 1592 and 1593–94, respectively, just before their publication. But the bonnets offer many and various problems; they cannot have been written all at one time, and most scholars set them within the period 1593–1600. "The Phoenix and the Turtle" can be dated 1600–01.

PUBLICATION

During Shakespeare's early career, dramatists invariably sold their plays to an actor's company, who then took charge of them, prepared working promptbooks, and did their best to prevent another company or a publisher from getting copies; in this way they could exploit the plays themselves for as long as they drew an audience. But some plays did get published, usually in small books called quartos. Occasionally plays were "pirated," the text being dictated by one or two disaffected actors from the company that had performed it or else made up from shorthand notes taken surreptitiously during performance and subsequently corrected during other performances; parts 2 and 3 of the *Henry VI* (1594 and 1595) and *Hamlet* (1603) quartos are examples of pirated, or "bad," texts. Sometimes an author's "foul papers" (his first complete draft) or his "fair" copy—or a transcript of either of these—got into a publisher's hands, and "good quartos" were printed from them, such as those of *Titus Andronicus* (1594), *Love's Labour's Lost* (1598), and *Richard II* (1597). After the publication of "bad" quartos of *Hamlet* and *Romeo and Juliet* (1597), the Chamberlain's Men probably arranged for the release of the "foul papers" so that second—"good"—quartos could supersede the garbled versions already on the market. This company had powerful friends at court, and in 1600 a special order was entered in the Stationers' Register to "stay" the publication of *As You Like It*, *Much Ado About Nothing*, and *Henry V*, possibly in order to assure that good texts were available. Subsequently *Henry V* (1600) was pirated, and *Much Ado About Nothing* was printed from "foul papers"; *As You Like It* did not appear in print until it was included in *Mr. William Shakespeares Comedies, Histories & Tragedies*, published in folio (the reference is to the size of page) by a syndicate in 1623 (later editions appearing in 1632 and 1663).

The only precedent for such a collected edition of public theatre plays in a handsome folio volume was Ben Jonson's collected plays of 1616. Shakespeare's folio included 36 plays, 22 of them appearing for the first time in a good text. (For the Third Folio reissue of 1664, *Pericles* was added from a quarto text of 1609, together with six apocryphal plays.) The First Folio texts were prepared by John Heminge and Henry Condell (two of Shakespeare's fellow sharers in the Chamberlain's, now the King's Men), who made every effort to present the volume worthily. Only about 230 copies of the First Folio are known to have survived.

The texts of *Venus and Adonis* (1593) and *The Rape of Lucrece* (1594) are remarkably free from errors. Shakespeare presumably furnished a fair copy of each for the printer. He also seems to have read the proofs. The sonnets were published in 1609, but there is no evidence that Shakespeare oversaw their publication (see below III. *Understanding Shakespeare: The contribution of textual criticism*).

POETIC AND DRAMATIC POWERS

The early poems. Shakespeare dedicated the poem *Venus and Adonis* to his patron, Henry Wriothesley, 3rd earl of Southampton, whom he further promised to honour with "some graver labour"—perhaps *The Rape of Lucrece*, which appeared a year later and was also dedicated to Southampton. As these two poems were something on which Shakespeare was intending to base his reputation with the public and to establish himself with his patron, they were displays of his virtuosity—diploma pieces. They were certainly the most popular of his writings with the reading public and impressed them with his

poetic genius. Seven editions of *Venus and Adonis* had appeared by 1602 and 16 by 1640; *Lucrece*, a more serious poem, went through eight editions by 1640; and there are numerous allusions to them in the literature of the time. But after that, until the 19th century, they were little regarded. Even then the critics did not know what to make of them: on the one hand, *Venus and Adonis* is licentiously erotic (though its sensuality is often rather comic); while *Lucrece* may seem to be tragic enough, the treatment of the poem is yet somewhat cold and distant. In both cases the poet seems to be displaying dexterity rather than being "sincere." But Shakespeare's detachment from his subjects has come to be admired in more recent assessments.

Above all, the poems give evidence for the growth of Shakespeare's imagination. *Venus and Adonis* is full of vivid imagery of the countryside; birds, beasts, the hunt, the sky, and the weather, the overflowing Avon—these give freshness to the poem and contrast strangely with the sensuous love scenes. *Lucrece* is more rhetorical and elaborate than *Venus and Adonis* and also aims higher. Its disquisitions (upon night, time, opportunity, and lust, for example) anticipate brilliant speeches on general themes in the plays—on mercy in *The Merchant of Venice*, suicide in *Hamlet*, and "degree" in *Troilus and Cressida*.

There are a few other poems attributed to Shakespeare. When the *Sonnets* were printed in 1609, a 329-line poem, "A Lovers complaint," was added at the end of the volume, plainly ascribed by the publisher to Shakespeare. There has been a good deal of discussion about the authorship of this poem. Only the evidence of style, however, could call into question the publisher's ascription, and this is conflicting. Parts of the poem and some lines are brilliant, but other parts seem poor in a way that is not like Shakespeare's careless writing. Its narrative structure is remarkable, however, and the poem deserves more attention than it usually receives. It is now generally thought to be from Shakespeare's pen, possibly an early poem revised by him at a more mature stage of his poetical style. Whether the poem in its extant form is later or earlier than *Venus and Adonis* and *Lucrece* cannot be decided. No one could doubt the authenticity of "The Phoenix and the Turtle," a 67-line poem that appeared with other "poetical essays" (by John Marston, George Chapman, and Ben Jonson) appended to Robert Chester's poem *Loves Martyr* in 1601. The poem is attractive and memorable, but very obscure, partly because of its style and partly because it contains allusions to real persons and situations whose identity can now only be guessed at.

The sonnets. In 1609 appeared *SHAKE-SPEARES SONNETS. Never before Imprinted*. At this date Shakespeare was already a successful author, a country gentleman, and an affluent member of the most important theatrical enterprise in London. How long before 1609 the sonnets were written is unknown. The phrase "never before imprinted" may imply that they had existed for some time but were now at last printed. Two of them (nos. 138 and 144) had in fact already appeared (in a slightly different form) in an anthology, *The Passionate Pilgrime* (1599). Shakespeare had certainly written some sonnets by 1598, for in that year Francis Meres, in a "survey" of literature, made reference to "his sugared sonnets among his private friends," but whether these "sugared sonnets" were those eventually published in 1609 cannot be ascertained—Shakespeare may have written other sets of sonnets, now lost. Nevertheless, the sonnets included in *The Passionate Pilgrime* are among his most striking and mature, so it is likely that most of the 154 sonnets that appeared in the 1609 printing belong to Shakespeare's early 30s rather than to his 40s—to the time when he was writing *Richard II* and *Romeo and Juliet* rather than when he was writing *King Lear* and *Antony and Cleopatra*. But, of course, some of them may belong to any year of Shakespeare's life as a poet before 1609.

The order of the poems. Elizabethan sonnet sequences (following the example of their Italian and French models) were generally in some kind of narrative order.

Contemporary reference to Shakespeare's "sugared sonnets"

Sir Philip Sidney's *Astrophel and Stella*, moreover, and Edmund Spenser's *Amoretti* each tells a reasonably well authenticated story.

Shakespeare's sonnets, however, do not give the impression of an ordered sequence as it exists in Sidney, Spenser, and others. It is only at times that a narrative can be sensed, frequently breaking off, then resuming later or reverting to an earlier stage of the "story." It is therefore often argued that there was an original order, which has been lost, and many efforts have been made to recover, by ingenious analysis, Shakespeare's "intended" order. Although some interesting observations about associations between widely separated sonnets have been the result, none of the schemes carries any conviction. Most critics feel that it is hopeless to try to replace the order of the 1609 edition with anything convincingly better, arguing that the sonnets have no pretensions to be complete or adequate as a narrative. They are mixed in mood, in quality, and in distinction. Some seem open, addressed to all the world. Some seem too cryptic and personal ever to be intelligible.

It is equally uncertain whether the 1609 arrangement bears any relation to the order in which the sonnets were actually written. It may reasonably be supposed that the printer followed, more or less, the order in which the sonnets appeared in manuscript (or manuscripts). It is quite likely, however, that single leaves of the manuscript got out of order (for the numbers attached to each poem could well be a printer's addition), which, if so, might explain why some groups or pairs of sonnets seem to be oddly separated.

Sonnets 1 to 17 are variations on one theme. A handsome young man is being persuaded to marry and beget offspring who will preserve his beauty in a new generation, though he himself will lose it as he grows old. Gradually this theme gives place to the idea that the beloved will survive through the poet's verse. (There is no discussion of the relative merits of the two kinds of immortality.)

Sonnets 18 to 126 are on a variety of themes associated with a handsome young man (who is presumably, but not necessarily, the youth of 1 to 17). The poet enjoys his friendship and is full of admiration, promising to bestow immortality on the young man by the poems he writes in his honour. But sometimes the young man seems cold. Sometimes he provokes jealousy by his admiration of another poet. The climax of the series comes when the young man seduces the poet's woman. But eventually the poet reconciles himself to the situation and realizes that his love for his friend is greater than his desire to keep the woman.

Sonnet 126 seems a kind of concluding poem (and is not in sonnet form). Then begins a new series, principally about a dark lady by whom the poet is enthralled, though well aware of her faults. At one point, she is stolen from him by his best friend. This faithlessness of both friend and woman wounds the poet deeply. He nevertheless tries to rise above his disappointment. (The two concluding sonnets are impersonal translations of a familiar Renaissance theme about Cupid.)

Artistic invention or real experience. Various persons are addressed or referred to in the poems, though whether they are real people or fictions of Shakespeare's dramatic imagination is not entirely clear. But if the "story" of the sonnets is an invention, then it is badly invented, showing nothing of the skill in storytelling that Shakespeare elsewhere reveals. The relationships between "characters," moreover, are so obscure, so irritatingly cryptic, that it is difficult to believe Shakespeare was devising the story for artistic purposes. The very clumsiness and obscurity of the narrative, if it is considered a fiction, are a strong argument that the sonnets are close to real experience; yet a degree of fictionalization in the sonnets would be in accord with Shakespeare's lifelong devotion to writing plays and with the pervasive "impersonality" of his art as a dramatist.

Some critics have been tempted to declare that it does not matter who the young man and the dark lady were—that the poetry is the important thing. Though as a ges-

ture of impatience this mood is understandable, the world will continue to be curious about the circumstances of these poems, and, if historical documents should be discovered bringing hard facts to bear on the matter, the sonnets would surely be reinterpreted in the light of those facts. But for now, the sonnets on the whole retain an obstinate privacy that is a bar to enjoyment and therefore must be judged a fault, one that would hinder altogether the appreciation of any poems less brilliant. The sonnets do not quite "create a world" within which they can be apprehended. There is the sense of a missing (or unascertainable) body of experience and reference that falls short of poetical mystery.

Human experience in the poems. From the beginning of the 19th century, explorations of Shakespeare's personality have constantly been made by studying the sonnets. William Wordsworth proclaimed that "with this key Shakespeare unlocked his heart." But many readers feel that Shakespeare the man is elusive in the sonnets, just as he is in the plays. It has been natural to look in the poems for "personal details" about the author. One can observe allusions to his insomnia, to his disapproval of false hair and painted cheeks, to his love of music, and, according to some, to his bisexuality. It does not amount to very much.

The experiences of love and friendship, as related in the sonnets, must be described as disheartening and disenchanted. On the plane of human experience, they are full of disappointment, separation, anxiety, estrangement, self-accusation, and failure. The triumph, or near triumph, of death and of time is deeply felt. Only on the transcendental plane and in the faith in the permanence of poetry does a positive or affirmative attitude assert itself and compensate for the outcast state of the poet and the dateless night of death. On the whole they are quieter and closer to normal human experience than are the plays. The storms of passion are absent. Instead, there is a refined analysis of feeling, somehow more characteristic of the method of Jane Austen and Henry James than of Shakespeare the playwright. There are, of course, many moments of comparable moral scrupulousness in the plays, but they come incidentally and sometimes a little irrelevantly, perhaps, or awkwardly. In the sonnets Shakespeare brilliantly controls the shifting texture of the words in accordance with the variations in mood and tone. Generally, a careful analysis of the words reveals the tone in which a sonnet should be read, though, it must be admitted, this can be ambiguous.

The attractions of the sonnets are indeed very great. They win the admiration of readers by a variety of virtues. They express strong feeling, but they preserve artistic control. They have a density of thought and imagery that makes them seem the quintessence of the poetical experience. They delight by a felicity of phrase and verse movement, no less memorable than that familiar in the plays. They have, in recent years, received more exegesis than any of Shakespeare's plays, except perhaps *Hamlet* and *King Lear*. This is not necessarily a testimony to their value, for they have a tantalizing quality that encourages continued commentary. But it would be ungenerous not to relate this keen interest in the sonnets to an appreciation of their poetic power, of their unembarrassed exploration of intimate human relationships, and of their sensitivity to the tragedy of human aspirations and the triumph of time.

The early plays. Although the record of Shakespeare's early theatrical success is obscure, clearly the newcomer soon made himself felt. His brilliant two-part play on the Wars of the Roses, *The Whole Contention between the two Famous Houses, Lancaster and Yorke*, was among his earliest achievements. He showed, in *The Comedy of Errors*, how hilariously comic situations could be shot through with wonder and sentiment. In *Titus Andronicus* he scored a popular success with tragedy in the high Roman fashion. *The Two Gentlemen of Verona* was a new kind of romantic comedy. The world has never ceased to enjoy *The Taming of the Shrew*. *Love's Labour's Lost* is an experiment in witty and satirical observation of society. *Romeo and Juliet* combines and inter-

Attempts to discover details of his life in the poems

The "dark lady" of the late sonnets

connects a tragic situation with comedy and gaiety. All this represents the probable achievement of Shakespeare's first half-dozen years as a writer for the London stage, perhaps by the time he had reached 30. It shows astonishing versatility and originality.

Henry VI, 1, 2, and 3. In *The Contention*, a two-part chronicle play (called in the First Folio 2 *Henry VI*; 3 *Henry VI*), Shakespeare seems to have discovered the theatrical excitement that can be generated by representing recent history on the stage—events just beyond living memory but of great moment in the lives of present generations. The civil wars (popularly known as the Wars of the Roses) resulted from the struggle of two families, York and Lancaster, for the English throne. They had ended in 1485 with Richard III's defeat at the Battle of Bosworth, when Henry Tudor, as Henry VII, established a secure dynasty. Queen Elizabeth I was the granddaughter of Henry VII, so the story of York and Lancaster was of great interest to Shakespeare's contemporaries. In 2 *Henry VI* the power struggle turns around the ineffective King Henry VI, until gradually the Duke of York emerges as contender for the throne. The climaxes of 3 *Henry VI* include the murder of the Duke of York by the Lancastrians and, in the final scene, the murder of King Henry by Richard (York's son and the future Richard III). Shakespeare already showed himself a master of tragic poetry, notably in the speech of the captured York (wounded, mocked by a paper crown on his head, and awaiting death under the cruel taunts of Queen Margaret) and in the meditation of the King on the miseries of civil war. The vigorous and comic scenes with Jack Cade, a rebel leader, and his followers anticipate the kind of political comment that Shakespeare handled with greater subtlety in introducing the mobs of plebeians in *Julius Caesar* and *Coriolanus*.

A third play, 1 *Henry VI*, about the early part of the reign of King Henry VI, concerns events preceding the opening of the first part of *The Contention*. This is less successful, and it is uncertain whether it was a first effort at a historical play, written before *The Contention*, or a preparatory supplement to it, written subsequently and less inspired. It was printed in the 1623 Folio as the first part of *King Henry VI*; *The Contention* appeared as the second and third parts of *King Henry VI*, on what authority is not known.

The Comedy of Errors. The title of this, Shakespeare's shortest play, speaks for itself (though the opening scene is, unexpectedly, full of pathos). The play is based on Plautus' *Menaechmi*, a play of the comic confusions deriving from the presence of twin brothers, unknown to each other, in the same town; but Shakespeare has added twin servants, and he fills the play with suspense, surprise, expectation, and exhilaration as the two pairs weave their way through quadruple misunderstandings. The play already reveals Shakespeare's mastery of construction.

Titus Andronicus. This play was highly popular and held the stage for many years. Its crude story, its many savage incidents, and its poetic style have led some critics to think it not by Shakespeare. But the tendency of recent criticism is to regard the play as wholly or essentially his, and, indeed, when considered on its own terms as a "Roman tragedy," it displays a uniformity of tone and reveals a consistency of dramatic structure as a picture of the decline of the ancient world (though, by the standards of Shakespeare's later Roman plays, this picture is much confused).

The Two Gentlemen of Verona. Shakespeare took this play's story from a long Spanish prose romance called *Diana*, by Jorge de Montemagor. He added new characters—including Valentine, one of the "Two Gentlemen," whose "ideal" friendship with Proteus is so developed that the plot is more than a love story; indeed, the play glorifies friendship to an extent that, by modern conventions, is absurd. The abrupt last scene suggests that something has gone wrong with the text, and certainly Shakespeare was never again so ready to abandon common sense in motivating the behaviour of his lovers. But it is also clear that Shakespeare is here feeling

his way toward a new kind of high comedy, later to find expression in *The Merchant of Venice* and *Twelfth Night*.

The Taming of the Shrew. Often played as a boisterous farce, this play is actually a comedy of character, with implications beyond the story of the wooing, wedding, and taming of Katharina, the "shrew," by Petruchio, a man with a stronger will than her own. Shakespeare arouses more interest in these two than farce permits. They gain, for example, by contrast with the tepid, silly, or infatuated lovers (Bianca, Lucentio, Hortensio, and Gremio), and their relationship is given an admirable vitality and energy; while in the play's last scene Katharina's discourse on wifely submission—if spoken with sincerity and genuine tenderness and without irony—has a moving quality in performance. The Italianate play about the shrew taming is set inside another play (concerning a trick played upon Christopher Sly, a drunken tinker), which gave Shakespeare an opportunity for some brilliant English country scenes. Originally, Sly was made the "audience" of the shrew play, a device that is abandoned after a little while (that is, in the text of the 1623 Folio). Probably the players' company came to abandon the Christopher Sly framing because the Katharina and Petruchio story was too strong not to be acted directly at the real audience in a theatre.

Love's Labour's Lost. Once regarded as obsolete, depending too much upon temporary and irrecoverable allusions, this play has come to life in the theatre only during the past 50 years. Its rejection by the theatre was a background for 18th- and 19th-century critics such as John Dryden, Dr. Johnson, and William Hazlitt, all of whom had severe things to say about it. But, once the play had been recovered for the theatre, it was discovered that it is full of humanity, exploring the consequences of man being made of flesh and blood. The central comic device is that of four young men, dedicated to study and to the renunciation of women, meeting four young women; inevitably they abandon their absurd principles. For variety, and as an escape from the pretty, gay, young royalty and courtiers, there is an entertaining band of eccentrics who are allowed their "vaudeville" turns: Sir Nathaniel the curate, Holofernes the schoolmaster, Dull the constable, Costard the clown, and Jaquenetta the country girl; linking both groups is Don Adriano de Armado the ineffable (who begins by being a bore but becomes interesting as he becomes pathetic). Toward the end, the play takes on a new dramatic vitality through a brilliant *coup de théâtre*: the sudden arrival of Mercade as the messenger of death and the herald of responsibility. The deliberate abstention from the customary conclusion of comedy is remarkable: "Jack hath not Jill," but he will have her after a twelvemonth, when he has done something to deserve her. Thus the play ends with hope—perhaps the best kind of happy ending.

Romeo and Juliet. The most complex work of art among these early plays of Shakespeare, *Romeo and Juliet* is far more than "a play of young love" or "the world's typical love-tragedy." Weaving together a large number of related impressions and judgments, it is as much about hate as love. It tells of a family and its home as well as a feud and a tragic marriage. The public life of Verona and the private lives of the Veronese make up the setting for the love of Juliet and Romeo and provide the background against which their love can be assessed. It is not the deaths of the lovers that conclude the play but the public revelation of what has happened, with the admonitions of the Prince and the reconciliation of the two families.

Shakespeare enriched an already old story by surrounding the guileless mutual passion of Romeo and Juliet with the mature bawdry of the other characters—the Capulet servants Sampson and Gregory open the play with their fantasies of exploits with the Montague women; the tongues of the Nurse and Mercutio are seldom free from sexual matters—but the innocence of the lovers is unimpaired.

Romeo and Juliet made a strong impression on contemporary audiences. It was also one of Shakespeare's first

His early mastery of tragic poetry

plays to be pirated; a very bad text appeared in 1597. Detestable though it is, this version does derive from a performance of the play, and a good deal of what was seen on stage was recorded. Two years later another version of the play appeared, issued by a different, more respectable publisher, and this is essentially the play known today, for the printer was working from a manuscript fairly close to Shakespeare's own. Yet in neither edition did Shakespeare's name appear on the title page, and it was only with the publication of *Love's Labour's Lost* that publishers had come to feel that the name of Shakespeare as a dramatist, as well as the public esteem of the company of actors to which he belonged, could make an impression on potential purchasers of play-books.

The histories. For his plays on subjects from English history, Shakespeare primarily drew upon Raphael Holinshed's *Chronicles*, which appeared in 1587, and on Edward Hall's earlier account of *The union of the two noble and illustre famelies of Lancastre and York* (1548). From these and numerous secondary sources he inherited traditional themes: the divine right of royal succession, the need for unity and order in the realm, the evil of dissension and treason, the cruelty and hardship of war, the power of money to corrupt, the strength of family ties, the need for human understanding and careful calculation, and the power of God's providence, which protected his followers, punished evil, and led England toward the stability of Tudor rule.

The Tragedy of King Richard III. In this play, the first history to have a self-contained narrative unity, Shakespeare accentuated the moment of death as a crisis of conscience in which man judges himself and is capable of true prophecy. He centred the drama on a single figure who commits himself to murder, treason, and dissimulation with an inventive imagination that an audience can relish even as it must condemn it; and in defeat Richard discovers a valiant fury that carries him beyond nightmare fear and guilt to unrepentant, crazed defiance.

The Tragedy of King Richard II. In the group of histories written in the late 1590s, Shakespeare developed themes similar to those of *Richard III* but introduced counter-statements, challenging contrasts, and more deeply realized characters. The first of this group, *Richard II*, concentrates on the life and death of the King, but Bolingbroke, his adversary, is made far more prominent than Richmond had been as Richard III's adversary. The rightful king is isolated and defeated by Act III, and in prison he hammers out the meaning of his life in sustained soliloquy and comes to recognize his guilt and responsibility. From this moment of truth, he rediscovers pride, trust, and courage, so that he dies with an access of strength and an aspiring spirit. After the death of Richard, a scene shows Bolingbroke, now Henry IV, with the corpse of his rival in a coffin; and then Bolingbroke, too, recognizes his own guilt, as he sits in power among his silent nobles.

1 Henry IV; 2 Henry IV. In the two plays that bear his name, Henry IV is often in the background. The stage is chiefly dominated by his son, Prince Hal (later Henry V), by Hotspur the young rebel, and by Sir John Falstaff. The secondary characters are numerous, varying from prostitutes and country bumpkins to a Lord Chief Justice and country gentlemen. There is a tension underlying the two-part play that sounds in the King's opening lines:

So shaken as we are, so wan with care,
Find we a time for frightened peace to pant,
And breathe short-winded accents of new broils
To be commenced in stronds afar remote.

When the Earl of Warwick counsels hope, the King sees how "chances mock, and changes fill the cup of alteration":

O, if this were seen,
The happiest youth, viewing his progress through,
What perils passed, what crosses to ensue,
Would shut the book, and sit him down and die.

(Act III, scene 1, 51–56)

Yet the two plays of *Henry IV* are full of energy. In Falstaff—that "reverend vice . . . that father ruffian,

that vanity in years"—Shakespeare has created a character who becomes a substitute father of license and good fellowship for Prince Hal and who comments on the political situation with inglorious, reckless, egotistical good sense. Falstaff is Shakespeare's major introduction into English history. His characterization is wholly original, for, although Shakespeare uses something of the earlier "vice" figure from early tragedies and comedies, something of the glutton and coward from allegorical, or morality, plays, something of the braggart soldier and the impotent old lecher from neoclassical comedy, he also studied life for this character of an out-of-work soldier, a knight without lands or alliances, a childless man whose imagination far outruns his achievement.

King John. Already in *King John*, Shakespeare had developed a subsidiary character to offset kings and princes. Here the Bastard, the son of Sir Robert Faulconbridge, is a supporter of the King and yet has soliloquies, asides, and speeches that mock political and moral pretensions. King John provides the central focus of the play, which ends with his death, but Shakespeare presents him on a rapidly changing course, surrounded by many contrasting characters—each able to influence him, each bringing irresolvable and individual problems into dramatic focus—so that the King's unsteady mind seems no more than one small element in an almost comic jumble of events.

Henry V. *Henry V* is the last of this group of history plays and the last until *Henry VIII* at the end of Shakespeare's career. Structurally the King is again central and dominant, but the subsidiary characters far outnumber those of the earlier plays. In the first two acts Henry is shown in peace and war, politic, angry, confident, sarcastic, and then vowing to weep for another man's revolt. There is an account of Falstaff's death, and, after scenes of military achievement, there is a nervous watch before the Battle of Agincourt when the King walks disguised among his fearful soldiers and prays for victory while acknowledging his own worthless repentance for his father's treason. The presentation of the battle avoids almost all fighting on stage, but recruits, professional soldiers, and dukes and princes are all shown making preparation for meeting defeat or victory. The King's speech to his troops before battle on St. Crispin's Day is famous for its evocation of a brotherhood in arms, but Shakespeare has placed it in a context full of ironies and challenging contrasts. The picture of two nations at war is full of deeply felt individual response: a boy comes to realize that his masters are cowards; a herald is almost at a loss for words; a common soldier has to justify his heart before his king. Just before the conclusion, the King woos the French princess; she knows almost no English, and so he is forced to plead on the merits only of his simplest words, a kiss, and the plain fact of himself and his "heart." There is no doubt that Kate marries Henry because he has won a battle and peace is necessary, but Shakespeare has developed the comedy and earnestness of their wooing so that the need for human trust and acceptance is also evident. This play is presented by a chorus, which speaks in terms of heroism, pride, excitement, fear, and national glory. But at the end, when the King prays that the oaths of marriage and peace may "well kept and prosperous be," the chorus speaks for the last time, reminding the audience that England was to be plunged into civil war during the reign of Henry V's son. The last of a great series of history plays thus concludes with a reminder that no man's story can bring lasting success.

The Roman plays. *Julius Caesar.* After the last group of English history plays, Shakespeare chose to write about Julius Caesar, who held particular fascination for the Elizabethans. He was soldier, scholar, and politician (Francis Bacon held him in special regard for the universality of his genius); he had been killed by his greatest friend (Shakespeare alluded to the "bastard hand" of Brutus in *2 Henry VI*); and he was seen as the first Roman to perceive and, in part, to achieve the benefits of a monarchical state. His biography had appeared in Sir Thomas North's translation, via a French version, of

Falstaff's characterization

The Elizabethans' fascination with the figure of Julius Caesar

Plutarch's *Parallel Lives*, published as *The Lives of the noble Grecians and Romanes* in 1579, which Shakespeare certainly read. To all of this, Shakespeare's response was surprising: Caesar appears in three scenes and then is murdered, before the play is half finished. But a variety of characters respond to and reflect upon the central fact of the great man. This is the dramatic strategy of an ironist, or of a writer who wishes to question human behaviour and to observe interactions and consequences. In fact, Caesar influences the whole play, for he appears after his death as a bloodstained corpse and as a ghost before battle. Both Brutus and Cassius die conscious of Caesar and even speak to him as if he were present. And then his heir takes command, to "part the glories" of what is for him a "happy day."

In other ways *Julius Caesar* is shaped differently from the histories and tragedies that precede it, as if in manner as in subject matter Shakespeare was making decisive changes. The scene moves only from Rome to the battlefield, and with this new setting language becomes more restrained, firmer and sharper. Extensive descriptive images are few, and single words such as "Roman," "honour," "love," "friend," and proper names are repeated as if to enforce contrasts and ironies. In performance this sharp verbal edge, linked with commanding performances and the various excitements of debate, conspiracy, private crises, political eloquence, mob violence, supernatural portents, personal antagonisms, battle, and deaths, holds attention. The play has popular appeal and intellectual fascination.

For six or seven years Shakespeare did not return to a Roman theme, but, after completing *Macbeth* and *King Lear*, he again used Plutarch as a source for two more Roman plays, both tragedies that seem as much concerned to depict the broad context of history as to present tragic heroes.

Antony and Cleopatra. The language of *Antony and Cleopatra* is sensuous, imaginative, and vigorous. "*Felicitate audax* ["happily bold"] is the motto for its style comparatively with his other works," said the poet Samuel Taylor Coleridge. Almost every character seems to talk of kingdoms and to envision heroic deeds: Dolabella, the Roman soldier, says that his "love makes religion to obey" Cleopatra in her last imprisonment; Antony's servant is called Eros, who kills himself before his "great chief"; his soldiers have seen his eyes "glow like plated Mars"; his enemies say that, even in defeat, he "continues still a Jove." Octavius knows, as he closes for the kill, that great issues are at stake. Yet, while the issues are thus enlarged (or inflated), the protagonists do not reveal themselves to an audience as they do in *Hamlet*, *Othello*, *Lear*, or *Macbeth*. Antony has soliloquies only in defeat, and then he addresses the sun or fortune, false hearts or his queen, rather than seeking to hammer out his thoughts or to explore his own response. In the last scene, however, the focus concentrates intensely on a single character, when Cleopatra, prepared for death in robe and crown, believing in immortality, and hearing the dead Antony mock "the luck of Caesar," seems indeed to be transfigured:

... Husband, I come:
Now to that name my courage prove my title!
I am fire, and air; my other elements
I give to baser life. ...

(Act IV, scene 2, 278 ff.)

Coriolanus. The hero of *Coriolanus* has still fewer soliloquies: one in rhyme as he arrives, a renegade in Antium, and another of a few sentences when he stands alone in the marketplace waiting for the citizens to express their choice of him for consul. Through many guises, the audience sees the same man: as a young nobleman in peacetime, as a soldier going to battle, as bloodstained fighter and then victor, as candidate for consul in the "napless garment of humility," as a muffled, banished renegade, and then as leader of the Volscians, enemies of Rome.

In this play Shakespeare's customary contrasts and ironies, which lead an audience to discover meanings for themselves, are replaced by repetitions within the single

narrative line: there are three Forum scenes, four family scenes, a succession of fights, four scenes of mob violence, and continual attempts to argue with Coriolanus and deflect him from his chosen course. The language is sometimes elaborate, but does not have the poetic richness of *Antony and Cleopatra*; images are compact, sharply effective. Those moments when the audience is drawn most intently into the drama are strangely silent or understated. The citizens "steal away" instead of volunteering to fight for their country; their tribunes stay behind to organize their own responses. When the banished Coriolanus returns at the head of an opposing army, he says little to Menenius, the trusted family friend and politician, or to Volumnia, his mother, who have come to plead for Rome. His mother's argument is long and sustained, and for more than 50 lines he listens silent, until his resolution is broken from within: then, as a stage direction in the original edition testifies, he "holds her by the hand, silent." In his own words, he has "obeyed instinct" and betrayed his dependence; he cannot

stand

As if a man were author of himself
And knew no other kin.

(Act V, scene 3, 35 ff.)

His desire for revenge is defeated, and the army retreats. Volumnia is hailed as "patronness and life of Rome," but she is silent while the drums, trumpets, and voices greet her. Coriolanus is seen only once more, in the enemy city where he is accused of treachery and is assassinated in the kind of mob violence he has previously withstood. So *Coriolanus* finishes with the audience observing a hero helpless to prevent his own death and with patterns of political, social, and personal behaviour repeated without hope of change. Nowhere has Shakespeare shown an aspect so severe as in the silent moments of this Roman tragedy, during which the actor is at a loss for words.

The "great," or "middle," comedies. The comedies written between 1596 and 1602 have much in common and are as well considered together as individually. With the exception of *The Merry Wives of Windsor*, all are set in some "imaginary" country. Whether called Illyria, Messina, Venice and Belmont, Athens, or the Forest of Arden, the sun shines as the dramatist wills. A lioness, snakes, magic caskets, fairy spells, identical twins, disguise of sex, the sudden conversion of a tyrannous duke or the defeat offstage of a treacherous brother can all change the course of the plot and bring the characters to a conclusion in which almost all are happy and just deserts are found. Lovers are young and witty and almost always rich. The action concerns wooing; and its conclusion is marriage, beyond which the audience is scarcely concerned. Whether Shakespeare's source was an Italian novel (*The Merchant of Venice* and *Much Ado About Nothing*), an English pastoral tale (*As You Like It*), an Italian comedy (the Malvolio story in *Twelfth Night*), or something of his own invention (probably *A Midsummer Night's Dream*, and parts of each), always in his hands story and sentiments are instinct with idealism and capable of magic transformations. *The Merry Wives of Windsor* differs from the other comedies in that it is set not in an imaginary country but in Windsor and the rural life of Shakespeare's own day. Fantasy occurs at the end, however, when the characters enter a land of make-believe around the folk fertility symbol of Herne, the Hunter's oak in the forest; and, as they leave to "laugh this sport o'er by a country fire," quarrels are forgotten. The more overtly fantastic plays, in their turn, contain observations of ordinary and (usually) country life.

Much Ado About Nothing is distinctive in many ways, for there is no obvious magic or disguise of sex. But many misunderstandings arise in a masked dance, and the play concludes with a pretended death and a simulated resurrection from behind yet another mask; moreover, the two main characters, Beatrice and Benedick, are transformed from within by what is called "Cupid, the only matchmaker."

In some ways these are intellectual plays. Each comedy has a multiple plot and moves from one set of characters

The tragic intensity of Cleopatra's death scene

The blend of fantasy and everyday experience in the comedies

to another, between whom Shakespeare invites his audience to seek connections and explanations. Despite very different classes of people (or immortals) in different strands of the narrative, the plays are unified by Shakespeare's idealistic vision and by an implicit judgment of human relationships, and all their characters are brought together—with certain significant exceptions—at, or near, the end.

The "outsider." The plays affirm truth, good order, and generosity, without any direct statement; they are shapely and complicated like a dance or like a game of chess. Yet at the general resolution all is not harmony: some characters are held back from full participation. At the end of *A Midsummer Night's Dream*, for example, the lovers' more callow comments on the rustics' play of *Pyramus* and *Thisbe* mark them as irresponsible to the imaginative world of Bottom and his fellows, who project themselves into their play's heroics almost without fear of failure; they are also distinct from the duke, *Theseus*, who says of the amateur performers:

The best in this kind are but shadows: and the worst are no worse, if imagination amend them.

In *The Merchant of Venice*, most of the unresolved elements in the comedy are concentrated in the person of Shylock, a Jew who attempts to use justice to enforce a terrible, murderous revenge on Antonio, the Christian merchant, but is foiled by Portia, in disguise as a lawyer, who turns the tables on the Jew by a legal quibble and has him at the mercy of the court. This strange tale is realized with exceptionally credible detail: Shylock is a moneylender, like many in Shakespeare's London, and a Jew of pride and deep religious instincts; the Christians treat him with contempt and distrust, and, when one of them causes his daughter to elope and steal his money and jewels, he suffers with an intensity equalled only by that of his murderous hatred of all Christians. In a scene written in prose that gives at one time both histrionic power and sensitive, personal feeling, Shylock identifies his cause with basic human rights:

I am a Jew . . . Hath not a Jew eyes? hath not a Jew hands, organs, dimensions, senses, affections, passions? fed with the same food, hurt with the same weapons, subject to the same diseases, healed by the same means, warmed and cooled by the same winter and summer, as a Christian is? If you prick us, do we not bleed? if you tickle us, do we not laugh? if you poison us, do we not die? and if you wrong us, shall we not revenge?

(Act III, scene 1, 50 ff.)

The happiness that follows the thwarting of his revenge, however, cannot be celebrated with full unison while there are reminders that he never reached "the beautiful mountain," Belmont.

In *As You Like It*, the melancholy character Jaques leaves the play before the concluding dances. He has seen, and voiced, the limitations of each of the pairs of lovers and is determined to hear more and learn more from the tyrant duke, so mysteriously converted to a "religious life." In *Twelfth Night*, Malvolio the steward is gulled by practical jokes that take advantage of his self-esteem; he is the last character to come onstage in the final scene, and he refuses reconciliation; he leaves after a noticeable silence with only these words: "I'll be revenged on the whole pack of you." This comedy has yet other "outsiders"; alone at the end, Feste the fool sings a strange song in which the whole of life is reduced to a melancholy tale sung by a knowing idiot. *Twelfth Night* is probably the last of the "great" comedies, and it is the saddest.

Wit and ambiguity. Incidental images, too, strike deep into the audience's remembrance of pain, fear, and suffering. In *Twelfth Night*, barren mountains, salt sea, and the smoke of war, storms, imprisonment, death, and madness are all invoked. When the king and queen of fairies quarrel in *A Midsummer Night's Dream*, Titania's speech evokes a world of chaos:

The ox hath therefore stretched his yoke in vain,
The plowman lost his sweat, and the green corn
Hath rotted ere his youth attained a beard:
The fold stands empty in the drowned field,
And crows are fattened with the murrion flock. . .

(Act II, scene 1, 81 ff.)

Yet the poetry also celebrates happiness and joy with a clearer note and quicker interplay of thought than had been achieved in English before. So, in *Twelfth Night*, from Orsino:

Then let thy love be younger than thyself,
Or thy affection cannot hold the bent:
For women are as roses, whose fair flower,
Being once displayed doth fall that very hour.

From Olivia:

Cesario, by the roses of spring,
By maidhood, honour, truth, and everything,
I love thee so that, maugre all thy pride,
Nor wit nor reason can my passion hide.

And from Viola:

And all those sayings will I over-swear,
And all those swearings keep as true in soul,
As doth that orb'd continent the fire
That severs day from night.

The wit and ambiguity through which the apparent meanings are laced with further indications of love, yearning, sexuality, unrest, and happiness glance continuously through the dialogue, especially perhaps in *Much Ado About Nothing*. Often the disguise of identity or sex or else misunderstandings or intentional counterfeiting serve to accentuate the varying levels of consciousness expressed; moments of near unmasking, or of recognition, hold the attention firmly. Witty debates between lovers were not unfamiliar; they had held the stage more than 10 years earlier in John Lyly's fantastic comedies that had been played at court by very young child actors. But never before had sharpness of wit been so matched by gentleness or fineness of sentiment.

Perhaps the most extraordinary achievement of these comedies—which change in mood so rapidly, which are so funny and yet sometimes dangerous and sad, which deal both with fantasy and eloquence—is that the recurrent moments of lifelike feeling are so expressed in words or action that an audience shares in the very moment of discovery. Sometimes this is a second thought, as in Viola's

I am all the daughters of my father's house,
And all the brothers too . . . and yet I know not . . .

Sometimes it is a single phrase—Sir Andrew Aguecheek's "I was adored once too"—and on several climactic occasions it is held in a song, whether of happiness, sorrow or peace, or of the "good life":

O mistress mine, where are you roaming?
O, stay and hear, your true-love's coming,
That can sing both high and low.

The structure of these comedies can be explained, their stage devices and language analyzed; but essentially they remain on the wing, alive with the "fancy" of art and sentiment. Puck's epilogue to the *Dream* is often quoted as their characteristic note:

If we shadows have offended,
Think but this, and all is mended,
That you have but slumbered here
While these visions did appear . . .

But Rosalind's epilogue to *As You Like It* is also apposite:

. . . I am not furnished like a beggar; therefore to
beg will not become me: my way is to conjure you . . .

The great tragedies. It is a usual and reasonable opinion that Shakespeare's greatness is nowhere more visible than in the series of tragedies—*Hamlet*, *Othello*, *King Lear*, and *Macbeth*. *Julius Caesar*, which was written before these, and *Antony and Cleopatra* and *Coriolanus*, which were written after, have many links with the four. But, because of their rather strict relationship with the historical materials, they are best dealt with in a group by themselves. *Timon of Athens*, probably written after the above-named seven plays, shows signs of having been unfinished or abandoned by Shakespeare. It has its own splendours but has rarely been considered equal in achievement to the other tragedies of Shakespeare's maturity.

Hamlet. Judged by its reception by the civilized world,

Shylock

The
"fancy" of
art and
sentiment
in the
great
comedies

Hamlet must be regarded as Shakespeare's most successful play. It has unceasing theatrical vitality, and the character of Hamlet himself has become a figure of literary mythology. Yet *King Lear* became for a time the fashionable play in 20th-century criticism, with many critics arguing that in *Hamlet* Shakespeare did not make a psychologically consistent play out of a plot that retained much of the crudity of an earlier kind of "revenge" drama—that he was trying to transform a barbaric "revenge" hero into a subtle, Renaissance prince but did not succeed in this impossible task.

Even if this opinion has become unacceptable, it nevertheless taught critics to look for elements other than psychological consistency. In particular, it is worth concentrating not on Elizabethan attitudes toward revenge but on Shakespeare's artistic balance in presenting the play's moral problems. It is likely that an artist will make his work more interesting if he leaves a dilemma morally ambiguous rather than explicit. The revenge situation in *Hamlet*, moreover, is one charged with emotional excitement as well as moral interest. Simply put, the good man (Hamlet) is weak, and the bad man (Claudius) is strong. The good man has suffered a deep injury from the bad man, and he cannot obtain justice because justice is in the hand of the strong bad man. Therefore the weak good man must go around and around in order to achieve a kind of natural justice; and the audience watches in suspense while the weak good man by subtlety attacks and gets his own back upon the strong bad man and the strong bad man spends his time evading the weak good man. Hamlet is given a formidable opponent: Claudius is a hypocrite, but he is a successful one. He achieves his desired effect on everybody. His hypocrisy is that of a skilled politician. He is not dramatically shown as being in any way unworthy of his station—he upholds his part with dignity. He is a "smiling villain" and is not exposed until the final catastrophe. The jealous Hamlet heaps abuse upon him, but Shakespeare makes Claudius the murderer self-controlled. Thus, theatrically, the situation is much more exciting.

Against this powerful opponent is pitted Hamlet, the witty intellectual. He shares his wit with the audience (and a few favoured characters such as Horatio), who thus share his superiority over most other personages in the play. His first words are a punning aside to the audience, and his first reply to the King is a cryptic retort. His sardonic witticisms are unforgettable ("The funeral baked meats/Did coldly furnish forth the marriage tables"; and "More honoured in the breach than the observance"). Hamlet is an actor in many parts of the play. The range of language in the roles he affects shows that his mimetic powers are considerable. He is skillful in putting on "an antic disposition" and gives a very funny performance in talking to Polonius. He condescends to talk the silly bawdry of Rosencrantz and Guildenstern. He can mimic Osric's style to perfection. He quarrels with Laertes beside Ophelia's grave in a display of verbosity that exceeds the modesty of nature in much the same way as does that of Laertes.

Besides Claudius, set off against Hamlet is Polonius. He is wrong in his judgments, one after another, and this leads to the audience's rejection of his political and human values. In all circumstances he seems slightly ridiculous—a foil for Claudius as he is for Hamlet. His astuteness suffers by comparison with that of the King. His philosophical view of life is hollow compared with Hamlet's. Hamlet has as many general maxims as Polonius; but his seem to be the product of a far more refined sensibility and of an ability to respond truthfully to experience. It is these qualities in the somewhat enigmatic characterization of Hamlet that have won him the fascinated admiration of the world.

Othello. Trusting to false appearances and allowing one's reason to be guided by one's passions had been a theme of many of Shakespeare's comedies. In *Othello* he showed that the consequences of so doing can be tragic rather than comic. Shakespeare adapted the story from an Italian model. His principal innovation consisted in developing the character of Iago, the villain, whose mo-

tives are represented as complex and ambiguous. Clearly Shakespeare was keenly interested in a villain who could successfully preserve an appearance of honesty; the bad as well as the good can be "the lords and owners of their faces" (Sonnet 94). Iago is made a plausible villain by being so interesting. He is an actor who enjoys playing his role of "honesty." Shakespeare makes him take the audience into his confidence at every stage of his plotting, and, as a consequence, they have a kind of non-moral participation in his villainy.

The pure and deep love between Desdemona and Othello is stressed from the beginning. Again and again the moral and intellectual stature of Othello is elevated by Shakespeare. He quells tumults in the streets with a few words; he bears himself with dignity before the Venetian council, defending himself compellingly from bitter accusations by Brabantio and accepting his military burden with quiet confidence. Even Iago, in the opening scene of the play, grudgingly admits the dependence of the Venetians on his valour. After his terrible murder of Desdemona, Othello's contrition is agonizing enough to swing the sympathies of the audience back to him.

King Lear. For Shakespeare's contemporaries, Lear, king of Britain, was thought to have been a historical monarch. For Shakespeare, however, although he gave the play something of a chronicle structure, the interest lay not in political events but in the personal character of the King. The main theme of the play is put into the mouth of the evil Regan, speaking to the pitiful Gloucester:

O sir, to wilful men
The injuries that they themselves procure
Must be their schoolmasters.

(Act II, scene 4, 301)

The various stages of Lear's spiritual progress (a kind of "conversion") are carefully marked. He learns the value of patience and the worth of "unaccommodated man." He begins to realize his own faults as a king and almost understands his failure as a father. He begins to feel for the "poor naked wretches" and confesses, "O I have ta'en too little care of this." His initial instability of mind, almost a predisposition to madness, is shown from the beginning. His terrible rages and curses, first upon Cordelia and later upon Goneril and Regan, and his ranting and tyrannical language all foreshadow his breakdown. His faithful counsellor is plain with him: "Be Kent unmannerly/When Lear is mad"; and his daughters shrewdly judge him: "he hath ever but slenderly known himself." He is painfully conscious of approaching madness, but gradually the bombast of his sanity gives place to a remarkable kind of eloquence, flowing easily and never incoherent. His "ravings" are intelligible to the audience, however perturbing they may seem to the other characters on the stage. They express a point of view that, had he understood it earlier, would have saved him from many errors of judgment. The mode of speech of the mad King contrasts strongly with the congenial inconsequentiality of his fool and the assumed madness of Edgar as "Poor Tom."

King Lear has a distinct underplot, a separable story of the fortunes of Gloucester—another father suffering from "filial ingratitude" and from his false judgment of the characters of his children. This underplot is introduced in the opening scene, in some detail, as if it were of as much importance as the main plot. The stages by which Gloucester similarly learns by suffering are clearly indicated. He begins by being the cheerful sinner, but gradually his sense of pity and duty become stronger, and he reveals himself to Edmund: "If I die for it (as no less is threatened me), the King my master must be relieved." This revelation of his good intentions to the treacherous Edmund leads directly to his downfall and to his being blinded.

Two of the "good" characters, Edgar and Albany, also grow in moral stature and strength in the course of the play. At first, Edgar seems rather ineffectual, quite unable to cope with the villainy of his half brother Edmund; but eventually he emerges as a strong character, confirmed by suffering and by compassion; able to fight

Lear's
predis-
position to
madness

Hamlet
himself
as an
actor

and overcome Edmund in the ordeal at arms; and eventually, as one of the survivors, he is entrusted, along with Albany, with the future of the kingdom. Albany, too, is gradually built up, from being the weak husband of Goneril to being the spokesman of virtue and justice, with an authority able to cope with the force of Edmund's malignant energy.

Yet the representatives of goodness and of hope in *King Lear* do not emerge dynamically, and it has been difficult for champions of Shakespeare's moral and religious orthodoxy to combat the pessimism and nihilism that most readers experience when reading the play—precisely the qualities that have made it a favourite in the 20th century.

Macbeth. *Macbeth* is the only play of Shakespeare that seems, to a large extent, to be related to the contemporary historical situation. It was intended to interest the new monarch, James VI of Scotland, who became James I of England. This was a matter of professional importance; for Shakespeare's company of actors had been taken over by the King on his accession, entitled to wear the royal livery as his retainers (as they did when they walked in the procession at his coronation). But more important than the flattering of the King was the way *Macbeth* satisfied public interest. For its subject was regicide, commonly regarded as the supreme crime. And the public had been profoundly moved by an attempted regicide in November 1605—the famous "Gunpowder Plot"—which the English people, even after three and a half centuries, have still not forgotten. The reign of Macbeth, king of Scotland, belonged, for Shakespeare and his audiences, to Scottish history of many centuries past. But the play of *Macbeth*, both in its treatment of the events of the story and in its details, was devised by Shakespeare with a very clear consciousness of the mood of his own times.

It is the first task of criticism to interpret the success of *Macbeth*, to explain how Shakespeare transformed a crude and horrible story of murderous ambition into a satisfying imaginative vision of good and evil. There are two principal artistic methods by which he effected this transformation. First, he made his play highly poetical; it is audacious in style, relying upon concentrated, brilliant brevity of phrase. So great is the imaginative verbal vigour that some critics, sensitive to poetry but unsympathetic to the theatre, have almost forgotten that *Macbeth* is a play and have encouraged readers to treat it rather as a poem. Second, Shakespeare has consistently humanized the two murderers, so that they almost become sympathetic—and, by making them husband and wife, their human relationship is as interesting as their motives for evil actions. This humanizing process is the key to Shakespeare's success in the play. His control of the reactions of an audience is an achievement of theatrical art, not of intellectual or moral subtlety.

Timon of Athens. *Timon of Athens* is yet another of Shakespeare's experiments—the exploration of a new kind of tragic form. Certain usual elements of Shakespearean tragedy are reduced in importance or eliminated from the structure of the play: the story, or "plot," is simple and lacks development. There is no maturing of characters—the only change is the single one of Timon, who moves from a fixed character of universal generosity to one of universal hatred. In the first half of the play, there is a consistent effort to build up a world around Timon in terms of which his behaviour can be judged. As he perceives characters and situations unrealistically and responds to them disproportionately, it becomes clear that his is a dream world. Into that world—as the audience watches, with some pain—reality intrudes. The second half of the play, however, is simply a series of interviews between Timon and his visitors, seemingly arranged solely to bring them under his curses; Timon's frenzied vituperation of his fellowmen becomes almost unbroken monotone. Eventually Timon rages himself to death, leaving Alcibiades to lament his death and punish his enemies.

Of the various explanations put forward for the uneven quality of the writing in *Timon of Athens* (collaboration;

incomplete revision; completion by an inferior dramatist), much the most probable is that this is Shakespeare's rough draft of a play. It certainly has close analogies with the great plays of the few years to which its composition belongs (iterative words and iterative imagery, ironic preparation and anticipation, "chorus" statements by disinterested observers, plot and subplot parallel, both complementary and contrasted). If it is a rough draft, then it presents a unique opportunity of getting close to Shakespeare's method of writing. It would prove that he put structure before composition; that he went straight ahead drafting the structure of a play, unifying it by means of theme, imagery, and ironic preparation, and paying less attention to prose-verse form and to the characterization of minor personages. It would indicate that his pen wrote speeches quickly, not wasting much time at first about verse form, putting down the gist of what the character had to say, sometimes with imagery that came to him on the spur of the moment, incorporating lines or half lines of blank verse and even occasionally rhymed couplets—all to be "worked up" later. Nor, by judging the play "unfinished," are its worth and importance diminished: certain parts may be roughly written, but the imaginative conception has a wholeness that imperfect composition does not obscure.

The "dark" comedies. Before the death of Queen Elizabeth I in 1603 the country was ill at ease: the House of Commons became more outspoken about monopolies and royal prerogative; uncertainty about the succession to the throne made the future unsettled. In 1603 the Plague again struck London, closing the theatres. In 1604 Shakespeare's patron, the Earl of Southampton, was arrested on charges of treason; he was subsequently released, but such scares did not betoken confidence in the new reign. About Shakespeare's private reaction to these events there can be only speculation, but three of the five plays usually assigned to these years have become known as "dark" comedies for their distempered vision of the world.

Troilus and Cressida. *Troilus and Cressida* may never have been performed in Shakespeare's lifetime, and it fits no single category. Based on Homer (as translated by George Chapman) and on 15th-century accounts of the Trojan War by John Lydgate and William Caxton, it explores the causes of strife between and within the Greek and Trojan armies and might well have been a history play of a newly questioning and ironic kind. But Shakespeare was also influenced by Geoffrey Chaucer's love poem, *Troilus and Criseyde*, and for the first time portrayed sexual encounters outside the expectation of marriage. Cressida desires Troilus (and later Diomedes) with physical as well as idealistic longing; she considers love frankly as a chase and acts on the principle

That she was never yet that ever knew
Love got so sweet as when desire did sue.

As in Shakespeare's earlier comedies, these lovers are contrasted with others—but with a difference, for they are set beside the shallow and jaded routine of Helen's life with Paris and the assembled Trojans, and beside the jealous humours of Achilles, lounging in his tent with Patroclus. Into Cressida's last scene, when she begs Diomedes to come to her tent, Shakespeare has further introduced three lookers-on who comment directly: the enslaved Troilus watching with the politically wily Ulysses and, at another corner of the stage, Thersites. The audience cannot identify simply with any one of the five characters but, instead, must take note of each varying discord.

In his ubiquitous commentary, Thersites, perhaps the most notable single invention in the play, expresses revulsion against the pursuit of both honour and love. When the lovers have left the stage he has the last word:

Would I could meet that rogue Diomed! I would croak like a raven; I would bode, I would bode. . . . Lechery, lechery! Still wars and lechery! Nothing else holds fashion. A burning devil take them!

He proclaims Agamemnon "both ass and ox"; Ajax he would scratch from head to foot, to make the "loathsome scab in Greece"; and as Menelaus and Paris fight

Timon of Athens a unique opportunity of seeing Shakespeare's working method

Thersites' revulsion from the pursuit of honour and love

The historical basis of *Macbeth*

in the last battle, he sees them as "bull" and "dog," cuckold and cuckold maker—and then he saves his own life by cowardice. Yet he is not the only commentator in the play. Priam sits on his throne, between his disputing sons; Ulysses arouses Achilles by praising Ajax; and Cassandra cries out from a supernatural certainty of doom. Pandarus describes the handsome warriors as food for love and hurries forward to take purient pleasure in Cressida's excitement.

Pandarus also speaks the epilogue, and something of the play's irony may be gauged by contrasting his weak and broken appearance as he speaks the last words with that of Prologue, who, dressed in *armour*, had announced the scene of Troy, the "princes orgulous," and all the brave and massy consequences of war. No history play by Shakespeare had run such a gamut from the heroic to the petty and familiar. Although the earlier comedies sometimes start with tyrannies and loss, they all conclude with a dance or, at their least hopeful, with a procession offstage until a "golden time convents." Nor could this play be called a tragedy, for, despite the death of Hector and the loss of all Troilus' hopes beyond those of hatred and revenge, there is no scope in the last disordered and inglorious battle for the intensity of tragedy. The stature of every character has been progressively diminished.

All's Well That Ends Well; *Measure for Measure*. The other two comedies of 1601–04, are less completely original. Both *All's Well That Ends Well* and *Measure for Measure* centre on stories of love that lead to marriage, and both end with complicated denouements superintended by a benevolent king or duke. The fantasy of the earlier comedies, however, is largely missing, and, although there are clowns, they haunt brothels or a prison, or they "love as an old man loves money, with no stomach." Subplots are about cowardice in battle or fornication. Only *Measure for Measure* has a song, and that "pleases" the woe of Mariana deserted by her unworthy Angelo.

Perhaps the most important element in both comedies is a new intensity. In *All's Well*, Helena's soliloquies of frustrated love and, sometimes, the brevity of her speech reveal her inner struggles; and a few words from her graceless husband indicate his new loss of assurance. In *Measure for Measure*, Isabella pleading for her brother's life and defending her chastity or the Duke disguised as a friar persuading Claudio to disdain life both carry their arguments fiercely and finely; and Angelo is shown twice in soliloquy, tempted to what he knows is evil by Isabella, whom he knows is good:

When I would pray and think, I think and pray
To several subjects. . . .

(Act II, scene 4, 1 ff.)

In this comedy the intensity of much of the dialogue, the overt religious and legal concerns, and the variety of plot and subplot in Shakespeare's earlier manner all combine to make a searching, unsettling, and, in the opinion of most judges, precarious play, a comedy that reaches its general conclusion only with difficulty, with adroitness, compromise, or dramatic necessity.

Although such issues are present in *All's Well*, they are more in the background, and Shakespeare ostensibly considers other themes—*inherited virtue opposed to virtue achieved by oneself, the wisdom of age over against the impressionability of youth, and the need for each man to make his own choice, even if wrongly.*

Only during the 20th century have the three "dark" comedies been frequently performed in anything like Shakespeare's texts, an indication that their questioning, satiric, intense, and shifting comedy could not please earlier audiences.

The latest plays. *Pericles*, *Cymbeline*, *The Winter's Tale*, *The Tempest*, and *Henry VIII*, written between 1608 and 1612, are commonly known as Shakespeare's "late plays," or his "last plays," and sometimes, with reference to their tragicomic form, they are called his "romances." Works written by an author in his 40s hardly deserve to be classified as "late" in any critical sense, yet these plays are often discussed as if they had been

written by a venerable old author, tottering on the edge of a well-earned grave. On the contrary, Shakespeare must have believed that plenty of writing years lay before him, and indeed the theatrical effectiveness and experimental nature of *Cymbeline*, *The Winter's Tale*, and *The Tempest* in particular make them very unlike the fatigued work of a writer about to break his staff and drown his book.

One of the common characteristics of these plays is that, although they portray a wide range of tragic or pathetic emotions, events move toward a resolution of difficulties in which reconciliations and reunions are prominent. They differ from earlier comedies in their structural emphasis on a renewal of hope that comes from penitence and forgiveness, together with a faith in the younger generation, who by love will heal or obliterate the wounds inflicted in the past.

There is also an extravagance of story and an unreality of motivation, both prompting the use of the label "romances." From *Coriolanus*, the most austere of his tragedies, Shakespeare turned immediately to *Pericles*, a fantastically episodic play set in a vaguely pre-Christian world. He no longer saw antiquity through the eyes of a historian like Plutarch but through the bright fictions of the imitators of late Greek romances, Heliodorus and Achilles Tatius. In *The Winter's Tale*, for instance, where events are determined by the god Apollo from his oracle on the island of Delphos, the kingdoms of Bohemia and Sicilia nevertheless contain Warwickshire country festivals and conycatchers; and Queen Hermione boldly asserts: "The Emperor of Russia was my father."

Some critics have attributed this change in theatrical manner to Shakespeare's boredom with everything except poetry; others have pointed to a revival of interest in romantic tragicomedy (in *Phylaster*, by Beaumont and Fletcher, many characteristics of Shakespeare's latest plays are discernible, but the precise date of this play is questioned, and thus it is difficult to decide whether the fashion was set by Beaumont and Fletcher with their play or by Shakespeare with *Pericles*). It is at least likely, however, that Shakespeare himself was the pioneer and originator of a new style. The King's Men took over the Blackfriars Theatre in 1608. It was a more expensive theatre, and it has reasonably been conjectured that its facilities influenced Shakespeare to produce a new kind of play for a sophisticated audience more responsive to imaginative experiment in drama.

Pericles. The first scenes of *Pericles* are often feeble in expression, frequently unsyntactical, and sometimes scarcely intelligible. The second half is splendidly written, in Shakespeare's mature style. It is now generally supposed that the inadequate parts of the play are due to its being a reconstruction of the text from the actors' imperfect memories. For the second half of the play, either the printer had a manuscript of good quality or the actors' memories were more accurate. Ben Jonson called it "a mouldy tale." Certainly it was a very old one. There was a Greek prose fiction on the story, which survives in a Latin translation. Versions of it are found in many European languages. John Gower, Chaucer's friend and contemporary, had included the story in his poem *Confessio amantis*, and there were two separate prose renderings in Shakespeare's time.

Cymbeline. The main theme of *Cymbeline*—Posthumus' wager on the chastity of his wife, Imogen—Shakespeare derived from a story in Boccaccio's *Decameron*. But he put this Italianate intrigue into a setting that, for his audience, was authentic. Cymbeline, king of Britain, and his two sons, Guiderius and Arviagus, who succeeded him, were, for Shakespeare's audience, historical monarchs. The play is carefully set in the pre-Christian Roman world. The Romans who invade Britain are recognizably derived from the same kind of exploration of the antique world that had produced *Julius Caesar*, *Antony and Cleopatra*, and *Coriolanus*.

Shakespeare shows great dramatic skill in weaving together many different elements of plot, period, and place. The open-air scenes in Wales, Iachimo's concealment in a trunk in Imogen's bedchamber, the supposed deaths of

The intensity of the "dark" comedies

The stylistic maturity of the second half of *Pericles*

Posthumus and of Imogen disguised as Fidele, the battle between the Britons and Romans, the vision of the eagle-borne Jupiter—all these in preparation for the amazing complications of the final scene of the play, where (it has been calculated) there are 24 distinct "revelations" in 455 lines.

The Winter's Tale. In *The Winter's Tale* Shakespeare's audacity had increased. He introduced a similar combination of heterogeneous civilizations. But he also abandoned a unity of development in the story: he made a break of 16 years in the middle of the play, introducing the figure of Time to persuade the audience to accept the rapid shift of dramatic time. Shakespeare similarly challenged their confidence by the pathos of the deaths of the little boy Mamillius and, seemingly, of his mother Hermione, followed by the repentance of his jealous husband Leontes. He also allows Antigonus a most attractive character, to be eaten by a bear. Shakespeare clearly intended the audience to become involved only at certain moments of the play, by intensifying particular episodes without allowing emotional commitment to the whole plot. Three times his characters use the phrase "like an old tale," as if they were themselves commenting on its incredibility. What might have been the most moving scene or series of scenes in this group of plays—the revelation of Perdita's true birth—is related only at second hand by a number of anonymous gentlemen. Presumably, Shakespeare did not wish to anticipate or reduce the theatrical effect of the final scene, in which the "statue" of Hermione comes to life. Or perhaps, having already shown a similar scene of recognition of father and long-lost daughter in *Pericles*, he did not wish to repeat himself.

Ingredients
in the plot
of *The
Tempest*

The Tempest. *The Tempest* shows even greater excellence in the variety of its ingredients. There is story enough, including two assassination plots. There is a group of quickly differentiated and interesting characters; there is elaborate dancing and singing; there is an inset entertainment, a marriage masque performed by the goddesses Iris, Ceres, and Juno; there is a theatrical "quaint device," the introduction and vanishing of a banquet; there is a tender love affair; there are marvellous comic turns. Yet a mood of seriousness is felt throughout the play; questions about freedom, about the instinct for revenge, and the conflicting claims of generosity are being asked; there is a sense of subtle seriousness when Prospero speaks his cryptic epilogue as an actor appealing for the good opinion of his audience.

Most of the action of the plot has taken place in the past; only the climax of reconciliation and the events immediately leading up to it are represented. But, although the "unity of time" is almost preserved, the amount of mental progress, the number of mental events, is large. The newcomers to Prospero's island grope their way toward repentance; the Prince finds his way to true love, after his previous tentative explorations; and Miranda awakens to womanhood. Caliban, the subhuman creature, rebels and then comes to learn the error of his ways; Ariel, the supernatural sprite, finds the means of regaining his freedom. Prospero resumes his political authority as duke and pardons all.

The play has a most interesting double focus, geographically speaking. Openly it is a story of Naples and Milan, a world of usurpations, tributes, homages, and political marriages that is familiar in Jacobean tragedy. At the same time the contemporary excitement of the New World permeates the play—a world of Indians and the plantations of the colonies, of the wonders and terrors and credulities of a newly discovered land. A lesser dramatist would surely have set his play far away in the west of the Atlantic to take advantage of this contemporary excitement. Perhaps with a surer theatrical instinct, Shakespeare offered his audience a familiar Italianate fictional world, which then became shot through with glimpses of the New World, too exciting to be fictional.

Henry VIII. *Henry VIII* is a play that has offered many difficulties to criticism. It has had a long and interesting stage history, but, from the mid-19th century, judgment has been confused by doubts about Shakespeare's

sole authorship of the play, for many scenes and splendid speeches are written in a style very close to that of John Fletcher (see below *Collaborative and attributed plays*). The best of recent criticism, however, is inclined to restrict itself to consideration of the play as it stands. Although a story of English history, it differs from the "histories" that Shakespeare had written earlier, during the reign of Queen Elizabeth I. It is more episodic—more of a pageant and a series of loosely connected crises—than a skillfully plotted drama. It has a different sort of unity: three tragic episodes involving the deaths of Buckingham, Wolsey, and Queen Katharine led to the prophecy of a new age. For Anne Boleyn's infant, whose christening closes the play, inspires Thomas Cranmer, archbishop of Canterbury, to a marvelous speech about the glories of her future reign as the first Elizabeth. Thus *Henry VIII*, in spite of many differences, resembles Shakespeare's other late plays in its emphasis on the way in which past tragic events lead to reconciliation and to hope for the new generation.

Collaborative and attributed plays. The busy competition of Elizabethan theatre encouraged collaboration between authors and was almost the rule in some companies. Naturally, therefore, scholars have sought "other hands" in Shakespeare's plays, but, following the magisterial arguments of the distinguished scholar Sir Edmund Chambers, critical opinion has held that each play in the Folio edition of 1623 is substantially Shakespeare's. The possibility remains that parts of the earliest plays, especially *I Henry VI* and *The Taming of the Shrew*, may derive from earlier plays by other hands. Stronger than this, however, are arguments that parts of *Henry VIII* were written by John Fletcher, who from 1608 onward wrote frequently for the King's Men. Fletcher's name has been linked with Shakespeare's elsewhere, most notably in the play *The Two Noble Kinsmen*, published as their joint work in 1634. Internal evidence of style and structure suggests that Shakespeare planned the whole work and wrote Act I; that then a need for haste arose and Fletcher took over responsibility for Acts II, III and IV, leaving Shakespeare to complete Act V. Some such story could account for a curious lack of cohesion in the writing and also for the closeness of the theme to interests apparent in Shakespeare's latest plays.

In his own lifetime and in later ages, several plays were attributed to Shakespeare (often with no justification at all). In his own handwriting, however, are 147 lines of a scene in *The Booke of Sir Thomas More*, a play written in about 1595 by a group of five authors (probably including Thomas Dekker, Anthony Munday, and Henry Chettle) and then suppressed by the censor. The attempts of Sir Thomas to quell the anti-alien riots are linked in sentiment to Shylock episodes from *The Merchant of Venice* and echo the plays of the 1590s in imagery and versification. Among the printed texts that have been ascribed to Shakespeare is the anonymous *Edward III* (1596); the stylistic evidence adduced for his authorship of an episode in which the King woos the Countess of Salisbury might, however, be the work of an imitator. Several plays were added to his works in the third edition of the Folio (1664): *Lochrine* (1595), *Sir John Oldcastle* (1600), *Thomas Lord Cromwell* (1602), *The London Prodigal* (1605), *The Puritan* (1607), and *A Yorkshire Tragedy* (1608). None is now considered to be of his authorship. Other plays, too, were printed as Shakespeare's, indicating the extent of his prestige—a brand name that could sell even rotten fish. No other dramatist of his time was so misused.

SHAKESPEARE'S READING

With a few exceptions, Shakespeare did not invent the plots of his plays. Sometimes he used old stories (*Hamlet*, *Pericles*). Sometimes he worked from the stories of comparatively recent Italian writers, such as Boccaccio—using both well-known stories (*Romeo and Juliet*, *Much Ado About Nothing*) and little-known ones (*Othello*). He used the popular prose fictions of his contemporaries in *As You Like It* and *The Winter's Tale*. In writing his historical plays, he drew largely from Plutarch's *Lives of*

Shakespeare's
plots

the *Noble Grecians and Romans* for the Roman plays and the chronicles of Edward Hall and Ralph Holinshed for the plays based upon English history. Some plays deal with rather remote and legendary history (*King Lear*, *Cymbeline*, *Macbeth*)—though it seemed more genuinely historical to Shakespeare's contemporaries than it does today. Earlier dramatists had occasionally used the same material (there were, for example, earlier plays called *The Famous Victories of Henry the fifth* and *King Lear*). But, because many plays of Shakespeare's time have been lost, it is impossible to be sure of the relation between an earlier, lost play and Shakespeare's surviving one: in the case of *Hamlet* it has been plausibly argued that an "old play," known to have existed, was merely an early version of Shakespeare's own.

Shakespeare was probably too busy for prolonged study. He had to read what books he could, when he needed them. His enormous vocabulary could only be derived from a mind of great celerity, responding to the literary as well as the spoken language. It is not known what libraries were available to him. The Huguenot family of Mountjoys, with whom he lodged in London, presumably possessed French books. There was, moreover, a very interesting connection between Shakespeare and the book trade. For there survives the record of apprenticeship of one Richard Field, who published Shakespeare's two poems *Venus and Adonis* and *Lucrece*, describing him as the "son of Henry Field of Stratford-upon-Avon in the County of Warwick, tanner." When Henry Field the tanner died in 1592, John Shakespeare the glover was one of the three appointed to value his goods and chattels. Field's son, bound apprentice in 1579, was probably almost exactly the same age as Shakespeare. From 1587 he steadily established himself as a printer of serious literature—notably of Sir Thomas North's translation of Plutarch (1595, reprinted in 1603 and 1610). There is no direct evidence of any close friendship between Field and Shakespeare. But it cannot escape notice that one of the important printer-publishers in London at the time was an exact contemporary of Shakespeare at Stratford, that he can hardly have been other than a schoolfellow, that he was the son of a close associate of John Shakespeare, and that he published Shakespeare's first poems. Clearly, a considerable number of literary contacts were available to Shakespeare, and many books were accessible.

That Shakespeare's plays had "sources" was already apparent in his own time. An interesting contemporary description of a performance is to be found in the diary of a young lawyer of the Middle Temple, John Manningham, who kept a record of his experiences in 1602 and 1603. On February 2, 1602, he wrote:

At our feast we had a play called *Twelfth Night*, or *What You Will*, much like *The Comedy of Errors*, or *Menaechmi* in Plautus, but most like and near to that in Italian called *Inganni*. . . .

The first collection of information about sources of Elizabethan plays was published in the 17th century—Gerard Langbaine's *Account of the English Dramatick Poets* (1691) briefly indicated where Shakespeare found materials for some plays. But, during the course of the 17th century, it came to be felt that Shakespeare was an outstandingly "natural" writer, whose intellectual background was of comparatively little significance: "he was naturally learn'd; he needed not the spectacles of books to read nature," said John Dryden in 1668. It was nevertheless obvious that the intellectual quality of Shakespeare's writings was high and revealed a remarkably perceptive mind. The Roman plays, in particular, gave evidence of careful reconstruction of the ancient world.

The first collection of source materials, arranged so that they could be read and closely compared with Shakespeare's plays, was made by Mrs. Charlotte Lennox in the 18th century. More complete collections appeared later, notably those of John Payne Collier (*Shakespeare's Library*, 1843; revised by W. Carew Hazlitt, 1875). These earlier collections have been superseded by one edited by Geoffrey Bullough as *Narrative and Dramatic Sources of Shakespeare* (7 vol., 1957–72).

It has become steadily more possible to see what was original in Shakespeare's dramatic art. He achieved compression and economy by the exclusion of undramatic material. He developed characters from brief suggestions in his source (Mercutio, Touchstone, Falstaff, Pandarus), and he developed entirely new characters (the Dromio brothers, Beatrice and Benedick, Sir Toby Belch, Malvolio, Paulina, Roderigo, Lear's fool). He rearranged the plot with a view to more effective contrasts of character, climaxes, and conclusions (*Macbeth*, *Othello*, *The Winter's Tale*, *As You Like It*). A wider philosophical outlook was introduced (*Hamlet*, *Coriolanus*, *All's Well That Ends Well*, *Troilus and Cressida*). And everywhere an intensification of the dialogue and an altogether higher level of imaginative writing together transformed the older work.

But, quite apart from evidence of the sources of his plays, it is not difficult to get a fair impression of Shakespeare as a reader, feeding his own imagination by a moderate acquaintance with the literary achievements of other men and of other ages. He quotes his contemporary Christopher Marlowe in *As You Like It*. He casually refers to the *Aethiopica* ("Ethiopian History") of Heliodorus (which had been translated by Thomas Underdown in 1569) in *Twelfth Night*. He read the translation of Ovid's *Metamorphoses* by Arthur Golding, which went through seven editions between 1567 and 1612. Chapman's vigorous translation of Homer's *Iliad* impressed him, though he used some of the material rather sardonically in *Troilus and Cressida*. He derived the ironical account of an ideal republic in *The Tempest* from one of Montaigne's essays. He read (in part, at least) Samuel Harsnett's *Declaration of egregious popish impostors* and remembered lively passages from it when he was writing *King Lear*. The beginning lines of one sonnet (106) indicate that he had read Edmund Spenser's poem *The Faerie Queene* or comparable romantic literature.

He was acutely aware of the varieties of poetic style that characterized the work of other authors. A brilliant little poem he composed for Prince Hamlet (Act II, scene 2, line 115) shows how ironically he perceived the qualities of poetry in the last years of the 16th century, when poets such as John Donne were writing love poems uniting astronomical and cosmogenic imagery with skepticism and moral paradoxes. The eight-syllable lines in an archaic mode written for the 14th-century poet John Gower in *Pericles* show his reading of that poet's *Confessio amantis*. The influence of the great figure of Sir Philip Sidney, whose *Arcadia* was first printed in 1590 and was widely read for generations, is frequently felt in Shakespeare's writings. Finally, the importance of the Bible for Shakespeare's style and range of allusion is not to be underestimated. His works show a pervasive familiarity with the passages appointed to be read in church on each Sunday throughout the year, and a large number of allusions to passages in Ecclesiasticus (Wisdom of Jesus the Son of Sirach) indicates a personal interest in one of the uncanonical books.

III. Understanding Shakespeare

SYMPATHETIC EXPLORATION OF THE TEXTS

On opening the works of Shakespeare, a reader can be held by a few lines of verse or a sentence or one complex, glittering, or telling word. Indeed, Shakespeare's supreme mastery of words and images, of sound, rhythm, metre, and texture, as well as the point, neatness, and lyricism of his lines, has enslaved countless people.

The next step in understanding, for most readers, is an appreciation of individual characters. Many of the early books on Shakespeare were about his "characters," and controversy about them still continues. Appreciation of the argument of the plays usually comes on insensibly, for Shakespeare is not a didactic playwright. But most persistent readers gain an increasing sense of a unity of inspiration, of an alert moral judgment and idealistic vision, both in the individual plays and in the works as a whole.

When the plays are seen in performance, they are fur-

Availability of literary contacts and accessibility of books

Acquaintance with the literary achievements of other writers

ther revealed in a new, three-dimensional, flesh and blood reality, which can grow in the minds of individual playgoers and readers as they become more experienced in response to the plays' many suggestions.

Shakespeare's direct appeal to readers

But, while various skills and learned guidance are needed for a developed understanding of Shakespeare, the directness of his appeal remains—the editors of the First Folio commended the plays to everyone "how odd soever your brains be, or your wisdoms." Perhaps most essentially, the plays will continually yield their secrets only to imaginative exploration.

CAUSES OF DIFFICULTY

Questions of authorship. The idea that Shakespeare's plays and poems were not actually written by William Shakespeare of Stratford has been the subject of many books and is widely regarded as at least an interesting possibility. The source of all doubts about the authorship of the plays lies in the disparity between the greatness of Shakespeare's literary achievement and his comparatively humble origin, the supposed inadequacy of his education, and the obscurity of his life. In Shakespeare's writings, people have claimed to discover a familiarity with languages and literature, with such subjects as law, history, politics, and geography, and with the manners and speech of courts, which they regard as inconceivable in a common player, the son of a provincial tradesman. This range of knowledge, it is said, is to be expected at that period only in a man of extensive education, one who was familiar with such royal and noble personages as figure largely in Shakespeare's plays. And the dearth of contemporary records has been regarded as incompatible with Shakespeare's eminence and as therefore suggestive of mystery. That none of his manuscripts has survived has been taken as evidence that they were destroyed to conceal the identity of their author.

The claims put forward for Bacon. The first suggestion that the author of Shakespeare's plays might be Francis Bacon, Viscount St. Albans, seems to have been made in the middle of the 19th century, inquiry at first centring on textual comparison between Bacon's known writings and the plays. A discovery was made that references to the Bible, the law, and the classics were given similar treatment in both canons. In the later 19th century a search was made for ciphered messages embedded in the dramatic texts. In *Love's Labour's Lost*, for example, it was found that the Latin word "honorificabilitudinitatibus" is an anagram of *Hi ludi F. Baconis nati tuiti orbi* ("These plays, the offspring of F. Bacon, are preserved for the world.") Professional cryptographers of the 20th century, however, examining all the Baconian ciphers, have rejected them as invalid, and interest in the Shakespeare-Bacon controversy has diminished.

Edward de Vere, earl of Oxford

Other candidates. A theory that the author of the plays was Edward de Vere, 17th earl of Oxford, receives some circumstantial support from the coincidence that Oxford's known poems apparently ceased just before Shakespeare's work began to appear. It is argued that Oxford assumed a pseudonym in order to protect his family from the social stigma then attached to the stage and also because extravagance had brought him into disrepute at court. Another candidate is William Stanley, 6th earl of Derby, who was keenly interested in the theatre and was patron of his own company of actors. Several poems, written in the 1580s and exhibiting signs of an immature Shakespearean style, cannot well have been written by Shakespeare himself. One of these is in Derby's handwriting, and three of them are signed "W.S." These initials are thought by some to have been a concealment for Derby's identity (for some such motives as were attributed to Oxford) and to have been later expanded into "William Shakespeare."

Christopher Marlowe

Shakespeare has also been identified with Christopher Marlowe, one theory even going so far as to assert that Marlowe was not killed in a tavern brawl in 1593 (the corpse of another being represented as his own) but was smuggled to France and thence to Italy where he continued to write in exile—his plays being fathered on Shakespeare, who was paid to keep silent.

The case for Shakespeare. In spite of recorded allusions to Shakespeare as the author of many plays in the canon, made by about 50 men during his lifetime, it is arguable that his greatness was not as clearly recognized in his own day as one might expect. But on the other hand, the difficulties are not so great as many disbelievers have held, and their proposals have all too often raised larger problems than they have resolved. Shakespeare's contemporaries, after all, wrote of him unequivocally as the author of the plays. Ben Jonson, who knew him well, contributed verses to the First Folio of 1623, where (as elsewhere) he criticizes and praises Shakespeare as the author. John Heminge and Henry Condell, fellow actors and theatre owners with Shakespeare, signed the dedication and a foreword to the First Folio and described their methods as editors. In his own day, therefore, he was accepted as the author of the plays. Throughout his lifetime, and for long after, no person is known to have questioned his authorship. In an age that loved gossip and mystery as much as any, it seems hardly conceivable that Jonson and Shakespeare's theatrical associates shared the secret of a gigantic literary hoax without a single leak or that they could have been imposed upon without suspicion. Unsupported assertions that the author of the plays was a man of great learning and that Shakespeare of Stratford was an illiterate rustic no longer carry weight, and only when a believer in Bacon or Oxford or Marlowe produces sound evidence will scholars pay close attention to it and to him.

Linguistic and historical problems. Since the days of Shakespeare, the English language has changed, and so have audiences, theatres, actors, and customary patterns of thought and feeling. Time has placed an ever-increasing cloud before the mirror he held up to life, and it is here that scholarship can help.

Problems are most obvious in single words. In the 20th century, "presently," for instance, does not mean "immediately," as it usually did for Shakespeare, or "will" mean "lust" or "rage" mean "folly" or "silly" denote "innocence" and "purity." In Shakespeare's day, words sounded different, too, so that "ably" could rhyme with "eye" or "tomb" with "dumb." Syntax was often different, and, far more difficult to define, so was response to metre and phrase. What sounds formal and stiff to a modern hearer might have sounded fresh and gay to an Elizabethan.

Ideas have changed, too, most obviously political ones. Shakespeare's contemporaries almost unanimously believed in authoritarian monarchy; they accepted a police state and recognized divine intervention in history. Most of them would have agreed that a man should be burned for ultimate religious heresies. It is the office of linguistic and historical scholarship to aid the understanding of the multitude of factors that have significantly affected the impressions made by Shakespeare's plays.

Textual and editorial problems. None of Shakespeare's plays has survived in his handwritten manuscript, and, in the printed texts of some plays, notably *King Lear* and *Richard III*, there are passages manifestly corrupt, with no clue to the words Shakespeare once wrote. Even if the printer received a good manuscript, small errors could still be introduced. Compositors were less than perfect; they often "regularized" the readings of their copy, altered punctuation because they lacked the necessary pieces of type, or made mistakes because they had to work too hurriedly. Even the correction of proof sheets in the printing house could further corrupt the text, since such correction was usually effected without reference to the author or to the manuscript copy; when both corrected and uncorrected states are still available, it is often the uncorrected version that is preferable. Correctors are undoubtedly responsible for many errors now impossible to right.

OVERCOMING SOME DIFFICULTIES

The contribution of textual criticism. The early editors of Shakespeare saw their task chiefly as one of correction and regularization of the faulty printing and imperfect texts of the original editions or their reprints. Many changes in the text of the quartos

and folios that are now accepted derive from Nicholas Rowe (1709) and Alexander Pope (1723–25), but these editors also introduced many thousands of small changes that have since been rejected. Later in the 18th century, editors compiled collations of alternative and rejected readings. Samuel Johnson (1765), Edward Capell (1767–68), and Edmond Malone (1790) were notable pioneers. Their work reached its most comprehensive form in the Cambridge edition in nine volumes by W.G. Clark, J. Glover, and W.A. Wright, published in 1863–66. A famous one-volume Globe edition of 1864 was based on this Cambridge text.

Each major editor had added to the great number of annotations on textual problems and on linguistic and historical difficulties, and in 1871 was published the first of a series of large volumes, one or two for each play, called "A New Variorum Edition," which aimed at bringing all previous textual scholarship together. The series remains incomplete, but A.W. Pollard published his *Shakespeare Folios and Quartos* in 1909 and, together with R.B. McKerrow, Sir Walter Greg, and Charles Sisson, began a concerted study of the manuscript plays surviving from Elizabethan theatres and the practice of Elizabethan printers. Their work was summed up in Greg's study *The Shakespeare First Folio* (1955) and Fredson Bowers' *On Editing Shakespeare and the Elizabethan Dramatists* (1955). By this time a new phase of bibliographic and textual inquiry had begun, and Bowers, with Alice Walker, Charlton Hinman, and others, began studying the smallest minutiae of each substantive early edition. Computers will analyze the huge mass of their detailed information and make available the full results of their investigations. Also, individual compositors who set in type the early editions are being identified, and already something of their work habits and habitual errors is known. Processes of correction in the Elizabethan printing houses are also being studied more intensively. Before the end of the 20th century, a new edition of Shakespeare may appear in which a multitude of small errors have been removed. But even then, nothing will compensate for the loss of Shakespeare's manuscripts, and numerous important readings and details of presentation will still have to be supplied by educated guesses.

Historical, linguistic, and dramatic studies. Since the end of the 19th century, many other problems that hinder the understanding of Shakespeare's texts have been at least partly overcome thanks to extensive investigation into, for example, his syntax, vocabulary, and word usage ---especially with regard to other Elizabethan and Jacobean literature. Such technical works, as well as studies of current theories of composition (the use of rhetoric, metaphor, and simile), have provided material for critical analysis, as have works that examine the ideas and life-style of Shakespeare's contemporaries. An increasingly large proportion of research is devoted to an investigation of contemporary literary and dramatic conventions.

LITERARY CRITICISM

Literary critics and the theatre. Shakespeare criticism must take into account the certainty that Shakespeare intended his plays to be acted, that he was the professional playwright of a repertory company, that the success of a play in performance by his company was what determined his income, and that during his lifetime he apparently made no effort (or perhaps was too busy) to gain a "literary" reputation from his plays. Yet, his contemporaries had no doubt about his literary eminence. Heminge and Condell, his fellow players, and Ben Jonson, his fellow playwright, commended the great Folio of 1623 to "the great variety of readers."

The situation has been complicated by the fact that the history of Shakespeare criticism and the stage history of his plays have run parallel but separate courses. It is fair to say that, from about the mid-18th century onward, there has been a constant tension between the critics and the theatres regarding treatment of Shakespeare. Although Dr. Johnson was the contemporary of David Garrick, Coleridge and Hazlitt the contemporaries of Ed-

mund Kean, Dowden of Sir Henry Irving, and Bradley of Beerbohm Tree, the links between these critics and actors were not notably strong. Theatregoers were usually impressed by character impersonations rendered by virtuoso actors, while readers became more and more impressed by an awareness and admiration of the special artistic form of the plays. Rather than by stage performances, Shakespeare criticism was influenced by the dominant literary forms of each age: by the self-revelatory poem of the Romantic period, the psychological and ethical novel of the Victorians, the fragmentary revelations of the human condition in 20th-century poetry. It is a platitude that each age finds what it wants to find in Shakespeare. It will only see what it can. It can only see what it must. But Shakespeare critics, if criticism is to be in a healthy condition, must pay more than lip service to that fact. However deeply embedded in its contemporary situation, good criticism, like all intellectual feats, is a leaping out of the situation. The history of Shakespeare criticism is a subject of more than scholarly interest. It is a cautionary tale. Sometimes it is an awful warning.

The progress of Shakespeare criticism. As a basis for the criticism of an author's work, it is reasonable to begin by inquiring how his contemporaries assessed his achievement. But contemporary literary criticism was surprisingly silent about the plays actually being written (though critics were reasonably articulate about the plays they thought ought to be written). Collections of references made to Shakespeare later, during the 17th century, show that many important writers paid little attention to him. Ben Jonson's reputation was, for a variety of reasons, probably superior for the first half of the century. He was, moreover, the most vocal literary critic of the early 17th century, and he thought of Shakespeare as a naturally gifted writer, who failed to discipline himself. From his criticism derived the distinction between "nature" and "art" that for long proved to be a pertinacious and unproductive theme of Shakespeare criticism. It was further encouraged by John Milton, when he contrasted Jonson's "learned sock" with Shakespeare's "native wood-notes wild" (which refers to the comedies but came to be treated as a general statement, especially the epithet "wild"). A good deal of the spirit of Ben Jonson's cavillings, rather than his magnificent praise in the poem prefixed to the Folio of 1623, was continued by later 17th-century and 18th-century critics, censuring Shakespeare's carelessness, his artistic "faults."

John Dryden (died 1700) was the first great critic of Shakespeare. Much concerned with his own art as a dramatist, he judged Shakespeare in a practical spirit. For 100 years after him, the best literary criticism of Shakespeare was an elaboration and clarification of his opinions. Dryden on some occasions praised Shakespeare in the highest terms and boldly defended the English tradition of the theatre, maintaining that, if it was contrary to the revered classical precepts of Aristotle, it was only because Aristotle had not seen English plays; had he seen them, his precepts would have been different. Dryden nevertheless at times attributes artistic "faults" to Shakespeare, judging him according to Neoclassical principles of taste that derived from France and soon prevailed throughout Europe. Shakespeare's dramatic art was so different from that of the admired tragedy of the times (that of Corneille and Racine) that it was difficult for a critic to defend or interpret it in reasonable terms. The gravest charge was the absence of "poetical justice" in Shakespeare's plays. Although some of the better 18th-century critics, such as Joseph Addison and Dr. Johnson, saw the limitations of "poetical justice" as an artistic theory, they nevertheless generally felt that the ending of *King Lear*, especially, was intolerable, offending all sense of natural justice by the death of Cordelia. The play was thus given a "happy ending"---one congruent with "poetical justice"---by the poet and playwright Nahum Tate: Lear was restored to his authority, and Cordelia and Edgar were to be married and could look forward to a prosperous reign over a united Britain. This change was approved by Dr. Johnson, and the revised play held the stage for generations and was the only

The "New Variorum Edition"

The tension between the critics and the theatre

form of *King Lear* performed on the stage until the mid-19th century.

In the early 18th century the cumbersome folio editions were replaced by more convenient editions, prepared for the reader. Nicholas Rowe, in a six-volume edition of 1709, tidied up the text of the plays, adding scene divisions, lists of dramatis personae, indications of locality, and so on. Rowe thus made a start in turning Shakespeare's plays into literature to be read, yet without neglecting the theatrical environment from which they emerged. Rowe was himself a practicing and successful dramatist, and on the whole he gave a good lead to the dramatic criticism of the plays. The preface to Alexander Pope's edition of 1725, however, had an unhappy influence on criticism. Shakespeare's natural genius, he felt, was hampered by his association with a working theatre. Pope fully accepted the artistic form of Shakespeare's writings as due to their being stage plays. But he regarded this as a grave disadvantage and the source of their artistic defectiveness. Lewis Theobald took the opposing view to Pope's, claiming that it was an advantage of Shakespeare that he belonged to the theatrical profession. Dr. Johnson similarly realized that methods of producing the plays on the stage influenced the kind of illusion created. In the splendid preface to his edition (1765), Johnson dismissed, once and for all in English criticism, the Neo-classical theories of "decorum," the "unities," and the mutual exclusiveness of tragedy and comedy—theories now seen as irrelevant to Shakespeare's art and as having confused the discussion of it. In many ways Johnson was the source of the notion of Shakespeare as a realistic dramatist, whose mingling of tragic and comic scenes was justified as "exhibiting the real state of sublunary nature," in which laughter and tears, rejoicing and misery, are found side by side.

Johnson censured Shakespeare as a dramatic artist for his lack of morality. Shakespeare, he wrote, "sacrifices virtue to convenience, and is so much more careful to please than to instruct, that he seems to write without any moral purpose." Later critics have felt compelled to controvert or to circumvent such a judgment. But Johnson's preface, if it did not give the discussion of Shakespeare's artistry a fresh start, cleared away some of the dead or irrelevant doctrines.

During the rest of the 18th century, after Johnson, it was scholarship rather than criticism that advanced in England. The best of literary criticism of the time was in the discovery of new subtleties in Shakespeare, especially in characterization; indeed, the acceptance of Shakespeare as a dramatic artist largely came about through his evident powers of characterization (to which probably the growth of the realistic novel in the 18th century had made readers more sensitive), and inadequate attention was paid to other aspects of his dramatic craftsmanship. There was nothing in England comparable to the brilliant Shakespeare criticism of Lessing, Goethe, and August von Schlegel in Germany. The latter's essay on *Romeo and Juliet* of 1797 demonstrated that, apart from a few witticisms, nothing could be taken away from the play, nothing added, nothing rearranged without mutilating the work of art and confusing the author's intentions. Here modern Shakespeare criticism begins. Indeed, from the time of Lessing, in the 18th century, to the mid-19th century, German critics and scholars made substantial and original contributions to the interpretation of Shakespeare, indicating Shakespeare's superlative artistry, at a time when in England he was admired more as a great poet and a brilliant observer of mankind than as a disciplined artist.

Samuel Taylor Coleridge, the greatest English critic of Shakespeare, vigorously denied that he had been affected by Schlegel (though he acknowledged the influence of Lessing), but there are many similarities between the two. His criticism—which has to be put together from reports of his lectures, from his notebooks, and from memories of his conversation, for he never succeeded in writing an organized book on Shakespeare—at first censured Shakespeare's lack of artistry, but in his lectures, given from 1810 onward, and in his *Biographia Literaria*

(1817), he demonstrated that Shakespeare's "irregularities" were in fact the manifestations of a subtle intelligence. It was the purpose of criticism to reveal the reasons why the plays are as they are. Shakespeare was a penetrating psychologist and a profound philosopher; but Coleridge claimed that he was an even greater artist, and his artistry was seen to be "unconscious" or "organic," not contrived. Thus the dominant literary forms of Coleridge's age, which were those of self-revelatory poetry, influenced the criticism of the age: Hamlet was felt to speak with the voice and feeling of Shakespeare, and, as for the sonnets, William Wordsworth, whose greatest achievement was writing a long poem on the growth of his own mind, explained that Shakespeare "unlocked his heart" in his sonnets.

These critical opinions were inclined to degenerate in inferior hands in the course of the 19th century: the belief in Shakespeare's all-pervading artistry led to over-subtle interpretations; the enthusiasm for character analysis led to excessive biography writing outside the strictly dramatic framework; and the acknowledged assessment of Shakespeare's keen intelligence led to his being associated with almost every school of thought in religion, politics, morals, psychology, and metaphysics. Nevertheless, it was the great achievement of the Romantics to have freed criticism from preoccupation with the "beauties" and "faults" in Shakespeare and to have devoted themselves instead to interpreting the delight that people had always felt in the plays, whether as readers or theatre-goers. Shakespeare's "faults" now became "problems," and it was regarded an achievement in literary criticism to have found an explanation for some hitherto difficult or irreconcilable detail in a play. Many of the most brilliant writers of Europe were critics of Shakespeare; and their utterances (whether or not they may be regarded as having correctly interpreted Shakespeare) are notable as recording the impressions he made upon great minds.

SHAKESPEARE'S INFLUENCE

Today Shakespeare's plays are performed throughout the world, and all kinds of new, experimental work finds inspiration in them: "... in the second half of the twentieth century in England," wrote the innovative theatre director Peter Brook, "we are faced with the infuriating fact that Shakespeare is still our model."

Shakespeare's influence on English theatre was evident from the start. John Webster, Philip Massinger, and John Ford are among the better known dramatists who borrowed openly from his plays. His influence is evident on Restoration dramatists, especially Thomas Otway, John Dryden, and William Congreve. John Osborne, Harold Pinter, Samuel Beckett, and George Bernard Shaw are among 20th-century writers in whose works Shakespearean echoes are to be found. Many writers have taken over Shakespeare's plots and characters: Shaw rewrote the last act of *Cymbeline*, Tom Stoppard invented new characters to set against parts of *Hamlet* in *Rosencrantz and Guildenstern Are Dead* (1968), and Edward Bond used *King Lear* as the starting point for his own *Lear* (1971).

Shakespeare has also influenced dramatists and theatre directors outside his own country. In Germany, English acting troupes were welcomed early in the 17th century, and the German version of *Hamlet*, *Der bestrafte Brudermord* ("Fratricide Punished"), testifies to the immediate influence of that play. His influence on later European dramatists ranges from a running allusion to *Hamlet* in Anton Chekhov's play *The Seagull* to imitation and parody of *Richard III* in Bertolt Brecht's *Arturo Ui*, adaptation of *King John* by Max Frisch, and André Gide's translation and simplification of *Hamlet*.

Shakespeare's influence on actors since his own day has been almost as widespread. Many European and American actors have had their greatest successes in Shakespearean roles. In England very few actors or actresses reach pre-eminence without acting in his plays. Each player has the opportunity to make a part his own. This is not because Shakespeare has created only outlines for others to fill but because he left so many and varied

Pope's theory that Shakespeare's natural genius was hampered by writing for the theatre

Coleridge's critical opinions

invitations for the actor to call upon his deepest, most personal resources.

Theatre directors and designers after Shakespeare's time, with every technical stage resource at their command, have returned repeatedly to his plays, which give opportunity for spectacle and finesse, ritual and realism, music and controlled quietness. Their intrinsic theatricality, too, has led to adaptations into very different media: into opera (as Verdi's *Otello*) and ballet (as versions of *Romeo and Juliet* from several nations); into sound recordings, television programs, and films. Musicals have been made of the comedies (as *Kiss Me Kate* from *The Taming of the Shrew*); even a tragedy, *Othello*, was the inspiration of a "rock" musical in 1971 called *Catch My Soul*, while *Macbeth* has yielded a political-satire show called *Macbird!* (1967).

Shakespeare has Hamlet say that the aim of theatre performance is to "hold the mirror up to nature," and this is what the history of his plays, from their first production to the latest, shows that he has, pre-eminently, achieved.

MAJOR WORKS

PLAYS: (probable dates of performance given): 2 *Henry VI*, 3 *Henry VI* (1589–91); 1 *Henry VI* (1591–92); *Richard III*, *The Comedy of Errors* (1592–93); *Titus Andronicus*, *The Taming of the Shrew* (1593–94); *The Two Gentlemen of Verona*, *Love's Labour's Lost*, *Romeo and Juliet* (1594–95); *Richard II*, *A Midsummer Night's Dream* (1595–96); *King John*, *The Merchant of Venice* (1596–97); 1 *Henry IV*, 2 *Henry IV* (1597–98); *Much Ado About Nothing*, *Henry V* (1598–99); *Julius Caesar*, *As You Like It* (1599–1600); *Hamlet*, *The Merry Wives of Windsor* (1600–01); *Twelfth Night*, *Troilus and Cressida* (1601–02); *All's Well That Ends Well* (1602–03); *Measure for Measure*, *Othello* (1604–05); *King Lear*, *Macbeth* (1605–06); *Antony and Cleopatra* (1606–07); *Coriolanus*, *Tirion of Athens* (1607–08); *Pericles* (1608–09); *Cymbeline* (1609–10); *The Winter's Tale* (1610–11); *The Tempest* (1611–12); *Henry VIII* (1612–13).

POEMS: (dates of publication given): *Venus and Adonis* (1593); *The Rape of Lucrece* (1594); "The Phoenix and the Turtle" (1601); *Sonnets* with "A Lovers complaint" (1609).

BIBLIOGRAPHY

Modern editions: One-volume editions of Shakespeare's Works are by GEORGE L. KITTREDGE (1936), PETER ALEXANDER (1954), HARDIN CRAIG (1951), and CHARLES J. Sisson (1954). Editions giving one volume for each play are ALFRED HARBAGE (gen. ed.), *The Pelican Shakespeare*, rev. ed. (1969); SYLVAN BARNET (gen. ed.), *The Signet Classic Shakespeare*, 27 vol. (1963–66); and the still incomplete revision of *The Arden Shakespeare*, ed. by UNA ELLIS-FERMOR, H.F. BROOKS, and H. JENKINS (1951–); and T.J.B. SPENCER (gen. ed.), *The New Penguin Shakespeare*; the *New Cambridge Edition* is also one volume for each play, but the early publications of the comedies and some histories are now considered eccentric (gen. eds., SIR A.T. QUILLER-ROUCH, J.D. WILSON et al.). The *New Variorum Edition*, started by HORACE HOWARD FURNESS in 1871, is still in progress, and the completeness of its textual apparatus and notes ensures continual usefulness.

Textual studies: WALTHER EBISCH and LEVIN L. SCHUCKING published a comprehensive *Shakespeare Bibliography* in 1931 (supplemented in 1937 for the years 1930–35). The account is updated by GORDON R. SMITH, *A Classified Shakespeare Bibliography*, 1936–1958 (1963). The *Shakespeare Quarterly* (New York) publishes an annual classified bibliography, while the *Shakespeare Survey* (London) publishes annual accounts of "Contributions to Shakespearean Study," together retrospective articles on work done on particular aspects during the present century. JOHN BARTLETT, *A New and Complete Concordance . . . to Shakespeare* (1894); and CHARLES T. ONIONS, *A Shakespeare Glossary*, 2nd ed. rev. (1919), are both still most useful reference works and are kept in print. On textual criticism as applied to Shakespeare, the following works represent latest thinking and practice: FREDSON BOWERS, *Bibliography and Textual Criticism* (1964) and *On Editing Shakespeare* (1966); WALTER W. GREG, *The Editorial Problem in Shakespeare*, 3rd ed. (1954), and *The Shakespeare First Folio* (1955); CHARLTON HINMAN, *The Printing and Proof-Reading of the First Folio of Shakespeare*, 2 vol. (1963); E.A.J. HONIGSMANN, *The Stability of Shakespeare's Text* (1965); RONALD B. MCKERROW, *An Introduction to Bibliography for Literary Students* (1927); ALFRED W. POLLARD, *Shakespeare Folios and Quartos: A Study in the Bibliography of Shakespeare's Plays, 1594–1685* (1909); ALICE WALKER, *Textual*

Problems of the First Folio (1953); and FRANK P. WILSON, *Shakespeare and the New Bibliography*, rev. ed. by HELEN GARDNER (1970). Facsimile editions of quartos and folio, which are necessary for any close work on textual problems, have been edited by WALTER W. GREG et al., *Shakespeare Quarto Facsimiles* (1939 and in progress); and by CHARLTON HINMAN, *The Norton Facsimile of the First Folio* (1968).

Biographies: A lively account of the various efforts that have been made to write a biography of Shakespeare from the available materials, with the help of imaginative interpretation, is SAMUEL SCHOENBAUM, *Shakespeare's Lives* (1970). The first detailed life of Shakespeare was written by NICHOLAS ROWE, *Some Account of the Life of Mr. William Shakespeare* (1709; photographic facsimile, 1948). EDMOND MALONE, from 1780 onwards added much new material; his final account is in the 1821 Variorum Edition. The best of the 19th-century biographies were J.O. HALLIWELL-PHILLIPS, *Outlines of the Life of Shakespeare* (1881; last revision, 1887); and SIDNEY LEE, *A Life of William Shakespeare* (1898; 14th ed., 1931). The standard work is E.K. CHAMBERS, *William Shakespeare: A Study of Facts and Problems*, 2 vol. (1930), of which there is a useful abridgement by CHARLES WILLIAMS, *A Short Life of Shakespeare with Sources* (1933). More recent works are E.I. FRIPP, *Shakespeare, Man and Artist*, 2 vol. (1938); PETER ALEXANDER, *Shakespeare's Life and Art* (1939, reprinted 1961); HAZELTON SPENCER, *The Art and Life of William Shakespeare* (1940, reprinted 1970); M.M. REESE, *Shakespeare: His World and His Work* (1953); G.E. BENTLEY, *Shakespeare: A Biographical Handbook* (1961), supplemented by his *Profession of Dramatists in Shakespeare's Time, 1590–1642* (1971); PETER QUENNELL, *Shakespeare* (1963); and A.L. ROWSE, *William Shakespeare* (1963). Studies of special aspects of the life and environment include JOHN LESLIE HOTSON, *Shakespeare Versus Shallow* (1931, reprinted 1970); THOMAS W. BALDWIN, *William Shakespeare's Petty School* (1943) and *William Shakespeare's Small Latine and Lesse Greeke*, 2 vol. (1944, reprinted 1966); and MARK ECCLES, *Shakespeare in Warwickshire* (1961). A valuable collection of background material is contained in *Shakespeare's England: An Account of the Life and Manners of His Age*, ed. by SIDNEY LEE and CHARLES T. ONIONS, 2 vol. (1916). Also helpful are E.M.W. TILLYARD, *The Elizabethan World Picture* (1943, reprinted 1966); and *Shakespeare in His Own Age*, ed. by ALLARDYCE NICOLL (1964). The standard works on the theatre of Shakespeare's professional life are E.K. CHAMBERS, *The Elizabethan Stage*, 4 vol. (1923); and GLYNNE WICKHAM, *Early English Stages 1300–1660* (vol. 2 on 1576–1600, published in two pt., 1963–72). Other helpful studies are ALFRED HARBAGE, *Shakespeare's Audience* (1941); A.M. NAGLER, *Shakespeare's Stage* (1958); and BERNARD BECKERMANN, *Shakespeare at the Globe, 1599–1609* (1962). Special aspects of the environment that throw light on the mentality of the dramatist are RICHMOND NOBLE, *Shakespeare's Biblical Knowledge and Use of the Book of Common Prayer* (1935, reprinted 1970); R. MUSHAT FRYE, *Shakespeare and Christian Doctrine* (1963); PAUL A. JORGENSEN, *Shakespeare's Military World* (1956); GEORGE W. KEETON, *Shakespeare's Legal and Political Background* (1967); and K.M. BRIGGS, *The Anatomy of Puck* (1959) and *Pale Hecate's Team* (1962), on belief in fairies and witchcraft. A survey of the theories that someone other than William Shakespeare of Stratford-upon-Avon was the author of the plays published under his name has been written by H.N. GIBSON, *The Shakespeare Claimants: A Critical Survey of the Four Principal Theories Concerning the Authorship of the Shakespearean Plays* (1962). See also R.C. CHURCHILL, *Shakespeare and His Betters* (1958); and FRANK W. WADSWORTH, *The Poacher from Stratford* (1958). The possibility of cryptic messages in the plays was conclusively investigated in W.F. and E.S. FRIEDMAN, *The Shakespearean Ciphers Examined* (1957). The following are some of the principal exponents of the theories: (Bacon): EDWIN DURNING-LAWRENCE, *Bacon Is Shakespeare* (1910, reprinted 1971); A.B. CORNWALL, *Francis the First, Unacknowledged King of Great Britain and Ireland . . .* (1936); see also J.M. ROBERTSON, *The Baconian Heresy* (1913, reprinted 1970). (Edward de Vere, 17th Earl of Oxford, 1550–1604): J.T. LOONEY, "Shakespeare" Identified (1920); PERCY ALLEN, *The Story of Edward de Vere as William Shakespeare* (1932); HILDA AMPHLETT, *Who Was Shakespeare?* (1955, reprinted 1970); GILBERT SLATER, *Seven Shakespeares* (1931), proposes Oxford and a group of his collaborators. (6th Earl of Derby): ABEL LEFRANC, *Sous le masque de "William Shakespeare,"* 2 vol. (1918–19) and *A la découverte de Shakespeare*, 2 vol. (1945–50). (Marlowe): CALVIN HOFFMAN, *The Man Who Was Shakespeare* (1955).

Critical studies: Early opinion about Shakespeare up to 1700 is collected in *The Shakespeare Allusion-Book*, ed. by

JOHN MUNRO, 2 vol. (1909), rev. by E.K. CHAMBERS (1932, reprinted 1970); and in G.E. BENTLEY, *Shakespeare and Jonson: Their Reputations in the Seventeenth Century Compared* (1945). Eighteenth-century criticism is surveyed in DAVID NICHOL SMITH, *Shakespeare in the Eighteenth Century* (1928) and in his collection of *Eighteenth Century Essays on Shakespeare* (1903; 2nd ed., 1963); his anthology *Shakespeare Criticism: A Selection* (1916), includes work up to about 1825. Dr. Johnson's criticism has been conveniently excerpted in *Johnson on Shakespeare*, ed. by WALTER RALEIGH (1908) and *Samuel Johnson on Shakespeare*, ed. by W.K. WIMSATT (1960). T.M. RAYSON prepared the standard edition of *Coleridge's Shakespearean Criticism* (1930; 2nd ed., 2 vol., 1960), but a useful compilation is *Coleridge on Shakespeare*, ed. by TERENCE HAWKES (1969). These can be supplemented by *Coleridge on Shakespeare: The Text of the Lectures of 1811-12*, ed. by R.A. FOAKES (1971). General surveys of the development of criticism are given by LOUIS MARDER, *His Exits and His Entrances* (1963); ALFRED HARBAGE, *Conceptions of Shakespeare* (1966); and A.M. EASTMAN, *A Short History of Shakespearean Criticism* (1968). The best brief accounts are by T.S. ELIOT and J. ISAACS, "Shakespearean Criticism," in *A Companion to Shakespeare Studies*, ed. by HARLEY GRANVILLE-BARKER and G.B. HARRISON (1934, reprinted 1960); and by M.A. SHAABER, "Shakespeare Criticism: Dryden to Bradley," and STANLEY WELLS, "Shakespeare Criticism Since Bradley," in *A New Companion to Shakespeare Studies*, ed. by KENNETH MUIR and SAMUEL SCHOENBAUM (1971). The situation outside Britain may be studied in *Shakespeare in Europe*, a collection edited by OSWALD LE WINTER (rev. ed., 1970). PATRICK MURRAY, *The Shakespearean Scene: Some Twentieth-Century Perspectives* (1969), gives a shrewd survey of recent criticism. The following 20th-century works may be regarded as having had a substantial effect on the criticism of Shakespeare. HARLEY GRANVILLE-BARKER, *Prefaces to Shakespeare* (5 series, 1929-47; 4 vol., 1963), set the plays firmly in their theatrical environment. Enquiries into the artistic conventions of Shakespeare's time were the basis of the criticism of LEVIN L. SCHUCKING, *Die Charakterprobleme bei Shakespeare* (1919; Eng. trans., *Character Problems in Shakespeare's Plays*, 1922); E.E. STOLL, *Art and Artifice in Shakespeare* (1933); O.J. CAMPBELL, *Shakespeare's Satire* (1943, reprinted 1971); and W.W. LAWRENCE, *Shakespeare's Problem Comedies*, 2nd ed. (1969); G. WILSON KNIGHT, *The Wheel of Fire* (1930), *The Imperial Theme* (1931), *The Shakespearean Tempest* (1932), and later books; and L.C. KNIGHTS, *How Many Children Had Lady Macbeth?* (1933), showed how Shakespeare achieved poetical and symbolic effects. The study of Shakespeare's imagery is best represented by the pioneer work of CAROLINE F.E. SPURGEON, *Shakespeare's Imagery and What It Tells Us* (1935); and WOLFGANG CLEMEN, *The Development of Shakespeare's Imagery* (1951), followed by ROBERT B. HEILMAN, *This Great Stage: Image and Structure in King Lear* (1948) and *Magic in the Web: Action and Language in Othello* (1956). An understanding of the intellectual and social background of the plays was notably advanced by WILLARD FARNHAM, *The Medieval Origin of Elizabethan Tragedy* (1936) and *Shakespeare's Tragic Frontier* (1950); HARDIN CRAIG, *The Enchanted Glass: The Elizabethan Mind in Literature* (1936); C.L. BARBER, *Shakespeare's Festive Comedy* (1959); THEODORE SPENCER, *Shakespeare and the Nature of Man*, 2nd ed. (1949); and L.B. CAMPBELL, *Shakespeare's "Histories": Mirrors of Elizabethan Policy* (1947). Some of the notable explorations of the artistry of the plays are MADELEINE DORAN, *Endeavors of Art* (1954); BERTRAND EVANS, *Shakespeare's Comedies* (1960); and ANNE RIGHTER, *Shakespeare and the Idea of the Play* (1962). JAN KOTT, *Szkice o Szekspirze* (1962; Eng. trans., *Shakespeare, Our Contemporary*, 1964), has been very widely read and influential on theatrical productions.

(J.R.Br./T.Sp.)

Shales

The sedimentary rocks that occur in nature generally are classified as clastic, chemical, or organic, depending upon their principal mode of origin. The clastic or particulate rocks are further divided on the basis of grain size, the coarsest being conglomerates or rudites, and the finest-grained, consisting of particles finer than sand size ($\frac{1}{16}$ to 2 millimetres) derived principally from the weathering of continental (*i.e.*, nonmarine) rocks, are called lutites, or pelites. Those lutites that are laminated (having bed thicknesses of less than one centimetre) and fissile (tending to split into thin layers, generally parallel to bedding) or both are called shales. A bipartite name is often used, with a prefix such as clay, silt, or mud indicating the dominant grain size and the suffix shale or stone indicating the presence or absence of lamination and fissility.

Commonly the term shale is used interchangeably with lutite, perhaps because such shales make up 50 percent of all sedimentary rocks, and a lutite fraction is a significant component in many more.

In addition to weathered continental debris, many shales contain appreciable chemical precipitates and volcanically derived components. Fragments of hard parts of calcareous and siliceous micro-organisms and fine particles of calcium carbonate that are precipitated by chemical or biochemical means are often present. Organic matter also is commonly an important component. Some fine-grained material is formed by chemical alteration *in situ*, partly as the reaction product of original fine clastic detritus (transported particles) but mostly by reaction of volcanic flows and ejecta with sea (or lake) water to form clay minerals and zeolites (a group of silicate minerals that readily exchange some of their ions—charged atoms—with those of the immediate environment). Extensive marine volcanic muds or continental bentonite (a type of clay) beds are thus formed.

The properties of shales are largely determined by the fine grain size of the constituent minerals. The accumulation of fine clastic detritus generally requires a sedimentary environment of low mechanical energy (one in which wave and current actions are minimal), although some fine material may be trapped by plants or deposited as weakly coherent pellets in more agitated environments. The properties of the clay mineral constituents of lutites are particularly important, even when they do not make up the bulk of a rock. The clay minerals have a platy (rarely fibrous) form and are electrically charged with charge balance achieved by associated ions. The plates may bond together face-to-face, and the interlayer and edge ions may be exchangeable with ions from surrounding waters. The clays also may absorb water; hydration of interlayer cations (positively charged atoms) leads to clay swelling that ranges from a few angstrom units (one angstrom unit equals 10^{-8} centimetre) to a widely dispersed state. The charge interactions between clay particles allows their association in a very open fabric of high porosity but low permeability. The potential in such materials for variation of fabric leads to plasticity at moderate water content: at higher water content the sediment may undergo sudden liquefaction (a process known as thixotropic behaviour).

The average abundance of organic matter in shales is about 1 percent, compared with 0.3 percent in limestones and 0.05 percent in sandstones; lesser amounts exist in the open ocean muds, and more than 30 percent is contained in muds entrapped in marsh environments. More than 75 percent of all buried organic matter is found in shales. With abundant deposition of suitable types of organic matter and its preservation in the sediment, the complex sequence of events leading to petroleum accumulation may begin. Low-temperature thermal degradation produces disseminated hydrocarbons, and, if the hydrodynamic situation is suitable, these may migrate to porous reservoir rocks. Further maturation and gravitational segregation may then lead to economic accumulations of natural gas and crude oil.

Some organic-rich shales, called oil shales or kerogen shales, contain kerogen (a chemically complex mixture of solid hydrocarbons from macerated plant matter) in sufficient amounts to make feasible petroleum production by distillation.

Both shales and clays are among the most important nonmetallic raw materials and find many applications, largely in the ceramics industry. Over a suitable range of moisture content, clays are plastic and will retain a molded shape when dried, allowing a variety of products (*e.g.*, pottery, porcelain, bricks, sewer pipes, electrical insulators) to be formed. Partial melting on firing leads to glassy interparticle bonds and a permanently hard product. The proportions of clay minerals, quartz, and feldspar that are used influence the manufacturing process and the final product. The plasticity depends largely on the clay-mineral content, whereas quartz reduces dry shrinkage, increases mechanical strength, and increases porosity and permeability. Feldspar acts like quartz and

Constituents and general properties

Economic importance

also lowers fusion temperature. Shales with high alumina content and low flux content have fusion temperatures above 1,500° C (2,700° F) and are used as refractories. The fired colour of a ceramic body is determined by trace pigments.

Shales and clays are used as sources of alumina and silica in portland cement, and kaolinitic clays are used as fillers and surface coatings in paper and plastics. Some types are also used extensively in the oil industry as constituents of drilling muds.

Shales are unsatisfactory structural materials. They have relatively low compressive strength, particularly if the water content is high, and clay minerals will expand if permitted to absorb water. The low coefficient of friction of shales, particularly when moist, makes them unsuitable as structural and dam foundations. Their high initial water content may allow serious compaction problems when they are subjected to a load. A notable example is the sinking of Mexico City, built on old lake sediments containing a high percentage of clay minerals.

This article treats the physical properties of shales, including their structure and fabric, the origin of shales, and their abundance and distribution in the geological record. For further information on the properties of clays, see CLAY MINERALS, and for coverage of the general transportation and deposition of sedimentary particles that precede final compaction and lithification of sedimentary rocks, see SEDIMENTARY ROCKS. See also MARINE SEDIMENTS; OIL SHALES; and PETROLEUM for related information. Structural problems pertaining to the presence of shales and clays are covered in EARTH MOVEMENTS ON SLOPES.

PHYSICAL PROPERTIES

Grain size, mineralogy, and chemistry. Lutites consist of an admixture of silt- and clay-sized particles. Silt is abundant in sediments, but, except for rare, thin blanket deposits of loess (predominantly windblown deposits), it generally occurs admixed with other grain sizes. The clay minerals make up more than 50 percent of all sediments, and more than 95 percent of all sediments contain appreciable clay minerals. The bulk of the clay minerals occur in shales, however, and sediments dominated by clay-sized particles are much more abundant than those dominated by silt. Quartz and feldspar generally dominate the silt fraction.

Reported shale grain-sized distributions depart markedly from those characteristic of most coarser sediments. Sorting is generally poor, and skewing toward the finer fraction is common. Fine quartz and feldspar are transported as single-grain entities, but the clay minerals may be transported and deposited as individual plates or as aggregates; the state of aggregation of clay minerals strongly influences their hydraulic behaviour. Old estimates suggesting rarity of clay shales and an average silt-to-clay ratio of about 2:1 were probably in error because of overestimation of silt in microscope observations and the difficulties of making settling-rate analyses. Recent electron-microscope and X-ray-diffraction analyses suggest that clay minerals constitute about 60 percent of the average shale.

The mineralogy of shales is highly variable. In addition to clay minerals (60 percent), the average shale contains quartz and other forms of SiO₂, notably amorphous silica and cristobalite (30 percent), feldspars (5 percent), and the carbonate minerals calcite and dolomite (5 percent). Iron oxides and organic matter (around 0.5 and 1 percent, respectively) are also important. Older estimates greatly underestimated clay minerals because of incorrect assignment of potassium to feldspar minerals. The most abundant clay mineral is illite; montmorillonite and mixed-layer illite-montmorillonite are next in abundance, followed by kaolinite, chlorite, chlorite-montmorillonite, and vermiculite. The quartz-to-feldspar ratio generally mirrors that of associated sands. In pelagic (deep-sea) sediments, however, feldspar may be derived from local volcanic sources, whereas quartz may be introduced from the continents by wind, upsetting simple patterns. A large number of accessory minerals occur in shales. Some of

these are detrital (*i.e.*, are transported grain fragments), but diagenetic or *in situ* varieties (*e.g.*, pyrite, siderite, and various phosphates) and volcanically derived varieties (*e.g.*, zeolites, zircon, biotite) have been noted.

The bulk of the weathering products of igneous rocks (those derived by crystallization from silicate melts) are incorporated in shales, and it is not surprising that the average shale is chemically little different from the average igneous rock. The differences reflect mainly the differentiation or selective distribution of sodium and magnesium to seawater, calcium and magnesium to limestones, and silicon to sandstones. One estimate of average shale composition in percent by weight is SiO₂, 58.1; Al₂O₃, 15.4; Fe₂O₃, 4.02; FeO, 2.45; MgO, 2.44; CaO, 3.11; Na₂O, 1.3; K₂O, 3.24; CO₂, 2.63; H₂O (110° C), 5; and other components, 2.31. Many trace metals are enriched in shales, particularly in organic-rich varieties. Variations in shale composition, generally quite minor, may reflect the silt-to-clay ratio, differential leaching of the source rock, the relative importance of biogenic components, and depositional variations in mineralogy throughout a basin. Pelagic muds of the South Pacific volcanic province differ from average shale, particularly in their greater abundance of soda (Na₂O), and geochemical calculations suggest that some shales (and some limestones also) may have an important volcanic component. The influence on shale composition will depend on the extent to which the calcium, magnesium, and iron leached from the (basaltic) volcanic material either form carbonates and iron oxides admixed with the plagioclase feldspar, clay minerals, and zeolites of the residual mud or are removed and deposited elsewhere.

Older shales tend to differ chemically from modern ones. It is sometimes difficult to determine whether this reflects variations in weathering and depositional conditions through time or whether the older shales sampled simply reflect selective preservation of certain environments and increased frequency of samples subjected to higher grades of diagenesis (*i.e.*, of alteration during the processes of rock formation)—metamorphism and metasomatism. Lower values of carbon dioxide and water in older shales represent loss during incipient metamorphism. Studies of younger shales show increased reduction of iron (accompanying oxidation of organic matter) with increasing depth of burial. The higher Fe²⁺:Fe³⁺ ratio found in older shales probably reflects this, although iron compounds may have been exposed to less efficient oxidation processes on weathering or to more reducing depositional environments on a younger Earth. Other major elements decrease, relative to chemically inert alumina, potassium, and, possibly, total iron increase in older shales.

Colour. The colours of the common abundant minerals in shales are nearly white. The wide variety of rock colour observed is caused by small amounts of finely disseminated pigmented material. The common pigments are organic matter and various iron-bearing minerals. A high organic content, often supplemented by very fine pyrite, gives a black colour. In general, the higher the organic content, the darker the shale, but in oil shales this may lead to a brown colour. The colour of iron-bearing minerals is controlled by oxidation state rather than by abundance of iron, and local variations in oxidation potential (*e.g.*, local concentrations of decomposing organic tissue, worm burrowing, or periodic exposure and aeration of tidal flats) may lead to colour mottling or banding. Hematite and limonite (ferric iron) impart reddish and purple colours. Blue, green, gray, and black colours generally indicate reducing conditions and ferrous iron, although the green clay mineral glauconite is rich in ferric iron. Many calcareous and siliceous shales are devoid of pigment and exhibit light gray or buff colour. In general, marine muds of the continental slope and continental rise are blue or green, whereas deep-sea muds are red.

Structure. Some shales, particularly those formed in lagoons, small lakes, or on floodplains, occur in relatively elongate or lenticular formations. The geographic requirements for a low-energy depositional environment of muds, however, coupled with their generally low deposi-

Relation to igneous rocks

The clay content

Bedding thickness and extent

tional rates, lead to the common occurrence of shales in extensive thin sheets. The wide extent of the environment may allow persistence over long time periods, and shale sequences many thousands of feet thick are found in geosynclinal regions where great depositional troughs existed in the Earth's crust. By contrast, the high-energy environment of sand deposition is usually restricted to relatively narrow zones such as river channels and along shorelines, and sheet formation requires lateral migration of such environments through time. The wide extent of some shale formations, a few feet thick and of different age in different localities, also requires environment migration. The source of the sediments may affect formation geometry. The silty muds of river deltas occur as lobate masses. In these, as in other subaerial environments, formations are often quite irregular.

Shales are generally characterized by very thin bedding or lamination because of grain-size variations or changes in mineralogy (e.g., different proportions of calcite or organic matter). Some, but by no means all, of these may reflect seasonal variations in mineral detritus or biologic productivity. Silt rarely forms thick deposits, except in windblown loess deposits. When not intimately associated with clays or sands, it occurs as thin lenses within the shales. Thick, homogeneous clay sequences are more common. The silts show the current scour and cross-bedding (micro-cross-bedding) features associated with sands. Water-saturated silts are particularly susceptible to differential compaction and soft sediment flowage. Dewatering of muds may lead to mud cracks. These are susceptible to re-erosion and transport as soft shale pellets, some being hydraulically equivalent to sand grains. On close examination, massive clay shales are often found to consist of aggregates of pellets. These may be transported clay floccules, re-eroded shale pellets, or fecal pellets. Burrowing by mud-dwelling organisms may homogenize sediments by wholly or partially destroying depositional laminae. Many shales are characterized by nodules and concretions because of element migration and accumulation under chemical gradients set up largely by localized accumulation of decaying biologic tissue.

Fabric. The water content of detrital sediments is, in general, inversely related to particle size, and some freshly deposited muds may contain up to 90 percent water by volume. The fabric of muds and shales is strongly influenced by the properties of the clay minerals, in particular their small size, high specific surface, platy morphology, and properties of water absorption and cation exchange. Depending on the type of clay minerals and the nature of the geochemical environment, the particles may be deposited individually from a dispersed state or as floccules (face-to-face, edge-to-edge, or face-to-edge associations of clay plates). The freshly deposited mud undergoes particle rearrangement and dewatering, either by subaerial dehydration (leading to mud cracks), by spontaneous expulsion of water from an unstable gel (syneresis), or as a result of the pressure of newly deposited sediments. At moderate water contents the sediments exhibit plastic behaviour, and structures caused by foundering and flow are common. Large-scale flowage may lead to diapiric (piercement type) mud intrusion. Muds with higher water content are metastable, and, when subjected to stress by earthquakes, sediment load, etc., the interparticle bonds may be broken, the particles will pack more closely, and oversaturation with water may lead to sudden initiation of flow as a viscous liquid.

The best fissility (tendency to split into layers) in shales is associated with a high degree of orientation of clay plates parallel to bedding. This may be the result of compactional rearrangement of flocculated particles or, perhaps, of diagenetic growth of clay minerals with orientation influenced by overburden pressure, but in most cases it is developed early, at deposition or during the first few metres of burial. This preferred orientation may result from the settling of clay plates particle by particle from a dispersed state or by particle rearrangement, a process for which a high initial water content appears necessary. Biogenic siliceous and calcareous matter decrease fissility. A high organic content and perhaps also deposition

from low-salinity waters are associated with high fissility, apparently through their effect on promoting clay dispersion or weak flocculation.

ORIGIN OF SHALES

Transportation and deposition of sediments. The formation of fine-grained sediments generally requires weak transporting currents and a quiet depositional basin. Water is the common transporting medium, but ice-rafted glacial flour (silt produced by glacial grinding) is a major component in high-latitude oceanic muds, and windblown dust is prominent, particularly in the open ocean at low and intermediate latitudes. Shale environments thus include the deep ocean; the continental slope and rise; the deeper and more protected parts of shelves, shallow seas, and bays; coastal lagoons; interdistributary regions of deltas, swamps, and lakes (including arid basin playas); and river floodplains. The deep-sea muds are very fine, but an orderly sequence from coarse sediments in high-energy nearshore environments to fine sediments at greater depths is rarely found. Sediments at the outer edges of present-day continental shelves are commonly sands, relict deposits of shallower Pleistocene (from about 10,000 to 2,500,000 years ago) glacial conditions, whereas muds are currently being deposited in many parts of the inner shelf. The nearshore deposition of clay minerals is enhanced by the tendency of river-borne dispersed platelets to flocculate in saline waters (salinity greater than about four parts per 1,000) and to be deposited just beyond the agitated estuarine environment as aggregates hydraulically equivalent to coarser particles. Differential flocculation leads to clay-mineral segregation, with illite and kaolinite near shore and montmorillonite farther out to sea. Advance of silty and sandy delta-slope deposits over clays also leads to complex grain-size patterns.

Shales may be deposited in environments of periodic agitation. Sediments deposited on submarine slopes are frequently mechanically unstable and may be redistributed by slumping and turbidity currents (density currents that result from an increase in sediment concentration) to form thick accumulations (possible present-day eugeosynclinal equivalents) on the lower continental slope and rise. Part of the shale in many graywacke-shale alternations (a graywacke is a sandstone with a muddy matrix and a high proportion of rock fragments) may be of turbidite origin. The fine matrix of the graywackes is partly original fine sediment, but much is probably the later diagenetic and metamorphic alteration product of chemically unstable rock fragments. Fine sediment can be deposited in marshes and on tidal flats. Trapping by marsh plants and binding of muds in fecal pellets are important. Because of electrochemical interactions among fine particles, muds plastered on a tidal flat by an advancing tide are difficult to re-erode on the ebb. This may lead, as in the present-day Waddenzees, in The Netherlands, to a size increase from nearshore tidal flat muds to lag sands seaward. Fine floodplain sediments may dry out to coherent shale pellets, and these, on re-erosion, can be redistributed as sands and gravels.

Diagenetic changes. The minerals deposited in a sedimentary basin may not be in physicochemical equilibrium among themselves and with the water. At any point on the sea floor, for example, there are too many aluminosilicate minerals to constitute an equilibrium assemblage, and common biogenic constituents (amorphous silica, magnesium-calcite, and aragonite) are metastable. Diagenetic reconstitution (alterations following deposition but prior to final lithification) is expected because of observed changes in water composition in laboratory experiments; there is some evidence for such reaction in nature. Clays entering the sea undergo a rapid re-equilibration of their exchange cations, and potassium and chloritic (iron- and magnesium-rich) interlayers may become strongly incorporated in some clays. Diagenetic palygorskites are associated with midoceanic ridge hydrothermal activity. Most unequivocal examples of marine diagenesis involve iron-rich clays. For example, glauconite and chamosite are shown to be diagenetic by

Reaction

seawater

Role of
water
content

their virtual restriction to marine sediments and to specific depth zones in present seas, by their occurrence in special micro-environments (concentrations of organic tissue), and by the smaller number of clay mineral types in glauconite pellets than in the surrounding muds. The montmorillonites formed with zeolites from volcanic material in the oceans are also iron rich.

The distribution of clay minerals in the present deep ocean can be related to source-area mineralogy and wind- and water-current patterns. Chlorite is concentrated at high latitudes where mechanical (glacial) weathering is dominant, whereas low-latitude concentration of kaolinite reflects intense chemical weathering on the adjacent continents. Illite (and quartz) concentrations in the central North Pacific are related to the path of midlatitude jet streams. Only the montmorillonite (and zeolite) concentration of the South Pacific, Indian Ocean, and Red Sea indicates extensive diagenesis, utilizing chemically reactive volcanic material. Nearshore gradients of proportion of different clay minerals are better explained by transport phenomena such as differential flocculation than by extensive diagenesis. Reaction is limited by the relatively short exposure time of clay minerals before burial (about one year) and the armouring of grains by reaction products.

Little further reaction occurs among the silicates on shallow burial, but dissolved silica levels are raised by the solution of siliceous diatoms, one-celled marine organisms, and bacterial attack of organic matter releases nutrient elements and alters the physicochemical properties of the sediment. In some cases, this leads to the formation of diagenetic sulfides and phosphates. This is particularly important in euxinic environments, in which stagnant conditions prevent introduction of oxygen to bottom waters from the atmosphere. Considerable amounts of organic matter (black shales) with their nutrient elements and adsorbed trace metals are thus incorporated into the sediment rather than being oxidized in the sea floor. With increased temperature of deeper burial (several thousand metres), extensive reconstitution of the silicates and carbonates occurs. The most obvious change is the evolution of montmorillonite, through mixed-layer minerals, toward illite and chlorite. Kaolinite and some feldspars and micas become unstable, and their breakdown provides elements for new mineral growth. There may be some additions from greater depth and some element exchange with associated sands, however.

SHALES IN THE GEOLOGICAL RECORD

Abundance and distribution. Estimates of the abundance of shales by direct measurement of stratigraphic sections have ranged from 42 to 57 percent of all sedimentary rocks. Independent estimates of lutites have been made by geochemical calculations, allocating the elements weathered from primary igneous rocks to the oceans and to major sediment types. Such estimates suggest that lutites should make up 70 to 80 percent of all sedimentary rocks. The discrepancy is partially resolved by recognition of a lutite fraction admixed in sandstones and limestones and of a high lutite content (more than 90 percent) in deep-ocean sediments, which are rarely incorporated into the sedimentary rock record of the continents. One difficulty, however, is uncertainty about the total amount of sediment in the oceans.

Apart from dominance of volcanically derived sediments during Precambrian time (all Earth history prior to 570,000,000 years ago) and an increase in carbonates at the expense of shales around the beginning of post-Precambrian time, the proportions of shales in the preserved sedimentary record are relatively constant through time. At any given time and place, however, the amount of shale deposited depends in part on the environment of the source area and depositional basin. For example, shale accumulations on stable continental shelves generally make up less than 20 percent of relatively thin deposits, whereas mobile belts—depositional troughs that are loci for later mountain building—are often characterized by thick accumulations of which shale is the dominant rock. About 80 percent of all the fine continental debris cur-

rently delivered to the ocean passes through Southeast Asia from adjacent high-altitude sources. The chances of a shale being preserved in the record depend on its resistance to weathering (relatively low) and to the tectonic environment of its deposition. This latter factor influences its chances of alteration by metamorphism after burial or its chances of exposure by erosion.

Contained fossils. The low mechanical energy of deposition, the infrequency of reworking of the sediment by currents (particularly in the abundant offshore marine varieties), and the fine grain size all aid in the greater preservation of fossils in shales. The fine grain size allows delicate molding and casting of biological remains. Because of the great degree of compaction of shales, many fossils are compressed and preserved as thin films, but the formation of concretions about remains may retain accurate shapes and details of structure. Putrefaction gases may prevent collapse of even such large delicate forms as cephalopods until they are incorporated into hard concretions. Shales of volcanic-ashfall origin may also provide excellent preservation. Many shales are deposited in environments connected to the open sea, and bottom conditions are suitable for the preservation of free-floating and swimming organisms. Shales have proved to be excellent hosts for the preservation of such delicate fossils as the graptolites, whose rapid evolution and ready dispersal allow detailed intercontinental correlation of time and rocks (see further STRATIGRAPHIC BOUNDARIES).

Microfossils also may be preserved in shales, often in large enough numbers to permit statistical analyses of their populations. Plant spores reflect changing vegetation patterns, and their remains in lake deposits allow reconstruction of regional climatic changes.

Present deep-sea and continental-slope muds and their ancient equivalents are characterized by virtual absence of benthos- or bottom-dwelling organisms; only a few burrowing organisms are present, and biologic degradation is carried out by anaerobic bacteria. Sulfur-reducing varieties may lead to pyritic fossilization in which pyrite (iron sulfide) replaces organic tissues. Phosphatic brachiopods, plant spores, and other such resistant forms, as well as radiolarians, foraminiferans, and rare invertebrates, are found. This characteristic of absence of benthos organisms applies particularly to black shales, regardless of the water depth. In other marine shales benthonic fossils are more abundant, however.

Shales formed in lakes may contain the remains of freshwater fish, mollusks, ostracods, insects, calcareous algae, pollen, etc. Occasionally terrestrial plants and vertebrates may be washed into the basin and preserved.

Famous shales. Shales are ubiquitous throughout the geological record and are of great importance in sedimentological and stratigraphic studies. A limited number of types are encountered again and again, however, and a particular shale generally attains more than local significance only as the host of important fossils or by virtue of its economic value.

The oldest known shales are carbonaceous varieties of the 3,200,000,000-year-old Figtree Series of South Africa. Associated cherts contain bacterial remains, and the shales contain organic compounds of probable biologic origin. An abundant fauna of soft-bodied creatures not normally fossilized has been preserved as detailed carbonaceous imprints in the Middle Cambrian Burgess Shale of British Columbia (the Cambrian Period began 570,000,000 years ago and ended 500,000,000 years ago). These remains provide perspective on the nature of early life, whose preserved remains, generally restricted to the hard parts of organisms, are not generally representative of life assemblages. Similar details of animal tissue (e.g., marine ichthyosaurs) are preserved in the Lower Jurassic shales of Holmaden, West Germany. Shale partings in the uppermost Precambrian Ediacara sandstone of South Australia also preserve traces of soft-bodied creatures (coelenterates, worms, arthropod-like forms, echinoderms, probable mollusks), showing an unexpectedly advanced metazoan evolution. Early and continued study of the Ordovician and Silurian shales of Wales have been important in the development of the

geologic time scale, concepts of sedimentation and mountain building, and of fossil (graptolite) zonation.

Black shales are often of economic importance as sources of petroleum products and metals, and this importance will probably increase in the future. The lacustrine Eocene Green River Shales of Colorado–Wyoming–Utah are potentially rich petroleum sources and are undergoing exploratory extraction. Bituminous layers of the Early Permian Irati Shales of Brazil are similarly important. These shales contain the remains of the marine reptile *Mesosaurus*, also found in South Africa, and have played a prominent part in the development of the concepts of continental drift. The very widespread thin Chattanooga Shale (Devonian–Mississippian) of the eastern United States has been exploited for its high (up to 250 parts per 1,000,000) uranium content. The Permian Kupferschiefer is a bituminous shale rich in metallic sulfides of primary sedimentary or early diagenetic origin; it covers a large area of central Europe as a band generally less than one metre thick, and in East Germany and in Poland there is sufficient enrichment in copper, lead, and zinc for its exploitation as an ore.

Shamanism

Shamanism is a religious phenomenon centred on the shaman, an ecstatic figure believed to have power to heal the sick and to communicate with the world beyond. The term applies primarily to the religious systems and phenomena of the north Asian, Ural-Altaic (e.g., Vogul, Ostyak, Samoyed, Tungus), and Paleo-Asian (e.g., Yukaghir, Chukchi, Koryak) peoples.

NATURE AND SIGNIFICANCE

The term shamanism comes from the Tunguso-Manchurian word *šaman*. The noun is formed from the verb *ša-* ("to know"); thus, "shaman" literally means "he who knows." Various other terms are used by other peoples among whom shamanism exists.

There is no single definition of shamanism that applies to the elements of shamanistic activity found in North and South America, in southeast India, in Australia, and in small areas all over the world as well as to the phenomena among the north Asian, Ural-Altaic, and Paleo-Asian peoples. It is generally agreed that shamanism evolved before the development of class society in the Neolithic Period and the Bronze Age; that it was practiced among peoples living in the hunting-and-gathering stage; and that it continued to exist, somewhat altered, among peoples who had reached the animal-raising and horticultural stage. According to some scholars, it originated and evolved among the more developed societies that bred cattle for production. Opinions differ as to whether the term shamanism may be applied to all religious systems in which the central personage is believed to have direct intercourse through an ecstatic state with the transcendent world that permits him to act as healer, diviner, and psychopomp (escort of souls of the dead to the other world). Since ecstasy is a psychosomatic phenomenon that may be brought about at any time by persons with the ability to do so, the essence of shamanism lies not in the general phenomenon but in specific notions, actions, and objects connected with the ecstatic state.

Among the peoples of northern Asia, shamanism developed into a more definitely articulated and specialized

form than among other peoples. Shamanism as practiced there is distinguished by its special clothing, accessories, and rites as well as by the specific world view connected with them. North Asiatic shamanism in the 19th century, which may be taken as the classical form, was characterized by the following traits:

- (1) A specialist (man or woman) is accepted by the society as being able to communicate directly with the transcendent world and thereby also possessed of the ability to heal and to divine; this person is held to be of great use to society in dealing with the spirit world.
- (2) This figure has special physical and mental characteristics; he is neurasthenic or epileptic, with perhaps some minor defect (e.g., six fingers or more teeth than normal), and with an intuitive, sensitive, mercurial personality.
- (3) He is believed to have an active spirit or group of spirits to assist him and may also have a passive guardian spirit present in the form of an animal or a person of the other sex—possibly as a sexual partner.
- (4) The exceptional abilities and the consequent social role of the shaman are believed to result from his being the "choice" of the spirits, though the one who is chosen—often an adolescent—may resist his selection, sometimes for years. Torture by the spirits, appearing in the form of illness, breaks the resistance of the shaman candidate and he (or she) has to accept the vocation.
- (5) The initiation of the shaman, depending on the belief system, may happen on a transcendent level or on a realistic level, or sometimes on both, one after the other. While the candidate lies as if dead, in a trance state, the body is cut into pieces by the spirits of the Yonder World or is submitted to a similar trial. The reason for cutting up his body is to see whether he has more bones than the average person. After awakening, the rite of symbolical initiation, climbing the World Tree, is occasionally performed.
- (6) By falling into ecstasy at will, the shaman is believed to be able to communicate directly with the spirits either by his soul leaving the body to enter their realm or by acting as their mouthpiece, like a medium.
- (7) One of the distinguishing traits of shamanism is the combat of two shamans in the form of animals, usually reindeer or homed cattle. The combat rarely has a definite purpose but rather seems to be a deed the shaman is compelled to do. The outcome of the combat means well-being for the victor and destruction for the loser.
- (8) In going into ecstasy, as well as in his mystical combat, certain objects are used: drum, drumstick, headgear, gown, metal rattlers, and staff. (The specific materials and shapes of these instruments are useful for identifying the types and species of shamanism and following their development.)
- (9) Characteristic folklore texts and shaman songs have come into being as improvisations on traditional formulas in luring calls and imitations of animal sounds.

As an ethnological term, shamanism is applied primarily to the religious systems of those regions in which all these traits are present together. In addition, there are primitive religions in which some of the above criteria are missing but which are still partially shamanistic; e.g., among the Chukchi of northeast Siberia, the specialist chosen by the spirits does not fall into ecstasy. Such religious systems may be regarded as marginally shamanistic.

Phenomena similar to some of the traits of shamanism may be found among primitive peoples everywhere in the world. Such detached traits, however, are not necessarily shamanistic. The central personalities in such systems—sorcerers, medicine men, and the like—may communicate with the other world through ecstasy, but, unlike the shaman, they have attained their position through deliberate study and the application of rational knowledge. Although they perform ceremonies as priests, hold positions of authority, and possess magical abilities, the structure and quality of their transcendental activities are entirely different from that of the shaman.

WORLD VIEW

The *universe*. The classic world view of shamanism is found among the peoples of northern Asia. In their view, the universe is full of heavenly bodies peopled by spiritu-

al beings. Their own world is disk-shaped — saucer-like — with an opening in the middle leading into the Netherworld; the Upper World stands over the Central World, or Earth, this world having a manifold vault. The Earth, or Central World, stands in water held on the back of a colossal monster that may be a turtle, a huge fish, a bull, or a mammoth. The movement of this animal causes earthquakes. The Earth is surrounded by an immense belt. It is connected with the Upper World by the Pillar of the World. The Upper World consists of several strata — three, seven, nine, or 17. On the navel of the Earth stands the Cosmic Tree, which reaches up to the dwelling of the upper gods.

Gods, spirits, and souls. All three worlds are inhabited by spirits. Among the Mongolian and Turkish peoples, *Ülgen*, a benevolent deity and the god of the Upper World, has seven sons and nine daughters. Among the Buryats of southern Siberia, *Tengri* (often identified with *Ülgen*) also has children, the *Khat's*—the western ones being good and the eastern ones wicked. The gods of the Buryats number 99 and fall into two categories: the 55 good gods of the west whose attribute is "white," and the 44 wicked gods of the east whose attribute is "black." The leader of the latter is *Erlen khan*, a figure equivalent to *Erlik khan* of the Altai Kizhi people, who is the ruler of the Underworld. Besides gods and the progeny of gods—both sons and daughters—other spirits also inhabit all the three worlds. Fire is also personified, as is the Earth itself. Such personifications are represented in idols as well. Man, besides his body, consists of a soul, even of several souls. Man also has a mirror soul, which can be seen when looking into water, and a shadow soul, which is visible when the sun is shining.

SOCIAL ROLE, PERSONALITY STRUCTURE, AND FUNCTIONS OF THE SHAMAN

Social role. The extraordinary profession of the shaman naturally distinguishes him socially. The belief that he communicates with the spirits gives him authority. Furthermore, the belief that his actions may not only bring benefit but also harm makes him feared. Even a good (white) shaman may do harm, and a wicked (black) shaman, who is in contact with the spirits of the Lower World, is very alarming. In consequence of his profession, the shaman cannot go hunting and fishing and cannot participate in productive work; therefore, he must be supported by the community, which considers his professional activity necessary. Some shamans make use of their special position for economic gain. Among the reindeer-raising Evenki of northern Siberia, poor families have to pay yearly one animal, and rich ones pay two, three, or even four, to the shaman for his activities. A saying of the Altai Kizhi illustrates this situation: "If the beast becomes ill, the dogs fatten; if man becomes ill, the shaman fattens."

Among the Evenki, it was the duty of every member of the clan to aid the shaman economically. When distributing the fishing spots in the spring and in the summer, the part of the river most abundant in fish was given to the shaman and even the fishing devices were set up for him. He was aided in grazing and herding the reindeer in autumn, and in winter the members of the clan went hunting in his stead. Even furs were presented to the shaman occasionally. The social authority of the shaman was shown through the honours bestowed on him and the practice of always giving him the best food. Generally, the shaman was never contradicted, nor was any unfavourable opinion expressed about him behind his back.

Such an economic and social position resulted in the shaman attaining political power. As early as 1752, for instance, it was noted that the Tunguso shaman was also the leader of his clan. Along the Yenisey River, shamans led armed groups of the Evenki on the left and the right banks who fought against each other. In the northern forest regions of Mongolia, the shamans stood at the head of the tribes and clans. In the fight of the Buryats against the Russians in the 17th and 18th centuries, the shaman always led the fight. The ruler of one domain among the Vadeyev Samoyed in northern Siberia was a

shaman as well as a reigning prince. Among the Eskimo of North America and Asia, the positions of leader and of shaman are often occupied by the same person: indeed, the two Eskimo terms *angakok* ("shaman") and *angajkok* ("leader") have the same root.

Personal makeup and selection. Scholars generally agree that the shaman acquires his profession through inheritance, learning, or an inner call, or "vocation," but each of these terms requires some qualification. "Inheritance" means that the soul of a dead shaman or the so-called shaman illness is inherited. "Learning" here does not usually mean the study of exact knowledge and explicit dogma, for the shaman, it is believed, is taught by the spirits. The inner "call" is in reality not the call of the person but of the spirit who has chosen him and who forces him to accept his vocation. This compulsion is unavoidable. "Had I not become shaman, I would have died," said a Gilyak (southeast Siberia). The future shaman of the Altai Kizhi was subjected to terrible torture until, finally, he grasped the drum and began to act as a shaman.

According to the abundant literature on the subject and the experience of investigators in the field, no one voluntarily ventures into the shaman role, nor does a candidate have time to study the role. Such study, however, is not necessary, because peoples born into a culture with shamanistic beliefs know them thoroughly, and when the "call" arrives, the future shaman can learn specific practice by close observation of active shamans, even the technique of "ecstasy." The shamanistic view of the world and spirits is already familiar to him. The various qualitative categories by which shamans are distinguished—small, intermediate, and great—are explained by the category of the spirit who chose the shaman. It is evident, however, that this depends on the personal abilities of the shaman himself, his mental capacities, his dramatic talent, and his power to make his will effective. All of these elements add to the quality of his shaman performance, the art expressed in it.

The shaman is born to his role, as is evident in certain marks distinguishing him from ordinary men. He may be born with more bones in his body—e.g., teeth or fingers—than other people. Therefore, he does not become a shaman simply by willing it, for it is not the shaman who summons up the spirits, but they, the supernatural beings, who choose him. They call him before his birth. At the age of adolescence, usually at the period of sexual ripening, the chosen one suddenly falls into hysterics with faintings, visions, and similar symptoms, being tortured sometimes for weeks. Then, in a vision or a dream, the spirit who has chosen him appears and announces his being chosen. This "call" is necessary for the shaman to acquire his powers. The spirit who has chosen him first lavishes the unwilling shaman-to-be with all sorts of promises and, if he does not win his consent, goes on to torment him. This so-called shaman illness will anguish him for months, perhaps for years, as long as he does not accept the shaman profession. When the candidate finally gives way to the compulsion and becomes a shaman, he falls asleep and sleeps for a long time—three days, seven days, or thrice three days. During the "long sleep," the candidate, according to belief, is cut into pieces by the spirits, who count his bones, determining whether he truly has an "extra bone." If so, he has become a shaman. Some people, such as the Mongolians and the Tunguso-Manchurians, still initiate the shaman. They introduce him to the supernatural beings, and he symbolically ascends the "tree-up-to-the-heavens," that is, the pole representing it.

The central activity of the shaman is ecstasy at the wish of his clients, and some have inferred from this that he is a psychopath. A person becomes a shaman at puberty, according to this view, when, especially in sub-Arctic and Arctic climatic conditions, changes in his constitution and nervous system may result in the loss of mental balance and in various mental disorders. Social and ethnic factors also may be seen to support the psychopathological factor. A person born with certain marks knows he is destined to the vocation and becomes apprehensive

The compulsory nature of shamanism as a vocation

Special economic position of the shaman

The shaman as psychopath

of the call of the spirits. His fears of the event, according to this theory, create the hallucinations, and the hallucinations reinforce the belief.

Types and functions. *Differences in quality and degree.* Shamans differ greatly in quality and in degree. Difference of quality is manifest in the kind of spirits the shaman communicates with. "White" shamans, for example, apply to a benevolent deity and the good spirits, while "black" shamans call on a wicked deity and the wicked spirits.

The difference in degree is exemplified in the Yakut belief (in northeastern Siberia) that the souls of the future shamans are reared upon an immensely high tree in the Upper World, in nests at various heights. The greatest shamans are brought up close to the top of the tree, the intermediate ones toward the middle, the smaller ones on the lower branches. Hence, shamans may be classified into three groups: great, intermediate, and last, according to their powers.

Basic tasks. It is the obligation of the shaman to know all matters that human beings need to know in everyday life but are unable to learn through their own capacities. He foresees events distant in time and space, discovers the place of a lost animal, forecasts prospects for fishing and hunting, and assists in increasing the gain. Besides these everyday functions, he is a healer and a psychopomp. He fulfills all these obligations by communicating with the spirits directly whenever he pleases.

The shaman's assistance is necessary at the three great events of life: birth, marriage, and death. If a woman bears no child, for instance, then, according to the belief of the Goldi, in the Amur region of northeast Asia, the shaman ascends to heaven and sends an embryo soul (*onzija*) from the tree of embryos (*omija muorzi*). Among the Buryats, the shaman performs libations after birth to keep the infant from crying and to help him develop more quickly. Among the Goldi, when death occurs the shaman is necessary to catch the soul of the deceased floating in the universe and to escort it to the Yonder World. Illness is believed to be caused by the spirits, who must be appeased for a cure to be effected. Among the Ostyak of northern Siberia, the shaman decides how many reindeer should be sacrificed to appease the spirit who causes an illness. Among the Altai Kizhi, he states which *körmös* (soul of the dead) caused the disaster and what to do to conciliate it. Illness might be caused by the soul having left the patient's body and fallen into the hands of spirits who are angry with it and therefore torment it; the shaman liberates the strayed soul. Illness may also be caused by spirits entering into a man; the shaman cures it by driving the spirits out.

Forms of ecstasy. The shaman may fulfill his obligations either by communicating with the spirits at will or through ecstasy. The latter has two forms: possession ecstasy, in which the body of the shaman is possessed by the spirit, and wandering ecstasy, in which his soul departs into the realm of spirits. In passive ecstasy, the possessed gets into an intense mental state and shows superhuman strength and knowledge; he quivers, rages, struggles, and finally falls into an unconscious trancelike condition. After accepting the spirit, the shaman becomes its mouthpiece—"he becomes him who entered him." In active ecstasy, the shaman's life functions decrease to an abnormal minimum, and he falls into a trancelike condition. The soul of the shaman, it is believed, then leaves his body and seeks one of the three worlds, or strata, of heaven. After awakening, he relates his experiences, where he wandered, and with whom he spoke. There are cases of possession ecstasy and wandering ecstasy combined, when the spirit first enters the shaman and then leads his soul to the world of supernatural beings. Scholars differ as to which is the original and which the derivative form; *e.g.*, the historian of religions Mircea Eliade does not consider possession ecstasy to be essential to shamanism.

SYMBOLISM IN OBJECTS AND ACTIONS

The shaman attains the ecstasy necessary for communicating with the spirits through the performance of the shaman rite, which requires certain appurtenances.

Dress. He wears a ritual gown, which usually imitates an animal—a deer, a bird, a bear. Similarly, the head-dress is a crown made of antlers or a band into which feathers of birds have been pierced. The footwear is also symbolic—iron deer hooves, birds' claws, or bears' paws. The clothing of the shamans among the Tofalar (Karagasy), Soyot, and Darhat are decorated with representations of human bones—ribs, arm and finger bones. The shamans of the Goldi-Ude tribe perform the ceremony in a singular shirt and in a front and back apron on which there are representations of snakes, lizards, frogs, and other animals.

Drums, sticks, and other objects. An important device of the shaman is the drum, which always has only one membrane. It is usually oval but sometimes round. The outer side of the membrane, and the inside as well among some peoples, is decorated with drawings; *e.g.*, the Turks, or Tatars, of Abakan mark the Upper and Lower World. The handle is usually in the shape of a cross, but sometimes there is only one handle in a vertical direction or in the shape of the letter Y or X. The drumstick is made of wood or horn and the beating surface is covered with fur. In some cases, the drumstick is decorated with human and animal figures, and rattling rings often hang down from it. During the ecstasy brought on by the sound of the drum, the spirits move to the shaman—into him or into the drum—or the soul of the shaman travels to the realm of the spirits. In the latter case, the shaman makes the journey on the drum as if riding on an animal, the drumstick being his lash. Sometimes the shaman makes the journey on a river and the drum is his boat, the drumstick his oar. All this is revealed in the shaman song. Besides the drum, the Buryat shaman sometimes makes the journey with sticks ending in the figure of a horse's head. The shaman of the Tungus people, who raise reindeer, makes the journey on a stick ending in the figure of a reindeer's head. Among some people, the shaman wears a metal disk, a "shaman-mirror."

Drama and dance. Shamanic symbolism is impressively presented in dramatic enactment and dance, as observed among the peoples where the shamanistic rites survived longest (such as the Samoyed, Tofalar, Buryat, and Tungus). The shaman, garbed in his ritual robes, lifts his voice in song to the spirits. This song is always improvised, with certain obligatory images and similes, dialogue, and refrains. The performance always takes place in the evening. The theatre is the conical tent, or yurt; the stage is the space around the fire where the spirits are invoked. The audience consists of the invited members of the clan, awaiting the spirits in awe. The stage lighter and decorator, the shaman's assistant, tends the fire so as to throw fantastic shadows onto the wall. All these effects help those present to visualize everything that the recited action of the shaman narrates. The shaman is an actor, dancer and singer, and a whole orchestra. This restless figure is a fascinating sight, with his cloak floating in the light of a fire in which anything might be imagined. The ribbons of his gown flit around him, his round mirror reflects the flames, and his tinkets jingle. The sound of his drum excites not only the shaman but also his audience. An integral characteristic of this drama is that those who are present are not mere objective spectators but rather faithful believers, and their belief enables the shaman to achieve results, as in healing mental illnesses. Among some people—the Altai Kizhi, for instance—a tall tree is set into the smoke opening at the top of the tent, symbolizing the Tree of the World. The shaman ascends the tree to the height of the Upper World, which is announced to his audience by the text of his song.

CONTEMPORARY RESIDUES

AND RECONSTRUCTIONS OF SHAMANISM

The residues of shamanism may be found among peoples who have been converted to religions of a later stage of culture; *e.g.*, Finno-Ugrian peoples who became Christians, Turkic peoples in Central Asia and Asia Minor who became Muslim, and Mongolians who became Buddhists. Among the Finns, the *tietäjä*, a figure equiva-

The drum as symbolic bearer of the shaman

The shaman as healer

The shaman Tulayev of the Karagas, Siberia, photographed in 1927. He wears a deerskin coat, embroidered with a rib cage and holds a drumstick of fur-covered reindeer horn and a deerskin-covered drum. The shaman's soul is said to "ride" the soul of the animal whose skin is stretched over his drum and to use the drumstick as a knout.

By courtesy of the Staatliches Museum für Völkerkunde, Munich

lent to the shaman, is also born with one more tooth than normal. Among the Osmanlı Turks of Asia Minor, the horned headwear of the shaman is remembered in popular belief. Among people who formerly believed in shamanism but later were converted to various world religions (*e.g.*, Christianity or Islām), former shamanism may be revealed through an analysis of their folklore and folk beliefs. An example of such a case is the discovery of former Hungarian shamanism. In north Asia, shamanism appears in various forms that may be attributed to differences in cultural phases. In the most northern parts, among the Chukchi, Koryak, and Kamchadal, the shaman does not exist as a member of a special profession: a suitable member of the family—often an old woman—performs the activity of the shaman. Often the shamans are of "changed sex"—effeminate men who have adopted feminine clothing and behaviour at the command of their "spirit." Among the Yukaghir of Arctic Siberia, shamanism is part of the cult of the clan; so also among pockets in the Obi-Ugrian peoples, and among all three Altaic peoples: Turkic, Mongol, and Manchu-Tungusic. These are instances of definitely professional shamanism, which, however have been excluded by so-called higher religions. Shamanism was excluded among the Khalkha-Mongolian and eastern Buryats, who became Buddhists, and among the Kazakh and Kirgiz who adopted Islām, and it was greatly changed and developed into an atypical form by the Manchurians.

Certain scholars have investigated ecstatic actions that may be adjudged outside the area of shamanism in the strictest sense. Mircea Eliade has studied North and South America, Southeastern Asia and Oceania, Tibet, and China, and S.P. Tokarev has also studied Africa. Some scholars suppose that the phenomena of shamanism spread to the two American continents when the first settlers migrated from Asia. The shamanistic phenomena in the Shintō religion of Japan are attributed to the migration of nomadic peoples from the territory bordering Northern Korea. No such theory of migration has yet

been developed to explain the "shamanism" of Southeast Asia and Oceania. Those who oppose this broad usage of the term shamanism argue that an apparent structural similarity among phenomena in widely separated areas does not justify an assertion of a common source or that typological similarity must be distinguished from a genetic connection. For them, shamanism may be attributed only to a precise pattern of cultural phenomena in a specific, well-defined territory, one that forms a concrete, systematic whole, such as the religious systems of the peoples mentioned at the beginning of this article.

BIBLIOGRAPHY. A thorough description of the shamanism of the peoples of Siberia is given in M.A.C. CZAPLICKA, *Aboriginal Siberia* (1914); and in MIRCEA ELIADE, *Le Chamanisme et les techniques archaïques de l'extase* (1951; Eng. trans., *Shamanism: Archaic Techniques of Ecstasy*, 1964). The latter not only deals with phenomena in Central and Northern Asia but also from North and South America, Southeast Asia, and Oceania. See especially the chapters on "Shamanic Ideologies and Techniques Among the Indo-Europeans" and "Shamanic Symbolisms and Techniques in Tibet, China, and the Far East." The English translation includes an extensive bibliography. Shamanism among the Finno-Ugrian Siberian peoples is described by UNO HOLMBERG in *The Mythology of All Races*, vol. 4 (1927). A very thorough summary of the world view and specific traits of shamanism in North Asia, based on a good knowledge of literature on the subject in Russian, may be found in GEORG NIORADZE, *Der Schamanismus bei den sibirischen Völkern* (1925). The shamanism of the same territory, but only the traits considered most significant, has been discussed by AKE. OHLMARKS, *Studien zum Problem des Schamanismus* (1939). The volume *Glaubenswelt und Folklore der sibirischen Völker* (1963; Eng. trans., *Popular Beliefs and Folklore Tradition in Siberia*, ed. by V. DIOSZEGI, 1968) contains studies on the shamanistic conceptions of the Lapp, Hungarian, and Siberian peoples.

(V.D.)

Shanghai

Shanghai (in Pin-yin romanization, Shang-hai), whose name literally means "on the sea," is one of the world's largest seaports and a major industrial and commercial centre of the People's Republic of China. It is located on the coast of the East China Sea between the mouth of the Yangtze River to the north and the bays of Hangchow and Yü-p'an to the south. The municipality covers a total area of 2,200 square miles (5,800 square kilometres), which includes the city itself, surrounding suburbs, and an agricultural hinterland. China's most populous urban area, metropolitan Shanghai contains between 5,500,000 and 6,000,000 inhabitants and the municipality, a total of about 10,800,000.

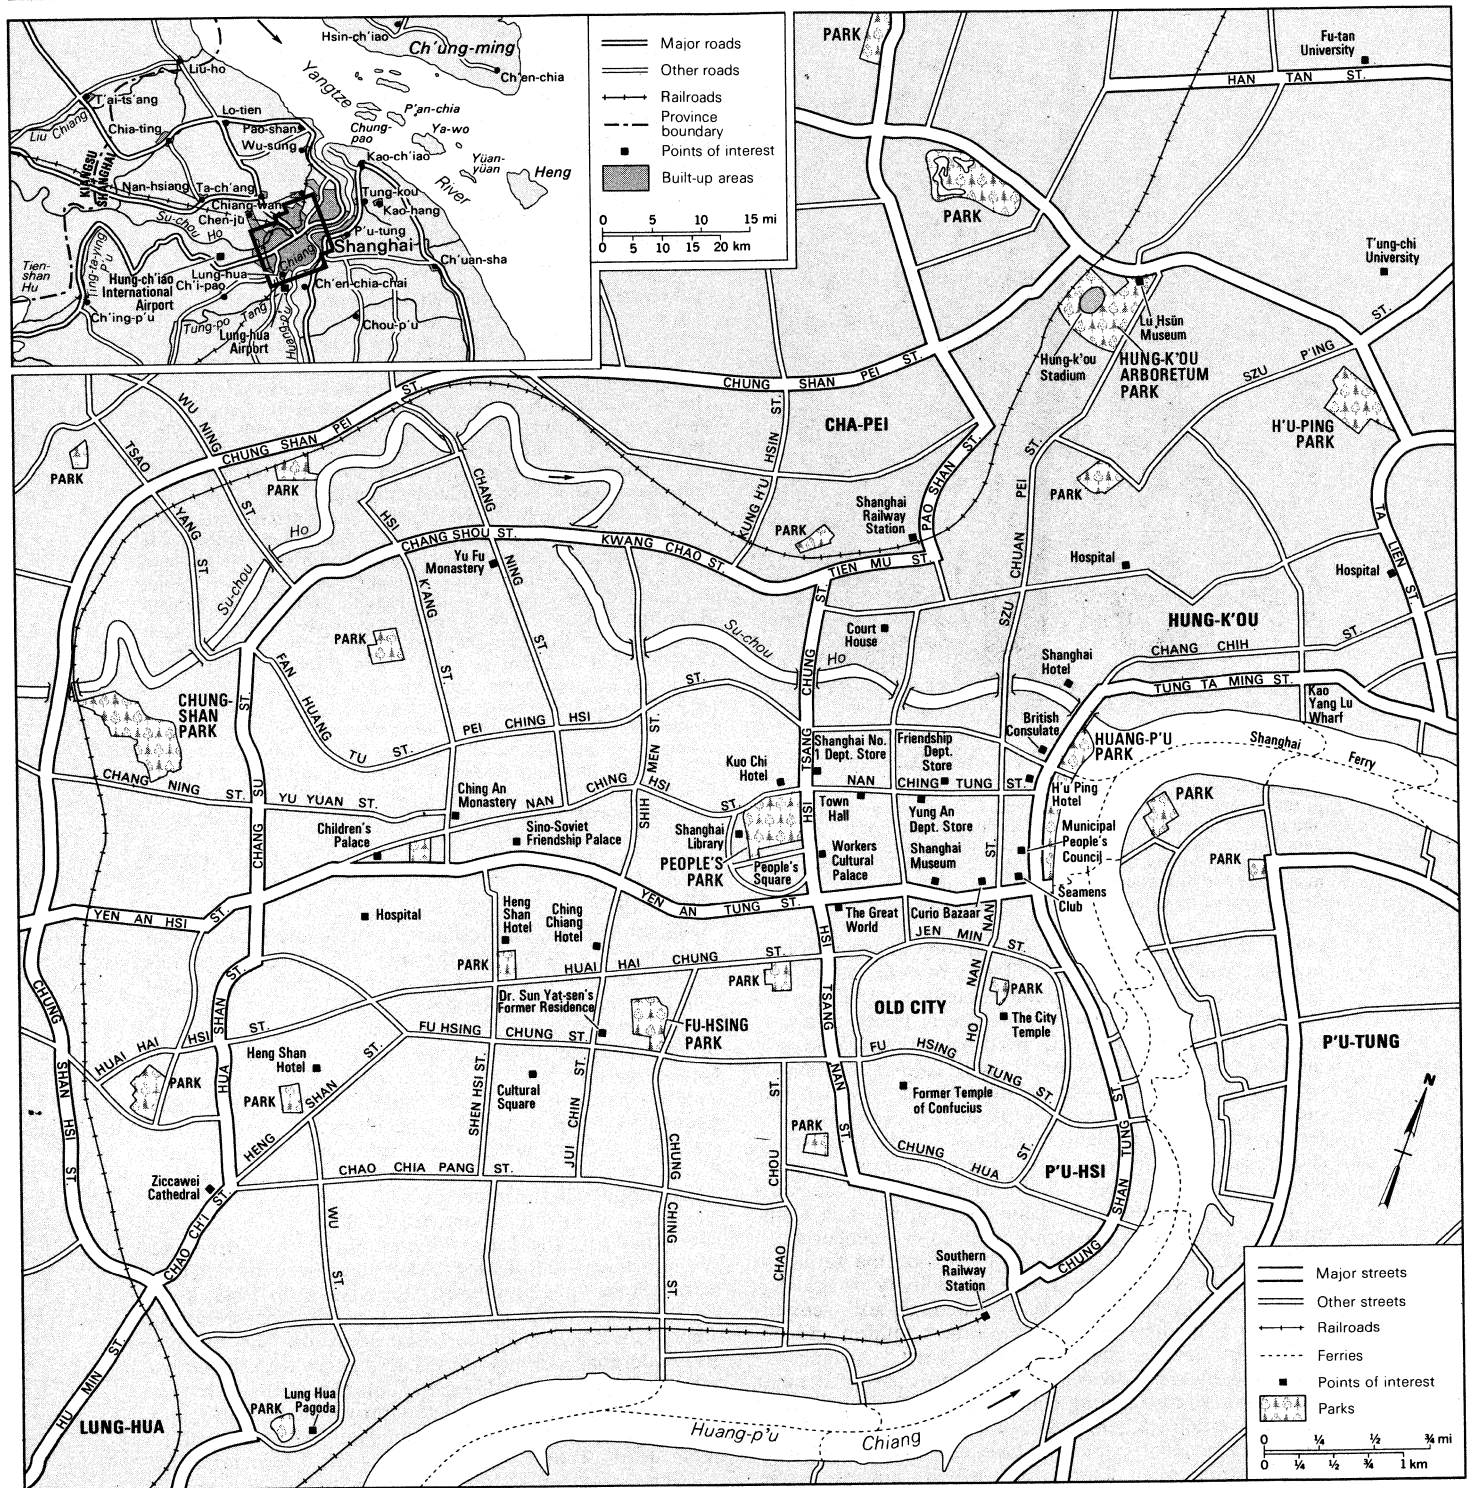

Shanghai was the first Chinese port to be opened to Western trade, and it long dominated the nation's commerce. Since the Communist rise to power in 1949, however, it has become an industrial giant whose products supply China's growing domestic demands. The city has also undergone extensive physical changes with the establishment of suburbs and housing complexes, the improvement of public works, and the provision of parks and other recreational facilities. Shanghai has attempted to eradicate the economic and psychological legacies of its exploited past and to create a burgeoning, and purely Chinese, urban area. (For a related physical feature see YANGTZE RIVER.)

HISTORY

As late as the 5th to 7th centuries AD, the Shanghai area, then known as Shen or Hu Tu, was sparsely populated and undeveloped. Despite the steady southward progression of Chinese settlement, the exposed deltaic position of the area retarded its economic growth.

During the Sung dynasty (960–1126) Shanghai emerged from its somnolent state as a small, isolated fishing village. The area to the west around T'ai Hu (T'ai Lake) had developed a self-sustaining agricultural economy on protected reclaimed land and was stimulated by an increase in population resulting from the southward migration of Chinese fleeing the invading Mongols in the north. The natural advantages of Shanghai as a

The city's origins

Central Shanghai and (inset) its metropolitan area.

deepwater port and shipping centre were recognized as coastal and inland shipping expanded rapidly. By the beginning of the 11th century, a customs office was established; and by the end of the 13th century, Shanghai was designated as a county seat and placed under the jurisdiction of Kiangsu Province.

During the Ming dynasty (1368–1644), roughly 70 percent of the cultivated acreage around Shanghai was given to the production of cotton to feed the city's cotton and silk-spinning industry. By the middle of the 18th century there were more than 20,000 persons employed as cotton spinners.

After the 1850s, the predominantly agricultural focus of the economy was quickly transformed, when the city became the major Chinese base for Western commercial

imperialism. Following their humiliating defeat by Great Britain in 1842, the Chinese surrendered Shanghai and signed the Treaty of Nanking, which opened the city to unrestricted foreign trade. The British, French, and Americans took possession of designated areas in the city within which they had special rights and privileges, and the Japanese received a concession in 1895 under the terms of the Treaty of Shimonoseki.

The opening of Shanghai to foreign business immediately led to the establishment of major European banks and multipurpose commercial houses. The city's prospects as a leading centre of foreign trade were further enhanced when Canton, a rival port in the southeastern coastal province of Kwangtung, was cut off from its hinterland by the Taiping Rebellion (1850–64). Impelled by

The impact of Western imperialism

this potential threat to the uninterrupted expansion of their commercial operations in China, the British obtained rights of navigation on the Yangtze in 1857. As the natural outlet for the vast hinterland of the Lower Yangtze, Shanghai rapidly grew to become China's leading port and by 1860 accounted for about 25 percent of the total shipping tonnage entering and departing the country.

Shanghai did not, however, show promise of becoming a major industrial centre until the 1890s. Except for the Chiang-nan Arsenal organized by the Ch'ing dynasty (1644–1911) in the early 1860s, most industrial enterprises were small-scale offshoots of the larger foreign trading houses. As the flow of foreign capital steadily increased after the Sino-Japanese War of 1894–95, light industries were established within the foreign concessions, which took advantage of Shanghai's ample and cheap labour supply, local raw materials, and inexpensive power.

By contrast, local Chinese investment in Shanghai's industry was minimal until World War I diverted foreign capital from China. From 1914 through the early 1920s, Chinese investors were able to gain a tenuous foothold in the scramble to develop the industrial economy. This initial involvement was short-lived, however, as the post-World War I resurgence of Western and Japanese economic imperialism—followed closely by the Depression of the 1930s—overwhelmed many of the newly established Chinese industries. Competition became difficult, as cheaper foreign goods were dumped on the Shanghai market, and labour was attracted to relatively higher paying jobs in foreign-owned factories. Prior to the Sino-Japanese War of 1937–45 the Japanese had gained control over about half of the city's yarn-spinning and textile-weaving capacity.

The 1920s was also a period of growing political awareness in Shanghai. Members of the working class, students, and intellectuals became increasingly politicized as foreign domination of the city's economic and political life became ever more oppressive. When the agreements signed by the United Kingdom, the United States, and Japan at the Washington Conference of 1922 failed to satisfy Chinese demands, boycotts of foreign goods were instituted. The Chinese Communist Party was founded in Shanghai in 1921, and four years later the Communist Party led the "May 30" uprising of students and workers. This massive political demonstration was directed against feudalism, capitalism, and official connivance in foreign imperialistic ventures. The student-worker coalition actively supported the Nationalist armies under Chiang Kai-shek, but the coalition and the Communist Party were violently suppressed by the Nationalists in 1927.

Shanghai was occupied by the Japanese during the Sino-Japanese War of 1937–45, and the city's industrial plants suffered extensive war damage. In the brief interim before the fall of Shanghai to the People's Liberation Army (PLA) in 1949, the city's economy suffered even greater dislocation through the haphazard proliferation of small, inefficient shop industries, rampant inflation, and the absence of any overall plan for industrial reconstruction.

After 1949, Shanghai's development was temporarily slowed because of the emphasis on internal regional development, especially during the period up to 1960 when close cooperation was maintained with the Soviet Union. With the cooling of relations after 1960, Shanghai has resumed its key position as China's leading scientific and technological research centre, with the nation's most highly skilled labour force.

THE CONTEMPORARY CITY

The city site. The province-level municipality (shih) of Shanghai has a total area of 2,200 square miles and is bordered by Kiangsu Province on the north and west and Chekiang Province on the south. It includes the city of Shanghai; the nine mainland counties (hsien) of Pao-shan, Chia-ting, Ch'ing-p'u, Sung-chiang, Chin-shan (Chu-ching), Shang-hai (Hsin-chuang), Feng-

hsien (Nan-ch'iao), Nan-hui, and Ch'uan-sha; and approximately 30 islands in the mouth of the Yangtze and offshore to the southeast in the East China Sea. The largest island, Ch'ung-ming, has an area of 270 square miles (1,220 square kilometres), extends more than 40 miles (65 kilometres) upstream from the mouth of the Yangtze, and is the tenth county in the greater Shanghai Municipality.

The mainland portion of the city lies on an almost level deltaic plain with an average elevation of 10 to 16 feet above sea level. It is crisscrossed by an intricate network of canals and waterways that connect the municipality with the T'ai Hu region to the west.

The environment. The city's maritime location fosters a mild climate characterized by minimal seasonal contrast. The average annual temperature is about 61° F (16° C); the July maximum averages about 80° F (27° C), and the average January minimum is about 37° F (3° C). About 45 inches of precipitation fall annually, with the heaviest rainfall in June and the lightest in December.

As China's greatest industrial agglomeration, Shanghai has been increasingly plagued by pollution. Industrial relocation and new construction away from the city centre have helped alleviate air pollution, while water pollution has been tackled in a comprehensive manner since 1968. The Su-chou and Huang-p'u rivers, which flow through the city, are being purified; and attempts to recycle industrial waste materials are encouraged as a contribution to the more comprehensive and efficient use of natural resources.

The city plan. The central urban core, composed of the city proper and ten contiguous counties, has an area of roughly 20 square miles. It radiates toward the north, west, and south from the confluence of the Su-chou Ho and the Huang-p'u Chiang, a tributary of the Yangtze. Surrounding the central core is a transitional zone on both banks of the Huang-p'u, which encompasses a partially rural area of about 160 square miles. It includes several self-contained villages and the industrial satellite towns of Tao-p'u, P'eng-p'u, Ts'ao-ho-ching, Min-hang, Wu-sung, Ho-chia-wan, and Wu-ching. The banks of the Su-chou, an important inland waterway connection to the interior hinterland, are occupied by a westward arterial extension of the transitional zone. To the south, however, the transitional zone terminates abruptly a few miles south of the central Shanghai urban core, at the Huang-p'u. Eastern Shanghai (P'u-tung), directly across the Huang-p'u from the central business district, was founded in 1870 as one of the earliest industrial areas; it was also notorious as the city's most extensive and appalling slum. Several of the post-1949 industrial workers' residential complexes are now located there.

The physical perspective of downtown Shanghai is much the same as in the pre-Communist period. Because of the policy of developing integrated residential and industrial complexes in suburban areas, central city development and renewal has been given low priority. Many of the pre-World War II buildings, which housed foreign commercial concerns and diplomatic missions, still dominate the area.

Extending southward and westward from the confluence of the Su-chou and Huang-p'u rivers, central Shanghai has a gridded street pattern and includes the area originally contained within the British concession. The area is bounded on the east along the Huang-p'u by Chung Shan Tung Lu (Chung Shan Tung Street); on the west by Hsi Tsang Chung Lu; and on the south by Yen An Tung Lu, which was built on the former Yang-ching-p'ang Canal that separated the British from the French concessions. Chung Shan Tung Lu has several hotels, the central administrative offices of Shanghai, and a residence for foreign seamen. The main commercial artery, Nan Ching Tung Lu, runs westward from the eastern road. On this street are Shanghai's largest retail establishment—the Shanghai No. 1 Department Store (which handles 150,000 customers daily), restaurants, hotels, and the central communications and telegraph building.

The Hung-k'ou district lies to the north and east of the Su-chou Ho. It was originally developed by American and Japanese concessionaires and in 1863 was combined with the British concession to the south to create the International Settlement. It is an important industrial area, with shipyards and factories spread out along the bank of the Huang-p'u in the eastern section of the district. Its best known building, the Shanghai Hotel (Shang-hai Ta-hsia), overlooks the Huang-p'u; and the district is also the site of Shanghai's main railroad station.

The old Chinese city, which is now part of central Shanghai, is characterized by a random and labyrinthine street pattern. Until the early 20th century the area was surrounded by a three-mile wall. It is now circumscribed by the two streets of Jen Min Lu and Chung Hua Lu, which follow the course of the original wall; and it is bisected by the main north-south artery, Ho Nan Nan Lu (South Ho Nan Street).

Western Shanghai is primarily residential in character and is the site of the Sino-Soviet Friendship Palace, a permanent industrial exhibition hall. To the southwest, the district of Zicawei (in Mandarin, Hsu-chia-hui) became a centre of Christian missionary activity in China in the 17th century. During the late 1800s, Jesuit priests established a major library, a printing establishment, an orphanage, and a meteorological observatory in the area.

Land-use patterns in metropolitan Shanghai mirror pre-1949 real-estate market conditions. Much of the high-value land given over to industrial plants, warehouses, and transport facilities lies close to the Huang-p'u and Su-chou rivers. South of the Su-chou, which is traversed by about 20 bridges within the city, residential areas extend south from the industrial strip to the Huang-p'u. North of the Su-chou, residential areas are less clearly demarcated, and there is a more gradual merging of city and country in the transitional zone. Continuous urban settlement is bounded on the north by the two major east-west arteries of Chung Shan Pei Lu and Szu P'ing Lu.

Retail trade is concentrated in the old central business district, although the volume of trade conducted here has diminished with the establishment of the new industrial satellite towns and new villages on the periphery of Shanghai.

Transportation. Shanghai is China's major transport centre. The central city is both a sea and river port, with the Huang-p'u Chiang serving as an excellent harbour; at high tide, oceangoing vessels can sail up the river to the city.

In the early 1950s, the harbour was divided into a number of specialized districts. P'u-tung, on the east bank of the Huang-p'u, is used for the storage of bulk commodities and for transportation maintenance and repair facilities, while P'u-hsi, on the west bank, and Fu-hsing Tao (Fu-hsing Island) are the sites of general cargo wharves. Kao Yang Lu Wharf and I-hui contain general and bulk cargo wharves, and the Su-chou Ho is lined with riverine and small-craft terminals and cargo-handling facilities. The ocean terminals constructed since 1952 are at Jih-hui Chiang, south of the city, and at Chang-hua-peng, to the north at Wu-sung.

Heavily used inland-waterway connections, via the Su-chou Ho, and an extensive canal network are maintained with Soochow, Wu-hsi, and Yang-chou in Kiangsu Province, and with Hangchow, in Chekiang Province.

The railway network reflects the efforts that have been made since 1949 to reorient the city's industrial economy to give maximum support to domestic development needs. Before World War II, Shanghai was the terminus of two major rail lines south of the Yangtze—the Hu-nan line, from Nanking to Shanghai, and the Hu-han-jung line, from Shanghai to the port of Ning-po in Chekiang Province. A short spur line also ran from Shanghai to Wu-sung.

Additional spur lines, built since 1949, connect the new industrial districts to the main trunk routes. Among these newly constructed spurs are the Wen-tsao-pin and Min-hang lines and several short spurs emanating from Nan-hsiang (just west of the central city) to Ho-chia-wan, Peng-p'u, and T'ao-p'u.

Shanghai is served by two airports, the older Lung-hua Airport, a few miles south of the city used mainly for domestic flights, and the Hung-ch'iao International Airport, southwest of Shanghai, one of China's busiest.

Intraurban transport by electric trolleybus, trolley, and motorbus has been substantially improved since 1949; and there are more than 900 miles of transit routes throughout the city.

The
port of
Shanghai

Railway
facilities

Demography. Shanghai's population has been estimated at between 6,000,000 and 11,500,000 persons. The wide range of estimated figures is due to a lack of differentiation in statistics between the city itself and Shanghai Municipality. The greater municipality can be divided into three distinct population zones—the densely populated central city, the transitional zones, and the rural hinterland, which is one of the world's most densely settled agricultural areas.

Population densities vary from a maximum of about 125,000 persons per square mile in the urban core to between 1,500 and 2,500 persons per square mile in the hinterland. The transitional zone, which is considered part of metropolitan Shanghai, has a density of roughly 15,000 to 18,000 persons per square mile. It would appear, then, that the population of metropolitan Shanghai is roughly 5,500,000 to 6,000,000 and that of the hinterland over 4,000,000.

Within metropolitan Shanghai, there are few, if any, concentrations of ethnic minority groups. The majority of the population is of Han Chinese origin. There is undoubtedly a significant Chinese Christian community, as well as a foreign community, although it is impossible to estimate their size.

Housing. Shanghai has made considerable progress since 1949 in providing new housing for its growing population. Construction of integrated, self-sufficient residential complexes in conjunction with industrial, agricultural, and commercial development throughout metropolitan and suburban Shanghai has helped disperse population from the overcrowded central city and has led to dramatic changes in the urban and suburban landscape.

The concept of state-supported housing was introduced in 1951 with the development of Ts'ao-yang Hsin Ts'un (Ts'ao-yang New Village) in an existing industrial zone on Shanghai's western periphery. Two- and three-story standardized structures were supplied with running water, adequate drainage, and modern sewage facilities. Attention was also given to landscape beautification, and to the building of nurseries, schools, recreational facilities, shops, and post offices.

Following the construction of the Ts'ao-yang Hsin Ts'un, at least ten other residential complexes have been built, housing more than 1,000,000 persons. Some of them were constructed with the partial support of government bureaus or industrial enterprises to satisfy the needs of their employees. Two of the earliest complexes in this category were the Railroad Village and the Post and Telegraph Village.

Five major housing developments were built in the former slum area of Yang-shu-p'u. These include the villages of An-shan, K'ung-chiang, Ch'ang-pai, Feng-ch'eng, and the Feng-nan Erh Ts'un. Other complexes are those at P'eng-p'u, Chen-ju, I-ch'uan, Jih-hui, and Ch'iang-wan. Some of these are in relatively remote suburban locations in the transitional and hinterland zones near older rural marketing centres. The P'eng-p'u workers' housing project is typical. Some 15,000 to 20,000 persons who work in nearby factories live in a garden-apartment complex that includes apartment buildings, administrative offices, workshops, clinics, and a nursery. The adjacent fields supply wheat, clover, beans, cabbage, melons, and rape-seed (for cooking oil) for consumption by the inhabitants of the complex.

The economy. Shanghai has become the nation's leading industrial and manufacturing centre because of a distinctive combination of factors. These include the availability of a large, highly skilled, and technologically innovative work force; a well-grounded and broadly based scientific-research establishment supportive of industry; a tradition of cooperation among producers; and excellent internal and external communication and supply facilities.

The industrial establishment supplies a wide variety of semimanufactured and finished products to factories throughout China. In 1970, for example, an exhibition of Shanghai-made machines and machine tools designed for provincial industries included such specialized products as high-capacity wire-drawing dies, multiple-use lathes,

and equipment for assembling radios and other electronic equipment. Many of these precision-ground products were made in the Shanghai Machine Tool Plant (China's largest), which employs 6,000 workers. The machine industry also produces mining machinery, printing presses, equipment for sugar refineries and cement factories, cars and trucks, and industrial ball bearings. It supports a growing shipbuilding industry and is presently developing a giant turbo-generator capable of generating 125,000 kilowatts of electricity.

The iron and steel industry, though not of the first order in terms of actual production or productive capacity, was one of the earliest to be established in China. In the 1950s, the blast-furnace capacity of the industry was enlarged, and attempts were made to integrate the operations of the iron and steel industry more closely with the machine-manufacturing industry.

The chemical and petrochemical industries are almost fully integrated, and there is increasing cooperation among individual plants in the production and supply of chemical raw materials for plastics, synthetic fibres, dyes, paint, pharmaceuticals, agricultural pesticides, chemical fertilizers, synthetic detergents, and refined petroleum products. Shanghai has also taken the lead in supplying plants and equipment for the nationwide network of small chemical-fertilizer plants.

The textile industry has been reorganized to assure efficient utilization of the mills' productive capacity at all stages of the manufacturing process. More than 160 textile mills cooperate in their use of raw materials and have established cooperative relationships with plants that manufacture rubber shoes, tires, zippers, industrial abrasives, and conveyor belts.

Shanghai is also a primary source of a wide variety of consumer goods such as watches, cameras, radios, fountain pens, glassware, stationery products, leather goods, and hardware. Since 1962, factories producing such goods have made a special effort to meet consumer demands and to produce durable and attractive products. Special teams of industrial designers and factory workers interview customers in large stores to determine their preferences.

The retail trade in manufactured consumer goods is managed by the First Bureau of Commerce, which is directly responsible to the Shanghai Municipal Revolutionary Committee, the chief municipal administrative body. A number of commercial corporations under the Bureau are responsible, in turn, for the wholesaling, distribution, and warehousing of specific commodity groups. A separate corporation manages the larger retail stores, while the smaller retail establishments and some specialized wholesaling organizations are controlled by local commerce bureaus in the various districts of the city.

Shanghai's two major banks—the People's Construction Bank and the Bank of Communications—function as administrative organs of the Ministry of Finance. They are responsible for the disbursement and management of capital investment funds for state enterprises. The two British banks, the Hong Kong and Shanghai Banking Corporation and the Chartered Bank, maintain Shanghai branch offices that underwrite foreign trade transactions and exchange foreign currency in connection with trading operations. Remittances from Chinese living abroad (mainly in Hong Kong and in a number of Southeast Asian countries) are managed and collected by the three overseas Chinese banks, the Bank of East Asia, the Chi-Yu Bank, and the Overseas Chinese Banking Corporation.

Industrial products are exported from Shanghai to all parts of China. Imports are mainly unprocessed food grains, petroleum and coal, construction materials, and such industrial raw materials as pig iron, salt, raw cotton, tobacco, and oils. In domestic trade, Shanghai still imports more than it exports. In foreign trade, however, the value of exported commodities exceeds that of imported goods, and the proportion of manufactured exports is steadily increasing.

Political and governmental institutions. As a first-order, province-level administrative unit, Shanghai Municipality

Banking
operations

China's
leading
industrial
centre

pality is, in theory, directly controlled by the central government in Peking. It is difficult, however, to gauge the precise nature of this relationship. Since the Cultural Revolution of the late 1960s, China's administrative apparatus at all levels of the hierarchy has been in a process of readjustment so as to bring governmental organization in line with political reality. Prior to 1966, central administrative authority was shared by representatives of the central government and the Communist Party. From 1966 through 1968, however, this joint leadership was shattered, and both party and governmental institutions were subject to drastic reorganization and realignment.

The Shanghai Municipal Revolutionary Committee, the top governing body in the municipality, was established in 1967 after a chaotic period in which a number of popular-based revolutionary organizations seized control of the city for brief periods. The committee is composed of representatives of the army; the mass revolutionary organizations, such as workers, peasants, and students; and some former Communist Party officials. It would appear at this time that the semblance of a unified party-governmental administrative structure is being re-established.

Public utilities. Public works improvements since 1949 include the installation and improvement of drainage and sewage treatment facilities, public water supply systems, street lights, and public refuse bins. Roads have been widened and repaired, flood walls constructed in low-lying areas subject to tidal inundation, and housing built. The Chao-chia-pin drainage project drains approximately five square miles in southwestern Shanghai. The course of the Jih-hui Chiang, a stream that frequently flooded before draining into the Huang-p'u Chiang, has been filled in and a large sewer installed that now channels the stream flow directly into the main river. The sea walls surrounding Shanghai have also been strengthened and enlarged; two long sea walls extend east of the Huang-p'u for a total of more than 13 miles.

Shanghai is also one of China's major electric power generating centres. About 500,000 kilowatts of electric power can be generated by coal-fired thermal plants; and the Shanghai area is linked via a major transmission network with Nanking to the northwest and with Hangchow and Hsin-an-chiang (the site of a new hydroelectric generating facility) in Chekiang Province to the southwest. China's largest gas works, the Wu-ching works at Lung-hua, is capable of producing about 35,000,000 cubic feet of coking coal gas daily.

Health and safety. Shanghai's health-care facilities range from thousands of small clinics associated with factories, schools, retail establishments, and government offices to several major research and teaching hospitals. The Shanghai No. 6 Hospital, a typical medium-sized institution, has 580 beds and a staff of 700. Most hospitals have facilities for practicing and teaching both traditional Chinese and Western medicine. Medical schools have concentrated on the training of "barefoot" doctors, practitioners with sufficient medical skills to supply basic care to people in rural areas.

Public security is maintained by both military and police units. During the Cultural Revolution, the army assumed a greater degree of control over civilian militia and police. Before 1966, the Shanghai Public Security Bureau was responsible for all security matters. It consisted of a number of sections, including a political-assistance group; a secretariat; agencies for political, internal security, and criminal investigation; a public-order section; and detention and technical experiments offices.

Education. Shanghai is China's leading centre of higher education and scientific research. There are about 25 universities—including Fu-tan, Chiao-t'ung, T'ung-chi, and the Hua-tung Shih-Fan ta-hsueh—with a total enrollment of more than 50,000 students. In addition, about ten technical and higher education institutes train another 10,000 students. Many factories have affiliated work-study colleges to equip workers for more highly skilled jobs. In 1960 the Shanghai Municipal Part-Work Part-Study Industrial University was established through the cooperation of more than 1,000 industrial establish-

ments. In the early 1960s, about one-fourth of the city's total work force of approximately 1,000,000 workers was enrolled in one of these schools.

The Shanghai Branch of the Chinese Academy of Sciences, China's leading scientific research and development body, is located in Shanghai. Since the Cultural Revolution, research work under the academy's auspices has been directed toward the solution of practical production problems. In Shanghai, therefore, much research is being carried out under the joint auspices of the academy and individual industrial establishments.

Cultural life. Shanghai's cultural attractions include museums, historical sites, and scenic gardens. The Shanghai Museum has an extensive collection of sculpture and pictorial art, and the Shanghai Revolutionary History Memorial Hall displays photographs and objects that trace the city's evolution. The Ta Shih-chieh ("Great World"), founded in the 1920s, is Shanghai's leading theatrical centre and offers revolutionary folk operas, dance performances, plays, story readings, and specialized entertainment forms typical of China's national minority groups. The city also has many workers' and children's recreational clubs and several large motion picture theatres, including the Kuang-ming Theatre.

The old Chinese city houses the 16th-century Yu-Yuan Garden, an outstanding example of late Ming garden architecture, and the Former Temple of Confucius. Other points of attraction are the Ch'ing dynasty Lung Hua Pagoda, the Sino-Soviet Friendship Palace, and the tomb and former residence of Lu Hsün, a 20th-century revolutionary writer.

The major publishing houses of Shanghai are a branch of the People's Literature Publishing House (at Peking) and the People's Educational Publishing House. In addition to the large branch of the Central Library of the Chinese Academy of Sciences, Shanghai has five other libraries with collections totalling more than 5,000,000 volumes. Shanghai's art and music schools include a branch of the Central Conservatory (Tientsin), the Shanghai Conservatory, and the Shanghai Institute of Drama.

Shanghai has two leading newspapers—the *Chieh-fang jih-pao* ("Liberation Daily") and the *Wen Hui Pao*. The television station was established in 1958. Stations serve as advertising media as well as vehicles for the dissemination of news and political propaganda. Other extensively used advertising media in Shanghai include magazines, billboards, telephone directories, and motion pictures.

Parks, open spaces, and playing fields were notably expanded after 1949. Two of the earliest to be opened for public use were the People's Park in central Shanghai and the Huang-p'u Park on the shore of the Huang-p'u Chiang. Every section of the city has large parks and playing fields. Among the largest are the Hung-k'ou Arboretum, Park, and Stadium in the north; the Peace Park and Hu-p'ing Park and playing field in the northeast; the P'utung Park in eastern Shanghai, the Hu-nan and Fu-hsing parks in the south, and the Chung-shan Park on the western periphery of the central city.

BIBLIOGRAPHY. RHOADS MURPHEY, *Shanghai: Key to Modern China* (1953), is an authoritative study of Shanghai's pre-World War II political and economic organization. Special attention is given to the city's role as a trading and manufacturing centre, as well as to its relationship with the hinterland. For the post-1949 period, NEALE HUNTER, *Shanghai Journal* (1969), recounts the author's experiences as an English teacher in the Shanghai Foreign Language Institute during the Cultural Revolution; and *Nagel's Encyclopedia-Guide to China* (1968), describes historically and artistically important places. More scholarly accounts of the organization and management of Shanghai's industry, trade, and financial institutions may be found in AUDREY G. DONNITHORNE, *China's Economic System* (1967); and BARRY M. RICHMAN, *Industrial Society in Communist China* (1969). Economic and political developments are treated in CHRISTOPHER HOWE, "The Level and Structure of Employment and the Sources of Labor Supply in Shanghai, 1949–1957," and LYNN T. WHITE III, "Shanghai's Polity in Cultural Revolution," in J.W. LEWIS (ed.), *The City in Communist China* (1971). An earlier study by CHRISTOPHER HOWE, "The Supply and Administration of Urban Housing in Mainland China: The Case

The mass media

of Shanghai," *China Quarterly*, 33:73-97 (1968), also concentrates on conditions in Shanghai.

(B.Bo.)

Shansi

Shansi (Shan-hsi in Pin-yin romanization) is a province (*sheng*) of northern China. With an area of about 60,700 square miles (157,200 square kilometres) and a population of about 20,000,000 people, Shansi is roughly rectangular in shape; it is bounded by the provinces of Hopeh to the east, Honan to the south and southeast, Shensi to the west, and by the Inner Mongolian Autonomous Region to the north. The name Shansi, which means Western Mountains, testifies to the rugged terrain of the territory. The largest city and provincial capital T'ai yuan, is located in the centre of the province.

Shansi has always held a strategic position as a gateway to the fertile plains of Hopeh and Honan. Since ancient times, it has also served as a buffer zone between China proper and the Mongolian and Central Asian steppes. A key route for military and trading expeditions, it was also one of the major avenues for the entrance of Buddhism into China from India. Today it is important for its vast reserves of coal and iron, which form the basis of heavy industrial development, and for its production of cotton for export. (For a related physical feature, see HUANG HO [RIVER].)

Early
settlements

History. Pollen analyses from western and southern Shansi reveal that several cereal plants were grown there as early as the 5th to the 3rd millennium BC. During the Western Chou period, from about 1122 to 771 BC, the fief of Chin (now a colloquial and literary name for Shansi) was established in the area of modern Ch'ü-wo (Hou-ma) along the Fen Ho in the southwest.

Under the Han dynasty (206 BC to AD 220) Shansi assumed what was to become its traditional role as a buffer state between the pastoral nomads to the north and west and the sedentary Chinese farmers to the south and east. Through successive dynasties, the political status of the region varied with the relative strength or weakness of the Chinese central government. A predilection for political autonomy was paralleled by a sense of commercial initiative and aggressiveness that led to the rise in the 18th and 19th centuries AD of a class of Shansi bankers and merchants famous throughout China.

From the end of the Han dynasty until the reunification of the empire under the Sui dynasty in 581, Shansi came under the dominance of several short-lived dynasties, most prominent of which was the Northern Wei dynasty (AD 386 to 534). Buddhism prospered for the first time during the Northern Wei period; it was from Shansi that the Chinese Buddhist monk Fa-hsien (q.v.) began his legendary journey to India. The Buddhist cave sculptures dating from this period and preserved at Yün-kang today constitute some of China's most precious art treasures.

From the 7th century until the end of the 14th century, control over the area shifted back and forth among local military leaders, invading Turkic and Mongol forces, and representatives of the Chinese dynasty in power. Some stability was restored during the Ming dynasty (1368-1644), when many of the present-day towns and cities were built.

Antiforeign feeling ran high during the latter years of the Ch'ing (Manchu) dynasty (1644-1911), despite the fact that there was relatively little foreign influence in the province. A few manufacturing establishments were set up in T'ai-yüan in 1898, and a French- and Chinese-financed railway between T'ai-yüan and Cheng-ting in western Hopeh was built from 1904 to 1907. In 1900, antiforeign feeling took a violent form when an English mission church in T'ai-yüan was burned by the I-ho t'uan (a secret society that came to be popularly known as the "Boxers"), and foreigners and Chinese Christian converts were killed. This led to the outbreak of the so-called Boxer Rebellion, which eventually spread to Peking.

The
Boxer
Rebellion

After the overthrow of the Ch'ing dynasty in 1911, the Shansi warlord Yen Hsi-shan (1883-1960) ruled as an absolute dictator until the end of World War II. Yen was instrumental in the establishment of the nucleus of a

heavy industrial base and the opening of the T'ung-p'u railway—a north-south extension of the existing T'ai-yuan-Cheng-ting line—in 1934.

During the Sino-Japanese War of 1937 to 1945, the Japanese developed coal resources in the T'ai-yüan Basin and expanded heavy industry. They were, however, continually harassed by Communist guerrillas who operated from mountain bases. The agricultural and handicrafts cooperatives established at these bases were instrumental in facilitating economic and social recovery after Communist forces assumed control of Shansi in 1949.

The natural landscape. Two-thirds of the province is composed of a vast plateau that lies at average elevations of between 1,000 and 3,000 feet above sea level. The plateau is bounded by the Wu-t'ai Shan (Wu-t'ai Mountains) and Heng Shan on the north, the T'ai-hang Shan on the east, and the Lu-liang Shan on the west. The eastern mountains average between 5,000 and 6,000 feet in height and reach their maximum elevation at Shih-kao Shan (8,300 feet or 2,530 metres). The highest peak in the west, Kuan-ti Shan, reaches an elevation of 9,135 feet (2,785 metres), while the northern ranges are crowned by Wu-t'ai Shan at 9,495 feet (2,894 metres).

Mountains
and
plateaus

The Huang Ho (Yellow River) flows through a mountain gorge from north to south and forms the western border with Shensi Province. At Feng-ling-tu, the river turns sharply eastward and forms part of the southern border with Honan Province. The southwest corner of the province is part of the highland region that extends from Kansu to Honan provinces and is covered with a layer of loess (a loamy deposit formed by wind).

The Fen Ho Valley is comprised of a chain of linked, loess-filled basins that crosses the plateau from northeast to southwest. The largest of the valley's basins is the 100-mile-long T'ai-yuan Basin. North of T'ai-yuan are three detached basins—Ning-wu, Hsin-hsien, and P'ing-ting—which are isolated areas of cultivation. Further north, the Ta-t'ung Basin forms a separate feature.

Several rivers drain eastward and southeastward, cutting valleys and ravines through the T'ai-hang Shan and the Wu-t'ai Shan. Among these are the Hu-t'o Ho and its tributaries the Cho-chang-pei Yuan, the Ch'ing-chang, the Cho-chang, and the Ching. In the west, several rivers cut across the Lü-liang Shan and drain into the Huang Ho. In addition to the Fen Ho, which flows southward through two-thirds of the province, these include the Lan-i Ho, the Ch'iu-shui Ho, the San-ch'uan Ho, the Ch'u-chan Shui, the Hsin-shui Ho, and the Sou Shui. The northern mountains are drained chiefly by the Sang-kan Ho, which flows eastward toward Peking.

In the mountains, several types of light-brown and brown forest soils are common, with meadow-steppe varieties found at higher elevations. Alluvial soils in the central and southern portions of the province are formed mainly of calcareous (lime-bearing) brown soils deposited by the Fen Ho. There are also loess and lime deposits. Natural organic materials are not abundant, and salinity—caused by a high degree of surface evaporation—is excessive.

Shansi has a semi-arid climate. The mean annual rainfall ranges from less than 10 inches a year in the northwest to a maximum of 20 inches in the southeast. Between 70 and 80 percent of the annual rainfall occurs between June and September. Temperatures range from a January mean of 17° F (−8° C) and a July mean of 77° F (25° C) at T'ai-yüan, to a January mean of 3° F (−16° C) and a July mean of 72° F (22° C) at Ta-t'ung.

The
climate

Winter droughts are common because the plateau is subject to the full force of the dry winter northwestern wind that blows from the Mongolian plateau. In summer, the southeastern monsoon (a rain-bearing wind) is blocked by the T'ai-hang Shan. Hailstones are a common natural hazard, as are frequent floods, particularly along the course of the Fen Ho.

Vegetation distribution primarily depends on the direction in which the mountain slopes face. The southern slopes are characteristically covered by species such as oak, pine, buckthorn, and honey locust, which are more tolerant to drier conditions than those such as linden,

hazel, maple, and ash that prevail on the more humid northern slopes. The province has long been cultivated, and such natural vegetation as remains consists mainly of shrubs and grasses; isolated forests occur on the north-facing slopes.

Destruction of the original forest cover in ancient times eliminated most animal species, although several species of steppe rodents—including the hamster and the vole (a small rodent-like animal)—are still prevalent.

People and population. Most of the province's 20,000,000 people are of Han (Chinese) origin and speak the Northern Mandarin dialect of Chinese. The small minority populations include the Hui, or Chinese Muslims, in the T'ai-yüan-Yü-tz'u area, and some Mongols and Manchus around Ta-t'ung.

Roughly 85 percent of the populace live in agricultural villages. The highest rural densities occur in the T'ai-yüan Basin, in the southeast around Ch'ang-chih, and in the Fen Ho Valley. In these areas, densities range from 500 to 800 persons per square mile. The average population density is about 330 persons per square mile. In some of the more remote mountain areas there are fewer than 130 persons per square mile.

The two principal urban areas are T'ai-yüan, the provincial capital and leading industrial and mining complex (1970-estimated population 2,725,000), and Ta-t'ung (1964 estimated population 500,000). A mining and rail transport centre near the borders of Hopeh Province and the Inner Mongolian Autonomous Region. Other manufacturing and transport centres include Yü-tz'u and Yang-ch'üan, both east of T'ai-yüan, and Ch'ang-chih in the southeast. Smaller cities are Ch'ü-wo (Hou-ma) and Lin-fen, both situated in the fertile Fen Ho Valley; Fen-yang, immediately southwest of T'ai-yüan; and Yü-ch'eng, on the Chieh Ch'ih salt lake in the southwest.

Administration and social conditions. The chief provincial administrative unit is the Shansi Provincial Revolutionary Committee. Formed in 1967 during the Cultural Revolution, it is composed of representatives of revolutionary mass organizations, members of the People's Liberation Army, and revolutionary cadres. The province is divided into two types of regional administrative units—the municipality (shih) and the special district (*chuan-ch'ü*). There are three municipalities—Ta-t'ung in the north, T'ai-yüan in the T'ai-yüan Basin, and Yang-ch'üan in the east. The five special districts are Yen-pei in the extreme northeast, Hsin-hsien in the north, Chin-chung in the centre of the province, Chin-tung-nan in the southeast, and Chin-nan in the southwest. On the local level, there are 96 counties (hsien) and one municipality—Cb'ang-chih in the Chin-tung-nan Special District.

The educational and medical institutions that were established in Shansi, mainly through foreign initiative, between 1898 and 1910 played a minor role in ameliorating widespread poverty, illiteracy, and substandard health conditions that then prevailed. Shansi University, founded in T'ai-yüan by an English missionary in 1902, was one of the first in China to offer Western curricula in liberal arts, law, and medicine but had an enrollment of no more than 400 students from its inception until 1949.

Since 1949, about a dozen technical schools for agriculture, mining, forestry, and machine technology have been established, as have about ten senior middle schools and more than 90 primary schools. Less than five percent of the population is now illiterate, and work-study facilities in factories are common. Educational planning centres on the practical requirements of industrial and technological development.

The four medical colleges and affiliated hospitals in T'ai-yüan offer treatment and full courses of study in both Western and traditional Chinese medicine. There are also smaller clinics in the industrial and mining areas. Public works projects include a centralized water supply system based at Lan-ts'un that regulates the flow of the underground water supply of the T'ai-yüan Basin; modernized sewerage and waste disposal facilities in the major cities; housing projects; and extensive "green belt"

areas that are planted with thousands of trees. Sports stadiums, physical education facilities, and three large parks have been built within the T'ai-yüan metropolitan area.

The economy. Sectors of the economy. Shansi is a major coal-producing region, and, together with Hopeh Province, it accounts for nearly 20 percent of China's total coal production. Estimated reserves of 400,000,000,000 tons include both anthracite and high-grade coking coal; these have supported the development of heavy industry as well as the thermal generation of electricity. The major mining operations, in order of annual production capacity, are located at Ta-t'ung, Hsi-shan, Yang-ch'üan, Fen-hsi, and Hsien-kang. Another 150 smaller coal mines are widely distributed throughout the province.

Iron ore is mined from vast deposits in the Ma-an Shan district of central Shansi, which have an estimated reserve of 100,000,000 tons. The largest titanium and vanadium (metallic elements used in alloys such as steel) deposits in China are located near Fen-hsi. Some silver and zinc is mined near Ta-t'ung; copper is mined in the southwestern mountains; and edible salt is produced from Chieh Ch'ih (Chieh Lake), near Yü-ch'eng in the southwest.

Most of the province's industries are concentrated in the T'ai-yüan-Yü-tz'u region. The iron and steel industry produces ingot steel, pig iron, and finished steel products. Heavy machinery and industrial chemicals and chemical fertilizers are produced, as are cement, paper, textiles, milled flour, and wine.

Other iron and steel centres include Yang-ch'üan, Ch'ang-chih, Ta-t'ung (which also produces cement and mining machinery), and Lin-fen. Manufacturing is important in P'ing-wang, Yü-hsien, Shou-yang, Ning-wu, Fen-hsi, and Ling-shih-hsien.

T'ai-yüan is an important electricity-generating centre. The thermal generating capacity exceeds 150,000 kilowatts; in addition, the basin is linked to the hydroelectric plant at San-men Gorge on the Huang Ho in Honan Province.

Because of widespread erosion, only about one-third of the province is under cultivation. Extensive soil and water conservation efforts since 1949 have taken the form of terracing, afforestation, the digging of irrigation canals, diking of cultivated plots, soil desalinization, and land reclamation along rivers.

In the extreme north, the short growing season and long, cold winter limit cultivation to one annual crop of spiked millet, spring wheat, naked oats (oats with no covering on the kernels), potatoes, and sesame. In the rest of the province—except for the mountainous areas—the longer growing season permits three crops in two years or two crops in one year. Winter wheat, millet, soybeans, kaoliang (a variety of grain sorghum), corn, and cotton are raised in adequately irrigated areas. Some tobacco and peanuts are produced in the central basins and on the Huang Ho flood plain as well as such fruits as grapes, apricots, persimmons, apples, peaches, and plums.

Only 10 percent of Shansi's cultivated acreage is devoted to cash crops. Shansi is the largest provincial producer of cotton, and sesame is grown both for its oil seeds and for its fibre. Other cash crops include castor beans, rape seeds, and Indian hemp.

The relatively low ratio of population to land over much of Shansi's hilly terrain has traditionally fostered animal husbandry. Before 1949, unsettled political and economic conditions interfered with the development of high-quality animal strains. Sheep are raised for their high wool yields. Domestic animals include pigs, horses, yellow oxen (for transport), donkeys, and chickens.

Transportation. Shansi relies heavily on three major rail lines, both for intraprovince transport and for shipping raw materials, industrial commodities, and foodstuffs outside the province. The longest of these, the T'ung-p'u trunk line, runs for 518 miles from Ta-t'ung to Feng-ling-tu in the southwest corner of the province. An additional 75 miles of branch lines connect the main line with newly opened industrial and mining sites. The

Mineral
resources

The main
cities

Agricultural
production

Ching-pao line from Peking to Pao-t'ou, Inner Mongolia, passes through Ta-t'ung; it carries the northern region's coal eastward to Hopeh Province and the Yangtze Delta region and westward to Lan-chou, Kansu Province, via the Pao-t'ou-Lan-chou railway. Central and eastern Shansi coal is carried eastward on the double-tracked Shih-t'ai (or Cheng-t'ai) line, which runs between T'ai-yuan and Shih-chia-chuang, Hopeh. A spur connects Yuan-p'ing, on the main T'ung-p'u route, with O-k'ou in the northeast, whereas the rich southeastern agricultural area is served by a line from Ch'ang-chih to Chiao-tso, Honan.

Long-distance, all-weather roads are not extensive; most roads serve as feeder routes to the rail lines. A road links T'ai-yuan to northern Shensi Province via Chun-tu on the eastern shore of the Huang Ho. It carries industrial products to Shensi and hides and other mountain products to Shansi. Other important long-haul highways run between T'ai-ku (just south of Yii-tz'u) and Honan Province, between Ch'ang-chih and Han-tan, Hopeh.

The Fen Ho is navigable for small flat-bottomed boats below Hsin-chiang. Freight traffic on the Fen, as well as on the north-south section of the Huang Ho, is insignificant, however.

Cultural life. Shansi's long-standing position as an avenue of communication between the North China Plain, the Mongolian steppes, and Central Asia gave rise to a rich and varied cultural and folkloric tradition. Several distinctive forms of Shansi opera became popular under the Ming and Ch'ing dynasties. Metalworking has been a specialty of Shansi craftsmen since the 2nd millennium BC. The province was also famous for the uniquely sculpted decorative tiles and glazed pottery figures used for temple decoration. The Chin-ssu, near T'ai-yian, is Shansi's best known temple complex; it was originally built in the 5th century AD. During subsequent periods, it served as a monastery and as the centre for several religious cults.

BIBLIOGRAPHY. YI-FU TUAN, *China* (1969), is a comprehensive and eminently readable account of the evolution and modification of the Chinese cultural landscape since prehistoric times. The final section of the book is concerned with landscape changes after 1850, with special attention given to developments since 1949. Although not focussed specifically on Shansi and Shantung, it stands as the outstanding concise statement of China's historical and contemporary geographical configurations. YU-TI JEN, *A Concise Geography of China* (1964), provides a brief introduction to the subject, organized along traditional lines, with sections on Shansi and Shantung. *The Physical Geography of China*, 2 vol. (1969), prepared originally by a group of Soviet earth scientists, is authoritative, but somewhat difficult to read because of awkward translation. Most topics bearing upon the physical geography of Shansi and Shantung are adequately treated. Four atlases are useful reference works: ALBERT HERRMANN, *An Historical Atlas of China*, new ed. (1966); *Communist China Administrative Atlas* (1969); *Communist China Map Folio* (1967); and *People's Republic of China Atlas* (1971). *Nagel's Encyclopedia-Guide to China* (1968) describes historically and artistically important places. An excellent documentary account of the period from 1948 to 1949 is found in WILLIAM HINTON, *Fanshen* (1966). Articles on current economic and political developments in Shansi and Shantung sometimes appear in the series: *China Quarterly*, *Far Eastern Economic Review*, *China News Analysis*, *China Reconstructs*, and *China Pictorial*.

(B.Bo.)

Shantung

Shantung (Shan-dong in Pin-yin romanization) is a north coastal province of the People's Republic of China across the Yellow Sea from Korea. It has an area of 59,300 square miles (153,600 square kilometres). Shantung is China's second most populous province, its estimated population of 57,000,000 in 1970 being exceeded only by that of Szechwan; its average population density of 961 persons per square mile is exceeded only by that of Kiangsu Province.

The province consists of two distinct segments: an inland zone bounded by the provinces of Hopeh to the north and west, Honan to the southwest, and Anhwei and

Kiangsu to the south; and a peninsula (the Shantung Peninsula) extending some 200 miles seaward from the Wei and Chiao-lai river plains, with the Gulf of Chihli (Po Hai) to the north and the Yellow Sea to the south, giving it a longer coastline than any other Chinese province (750 miles). The peninsula, which encloses the Gulf of Chihli on the south, is separated from the Liaotung Peninsula to the north by a 100-mile-wide strait extending from P'eng-lai on the north coast of the Shantung Peninsula, to Port Arthur (Lü-shun), a rail terminus at the tip of the Liaotung Peninsula in Liaoning Province.

The inland zone, covering roughly two-thirds of the province's total area, includes a hilly central region centred on the famous T'ai Shan (Mt. T'ai) complex, and a fertile and intensively farmed agricultural area surrounding the central mountainous mass on the north, west, and south, which forms part of the Huang Ho (Yellow River) Basin and the North China Plain. The provincial capital, Tsinan, is situated just west of T'ai Shan and three miles south of the Huang Ho, which flows from southwest to northeast through the province before emptying into the Gulf of Chihli.

The Shantung Peninsula, in contrast, is entirely an upland area, and, with its seaward orientation and indented coastline, has traditionally depended on fishing, mining, and port-related activities. Long a focal area in the evolution of Chinese civilization and institutions, the province's natural inland-peninsular division is paralleled by a dual orientation in its past and present political and economic configurations. The eastern peninsula, with its seaward focus, historically has coveted autonomy, whereas the larger and more densely settled inland portion has been closely tied to the inward-facing empire.

The name Shantung means "Eastern Mountains" and was first officially used during the Chin dynasty in the 12th century. For an associated physical feature, see HUANG HO (RIVER).

HISTORY

A Neolithic culture—known as the Lung-shan because of archaeological remains discovered near the township of that name—existed on the Shantung Peninsula in the 3rd millennium BC; it played a key role in the establishment of a common rice-based cultural grouping that apparently spread along the Pacific seaboard from the Shantung Peninsula to Taiwan and eastern Kwangtung.

Western Shantung formed part of the Shang Kingdom (1766–c. 1122 BC). By the Spring and Autumn (Ch'un ch'iu) Period (722–481 BC) it had become the centre of political and military activity that resulted from the eastward expansion of the Chou, following their conquest of the Shang. One of the small southern Shantung states was Lu, the birthplace of Confucius and Mencius. Also in the "Eastern Territory"—an early name for Shantung—was Gh'i, extending over the major part of Shantung Peninsula; it became an important economic centre, exporting hemp clothing, silk, fish, salt, and a unique variety of purple cloth to all parts of China. Beginning in the Six Dynasties period (AD 222–589), Shantung became North China's leading maritime centre, receiving commodities from the South China coastal area (now Fukien and Kwangtung) for transshipment to destinations north and south of the Huang Ho. Thus, Shantung has been a part of China from its very beginning as an organized state.

In 1293 the Grand Canal (Yün Ho), running generally north to south, was completed, making western Shantung a major inland trading route. (The 1,200-mile-long canal is one of the longest in the world; it connects Peking with the Yangtze River; and sections of it may have been begun as early as the 5th century BC). Yet even after the completion of the canal, maritime trade still remained important to Shantung, and the peninsula retained its dominant economic position. In the great agricultural areas of the province, however, early deforestation and the long-established practice of clearing land for cultivation without providing for flood prevention and control measures, led to serious and ultimately disastrous erosion and wastage of valuable agricultural land. In the 19th

The
Shantung
Peninsula

The
Grand
Canal

Ancient
handicrafts

century this problem was intensified by shifts in the course of the Huang Ho. From 1194 until the early 1850s the Huang Ho followed the original bed of the Huai River along the Shantung-Kiangsu border before emptying into the Yellow Sea. After 1855, when a series of devastating floods was followed by extensive dike construction, the river changed to its present course some 250 miles to the north. Hardships and food shortages from floods and other natural calamities increased in intensity throughout the 19th and 20th centuries. This resulted in a substantial emigration of Shantung peasants to the Northeast (Manchuria) and to the Inner Mongolian Autonomous Region, with more than 4,000,000 emigrating between 1923 and 1930.

In the closing decade of the 19th century, Shantung came under the influence of German, British, and Japanese interests. It was occupied briefly by Japanese troops after the Sino-Japanese War of 1894 to 1895. In 1897 Germany landed troops, and in 1898 a treaty was signed by which China ceded to Germany, for 99 years, two entries to Chiao-chou Wan (Bay) and the islands in the bay and granted the right to construct a naval base and port, Tsingtao. Germany used Tsingtao as a base to extend its commercial influence throughout the peninsula; it developed coal mines and constructed a railway (1905) from Tsingtao to Tsinan. Similarly, in 1898 Great Britain obtained a lease for Wei-hai-wei (modern Wei-hai), another strategic port near the northern tip of the peninsula. This was in response to the Russian occupation of Port Arthur. With the advent of World War I, Japan took over German interests in the peninsula and in 1915 compelled the Chinese to give official recognition to their renewed occupation, which they maintained until 1922.

In the Sino-Japanese War of 1937 to 1945, even though the Japanese had gained control of most of Shantung by the end of 1937, they miscalculated Chinese strength and suffered a serious defeat—their first—at T'ai-erh-chuang, in southern Shantung, in 1938. In the postwar struggle between the Chinese Communists and Nationalists, Shantung came under Communist control by the end of 1948, with Tsinan falling in the autumn of that year.

THE LANDSCAPE

Shantung is dominated by two hill masses to the east-northeast of the Grand Canal and to the south-southwest of the present course of the Huang Ho. These hills are geologically similar to the mountains of the eastern Manchurian region, the Liaotung Peninsula, and Korea to the northeast. They are formed mainly of ancient crystalline shales and sedimentary rocks on their flanks and of hard, very ancient rocks with granitic intrusions in their core. Both masses are detached remnants of China's most ancient geologic core. The easternmost (peninsular) mass is connected to the Liaotung Peninsula by a submerged ridge, emerging periodically in the Gulf of Chihli as the Ch'ang-shan Ch'iin-tao (archipelago). In fairly recent geological times, the Shantung hill masses stood as islands in an inland sea that separated them from the Tai-hang Shan (mountains) of Shansi to the west.

Relief and drainage. *The plains areas.* A broad, marshy depression, the Chiao-lai Plain (sometimes known as Wei-hsien Valley), extends for about 100 miles from Lai-chou Wan (bay) in the Gulf of Chihli, south to Chiao-chou Wan in the Yellow Sea, near Tsingtao, and westward into the North China Plain. This plain ranges in width from 18 to 30 miles and has an average elevation of less than 150 feet. Its generally flat surface is interrupted occasionally by bedrock-derived monadnocks, or residual rocks or hills, that have resisted erosion. Another depression, part of the inland zone of western Shantung, forms the central segment of the North China Plain. It slopes eastward into a northwest-southeast trough skirting the western perimeter of the central Shantung hill mass and is filled with a mixture of loess (a loamy soil, deposited by wind) and alluvial materials (sand, clay, and gravel), along with more recently deposited alluvium, resulting from the building up of the Huang Ho flood plain. Five narrow lakes forming part of the Grand Canal system—Tung-p'ing Hu, Nan-yang Hu, Tu-

shan Hu, Chao-yang Hu, and Wei-shan Hu—stretch out along this depression and are also linked to a series of saline marshes (indicative of earlier swamp conditions) that separate the fertile margin at the western edge of the central hills from the main sections of the North China Plain to the south and west.

The two hill masses. Of the two main hill masses, the westernmost (inland) complex is the most extensive. It consists of a northern series of three parallel faulted ranges—the Hsing Shan, Lu Shan, and T'ai Shan, that stretch northeastward for more than 200 miles—and a more diversified, lower, and more exposed southern portion. The granitic T'ai Shan, dominated by Mt. T'ai, the most famous of China's five sacred mountains, attains a maximum elevation of over 5,000 feet just above the city of T'ai-an. While the elevation of the three northern ranges averages from 1,000 to 3,000 feet, several other peaks exceed this level. Drainage is predominantly radial and subject to the prevailing configuration of the mountains. The only navigable river (other than portions of the Huang Ho) is the Hsiao-ch'ing Ho which emerges from a small spring-fed lake in a limestone outcrop zone near Tsinan and flows parallel to the Huang Ho, before emptying into Lai-chou Wan. The southern hills, in contrast, are drained by several rivers in arable valleys, typified by those of the Tung-wen Ho system, which eventually terminate in the marshy plain east of the Grand Canal in Kiangsu Province. The most prominent of these are the Tung-wen, the I, the Shu, and the Hsin-shu.

The mountains of the peninsular mass to the east seldom rise above 700 feet. Here, surface erosion has etched irregular and deeply cut valleys, and rounded hills contrast sharply with small intermontane basins. Both the north and south coasts of the peninsula are rocky, with hills dropping precipitously to the sea and separating a series of intensively cultivated crescent-shaped plains. The granitic bedrock of the peninsular core is sometimes broken by igneous intrusions, most notably on Lao Shan, northeast of Tsingtao with an elevation of 3,700 feet.

Soils. The soils of Shantung fall into two broad categories associated with upland or lowland distributions. The so-called Shantung brown soils are found over most of the two major hill masses and include a variety of brown forest and cinnamon-coloured soils formed through clay accumulations and sod processes. Although the depth of the soil cover varies with altitude because of severe erosion (especially on the northwest-facing surfaces), these soils are quite consistent in their composition. Typically, they are either leached brown forest soils or slightly leached calcareous (chalky) brown soils.

A distinctive variant of the typical Shantung brown soil is the recalcified soil (soil that has again been made hard or stony by the deposit of calcium salts); it is found on the northern perimeter of the central hill mass. This area, subject to the full blast of the northwest winter monsoon (rain-bearing winds) has been inundated for centuries with limestone dust of loessal origin. The accumulation of this surface cover has outpaced the soil's ability to leach out the limestone, with the result that many soils in the area have a characteristic upper layer as well as a lower layer of calcium carbonate.

Calcareous alluvial soils predominate in both lowlands and plains. They are usually quite fertile, depending on both the length of time they have been cultivated and their proximity to urban centres (where heavier fertilization with human and animal wastes results in rich, dark-coloured soils). Silty alluvium covers most portions of the North China Plain area of the province. Variants include a clayey calcareous alluvium that appears in western and southern Shantung in low-lying areas away from rivers and a sandy calcareous alluvium found along the present and past courses of the Huang Ho. Before 1949, when the Huang Ho frequently flooded, sandy materials were deposited close to the riverbanks. The winds blew the lighter sandy loams into 45-to-60-foot dunes that moved unchecked over fertile farmlands. More limited distributions of noncalcareous alluvium are formed of loam and sand deposits eroded from the hilly brown forest soils. Those in Shantung usually occur at the base of

Shantung
brown
soils

The hill
regions

The
stone
ginger soil

granitic and sandstone hills and are composed of sandy or fine gravelly loams. Another distinctive soil type found in central and western Shantung on the North China Plain is the subsurface *sha-chiang* t \dot{u} , or "stone ginger soil." This appears at the lowest elevations of alluvial plains where surface water remains unevaporated for several months until the dry season and also in sections of the plains subject to annual alluvial inundation. Such soils are located anywhere from one to six feet below the surface and are always covered with alluvium or redeposited loess. Their name derives from the appearance of lime concretions that resemble the shape of ginger roots. Other *sha-chiang* t \dot{u} soils develop impervious layers of limestone hardpan up to 20 inches thick.

Climate. Shantung falls within the North China climatic region, which extends from the Huai Ho in the south to the Hopeh-Liaoning border in the north; it is characterized by a continental climate with cold winters and hot, dry summers. Climatic variation prevails, however, between the peninsular and inland zones of the province. The inland zone, especially in its northern sections, is subject to the full effect of the winter monsoon, when cold, northwesterly winds continue through December. By March, when the Siberian high-pressure concentration weakens, wind direction gradually reverses, and warmer, southeasterly winds prevail throughout the summer.

The inland zone. In the inland zone, annual precipitation ranges from 10 inches in northwest Shantung to 20 to 24 inches as one approaches the mouth of the Huang Ho. Of the total annual precipitation, only 2 to 6 percent falls during the winter, with 70 to 80 percent occurring in summer. The interior areas of Shantung are also subject to severe winter and spring dust storms, sometimes followed by droughts and frequent summer floods.

Temperatures in the inland zone range from a mean January reading of 25° F (−4° C) in the northern interior to a mean of 82° F (28° C) in July. In common with the rest of the North China Plain, this area is subject to freezing temperatures from one to three months, with frosts common from late October to April. It is also not unusual for rivers to freeze over for extended periods during the winter months. In the interior zone, the growing season extends 200 to 250 days.

The maritime zone. The maritime orientation of the Shantung Peninsula tends to modify the climatic extremes of the inland zone. The northern half of the peninsula is subject to winter snow and rainstorms and to extensive coastal ice from the mouth of the Huang Ho to Wei-hai and Chefoo (Yen-t'ai); the southern half is somewhat warmer. Mean January temperatures range from 25° F (−4° C) on the northern coast of the peninsula to 32° F (0° C) in the south. Northwest winds pick up moisture as they pass over the Gulf of Chihli and deposit snow on north-facing slopes. There is less temperature differential during the hot summer months when the mean July temperature is 79° F (26° C), but the ports of Chefoo and Tsingtao are cooler than interior stations. Maximum summer temperature in these ports rarely exceeds 77° F (25° C).

Sea fog is common along the north and south coasts of the peninsula, with an average of eight fogbound days in February at Wei-hai increasing to 15 to 20 days during June and July. Because of the high relative humidity, annual mean precipitation over the peninsula reaches 31 inches, with less seasonal contrast than in the interior of the province. Heaviest precipitation occurs on the south-facing slopes of the central and peninsular hill masses. Spring droughts on the peninsula are also less common because of the high relative humidity.

Vegetation and animal life. *Plant life.* The limited natural vegetation that remains in the intensively cultivated inland zone of Shantung is found in minor depressions in the flat, alluvial landscape. Species there included reeds, grassy legumes, and several varieties of shrubs, notably tamarisk. Halophytic (salt-tolerant) vegetation is common in alkaline and saline soil areas along the coasts of the Gulf of Chihli and southern Shantung near the Kiangsu border. Many of the halophytic shrubs are har-

vested for fuel and are used for salt manufacture. *Lien-liu*, a shrub with long willowy branches, is used for basket weaving, while other plants are woven into thatch matings and sunshades. Poplar, pine, and arbor vitae (an aromatic evergreen tree of the cypress family) are planted around settlements, along roads, and on the coasts to deter the movement of sand dunes.

The mountainous zones of Shantung are almost completely deforested, with only 2 percent of the area covered by scattered deciduous and coniferous forests interspersed among barren, eroded hills. Residual coniferous forests are found on higher foothills and mountain slopes, while deciduous trees appear on the lowest hills and on fan-shaped heaps of alluvial detritus at the base of mountains. Several types of pine grow at higher elevations on rocky, shallow soils in association with Alpine meadow species. On the lower slopes and in the valleys, mixed oak, elm, cedar, linden, ash, maple, and chestnut forests appear along with such economically important fruit trees as apple, pear, apricot, and peach. Other deciduous species found at the lower elevations include the pagoda, or "Chinese scholar's tree," the white mulberry, Persian walnut, the silk tree, and the acacia.

For centuries Shantung forests were overharvested for fuel and timber, and natural regeneration became extremely difficult. With a long dry season young trees had difficulty becoming established, and heavy summer rains eroded the thin soil cover. Since 1949, reforestation and closer regulation of timber harvesting has resulted in more extensive growth.

Despite the obliteration of much of Shantung's natural vegetation cover, the peninsular zone still exhibits an interesting mixture of northern and southern vegetation. Along with common northern plants, uniquely southern varieties, such as wingnut, magnolia, and styrax, are common.

Animal life. Through long periods of human settlement, intensive cultivation, and destruction of forests, animal life has suffered drastic declines. Animals include roe deer and field and harvest mice; birds include mandarin ducks, dollar birds (belonging to the roller group), and large owls. Even with recent attempts at reforestation, formerly extensive populations of native birds and mammals have almost vanished. Species of insects, beetles, and moths, however, are still unusually diverse and varied.

POPULATION

Shantung's population is predominantly Northern Mandarin-speaking and of Han Chinese origin, but there are small concentrations of Hui (Chinese Muslims) in Tsinan, the capital, in Chou-ts'un (just west of Tzu-po), and in Chi-ning and Lin-ch'ing (trading centres on the Grand Canal in western Shantung near the Hopeh border). The population, over 90 percent rural, is fairly evenly distributed over the level, cultivated areas of the province.

Urban settlement. The two largest cities are Tsingtao and Tsinan, with estimated populations of 2,000,000 and 1,000,000, respectively, followed by the Tzu-po conurbation, a leading mining and industrial zone at the northern edge of the central hill mass, about 20 miles east of Tsinan, with a combined population of over 800,000. Tzu-po includes the important mining, glass and pottery centre of Po-shan and the smaller towns of Chang-chou, Tzu-ch'eng, Hung-shan, Lu-chia-chuang, Po-t'ou, and Nan-ting. Other cities with populations of between 100,000 and 500,000 include: Chefoo and Wei-hai, ports and fishing centres on the northeast coast of the Shantung Peninsula; Wei-fang, an industrial and commercial town on the central Chiao-lai Plain; and Hsin-t'ai, another mining town south of Po-shan. Smaller cities with populations of from 50,000 to 100,000 include I-tu, a transport junction between Tzu-po and Wei-fang; Yen-chou, a rail centre in the southwest; and Chi-ning. **Te-chou**, a minor industrial town on the Grand Canal, north of Lin-ch'ing; T'ai-an, in central Shantung at the base of Mt. Tai; and Ho-tse, a rail junction and special district (*chuan-ch'ü*) seat in the southwest, all have populations of 30,000 to 50,000 persons.

Rural settlement. The greatest rural population densities are found in three areas: The first is one of the earliest settled places in the province where irrigation works were constructed as long ago as the Han dynasty (206 BC–220 AD); it lies along the foothills of the central hill mass, bounded by Tsinan on the northwest, T'ai-an on the southwest, and I-tu to the northeast. The second, the southwestern Ho-tse–Ting-t'ao–Chi-ning area, is bounded on the northwest by the Huang Ho and on the southwest by the former course of the Huang Ho. This area was frequently subject to flood, but because of its fertility and level terrain gradually became densely settled. The third area constitutes a fertile, irrigated strip along the north coast of the Shantung Peninsula between I-hsien and Lung-k'ou; this was a major zone of emigration during the 1920s and 1930s when Shantung farmers left to settle in Manchuria.

Before 1949, Shantung was seriously affected by an imbalance in the ratio of population to land. With 95 percent of the population engaged in agriculture, the per capita holdings were extremely small. Since 1949, the government of the People's Republic has encouraged the emigration of Shantung farmers to the Manchurian and to other underpopulated regions, such as the Sinkiang Uighur Autonomous Region in the northwest.

ADMINISTRATION AND SOCIAL WELFARE

Government. Shantung is divided into nine special districts (*chuan-ch'ü*) and four municipalities (*shih*) directly under provincial administration. At the lowest administrative level there are 107 counties (*hsien*) and five smaller cities (also designated *shih*) administered by the county. Although the total number of counties has not changed since the 1930s, local adjustments in the area and number of the counties were made in connection with the establishment of the special districts by the People's government after 1949. The special districts, while never officially acknowledged in the 1954 Constitution of the People's Republic of China, have facilitated major improvements in administrative efficiency and control and play an important role in the process of administrative streamlining leading to implementation of central government directives at the provincial and subprovincial levels. The Shantung Provincial Revolutionary Committee, the chief provincial administrative body, was established in 1967.

Rural people's communes, made up of production teams and production brigades, serve as the lowest level administrative units. In many special districts, county seats operate as coordinating centres for the production and distribution of agricultural and industrial commodities produced in the communes under their administrative jurisdiction. In most of the agricultural areas of Shantung, the communes are spatially coterminous with the pre-1949 townships (*hsiang*) and function economically as natural marketing areas.

Social conditions. Before 1949, Shantung was a particularly hard-pressed area because of the pressure of population on the land; because of the common occurrence, especially since the later half of the 19th century, of such natural hazards as floods, droughts, dust storms, excessive soil salinization and alkalization, and insect infestations; and because of frequent military and civil disturbances. Few serious attempts had ever been made by officials of either the Ch'ing (Manchu) dynasty (1644–1911) or, later, by the Republic of China to ameliorate the difficult social conditions of the peasant population. With the exception of missionary financed and controlled undertakings in areas under foreign influence or administration, such as Tsingtao, Chefoo, and Tsinan, modern intensive health-care facilities were virtually nonexistent, and there was only token support for public higher education. Water supplies, environmental sanitation facilities, and public housing were similarly inadequate to the needs of the populace, and public health services were neglected and understaffed.

Public health and recreation. Since 1949, the public health services in both rural and urban areas have been improved, and formerly common ailments such as kala

azar, (a severe infectious disease transmitted by the sand fly), leprosy, and a variety of nutritional deficiency diseases have been eliminated. Most large and medium cities now have adequate water-supply systems, often built in conjunction with multi-purpose water conservancy schemes to improve and stabilize the watersheds of nearby rivers. Near Tsingtao the watershed storage facilities of the Chang-ts'un and Yuan-t'ou rivers have been enlarged, and the Lao-shan reservoir northeast of the city furnishes an ample supply of potable water. Similarly, in T'ai-an, central Shantung, a modern high-pressure water system has been installed and is coordinated with the Huang-ch'ien reservoir outside the city. Along with water supply, the construction of sewage treatment facilities in many cities has also helped raise public-health standards.

Not only has extensive tree planting enhanced the beauty of most Shantung cities, but "turning green" has been officially designated as a primary task of urban reconstruction in order to ameliorate the effects of harsh climates and to improve health conditions. In Tsingtao alone, some 4,000,000 trees were planted from 1949 to 1959; while in Tsinan, a green belt has been built on the site of some dilapidated sections of the ancient city wall. Along with urban reforestation, recreational facilities have been expanded, improved, and made readily available for public use. Many famous temples, hot springs, shrines, parks, lakes, and museums are frequented by the populace. In Tsinan, a city famous for its 72 hot springs where, for centuries, poets, scholars, and officials enjoyed diverse pleasures, several new parks have been built and old buildings restored. Tsingtao, known as the most pleasant beach resort in North China, is also famous for its parks. Ten public parks are complemented by six large beaches. The city is also famous for its workers' convalescent facilities and recreation clubs near picturesque Lao Shan.

Education. Most of Shantung's institutions of higher education are located in the provincial capital, Tsinan, with smaller or special-purpose schools scattered widely throughout the province. Among those in Tsinan are the Shantung Medical College, and the Shantung Institute of Technology. Shantung University is in Tsingtao. The Shantung Provincial Museum and Shantung Library are located in Tsinan. A small teachers' training college and a water-conservancy institute are located in Ch'ü-fu, a county seat in the Chi-ning special district, which is most famous as the ancestral home of Confucius and his lineal descendants, the Kungs. Facilities for primary and secondary education throughout the province have also been expanded and improved.

THE ECONOMY

Shantung has a diversified agricultural and industrial economy. With the highest ratio (more than 60 percent) of cultivated to available arable land of any Chinese province, a broad range of food and cash crops are grown for internal consumption and export to other provinces and overseas. The province's industrial base has been expanded since the establishment of the People's Republic of China in 1949. Before World War II, light industrial enterprises in Tsinan and Tsingtao produced limited quantities of machine tools, electrical components, textile products, processed foods, and alcoholic beverages—primarily for export overseas, mainly in response to foreign commercial initiative. Despite the fact that the province often suffered a food deficit, agricultural products, such as vegetable oil, cotton, peanuts, and tobacco, were continuously exported along with salt, coal, iron ore, and bauxite.

Since 1949, relatively greater emphasis has been given to the development of industry and mining at the expense of agriculture, although the absolute overall level of agricultural output continues to rise, attributed, in part, to increased mechanization. By 1960, Shantung also had 18 state farms—ten arable (crop raising) and eight livestock.

Agriculture. The leading food crops—wheat, soybeans, kaoliang (grain sorghum), spiked millet, corn (maize), and sweet potatoes—account for 90 percent of

Multi-purpose systems of water supply

Higher education complex in Tsinan

The special districts and people's communes

the total cultivated acreage of the province. The remaining arable land is given over to cash crops, chiefly cotton, peanuts, tobacco, and fruit. More than 30 to 40 percent of the food crop acreage is planted to wheat, followed by soybeans (15 to 20 percent), kaoliang and spiked millet (sharing about 10 percent), and corn and sweet potatoes (10 to 15 percent).

Principal cash crops

The cash crops are grown on only 10 percent of the province's cultivable land, yet contribute substantially to agricultural earnings. Cotton, a leading cash crop, is grown throughout the province but is concentrated in the western and northern sections on the intensively irrigated lands near the mouth of the Huang Ho.

Shantung's other major cash crop, peanuts, is grown over approximately the same number of acres as cotton, but its cultivation is centred in the peninsular uplands and in the south central sector. The large variety of peanuts grown in Shantung is especially well suited for oil pressing, and Shantung is a leading manufacturer of peanut oil for cooking. Shantung's average annual peanut crop amounts to between one-third and one-half of the total national output, and some of the crop is exported.

Other cash crops include tobacco, grown chiefly on irrigated land in the vicinity of I-tu and Wei-fang; hemp, produced on low ground in the southwest; and fruit, grown on the lower slopes of the central and peninsular hill masses. Common fruits include peaches, pears, apricots, apples, grapes, persimmons, and dates.

Animal husbandry plays an important role. The most common animals are yellow oxen and donkeys. Both are used as draft animals, with oxen more prevalent in the level areas in the north and west and donkeys in the uplands. Some sheep are also raised in the uplands.

Sericulture (silkworm raising), another important subsidiary activity, has been carried out in Shantung for hundreds of years. The popular fabric known as shantung was originally a rough-textured tussah, or wild silk, cloth made in the province. Silkworm raising is most common in the central hills near I-tu, Lin-ch'ii, Tzu-ch'uan, and Lai-wu, and most of the raw silk is sent to other provinces for processing and spinning.

Irrigation and flood control

Irrigation and flood control are crucial to the success of Shantung's agricultural economy and the province was one of the first to put irrigation districts (after 1958) under commune control. Before World War II, only 3 percent of the province's cultivable land was irrigated, with major irrigation works being situated throughout the level zones north and west of the central hill mass, and on the peninsular north coastal plain. The irrigated areas have been continuously expanded since 1949, and by the early 1970s more than 90 percent of the cultivable and sown acreage of the province was irrigated. Irrigation water is derived chiefly from wells, although much effort also has been given to the construction of multipurpose flood control and irrigation systems associated with the natural watersheds of rivers. The most extensive projects have been carried out on the Hsiao-ch'ing Ho system south of the Huang Ho near Tsinan and Tzu-po Shih. Canals, dikes, and retention dams have been built and riverbeds widened and straightened.

Fishing. Shantung's seaward orientation and its excellent harbours, as well as the convergence of cold and warm currents in offshore waters, have fostered a thriving ocean fishing industry, complemented by the intensive development of pisciculture in the province's western lake region. Trawlers and smaller fishing craft operate from more than 70 ports around the peninsula and off the Huang Ho delta. The leading ports, by tonnage of fish landed, are Tsingtao, Chefoo, Wei-hai, Shih-tao, and Lung-k'ou. Annual fish production comes to more than 600,000 tons—second only to Kwangtung Province. The ocean catch, amounting to nearly 90 percent of the annual total, consists mainly of eels, herring, gizzard-shad, fish roe, and several varieties of shrimp and crab. Freshwater varieties raised artificially are chiefly carp and crucian carp.

Minerals and mining. Shantung's industrial base is supported by extensive mining activities. Coal mines were originally developed by German concessionaires

between 1898 and 1915. The annual production capacity of one of the earliest and largest coal-mining complexes, Po-shan (part of Tzu-po Shih), approaches 6,000,000 tons, or nearly 70 percent of the province's total. Other pre-1949 mining sites, since enlarged, include Chai-wang, south of Tsao-chuang, near the Kiangsü border; and T'ao-chuang, in the south central hills north of Chi-ning. Newly developed mines, largely mechanized, are at Chiung-ch'eng, at the tip of the peninsula; Hsin-wen (Sun-ts'un), in the central hills south of Tzu-po; and Fei-ch'eng, west of T'ai-an also in the central hills.

Major iron-ore deposits are located north of Tzu-po at Chin-ling-chen, with reserves estimated at 100,000,000 tons; minor deposits are found near Tsao-chuang and Tsingtao. Some bauxite is mined near Tzu-po Shih (Nan-ting), and gold is scattered throughout the peninsular hills. One major oil field is in operation at Sheng-li, in the Huang Ho delta region north of Tzu-po.

Edible salt is produced on both the north and south coasts of the Shantung Peninsula. Production from the largest field, along the shores of Chiaio-chou Wan near Tsingtao, accounts for over three-fifths of the province's total. Salt, formerly exported in large quantities to Japan, is largely consumed domestically.

Industry. The province is still especially well-known for its light industrial products, despite post-1949 gains in heavy industry. The leading manufacturing centres, accounting for nearly 80 percent of the province's total industrial output, are Tsingtao, Tsinan, Tzu-po, and Wei-fang, all situated along the Tsinan-Tsingtao railway and all but Wei-fang with major thermal electric installations.

Tsingtao, the major manufacturing centre, has a large textile industry—five-sixths of the province's total plants—a locomotive works, industrial chemical, tire, and machine-tool factories. Pre-World War II oil pressing (peanut oil), cigarette making, flour milling, brewing, and beverage distilling installations are still important. Tsinan—long famous for its silks, precious stones, handicrafts, munitions, flour, and electrical components—now also manufactures trucks, agricultural machinery, machine tools, precision instruments, industrial chemicals, chemical fertilizers, paper, and textiles. Tzu-po produces glass, porcelain and ceramics, silk and textiles; while Wei-fang is an important food-processing centre, and has metal-processing and textile factories. Other, secondary industrial centres include Nan-ting, Hsin-t'ai-hsien, Hanchuang, Tsao-chuang, I-hsien, Tung-liang-chuang, and Chefoo.

Some of Shantung's better known handicraft goods are embroidered tablecloths from Chefoo and Lin-tzu (east of Tzu-po), straw braids for hat weaving from P'ing-tu (east of Wei-fang), poplins, pottery, and ceramics.

Transportation and communications. Shantung's first railways were built in the first decade of the 20th century during the time of the German concession. One of the lines traverses the province from north to south and another east and west, connecting Tsingtao and Tsinan. Since 1949 new lines have been built, and some sections of the existing routes converted to double track. A major new trunk line was completed in 1956, from Tsingtao north to Chefoo. The province has a total of 518 miles of rail trunk lines and 90 miles of branch lines.

Shantung's highways connect every district in the province, but most of them have earthen surfaces and are used either for short-haul transport or as feeder routes for the three major railways. Of the roughly 6,000 miles of roads in the province, only about a quarter are suitable for all-weather use. Nevertheless, truck traffic accounts for more than 60 percent of the total annual vehicular movement over Shantung's highways, as compared with only 20 percent (estimated) in other North China provinces.

Except for portions of the Huang Ho and of the Hsiao-ch'ing Ho in northern Shantung, part of the Grand Canal in the west, and the I Ho in the southeast, inland-waterway transport is limited. The chief route—for shallow-draft craft only—extends upstream from Li-chin, about 50 miles inland from the mouth of the Huang Ho, for about 125 miles to Ch'i-ho, the main Huang Ho river

Light industry and handicrafts

Limited use of inland waterways

port in Shantung and just northwest of Tsinan. The Grand Canal is navigable only to a limited extent south of the Huang Ho.

Shantung has a number of excellent seaports. Tsingtao, the largest in tonnage handled, can berth vessels of more than 10,000 deadweight tons at its piers. On the north coast of the peninsula, Chefoo, Wei-hai, and Lung-k'ou can handle vessels up to 6,000 tons. Coastal shipping also plays an important role in Shantung's economy. Tsingtao alone handles over a third of the province's intraprovince trade. Goods transshipped at Tsingtao for coastal distribution within Shantung include cotton cloth, coal, general cargo, and fertilizer. Salt, tobacco, chemicals, coal, processed foods, and sea products are shipped southward along the China coast as far as Foochow and Swatow, as well as to points along the Gulf of Liaotung and the Liaotung Peninsula to the north. Trade between Tsingtao and Shanghai and Tsingtao and Dairen (Lii-ta) is particularly heavy.

CULTURAL LIFE AND INSTITUTIONS

Shantung's rich cultural and folklore tradition is most clearly evidenced in the temples, shrines, legends, and cults associated with T'ai Shan (Mt. T'ai) and with the temple and tomb of Confucius at Ch'ü-fu, north of Chining. Since 1949, despite official disavowal of their religious, parareligious, animistic, and superstitious connotations, the temples, shrines, and their surrounding areas have been restored, renovated, and converted to public parks so as to assure their preservation as important symbols of the national cultural heritage. T'ai Shan—known also as *tung-yüeh*, or "Eastern Peak," to distinguish it from the "Southern Peak" (in Hunan); the "Central Peak" (Honan); the "Western Peak" (Shensi); and the "Northern Peak" (Shansi)—is the most prominent of these five sacred mountains where the emperors once offered sacrifices to Heaven and Earth. It was also the place where for centuries Buddhists, Taoists, and Confucianists built more than 250 temples and monuments to honour deified historical personages and to immortalize the sacred presence and supernatural powers of the supreme mountain deity, the T'ai Shan. The mountain rises precipitously to a height of 5,069 feet (1,545 metres); as the highest peak in the central Shantung hill mass, it affords spectacular views of the surrounding areas from its summit. The mountain was deified at least as early as Han times (2nd century BC–2nd century AD), and in the Sung dynasty it was elevated by the emperor, Chen-tsung, to the position of "Equal with Heaven." Incantations and prayers offered to the T'ai Shan deity by countless emperors are inscribed in steles along the ascent to the summit, and the temples are distributed in T'ai-an and on the mountain itself. T'ai Shan was also thought to be the gathering place for souls of deceased persons.

The Temple of Confucius, Confucius' tomb, and the residence of the Kungs (Confucius' lineal descendants) at Ch'ü-fu are also maintained as national historic monuments. Both the temple and the Kung residence are laid out with elaborate temples, monuments, pavilions, and gates, and have collections of steles dating, in some cases from the Han dynasty.

There are no television stations in the province but there are several theatres and cinemas in Tsiman. Tsingtao has a municipal museum, as well as a Marine Products Museum.

BIBLIOGRAPHY. Sources of information on Shantung are given in the bibliography of the article SHANSI.

(B.Bo.)

Shāpūr II of Persia

Shāpūr (reigned AD 309–379) was tenth in the long line of the "kings of kings" who ruled the Sāsānian Empire of Persia (Iran). A general who personally led vast armies in battle, he was a remarkable tactician and a consummate politician who succeeded in spreading dissension among his enemies. Though usually merciful and just, he was savage in his persecution of Christians and unfeeling

in the enslavement and forced resettlement of prisoners of war in Persia. But in those few words of his own that have survived, he speaks of his virtuous conduct and of his clear conscience. Shāpūr's unflinching devotion to the empire brought it to the zenith of its power and glory.

Shāpūr II, gold coin, 4th century. In the British Museum.

BY courtesy of the trustees of the British Museum; photograph, J.R. Freeman & Co. Ltd.

The name Shiipiir, "son of a king," was common in the Sāsānian period and was often given to sons other than princes. Numerical designations were not used to distinguish kings of the same name; instead, the family genealogy was cited. Thus, in one inscription, Shāpūr styles himself,

the Mazdāh-worshipping god Shāpūr, king of kings of Iran and non-Iran, who is a scion of the Gods, the son of Hormizd (Ormizd II), the grandson of Narses.

According to tradition, he was a posthumous child proclaimed king by the Persian nobility at his birth in 309, in preference to his brothers. After a regency, he apparently took the realm into his own hands in 325 at the age of 16.

A contemporary account describes his appearance and courage in battle:

And he himself, mounted on his charger, and being taller than the rest, led his whole army, wearing instead of a crown a golden figure of a ram's head inlaid with jewels; being also splendid from the retinue of men of high rank and of different nations which followed him . . . He rode up to the gates [of Amida]; escorted by the cohort of his royal guard; and while pushing on more boldly, so that his very features might be plainly recognized, his ornaments made him such a mark for arrows and other missiles, that he would have been slain, if the dust had not hindered the sight of those who were shooting at him; so that after a part of his robe had been cut off by a blow of a javelin, he escaped to cause vast slaughter at a future time.

In 337 Shāpūr sent his forces across the Tigris River, the uneasy frontier, to recover Armenia and Mesopotamia, which his predecessors had lost to the Romans. Until 350 conflict raged in northern Mesopotamia, with neither side a clear-cut victor. Shortly after 337, Shāpūr took an important policy decision. Although the state religion of the Sāsānian Empire was Mazdaism (Zoroastrianism), Christianity flourished within its boundaries. The Roman emperor Constantine the Great had granted toleration to Christians in 313. With the subsequent Christianization of the empire, Shiipiir, mistrustful of a potential force of a fifth column at home while he was engaged abroad, ordered the persecution and forcible conversion of the Christians; this policy was in force throughout his reign.

In 358 he was ready for a second encounter with Rome and sent an ambassador to the emperor Constantius II, bearing presents and a letter wrapped in white silk. This letter read, in part,

I Sapor, king of kings, partner of the stars, brother of the sun and the moon, to Constantius Caesar my brother send much greeting. . . . Because . . . the language of truth ought to be unrestrained and free, and because men in the highest rank ought only to say what they mean, I will reduce my propositions into a few words . . . Even your own ancient records bear witness that my ancestors possessed all the country up to the Strymon and the frontier of Macedonia. And these lands it is fitting that I who (not to speak arro-

Temples
and
shrines

Persecu-
tion of
Christians

gantly) am superior to those ancient kings in magnificence, and in all eminent virtues, should now reclaim. But I am at all times thoughtful to remember that, from my earliest youth, I have never done anything to repent of.

When Constantius politely refused to hand over these lands, Shāpūr marched into northern Mesopotamia, this time with marked success. In 363, however, the emperor Julian led a huge army into Persia, creating havoc and advancing to the very gates of Ctesiphon on the Tigris, a major Sāsānian city. Julian was mortally wounded in a skirmish, and his successor, Jovian, was compelled to accept an ignominious 30 years' truce and surrender of five Roman provinces.

Shāpūr then turned his attention to the subjugation of Armenia. He defeated its pro-Roman ruler and attempted to force Zoroastrianism on the country. The Romans, however, regained their influence in Armenia, and a precarious balance between Romans and Persians existed from about 374. For five years, Armenia was weakened by internecine strife, and one of Shapur's last acts was to win it over by discreet gifts. Shāpūr's death in 379 left Persia with its territory considerably augmented: he had pacified the eastern frontier and gained control over Armenia; the Persian Empire had never been stronger. But war with Rome had become habitual and eventually undermined the strength of the Sāsānians.

As did the other great rulers of his line, Shāpūr considered himself an heir of the great Achaemenid Empire and strove to renew its glory. Indeed, his letter to Constantius contains a distant echo of the wording of the inscriptions of Darius I the Great, the Achaemenid ruler, when he writes of his devotion to truth and righteousness. Shāpūr was called a god, and he lived up to this exalted status, becoming irascible, even violent, when individuals summoned to his presence appeared to pay insufficient respect to his awesome majesty.

The figure of Shapur survives. A large silver plate has a scene in relief that shows him hunting lions with bow and arrow, and countless silver coins portray his face in profile. At Bishāpūr in southwestern Iran, a tremendous rock-cut relief depicts him seated on a throne and witnessing a triumph of his army: in the top row he is flanked by nobles of the court, and the lower row contains soldiers who present captives and trophies of victory.

BIBLIOGRAPHY. *The Roman History of Ammianus Marcellinus During the Reigns of the Emperors Constantius, Julian, Jovianus, Valentinian, and Valens*, trans. by C.D. YONGE (1902), is a detailed, often fascinating, account of Rome's wars against major enemies. The information on those with the Sāsānian Empire is not duplicated by any other source. SIR PERCY SYKES, *A History of Persia*, vol. 1 (1915, 3rd ed. reprinted 1958), is a major work, although the facts are not always documented and parts are now outdated (contains an extensive bibliography).

(D.N.W.)

Shaw, George Bernard

The most significant British playwright since the 17th century, George Bernard Shaw was more than merely the best comic dramatist of his time, for some of his greatest works for the stage—*Caesar and Cleopatra*, the "Don Juan in Hell" episode of *Man and Superman*, *Major Barbara*, *Heartbreak House*, and *Saint Joan*—have a high seriousness and prose beauty unmatched by his stage contemporaries. A visionary and mystic whose philosophy of moral passion permeates his plays, Shaw was also the most trenchant pamphleteer since Swift; the most readable music critic in English; the best theatre critic of his generation; a prodigious lecturer and essayist on politics, economics, and sociological subjects; and the most prolific letter writer in literature. Impudent and irreverent, always a showman, he used his buoyant "Shavian" wit to keep himself in the public eye to the end of his 94 years; his wiry figure, bristling beard, and dandyish cane were as well-known throughout the world as his plays.

Early life and career. George Bernard Shaw was born on July 26, 1856, in Dublin, the third and youngest child (and only son) of George Carr Shaw and Lucinda Elizabeth Gurly Shaw. Technically, he belonged to the Protes-

tant "ascendancy"—the landed Irish gentry; but his father (first a sinecured civil servant and then an unsuccessful grain merchant) was too impractical and intemperate to sustain anything more than a "downstart" atmosphere of genteel impecuniosity, which to his son was more humiliating than being born poor. At first tutored by a clerical uncle, Shaw then attended—briefly—both Protestant and Catholic day schools. Before he was 16, he was working in a land agent's office.

Music pervaded the Shaw household. When Shaw was a child his mother turned for consolation not only to music but also to her music teacher, George John Vandeleur Lee, a mesmeric figure in Irish music circles, who, by 1866, shared households in Dublin with the Shaws. When his mother and sisters left his father in Dublin and followed Lee to London in 1875, young Shaw followed the next year.

Shaw in his 20s suffered continuous frustration and poverty. For a brief period, he produced ghost-written musical criticism for Lee, and from late 1879 to mid-1880, he worked for the Edison Telephone Company of London. It was his last non-literary employment. Living with his mother and elder sister Lucy (Agnes, his other sister, had died in 1876), he depended upon their pound a week from a family bequest and his mother's earnings as a music teacher. He spent his afternoons in the British Museum reading room, writing novels and reading what he had missed at school, and his evenings in search of additional self-education in the lectures and debates that characterized middle-class London intellectual ferment.

His fiction failed utterly. The semi-autobiographical and aptly titled *Immaturity* (1879; published 1930) repelled every publisher in London. His next four novels, similarly refused, soon padded propagandist magazines edited by Shaw's Socialist friends. Shaw later pronounced *The Irrational Knot* a forerunner of the dramatist Henrik Ibsen, of whom he had not yet heard, for the hero marries at the beginning and abandons his wife at the end. With his halthearted attempts at job hunting still fruitless, he began *Love Among the Artists*, in which the neglect of "a British Beethoven" among dilettantes and mediocrities reflected Shaw's passionate belief in his own talents and his bitterness at being thwarted; midway through the manuscript he was stricken during the 1881 smallpox outbreak in London, but he stubbornly completed the unsalable novel. The following year he began another novel, *Cashel Byron's Profession*. Its exuberance belied Shaw's lack of success, and its core ("immoral" and "retrograde" professions—in this case, prizefighting—as an indictment of society) anticipated such early plays as *Mrs. Warren's*

Failure
at fiction

Profession. (In 1901 he satirized this novel in a burlesque Elizabethan blank-verse adaptation. *The Admirable Bashville* [performed 1902].) The Socialism in *Cashel Byron* had been an afterthought, most of it inserted for its magazine appearance after a lecture in 1882 by the U.S. economist Henry George spurred Shaw to a reading of Marx. The new gospel was also the stimulus for his last novel, *An Unsocial Socialist*, which broke down under the weight of its incongruities, among them a runaway husband, a finishing school for girls, and ponderous paraphrases from Marx's *Capital*. A fragment posthumously published as *An Unfinished Novel* in 1958 (but written 1887-88) was his final false start in fiction (but for a 1932 *Candide*-like novella, *The Adventures of the Black Girl in Her Search for God*).

Despite his failure as a novelist in the 1880s, Shaw found himself during this decade. He became a vegetarian, a Socialist, a spellbinding orator, a polemicist, even tentatively a playwright. He became the force behind the newly founded (1884) Fabian Society, a middle class Socialist group that aimed at the transformation of English society not through revolution but through "permeation" (in Sidney Webb's term) of the nation's intellectual and political life. Shaw involved himself in every aspect of its activities, most visibly as editor of one of the classics of British Socialism, *Fabian Essays in Socialism* (1889), to which he also contributed two sections.

A pamphleteer and platform speaker of rare dialectical skill, he spoke to crowds of any size, often as frequently as three times a week, and always without compensation. The experience forged the forceful prose of his missionary books *The Quintessence of Ibsenism* (1891, 1913) and *The Perfect Wagnerite*—on behalf of Ibsen and the composer Richard Wagner, respectively—and *The Common Sense of Municipal Trading*—the result of his years, from 1897 to 1903, as vestryman and borough councillor of St. Pancras Parish, London. His early journalism ranged from bread-and-butter book reviews in the *Pall Mall Gazette* (1885-88) and art criticism in the *World* (1886-89) to brilliant (and often brilliantly digressive) musical columns in the *Star* (as "Corno di Bassetto"—basset horn) from 1888 to 1890 and in the *World* (as "G.B.S.") from 1890 to 1894. With passionate objectivity (but for his Wagnerism), he scorned mediocrity and applauded excellence in a manner consistent with his contention that the true critic "is the man who becomes your personal enemy on the sole provocation of a bad performance, and will only be appeased by good performances." Recruited by Frank Harris to the *Saturday Review* as theatre critic (1895-98), he campaigned there to displace the artificialities and hypocrisies of the Victorian stage (Shaw called them "Sardoodledom"—an allusion to the prolific French dramatist Victorien Sardou) with a theatre of vital ideas.

First plays. With the "New Drama" in England little more than "a figment of the revolutionary imagination," Shaw determined that since "I had rashly taken up the case . . . rather than let it collapse I manufactured the evidence." That effort became his primary activity during the 1890s. Shaw began his first major experiment as playwright in 1884, when the critic William Archer suggested a collaboration (Archer to supply the plot, Shaw, the dialogue). Eight years later, in 1892, Shaw completed the abortive drama on his own; *Widowers' Houses* had two performances and created a newspaper sensation. Combining Ibsen, Socialism, and slum landlordism, it flouted the threadbare romantic conventions that were still being exploited, even by the most daring new playwrights.

Next, unafraid to satirize himself, Shaw in *The Philanderer* invented an "Ibsen Club" and even ridiculed the socially emancipated "New Woman," thereby mocking two new movements he championed. No one would produce the play, but Shaw, undeterred, began the sardonic *Mrs. Warren's Profession*. The lord chamberlain, as the censor of plays, refused it a license although its ostensible subject—prostitution—was treated remorselessly and without the titillation of fashionable comedies about "fallen women."

Shaw's first volume of collected plays, *Plays, Pleasant*

and *Unpleasant*, was published in 1898. Labelling the first three "unpleasant," Shaw explained that "their dramatic power is used to force the spectator to face unpleasant facts." The "pleasant" plays were Shaw's attempt to find the producers and audiences that his mordant comedies put off. "To me," he explained, "[both] the tragedy and comedy of life lies in the consequences, sometimes terrible, sometimes ludicrous, of our persistent attempts to found our institutions on the ideals suggested to our imaginations by our half-satisfied passions, instead of on a genuinely scientific natural history." *Arms and the Man*, in a spoof-Balkan setting, satirized romantic falsifications of love, war, and upward mobility and was itself romanticized (unauthorized by Shaw) in the Oscar Straus operetta *Der tapfere Soldat* (1908), translated as *The Chocolate Soldier* (1909). In *Candida*, the wife—who represents herself in a tour de force "auction scene" as being compelled to choose between her clergyman husband (a well-meaning Christian Socialist) and an immature young poet—chooses her stuffy husband, while the interloper renounces what Shaw later called "the small beer of domestic happiness" for the larger creative purpose he senses within himself. The two other "pleasant" plays were of lighter weight. The one-act *Man of Destiny*, about Napoleon I, was described by Shaw as merely "a bravura piece to display the virtuosity of two performers"; his antidote to the "older, coarser Napoleon" of previous plays, it was his first study in greatness.

The strain of writing these plays, while his critical and political work went on unabated, so sapped his strength that a minor illness became a major one. In 1898, during the process of recuperation, he married his unofficial nurse, Charlotte Payne-Townshend, an Irish heiress and friend of Beatrice and Sidney Webb. The apparently celibate marriage lasted all their lives, Shaw having satisfied his sexual needs in premarital affairs with an aggressive widow and several actresses, and his later emotional requisites in paper-passion correspondences with Ellen Terry, Mrs. Patrick Campbell, and others.

Shaw's next collection, *Three Plays for Puritans* (1901), continued what became the traditional Shavian preface—an introductory essay in an electric prose style dealing as much with the themes suggested by the plays as the plays themselves. The texts, made available to the wider reading public for many of whom the plays were inaccessible even when produced, included—a Shaw innovation—stage directions and descriptions in narrative form rather than in the brevity of directorial jargon. In *The Devil's Disciple*—a play set in New Hampshire during the American Revolution and written as an inversion of traditional melodrama—Dick Dudgeon, the black sheep of his family (because he rejects Puritan masochism and hypocrisy), heroically substitutes for a rebel minister condemned to the gallows, acting spontaneously out of some instinctive imperative. As with Caesar and similar Shavian protagonists, virtue is a quality, not an achievement.

In his preface to *Caesar and Cleopatra*, Shaw lays down the challenge "Better than Shakespear?" but evades it by dramatizing a 16-year-old Cleopatra rather than the 38-year-old temptress of Shakespeare's *Antony and Cleopatra*. In addition, Shaw's Caesar in Egypt has not yet been enticed into the domestic demagoguery against which Brutus reacts in Shakespeare's *Julius Caesar*. Shaw's feline Cleopatra, however, is a logical precursor to Shakespeare's; and his Caesar, as much philosopher as soldier in this mentor-disciple play, is meant to be a study in credible magnanimity and "original morality" rather than a superhuman hero on a stage pedestal—in Shaw's words, a hero "in whom we can recognize our own humanity." In this serio-comic chronicle play, Shaw rises to prose-poetic eloquence and wisdom.

International importance. In *Man and Superman* Shaw took the legend of Don Juan as found in Mozart's opera *Don Giovanni* and made it a dramatic parable prefiguring the philosophy expounded in Henri Bergson's *Creative Evolution* (1907). Shaw described a purposeful and eternal movement toward ever-higher organisms; he

The Shavian preface

Pamphleteer and platform speaker

saw this to be a more satisfactory explanation of the nature of things than "blind" Darwinian evolution and one that restored a sense of divinity to the universe as well. Subtitled "A Comedy and a Philosophy," the play on the surface is a comedy of manners about the relations between the sexes in which a resourceful young woman schemes to capture her man, who is a social philosopher and Socialist propagandist. The action provides the basis for Shaw to explore the intellectual climate of the new century in a series of interlocking debates and discussions. Its nonrealistic third act, the "Don Juan in Hell" dream scene (performed 1907), is often played independently: mythic counterparts to the major characters in *Man and Superman*, including Don Juan and the devil, play out a dramatic quartet that is spoken theatre at its most operatic.

The eminent poet William Butler Yeats asked Shaw to write a play for the Irish Literary Theatre, Dublin, but when Shaw presented him with *John Bull's Other Island*, Yeats timidly rejected it. Although its politics have dated, the play when performed as a period piece reveals Shaw's perceptiveness about the Irish character, and it remains one of his most amusing comedies. The minor but exquisitely drawn character of the unfrocked priest Father Keegan is one of his earliest explorations of the religious rebel as saint.

Shaw had already become established as a major playwright on the Continent by the performance of his plays there, but, curiously, his reputation lagged in England. It was only with the production of *John Bull* in London, with a special performance for Edward VII, that Shaw's stage reputation was belatedly made in England. He backed the actor-manager Harley Granville-Barker's management of the Royal Court Theatre, not only with his own capital but also with his plays; and in the years of their association (1904–07), Shavian drama reached a seldom-equalled level of performance.

Shaw continued, through high comedy, to explore religious consciousness and to point out society's complicity in its own evils. In *Major Barbara*, Shaw has his heroine, a major in the Salvation Army, discover that her estranged father, a munitions manufacturer, may be a dealer in death but that his principles and practice, however unorthodox, are religious in the highest sense, while those of the Salvation Army require the hypocrisies of often-false public confession and the donations of the distillers and the armourers, against which it inveighs. In *The Doctor's Dilemma*, Shaw produced a comedy with a seriocomic death scene, a satire upon the medical profession (representing the self-protection of professions in general) and upon both the artistic temperament and the public's inability to separate it from the artist's achievement. In *Androcles and the Lion*, Shaw dealt with true and false religious exaltation, combining the traditions of miracle play and Christmas pantomime into a philosophical farce about early Christianity; its central theme, recurrent in Shaw, is that one must have something worth dying for—an end outside oneself—in order to make life worth living. His other plays of the prewar period include self-described pot-boilers, discussion-drama, and serious farce.

Possibly Shaw's comedic masterpiece, and certainly his funniest and most popular play, *Pygmalion*, was claimed by Shaw to be a didactic drama about phonetics, and its anti-heroic hero, Henry Higgins, is a phonetician; however, the play is a humane comedy about love and class, about a Cockney flower girl trained to pass as a lady and the repercussions of the experiment's success. It has been both filmed (1938), winning an Academy Award for Shaw for his screenplay, and adapted into an immensely popular musical, *My Fair Lady* (1956).

Works after World War I. World War I was a watershed for Shaw. At first he ceased writing plays, publishing instead a controversial pamphlet, "Common Sense About the War" (*New Statesman*, supplement, November 14, 1914), which called Britain and its Allies equally culpable with the Germans and argued for negotiation and peace. It made him notorious. Some of his anti-war speeches were erased from history by newspaper censorship, and he was ejected from the Dramatists'

Club, although he was its most distinguished member. Only when the nation was ground down by astronomical casualties and home-front austerities did a more rational attitude toward him prevail. In *Heartbreak House*, Shaw exposed, in a country-house setting on the eve of war, the spiritual bankruptcy of the generation responsible for the bloodshed. Combining discursive high comedy with a new symbolism, he produced a sombre vision owing much in mood to Chekhov's *Cherry Orchard* and, in its patriarchal protagonist, to Shakespeare's *Lear*.

Attempting to keep from falling into "the bottomless pit of an utterly discouraging pessimism," Shaw wrote five linked plays under the collective title *Back to Methuselah*; together they comprise a parable of creative evolution that progresses from the Garden of Eden to AD 31,920. The first of the five plays, *In the Beginning*, through Adam and Eve (and the Serpent) and Cain and Abel, dramatizes the need to have aspirations beyond mere subsistence. (Serpent: "You see things; and say 'Why?' But I dream things that never were; and I say 'Why not?' "). The *Gospel of the Brothers Barnabas*, set just after World War I, indicts the politicians who made the war and suggests that sufficient longevity to learn from experience—perhaps 300 years—might be willed. Two undistinguished characters from the cycle's second play prove to be still alive in *The Thing Happens*, in AD 2170, and longevity has given them wisdom. In *The Tragedy of an Elderly Gentleman*, a survivor from the dwindling race of short-livers confronts the passionless and ascetic long-livers, who possess extraordinary powers over nature, but—to the Gentleman—no soul. And in the last play, *As Far as Thought Can Reach*, humans are born, fully developed, from eggs and after a brief adolescent phase of physical pleasure live lives of contemplative ecstasy achieved through creative use of intellect; and Shaw speculates, in satire ranging from bright to bleak, about the values of escaping from "this machinery of flesh and blood."

The canonization of Joan of Arc in 1920 reawakened within Shaw ideas for a chronicle play about her. The Maid became not only a Catholic saint and martyr but a Shavian one as well, a combination of practical mystic, heretical saint, and inspired genius. Joan, as the superior being (in the Inquisitor's words), "crushed between those mighty forces, the Church and the Law," is the personification of the tragic heroine, but to Shaw classical tragedy was not enough: thus, in the *dream-epilogue*, he moves from satire to litany and transforms the play from a tragedy of inevitability to an embodiment of the paradox that humankind fears—and often kills—its saints and heroes and will go on doing so until the very qualities it fears become the general condition of man. Acclaim for *Saint Joan* resulted in a Shavian apotheosis, including the 1925 Nobel Prize for Literature.

In his last plays Shaw intensified his explorations into tragicomic and nonrealistic symbolism, using an extravagance reminiscent of the comedy of the ancient Greek master Aristophanes; it was designed to explode the verisimilitude Shaw had taken from Ibsen and to remind audiences that these were performances in a theatre. For the next five years, he wrote nothing for the theatre but worked on his collected edition of 1930–38 and the encyclopaedic political tract "The Intelligent Woman's Guide to Socialism and Capitalism" (1928). Then he produced the Platonic "political extravaganza" *The Apple Cart*, a futuristic high comedy that emphasized Shavian inner conflicts between his lifetime of radical politics and his essentially conservative mistrust of the common man's ability to govern himself. His later plays included apocalyptic imagery, warning that 1914–18 was about to be repeated. The deliberately absurd *Too True to Be Good* (performed 1932; published 1934) is a dream-fantasy including a Bunyanesque prophet, a Lawrence of Arabia caricature, and a burglar-turned-preacher who, as the curtain closes upon him, suggests Shaw confronting his own obsolescence. (From their first meeting in 1922 until Lawrence's death in 1935 the Shaws treated the colonel-turned-private—"Private Meek" in the play—as a surrogate son, Lawrence even implicitly acknowledging

the relationship in his legal change of name to T.E. Shaw in 1927.) In *On The Rocks* (performed 1933; published 1934), he predicts the collapse of parliamentary government in a protofascist, depression-ridden England, and in *The Simpleton of the Unexpected Isles* (performed 1935; published 1936), set in a futuristic South Seas, he satirizes a eugenic solution to human problems and ends with a Day of Judgment. In *Geneva* (performed 1938; published 1939; revised 1947), Shaw lampoons the futile League of Nations, and the dictators Hitler, Mussolini, and Franco appear on the stage, thinly disguised; that the despots are treated so lightly suggests that Shaw's flirtation with dictatorships, which arose out of the 1914–18 disillusionment with democracies, was slow in dying, the one with Stalin stubbornly enduring to the end. In *Good King Charles's Golden Days* (performed and published 1939), his last play before World War II, is a throwback to the mood of *The Apple Cart*, a warm yet discursive high comedy in which Charles II, Sir Isaac Newton, Charles James Fox, Nell Gwyn, and luminaries of 17th-century England debate leadership, science, art, and religion; in it Shaw again dwells upon the major preoccupation of his later years: "The riddle of how to choose a ruler is still unanswered," says Charles, "and it is the riddle of civilization."

Late works after World War II. After a wartime hiatus, Shaw, now in his 90s, produced several more plays. In *Farfetched Fables* (performed 1950; published 1951), a farce in six short scenes, Shaw again attempted to see ironically into a timeless future; *Shakes Versus Shav* (performed 1949; published 1951) is a brief puppet play in which the "rival" playwrights confront each other. A last playlet, *Why She Would Not* (published 1956), is a fantasy with only flashes of the earlier Shaw.

When Shaw's wife, Charlotte, died of a lingering illness in 1943, in the midst of World War II, Shaw, frail and feeling the effects of wartime privations, made permanent his retreat from his London apartment to his country home at Ayot St. Lawrence, a Hertfordshire village in which he had lived since 1906. He died there at 94 on November 2, 1950, having continued to write and to maintain the indomitable "G.B.S." persona to the end.

Although Shaw left his estate for research into a 40-letter phonetic alphabet, his residual legatees, the British Museum, the Royal Academy of Dramatic Art, and the National Gallery of Ireland, overturned the will in their favour, settling a token sum for an alphabet competition and publication of *Androcles and the Lion* in the winning system (1962). He also directed the public trustee to publish his work under the name of Bernard Shaw, hoping thus to forever eliminate from his authorized writings the "George" he disliked.

Shaw left no school of playwrights as such. Yet his development of a drama of moral passion and of intellectual conflict and debate, his revivifying the comedy of manners, his ventures into symbolic farce and into a theatre of disbelief helped shape the theatre of his time and after. By bringing a bold critical intelligence to his many other areas of interest, he helped mold the political, economic, and sociological thought of three generations.

MAJOR WORKS

PLAYS AND DRAMATIC PIECES: *Widowers' Houses* (performed 1892, published 1893); *Mrs. Warren's Profession* (performed 1902, published 1898); *Arms and the Man* (performed 1894, published 1898); *Candida* (performed 1897, published 1898); *You Never Can Tell* (performed 1899, published 1898); *The Man of Destiny* (performed 1897, published 1898); *The Philanderer* (performed 1898, published 1898); *The Devil's Disciple* (performed 1897, published 1901); *Caesar and Cleopatra* (performed 1901, published 1901); *Captain Brassbound's Conversion* (performed 1900, published 1901); *Man and Superman* (performed 1905, published 1903); *John Bull's Other Island* (performed 1904, published 1907); *Major Barbara* (performed 1905, published 1907); *The Doctor's Dilemma* (performed 1906, published 1911); *The Shewing-Up of Blanco Posnet* (performed 1909, published 1911); *Getting Married* (performed 1908, published 1911); *Misalliance* (performed 1910, published 1914); *Fanny's First Play* (performed 1911, published 1914); *Overruled* (performed 1912, published 1916); *Androcles and the Lion* (performed 1912, published 1916); *Pygmalion* (per-

formed 1913, published 1916); *Heartbreak House* (performed 1920, published 1919); *Back to Methuselah* (performed 1922, published 1921); *Saint Joan* (performed 1923, published 1924); *The Apple Cart* (performed 1929, published 1930).

OTHER WRITINGS: (POLITICAL): *Fabian Essays in Socialism* (1889); *The Common Sense of Municipal Trading* (1904, 1908); "Common Sense about the War" (1914); "The Intelligent Woman's Guide to Socialism and Capitalism" (1928); "What I Really Wrote About the War" (1931); "Everybody's Political What's What?" (1944). (NOVELS): *An Unsocial Socialist* (serialized in *To-Day* 1884, published as book 1887); *Cashel Byron's Profession* (serialized in *To-Day* 1885–86, published as book 1886); *The Irrational Knot* (serialized in *Our Corner* 1885–87, published as book 1905); *Love Among the Artists* (serialized in *Our Corner* 1887–88, published as book 1900). (MISCELLANEOUS): *The Quintessence of Ibsenism* (1891, 1913); *The Perfect Wagnerite* (1898); *Dramatic Opinions and Essays* (1907); *The Adventures of the Black Girl in Her Search for God* (1932).

Shelley, Percy Bysshe

Shelley was a poet, philosopher, reformer, novelist, and essayist. In a period of great poetry he wrote the greatest lyrical drama, the greatest tragedy, the greatest poem on love, the greatest pastoral elegy, and a body of short and long poems that many believe are unequalled in range of form and style, imagery and symbolism.

He was, however, not merely a man who wrote rapturous poetry. He was an idealist who loved mankind and a philosopher who sought reality and truth through reason and knowledge. He was also a rebel against all forms of wrong, to which he was as sensitive "as a nerve o'er which do creep/The else unfelt oppressions of this earth," a reformer of these evils in politics, religion, and conventional opinions and customs.

EARLY YEARS

Childhood and education. Percy Bysshe Shelley was born on August 4, 1792, at Field Place, the family estate, near the market town of Horsham, in Sussex. He was the eldest son of Timothy Shelley (baronet, 1815), one of the wealthiest of the landed gentry, a Whig member of Parliament, and a follower of the Duke of Norfolk.

Shelley's difference from the common or normal man must not be overlooked. Most people, talented and untalented, have personal oddities and eccentricities. Shelley's difference is far deeper and very important. During a conversation Shelley's mother asked advice as to a proper school for her son Percy Bysshe. Her friend said offhand: "Oh, send him somewhere where they will teach him to think for himself." Mrs. Shelley replied: "Teach him to think for himself? Oh, my God, teach him rather to think like other people!" Shelley also felt keenly his difference from the common man. More than once he refers to

himself as an imprisoned spirit, and in his "With a Guitar, to Jane" he identifies himself with Shakespeare's delightful spirit Ariel.

Shelley attended Syon House Academy, Brentford, Middlesex, while his cousin Thomas Medwin was there. Then came four years at Eton College, where he was dubbed "Mad Shelley." In October 1810 he took up residence at Oxford as a member of University College. His father accompanied him and introduced him to his former booksellers, Slatter and Munday, with the request that they indulge his son in his "printing freaks." These freaks began at Eton with the publishing of the short Gothic novel *Zastrozzi* (1810) and a volume of poems entitled *Original Poetry by Victor and Cazire* (Shelley and his sister Elizabeth), 1810. A second Gothic novel, *St. Irvyne*, was published at Oxford early in 1811.

On the very first evening in the college dining hall occurred an event that was of great importance in Shelley's life: he met another beginning student, by name Thomas Jefferson Hogg, the son of John Hogg, a nonpracticing barrister of a well-established family at Norton, Yorkshire. Shelley and Hogg took an instant mutual liking and spent their days and evenings together, to almost the entire exclusion of others. They talked, walked, read, and studied philosophy and inevitably were regarded as oddities. In his life of Shelley, Hogg portrays himself as a man with his feet on the ground, loving Shelley but partly because he was amused by his eccentricities. This is a false view; Hogg shared all of his friend's enthusiasms and extravagances. Through Shelley's praise of her, Hogg fell in love with Shelley's sister Elizabeth; he made love to both of Shelley's wives and married one of Shelley's favourite friends, Jane Williams.

Shelley was happy with his freedom and thought four years far too short a time for reading and study. He was therefore greatly shocked when he was expelled by his college, on March 25, 1811, for "contumaciously refusing" to answer any questions about a brief pamphlet called "The Necessity of Atheism." This pamphlet, a digest of the arguments of Locke and Hume, he and Hogg had sent to the bishops and archbishops and the heads of the colleges. The authorship became known at once, except for Hogg's complicity. When Hogg also refused to answer questions, he too was expelled. The friends left the university together, on March 26, for London.

The preceding Christmas holidays had been very unhappy. In addition to persecution at home for his religious opinions, Shelley suffered the loss of his first serious love. His lovely cousin Harriet Grove, a year older than Shelley, alarmed by the opinions expressed by Shelley in his letters, consulted her parents, and their engagement, existing by common consent of their families, was broken off.

Shelley and Hogg, at their fathers' insistence, soon separated, though Shelley put up a stiff resistance and capitulated only after significant concessions had been made. Father and son now disliked each other heartily, and their relations were soon broken for life by Shelley's elopement with and marriage to Harriet Westbrook; all further communications were to be carried on through Timothy Shelley's London solicitor. The father outlived the son by 22 years but never forgave him and took no pride in his growing fame.

Harriet Westbrook (1795–1816) was the beautiful 16-year-old daughter of John Westbrook of London, a wealthy retired tavern keeper. Shelley became acquainted with Harriet through his sisters Mary and Hellen, who attended the same school at Clapham. Harriet agreed with Shelley's radical views and gave him the companionship and encouragement the lonely radical needed. Shelley's love for her appears to have been ardent and sincere when they were married at Edinburgh, on August 29, 1811, by Scotch law. During his vacation Hogg joined them in Edinburgh. They returned with him to York, where he was studying law. Shelley left Harriet there for a trip south to recruit funds, his allowance having been stopped. During his absence Hogg attempted to seduce Harriet, who told Shelley. The poet instantly fled the city

with his wife and her sister Eliza, whom Harriet had summoned and who remained a member of the family from then on.

Years in the Lake District. The Shelleys settled at Keswick, in the Lake District, hoping to meet the older poets Wordsworth, Coleridge, and Robert Southey, but they had to content themselves with Southey, whose liberalism and poetry Shelley had ardently admired. He was disappointed, however, when he found Southey to be a conservative who uttered platitudes about morals, religion, politics, and the errors of youth and immaturity.

Shelley now discovered that the philosopher William Godwin was still alive. On January 3, 1812, he wrote to Godwin, introducing himself, and on the 16th he sent a colourful sketch of his life. He wrote that while at Eton he had read Godwin's masterpiece, *An Enquiry Concerning Political Justice* (1793). This work had been relatively popular for a few years and had influenced Wordsworth and Coleridge. For Shelley it became a master guide. To the end of his life he read it with the highest regard for its ideas and veneration for the intellectual powers of its author. No book has ever so completely furnished another great writer with his principal ideas.

William Godwin was a professional writer, primarily a philosopher, who wrote essays, biographies, histories, novels, and books for children. He married Mary Wollstonecraft, author of *A Vindication of the Rights of Woman* (1792), and was the father of Mary Wollstonecraft Godwin, Shelley's second wife. In those years he was a powerful writer and a man of strict integrity. After the death of Mary Wollstonecraft, he married Mrs. Mary Jane Clairmont, a woman of uncertain origin with two children of her own, Claire and Charles. Mary Wollstonecraft left a daughter, Fanny, by Major Gilbert Imlay, and Godwin and Mrs. Clairmont had a son William. Quite a mixed household it was. Mrs. Godwin was heartily disliked by the writer Charles Lamb and by most of Godwin's friends.

When Shelley wrote to him, Godwin had already degenerated into a cunning and impecunious man who spent a good part of his time borrowing and then borrowing again to repay the first loan. The young man now addressing him might therefore be useful; he was the son of a member of Parliament soon to be a baronet and the heir to a great fortune. Godwin's speculations proved to be correct for a time, for as soon as he was of age, Shelley borrowed large sums on bonds, the greater part of the proceeds going to Godwin to set him firmly on his financial feet. But it was all in vain, and in 1818 Shelley stopped ruining his own future estate in efforts to save Godwin. He said to him in a letter of August 7, 1820:

I have given you within a few years the amount of a considerable fortune, & have destituted myself, for this purpose of realising it of nearly four times the amount. . . . this money, for any *advantage* that it ever conferred on you, might as well have been thrown into the sea. Had I kept in my own hands this £4 or £5,000 & administered it in trust for your permanent advantage I should have been indeed your benefactor.

Godwin never forgave Shelley.

The years 1812 and 1813 did much to mature the young Shelley. His two trips to Ireland and wanderings in Wales and northwest Devonshire enlarged his knowledge of the physical world: the sea, mountains, a foreign country. His efforts to free the Irish people from the Act of Union, which brought about the union of Great Britain with Ireland and to bring about Catholic emancipation widened his understanding of politics and social reform; in fact, he learned by experience and Godwin's admonitions the slowness with which practical reform can be accomplished and the still more important lesson that the reform of men's minds must precede practical reforms. Virtually all of Shelley's activities as a practical reformer are confined to his prose works of this time.

His intellectual life grew in his association with Godwin, whom he finally got to know personally on October 4, 1812, and those to whom Godwin introduced him in Ireland and England. He also came to know Thomas Hookam, Jr., a publisher and bookseller; and the youth-

ful Thomas Love Peacock, a thorough classicist and poet who became famous for his short satirical novels. Peacock became one of Shelley's closest friends, and it was he more than anyone else who, in 1817, turned Shelley to a serious study of the Classical writers.

Shelley had not neglected poetry. He had written enough to make a short volume and a long poem entitled *Queen Mab*, which was finished in February 1813.

On July 17 or 18, 1812, while the Shelleys were at Lynmouth, North Devonshire, Miss Elizabeth Hitchener had joined them, presumably as a permanent inmate. She and Shelley were to supply the world with the ideas and arguments they deemed necessary for the liberation of mankind.

Miss Hitchener was a school teacher of 29, tall, thin, dark, with long, black hair. She was introduced to Shelley in 1811 by his favourite uncle, Captain John Pilfold, of the Royal Navy, whose daughter was one of Elizabeth's pupils; her father kept a public house. Shelley was powerfully attracted to Elizabeth, for this woman thought independently and liberally. He began a correspondence that is very curious and instructive: it shows with starkness his tendency to idealize intellectual women.

Finally, his incessantly repeated invitation that she should live with them, in which Harriet joined, led her to attach herself to his family. The result was disastrous. It soon became clear that she was more interested in Shelley than in human freedom. After changing her name from Elizabeth to Portia to Bessy, then to the Brown Demon, the Shelleys expelled her on November 8, 1812. On December 3 he described her to Hogg as "an artful, superficial, ugly, hermaphroditical beast of a woman." Quite unfair, but expressive of his feelings.

Queen Mab sums up poetically this practical reforming phase of Shelley's life. Biographically the poem is of great importance, and no other poem is so complete an expression of all of Shelley's principal ideas. To class it as a bad piece of juvenilia, as some have done, is sheer folly. Its 2,014 lines of blank verse and unrhymed lyrical verse were written with great intensity, and the wonder is that Shelley already knew distinctly the functions of poetry and of didactic verse; for him "didactic poetry is my abhorrence." To the soul of Ianthe, *Queen Mab* shows the earth of the past, present, and future: excoriated tyranny, organized religion, war, commercialism, and marriage. Long philosophical notes or essays (the first, "The Necessity of Atheism") explain the main ideas in clear-cut language and forceful logic. To accept Shelley's half-derogatory, half-amused remarks about the poem in 1821 as his full view of it, is a mistake.

Queen Mab was begun in February 1812 and completed in February 1813. Shelley wished to have it published, but no publisher would risk the danger of prosecution. He therefore printed it privately and distributed copies among his friends.

The events of 1814-16 not only broadened Shelley but led him to mature as man and poet. His residence in Bracknell brought him more satisfying intellectual companionship with the widow of Jean-Baptiste Chastel de Boynville and her clever and talented daughter Mrs. Cornelia Turner, as well as intimacy with the vegetarian family of John Frank Newton, whose *The Return to Nature, or a Defense of the Vegetable Regimen* (1811) Shelley adopted as authoritative.

Harriet was not happy with these people and was often away from home. In fact, a dangerous estrangement between Shelley and Harriet, which began in 1813, was growing, so that by April 1814, the possibility of a separation existed. The birth of their daughter Ianthe rather aggravated than improved the situation. Hogg is of the opinion that Harriet became a conventional wife who desired new hats, greater stability, and the pleasure of her husband's rank. However that may be, it is beyond any doubt that Shelley and Mary Godwin fell instantly in love when they met at Godwin's house on May 5 or 6, 1814, after her return on March 30 from a protracted stay in Scotland. Mary (1797-1851) was 16, pretty, highly intellectual, and accustomed to unconventional thought, being the child of the famous Mary Wollstonecraft and the

philosopher **Godwin**. She was the kind of person whom Shelley said his wife must be: "one who can feel poetry and understand philosophy."

Elopement with Mary **Godwin**. The two eloped on July 28, 1814, and accompanied by Claire Clairmont, who knew French, they toured France and Switzerland for six weeks but had to return home (down the Rhine and through Holland) because of lack of funds. From Troyes, France, Shelley wrote the famous letter to Harriet inviting her to join them.

In London, Shelley had to go into hiding for a while to avoid arrest, to haunt the offices of lawyers and moneylenders, chiefly to raise large sums for **Godwin**, who now refused all personal contact; moreover, Harriet gave birth to his son Charles Bysshe on November 30. Through these harrowing months, which included the frequent shifting of lodgings, Shelley and Mary were nevertheless happy. They read incessantly, enjoyed again the company of Thomas Hogg, now pursuing his law studies in London, and were buoyed up by their love for each other.

Comparative peace came to them upon the death of Shelley's grandfather, Sir Bysshe, on January 6, 1815. Most of Shelley's ruinous debts were paid, and the sum of \$1,000 a year settled upon him.

On August 3, Shelley and Mary took a pleasant cottage at Bishopsgate, near the entrance to Windsor Park, where they often had the company of Peacock, who lived at Marlow. Late in the summer of 1815, Shelley made a boat trip up the Thames, stopping at Oxford and getting as far up the now shallow stream as Lechlade; his companions were Mary, Peacock, and Charles Clairmont.

Shelley had been suffering from bad health. He had consulted the eminent London physician Sir James Henry Lawrence, who said he had tuberculosis. When he returned to Bishopsgate after the boat trip, Shelley produced his first truly great poem, *Alastor, or the Spirit of Solitude*, published with a few short poems early in 1816. Though some of his later poems are greater, none is more beautiful. The blank verse is influenced by John Milton and Wordsworth but is distinctly Shelleyan, as are the melody of sound and richness of imagery and metaphor and symbolism, which differ so much from *Queen Mab* and are to be henceforth his mode of expression. And in *Alastor*, Shelley introduces the most important theme in his poetry: that of vision and pursuit. It is repeated in varying combinations in the "Hymn to Intellectual Beauty," the "Dedication" of *The Revolt of Islam*, *Epipsychidion*, "Adonais," "The Zucca," and *The Triumph of Life*.

On January 24, 1816, Mary gave birth to their son William at Bishopsgate; August 16 found them in a cottage on the shores of Lake Geneva, Switzerland. Just above them, Lord Byron occupied the Villa Diodati, famous because Milton had stayed there in 1639. Mutual visits, animated conversations, reading, and excursions on the water led to daily intimacy. Especially notable is the ten-day trip around the lake taken by the poets. Unfortunately, what might have been a most gratifying friendship was complicated by the birth of a daughter, fathered by Byron, to Claire Clairmont on January 12, 1817; she was named Allegra by Byron.

On returning to England in September, Shelley took lodgings at Bath. Here, on December 15, he learned that Harriet Shelley had taken her own life by drowning, in London. Her death was a terrible shock to Shelley, and he was denied possession of his two children by the Lord Chancellor, which intensified his suffering. On December 30, 1816, at St. Mildred's Church and in the presence of **Godwin**, with whom he had become reconciled, he married Mary Wollstonecraft **Godwin**.

It was at this time that James Henry Leigh Hunt became a beloved and lifelong friend of Shelley, to whom he now gave the assistance he so desperately needed: deep personal sympathy, a temporary refuge in his home at Hampstead, intellectual stimulation, new friends, zeal for the liberal causes to which Shelley was devoted, and encouragement as a poet.

Hunt had won popular admiration when, in 1812, he had published a severe article on the Prince Regent in

The Examiner and had then spent two years (1813–14) in prison for libel, as did his brother John, printer and publisher of the article. Equally important to Shelley was Hunt's publication on December 1, 1816, of a short article on "Young Poets", John Keats, Shelley, and John Hamilton Reynolds. Throughout his long life, Hunt was Shelley's chief defender against personal attack and criticism of his poetry; hence, Shelley had good reason to address Hunt, as he often did, as his dearest friend.

Shelley had long wished to own a house and to settle down. Only once was he to make the experiment. In February 1817 he settled in Albion House, Marlow, Buckinghamshire, a small town 30 miles (50 kilometres) up the Thames River, where Peacock lived. He bought the lease and furnished the house. The experiment lasted a year and was not a complete success. Here he and Mary read aloud to each other in the evenings, and here Shelley felt the full influence of Peacock's classicism, which led him to a devotion to the classics that is impossible to exaggerate. They were abetted in this by Hogg, who visited both Peacock and Shelley. Other visitors were **Godwin**, and Leigh Hunt and his large family, including Mrs. Hunt's sister Bessy Kent. Here Mary put together her useful *History of a Six Weeks' Tour* (1817), wrote her famous *Frankenstein* (published 1818), and gave birth to their daughter, Clara, on September 2. And, in the first six months at Albion House, Shelley wrote his longest poem, *Laon and Cythna* (renamed *The Revolt of Islam*, 1818). During this period Shelley assisted the poor of the neighbourhood by visiting them and supplying them with blankets.

But the couple were not ideally happy, for they, especially Mary, lived in a state of uneasiness and embarrassment in the presence of Claire Clairmont, who was also there with Byron's child Allegra. Her equivocal state of being a "Mrs." who was bringing up someone else's child became impossible; Shelley's reputation was in danger. In March 1818 they therefore left England to turn over to Byron at Venice the child he freely offered to accept and rear as his own, provided he had nothing to do with her mother.

Shelley was persuaded by his friends and publisher to make a few alterations in *Laon and Cythna*. These consisted mainly in changing the relationship of **Laon** and **Cythna** from brother and sister to **Laon** and an orphan, who are in love and share the same ideals about freedom, and toning down a few denunciatory expressions about God. The title was altered to *The Revolt of Islam* as more suitable.

The poem, in Spenserian stanzas, united the themes of *Queen Mab* and *Alastor*: the lover of mankind and the poet dying young. In a letter to **Godwin**, Shelley says he wrote the poem with the ardor of a dying man. His overall purpose was to show his contemporaries that they should not lose hope because the French Revolution had failed. It was but one of many revolutions that must occur before universal good is victorious over universal evil. The poem has a superfluous profusion of cloud and other natural imagery and shows that Shelley is not at his best as a narrative poet. Much of the poetry, however, has a greater variety and power than any previous composition.

YEARS IN ITALY

To the reasons already given for the Shelleys' migration to Italy must be added two more: Shelley's health and the fear that his children by Mary might be taken from him by law, as Harriet's had been. But not even to **Godwin** or his friends did he ever make all his motives clear.

Personal life. They stopped briefly at Milan, Como, Pisa, and spent a month at Leghorn (May 9–June 11). On April 28, from Milan, they had sent Allegra to Byron in Venice in the care of one of their maids. Though Claire was of very great importance in Shelley's life, her relationship with Byron became so complicated that it is necessary to omit her hereafter, except for the necessary details. It should be noted, however, first, that Shelley was always very fond of Claire, who lived in his house most of the time during his union with Mary. Second, she was

Meeting
with
Lord
Byron

highly imaginative, nervous, and demonstrative, the antithesis of Mary; in consequence Mary and Claire could never live happily together, even through the many years after Shelley's death. At certain times Mary required Shelley to make arrangements for Claire to live elsewhere. Third, Shelley was obliged to be the arbiter between Byron and Claire, a painful task that he managed with great understanding and delicacy.

At Leghorn, the Shelleys made fast friends of John Gisborne, his wife Maria, and her young engineer son by a previous marriage, Henry Reveley. John Gisborne, Shelley said, was "an excessive bore. His nose is something quite Slawkenburgian." Maria had led an adventurous life and soon after Mary's birth in 1797 had been proposed to by Godwin, who needed a wife to care for his baby daughter. Maria at once won the love and admiration of the Shelleys. She fitted the type of woman Shelley always admired, regardless of age: she was intellectual, learned, liberal, strong in character.

In August, Claire's anxiety about Allegra induced Shelley to make with her the long and exhausting journey from the Baths of Lucca to Venice. She stopped at Padua, her presence to be kept a secret, while Shelley went on to Venice to meet Byron, who was delighted to see him and offered the use of his villa at Este, the Capuccini, a lovely mainland estate that Byron himself had never used. Shelley wrote hastily and eagerly to Mary, asking her to bring their family there at once. She did so, but as a result their baby girl Clara died (September 24). Mary secretly blamed Shelley and Claire for this calamity, and the strained relations, her "coldness," led Shelley to write (or alter) *Julian and Maddalo* and a group of poems, including "Lines Written Among the Euganean Hills," which are, in his own words, "my saddest verses raked up into one heap." Mary would never again be the radiant mate whom he had addressed in the "Dedication" of *The Revolt of Islam*. Not until after his death did Mary realize how she had become "cold moonshine" to Shelley. Her repentance was very bitter, as her poem "The Choice" reveals.

Better things also occurred at Este. Shelley wrote the first act of *Prometheus Unbound* and entered upon the period of his greatest achievement as a poet.

The Shelleys left Este early in November to spend the winter at Naples, which they reached on December 1. They made several excursions about the beautiful bay—to Pompeii, Paestum, Sorrento, Mt. Vesuvius—and visited the museums. Shelley wrote wonderful travel letters to Peacock for his English friends; but otherwise the creative spirit lay dormant in him. It came to life again in Rome, where from March to June 10, 1819, they revelled in this "Paradise of exiles," this "Niobe of nations." Amid the vast ruins of the Baths of Caracalla he wrote Acts II and III of *Prometheus Unbound*. He began *The Cenci*. Misfortune, however, continued to dog the Shelleys. Their three-year-old son William died on June 7 and left them childless. He was buried in what is now the old section of the English Protestant Cemetery in Rome, the loveliness of which, Shelley said, "might make one in love with death."

Leaving Rome on June 10, the Shelleys spent the summer at Montenero, near Leghorn. Here Shelley finished *The Cenci* with unusual rapidity. From October 2 to January 25, 1820, they lived in Florence rather uncomfortably, Shelley because of bad health and the cold weather. Mary's deep melancholy was much relieved by the birth of a son, named Percy Florence after Shelley and the city of his birth, on November 12. He was to be Mary and Shelley's only surviving child.

The removal to Pisa late in January 1820 was to be their last, except for summers at the baths of Pisa, about four miles from the city, occasional trips to Leghorn and Lucca, and the final summer at Casa Magni, near Lerici; for in Pisa they had for the first time put down roots.

Shelley went to Pisa chiefly to consult the famous Italian physician Andrea Vaccà Berlinghieri. Here he became the nucleus of a considerable group of people, English, Irish, Italian and Greek. On November 1, 1821, Byron and the Gambas joined them. The "Pisan Circle" is quite

a study in itself. It consisted of former members of Shelley's circle—the Gisbornes, Shelley's cousin Thomas Medwin, and an adventurous Cornishman named Edward John Trelawny—and new acquaintances, among whom Edward Ellerker Williams, and his wife Jane and the "Masons" were of special importance. The Williamses had come to Pisa to meet Shelley. They arrived there on January 15 or 16, 1821, and became the Shelleys' closest associates. With meticulous regularity Edward Williams kept a daily journal of this period. Of quite a different sort were the "Masons," much older and highly cultivated people. Though known in the town as "Masons," they were in reality Lady Mountcashell and George William Tighe. The former had separated from Lord Mountcashell in 1805 after bearing him several children. She and Tighe had settled in Pisa in 1814 and had two daughters. Mrs. Mason, also an intellectual, became closely attached to the Shelleys and was especially helpful to Claire Clairmont.

Mature works. During his four years in Italy, Shelley had composed not only the universally known "Ode to the West Wind," "To a Skylark," and "The Cloud," but also a series of major poems wherein his true greatness lies. They are *Rosalind and Helen* (1817–18; 1819), *Julian and Maddalo* (1818; 1824), *Prometheus Unbound* (1818–19; 1820), *The Cenci* (1819), *The Masque of Anarchy* (1819; 1832), *Peter Bell the Third* (1819; 1839), *The Witch of Atlas* (1820; 1824), *Oedipus Tyrannus, or Swellfoot the Tyrant* (1820), *Epipsychidion* (1821), "Adonais" (1821), *Hellas* (1821; 1822), and *The Triumph of Life* (fragment: 1822; 1824). Double dates indicate composition and date of publication.

Prometheus Unbound, a lyrical drama, is his greatest poem, which many believe is the greatest long poem in English since Milton's *Paradise Lost*. It is a modern myth still valid for the astronomical universe, just as the ancient myth as treated by the Greek dramatist Aeschylus was valid for the age in which it was composed. Though the narrative can be read as an interesting story, it is as a whole and in its parts an elaborate symbol of the triumph of the universal principle of good (Prometheus) over the universal principle of evil (Jupiter). Many readers miss the universality of the theme because they are preoccupied with identifying Prometheus with the mind of man and as the champion of mankind. He is those, indeed, but more. He is the champion of the gods, too, and of all that is good. The poem is intended to inculcate "beautiful idealisms of moral excellence," through the imagination and the heart, not through reason. The beauty and diversity of verse forms is not matched elsewhere. The last act (written as a kind of afterthought in December 1819) has been called "the greatest lyrical outburst in poetry."

The Cenci is astonishingly different from *Prometheus Unbound*. It is the greatest tragedy of the period, and it is the only one of Shelley's works to go into a second edition in his lifetime. Moreover, it is the only work in which he dealt with real human beings. Shelley wrote the play for the stage, and it would have been accepted gladly had not the theme of incest made public performance in his day impossible. Shelley had learned much about human beings as they are and about the necessities of dramatic style and construction. The straightforward, forceful, unadorned style, the noble character of Beatrice, and the monstrosity of Cenci are sharp contrast to the rich ornamentation of the ethereal beings of *Prometheus Unbound* and other of his poems. Mary encouraged Shelley to seek public recognition with more poems like *The Cenci*; Shelley laughed at her gently in *The Witch of Atlas*.

Epipsychidion is often regarded as the greatest poem on love in the language. Shelley was apparently planning a poem on his spiritual life, when a beautiful Italian girl, Teresa Emilia Viviani, was introduced to him and his family. She was ardent, poetical, philosophical, 19 years old, and a victim of parental tyranny. Her father, a nobleman and governor of Pisa, kept her in the Convent of Santa Anna until he could find a husband for her. Shelley's poem was precipitated and changed in direction when he thought that at last he had found the perfect woman, an incarnation of the veiled maid of *Alastor*, of

theus
Unbound*

intellectual beauty. The poem he wrote in an almost hypnotic state is in three parts. The first is addressed to Emilia and concludes with plain and eloquent lines on his concept of marriage and true love. The second traces his spiritual life and is Shelley's most pronounced presentation of the vision and pursuit theme. It differs from *Alastor*, in that now the poet pursues not the vision of intellectual beauty but one among human beings who incarnates the essential qualities of this divine vision. There are experiences recounted with one whose "touch was as electric poison," and others, until he was rescued by Mary, who sustained him during the horrors of Harriet's suicide. Then Emilia, the perfect one, came. In a beautiful passage borrowed from Milton, Shelley likens himself to the Earth ruled by the "Twin Spheres of light," the Sun and Moon (Emilia and Mary). The third part is an invitation to Emilia to join him in living in an earthly paradise on an isolated Greek isle. In a few concluding lines, Shelley sends his poem as an invitation to his friends to join him in a perfect social order governed by reason and the highest ideals of love. Shelley invented the word "Epipsychidion" and in the poem translates it as "this soul out of my soul." Along with the poem should be read his prose fragment "On Love," which gives his broader views on love. It should be noted that the poem is in iambic pentameter couplets, which move with rare rapidity and fluency.

Shelley's
most
perfect
poem

Shelley considered "Adonais" his most perfect poem. When in March he heard of the death of Keats, at Rome on February 23, 1821, he was deeply moved, not so much by the physical removal of a friend as by the early loss of a poet who had suffered neglect and abuse as Shelley himself had done. In slowly meditating the proper form to signify the loss, Shelley chose the Classical pastoral elegy. Though following the traditional structure and clearly using details suggested by the Classical poets, but especially Milton's "Lycidas," Shelley composed his poem of 55 Spenserian stanzas with feverish enthusiasm in the first days of June. On it he lavished all his art. It was printed at Pisa under his personal supervision, for he intended to present to the public a poem that was free from reform and political, religious, and social opinions distasteful to them. When the reviews proved as obtuse as ever, Shelley was so bitterly disappointed that he found it impossible for a considerable time to write again.

The following stanzas mark the opening of the four divisions of the poem, the fourth being an addition to the traditional structure: (I: stanza 1) "I weep for Adonais—he is dead!/O, weep for Adonais"; (II: stanza 18) reflections on life and death; the death of winter, the renewed life, joy, and beauty of spring; (III: stanzas 38–39) "Dust to the dust! but the pure spirit shall flow/ Back to the burning fountain whence it came,/ . . . Peace, peace! he is not dead, he doth not sleep—/He hath awakened from the dream of life—" (IV: stanza 47) "Who mourns for Adonais? Oh, come forth,/Fond wretch! and know thyself and him aright"; truth is beyond the grave.

Hellas was occasioned by the beginning of the Greek Revolution, in 1821. Though Shelley called it only an "improvised," it is more than that, and three of its choruses are famous.

The Triumph of Life (a fragment) was Shelley's last major poem. Strongly influenced by the *Triumphs of Petrarch*, especially "The Triumph of Love," it reflects the philosophy first found in "Adonais," that the world of so-called reality is a world of illusion and asserts that all are the victims of life except Socrates and Christ. Though the poem stops with that passionate cry of his whole life—"Then, what is life?"—it does not leave the reader without hope. Again the vision and pursuit theme makes one feel the presence of the ideal and impels one to pursue it, even though it is beyond the grave.

It must not be forgotten that Shelley wrote a considerable quantity of prose. In it he expresses more clearly his ideas than he does in his poetry. "A Philosophical View of Reform" (1819–20; 1920) shows a sensible approach to practical reform. Most of his prose is fragmentary. Even the famous "A Defence of Poetry" (written 1821)

is but the first of three projected parts. For power of analysis and beauty of expression, the "Defence" is unsurpassed. Unfortunately, it was not published until 1840.

Though Shelley thirsted for fame, his poetry could never be popular, for it is addressed to the "highly refined imagination of the more select classes of poetical readers."

The death of Byron's daughter Allegra on April 20, 1822, caused the Shelleys and Williamses to begin their projected summer on the coast precipitately and early; they wished to remove Claire from the vicinity of Byron before she knew of her terrible loss. They rented Casa Magni at San Terenzo, facing Lerici, on the Gulf of Spezia, and occupied it on April 8.

Death. On July 1, Shelley sailed his trim yacht, the "Don Juan," with Williams to Leghorn to welcome Leigh Hunt and his wife and six children to Italy, to help them settle in Byron's *palazzo* in Pisa, and to make some definite arrangements with Byron concerning *The Liberal*, a periodical Byron wished to establish and had, through Shelley, brought Leigh Hunt to Italy to edit. On the return trip on July 8, a sudden squall struck and sank the boat, and Shelley and Williams were drowned.

Trelawny took charge of recovering the body, cremating it on the shore at Viareggio, and sent the ashes to Rome for burial in the new section of the Protestant Cemetery. Some weeks after the burial, Trelawny visited the grave, with which he was much dissatisfied. With his limited means he bought a plot up against the old Roman wall, built two tombs, to one of which he transferred the ashes of Shelley; he also enclosed the plot and decorated it with cypresses and laurels. To Shelley's wife Mary he wrote an account of these transactions. The second grave, he said, was not for Mary but for himself. Fifty-nine years later his ashes were buried in the long-empty tomb next to Shelley. Trelawny had known Shelley personally only during the last six months of his life.

Immediately after her husband's death Mary resolved to devote her life to the ordering, preservation, and publication of Shelley's manuscripts and to write a biography. In 1824 she published *Posthumous Poems*; Shelley's father, Sir Timothy, however, frustrated further publication until 1839, and in the *Poetical Works* Mary's invaluable notes are primarily biographical.

All of Shelley's intimate friends later made contributions of importance to Shelley's biography: Thomas Medwin and Thomas Jefferson Hogg wrote biographies, and Leigh Hunt and Thomas Love Peacock published works of a more miscellaneous kind. Each of these friends felt that Shelley was the most important influence in his life.

MAJOR WORKS

VERSE: *Queen Mab, a Philosophical Poem* (1813); *The Cenci, a Tragedy in Five Acts* (1819); *Prometheus Unbound* (1820); *Epipsychidion* (1821); "Adonais" (1821); *Hellas, a Lyrical Drama* (1822); *Posthumous Poems*, ed. by Mary Shelley (1824).

PROSE: "A Philosophical View of Reform" (written 1819, first published 1920) and "A Defence of Poetry" (written 1821, published 1840) are included in *Political Tracts of Wordsworth, Coleridge, and Shelley*, ed. by R.J. White (1953).

BIBLIOGRAPHY. The following are valuable for the scholar; there is no general bibliography for the general reader unless that in the *New Cambridge Bibliography of English Literature*, vol. 3 (1969), can be so classed: H. BUXTON FORMAN, *The Shelley Library* (1886); RUTH S. GRANNIS, *A Descriptive Catalogue of the First Editions in Book Form of the Writings of Percy Bysshe Shelley* (1923); T.J. WISE, *A Shelley Library* (1924); SEYMOUR DE RICCI, *A Bibliography of Shelley's Letters, Published and Unpublished* (1927).

Collections: There are three great collections of Shelley's manuscripts and materials. First is the unrivalled collection in the Bodleian Library, which consists mainly of two-thirds of the Shelley family papers. Second is the collection of Lord Abinger, who owns the third part of the Shelley family papers. The third-ranking collection is that of the Carl H. Pforzheimer Library. Unfortunately, public use of these materials is not possible until the Library has published them in the projected eight volumes of its *Shelley and His Circle, 1773–1822*, ed. KENNETH N. CAMERON, vol. 1–2 (1961) and 3–4 (1970), have been published. Smaller but valuable collections are at

the British Museum, the University of Texas, and the Henry E. Huntington Library.

Works: The editions cited below are both useful and valuable: *Posthumous Poems* (1824); *Poetical Works* (1839), and *Essays, Letters from Abroad, Translations, and Fragments* (1840), ed. by MARY SHELLEY; *Poetical Works* (1876) and *Prose Works* (1880), ed. H. BUXTON FORMAN; *Complete Poetical Works*, ed. by THOMAS HUTCHINSON (1904); *Shelley's Literary and Philosophical Criticism*, ed. by JOHN SHAWCROSS (1909); *Poems*, ed. by C.D. LOCOCK (1911); *Complete Works*, ed. by ROGER INGPEN and WALTER E. PECK, 10 vol. (1926–30), and known as the Julian Edition, is the best complete edition of the works today; *Shelley's Prose*, ed. by DAVID LEE CLARK (1954), is inferior but makes the prose works of Shelley more easily accessible; *Letters of Shelley*, ed. by F.L. JONES (1964).

Biography: Basic biographical materials by Shelley's friends are MARY SHELLEY'S Notes for the *Poetical Works* (1839), her *Journal* (1947) and *Letters* (1944); and *Maria Gisborne and Edward E. Williams, Shelley's Friends: Their Journals and Letters* (1951), ed. by F.L. JONES; *The Journals of Claire Clairmont*, ed. by MARION K. STOCKING (1968); JAMES HENRY LEIGH HUNT, *Lord Byron and Some of His Contemporaries* (1828) and *Autobiography* (1850); THOMAS MEDWIN, *Life of Shelley* (1847; ed. by H. BUXTON FORMAN, 1913); T.J. HOGG, *Life of Percy Bysshe Shelley* (1858; goes only to 1814), is an authorized life denounced after publication by Shelley's son and his wife; LADY JANE SHELLEY, *Shelley Memorials* (1859), contains important documents refuting Hogg; E.J. TRELAUNY, *Recollections of the Last Days of Shelley and Byron* (1858; 2nd ed., *Records*, 1878, is less reliable); THOMAS LOVE PEACOCK, *Memoirs of Shelley*, ed. by H.F.B. BRETT-SMITH (1909). Hogg, Trelawny, and Peacock, with an Introduction by Humbert Wolfe, were published together in 1933; this is now the standard reference for the books above. In 1882 PERCY FLORENCE and LADY JANE SHELLEY arranged, transcribed, and printed in chronological order a great quantity of their family collection, including Mary Shelley's *Journal*; the privately printed volumes (3, sometimes 4) are rare and very valuable. Scholarly biographies are NEWMAN I. WHITE, *Shelley* (1940; corrected ed., 1947; 1-volume condensation, *Portrait of Shelley*, 1945), which is masterly and definitive; D.F. MCCARTHY, *Shelley's Early Life from Original Sources* (1872); EDWARD DOWDEN, *Life of Percy Bysshe Shelley* (1886), the standard life until White's 1940 biography, and still of great importance; A.H. KOSZUL, *La Jeunesse de Shelley* (1910); HELEN ROSSETTI ANGELI, *Shelley and His Friends in Italy* (1911); ROGER INGPEN, *Shelley in England* (1917), which utilizes for the first time the Shelley-Whitton papers; WALTER E. PECK, *Shelley: His Life and Work* (1927); EDMUND BLUNDEN, *Shelley: A Life Story* (1946); D.G. KING-HELE, *Shelley: His Thought and Work* (1960), which deservedly has been very popular.

Criticism: In criticism the following are all solid contributions: MATTHEW ARNOLD, "Shelley," in *Essays in Criticism*, 2nd Series (1888), in which a great critic made the worst mistake of his career; FRANCIS THOMPSON, *Shelley* (1889), in beautiful poetic prose; E.S. BATES, *A Study of Shelley's Drama The Cenci* (1908); A.C. BRADLEY, "Shelley's View of Poetry," in his *Oxford Lectures on Poetry* (1909); A. CLUTTON-BROCK, *Shelley: The Man and the Poet* (1910, revised 1923); CARL GRABO, *A Newton Among Poets: Shelley's Use of Science in Prometheus Unbound* (1930) and *The Magic Plant: The Growth of Shelley's Thought* (1936), the first comprehensive work of its kind; A.M.D. HUGHES, *The Nascent Mind of Shelley* (1947); CARLOS BAKER, *Shelley's Major Poetry* (1948), excellent; KENNETH N. CAMERON, *Young Shelley: The Genesis of a Radical* (1950), the best book on his early prose.

(F.L.J.)

Shensi

Shensi Province (Shen-xi in Pin-yin romanization) is a province of China, bordered by the Huangho and Shansi Province in the east, by the Ningsia Hui Autonomous Region and Kansu Province on the west, the Inner Mongolian Autonomous Region to the north, by Szechwan Province in the south, and Hupeh and Honan provinces in the southeast. Its total area is 75,600 square miles (195,800 square kilometres). In 1970 its estimated total population was 21,000,000. The capital is Sian. (For an associated physical feature, see HUANG HO [RIVER].)

HISTORY

Northern Shensi. *The early period.* The northern parts of Shensi, particularly the Wei Ho Valley (which runs from west to east across the centre of the province), were

some of the earliest settled parts of China. In the valley some remains of the Mesolithic Period have been found, while there are New Stone Age (Neolithic) Yang-shao culture sites spreading along the whole of the west-east corridor through Kansu, the Wei Ho Valley, and the Huang Ho Valley into Honan, showing that this was already an important route for the movement of peoples. Chinese Neolithic culture was probably first developed in the Wei Ho Valley. It remained an important centre of the later Neolithic Lung-shan culture and then became the first home of the Chou people, who, in 1122 BC, invaded the territories of their overlords, the Shang, to the east, and set up a dynasty that exercised some degree of political authority over much of North China. Until 771 BC, the political centre of the Chou was at Hao, near modern Sian.

For the early agriculturalists, working the ground with primitive stone-tipped tools, the slopes of loess (unstratified windborne deposits of loam) and river terraces provided ideal farmland—light, stone free, and fertile. The natural cover, too, was mostly grass and scrub and could be easily cleared for temporary cultivation.

After the 8th century BC the Chou lost much of their authority and moved their capital eastward to Lo-yang in Honan Province, after which Shensi became something of a backwater. Gradually, however, the pre-dynastic Ch'in state, which controlled the area, began to develop into a strong centralized polity of a totally new kind, able to mobilize mass labour for vast construction projects, such as the part of the Great Wall of China built between Shensi and the Ordos Desert. One of the greatest of these tasks was the completion in the Wei Ho Valley of a very large and efficient irrigation system based on the Cheng-kuo and Pai-kung canals and centred around the junction of the Ching Ho with the Wai Ho. This system, completed in the 3rd century BC, watered some 450,000 acres (180,000 hectares) and provided the powerful economic base for the Ch'in's eventual conquest of the whole of China.

The middle period. In 221 BC Hsien-yang, in Shensi, became the capital of the Ch'in dynasty, which unified China for the first time; it was a city of vast wealth, the focus of a nationwide road system. The area remained extremely populous and was a major centre of political authority for the next millennium. The Han (206 BC to AD 221), successors of the short-lived Ch'in dynasty, made their capital Ch'ang-an, near Hsien-yang. Later, in the 6th century, when after some centuries of disunion the Sui (581 to 618) again unified the empire, their capital—Ta-hsing—was on the same site as Ch'ang-an, which also was the capital of the T'ang (618–907). Ch'ang-an, as the capital was now once more known, was by far the largest and most magnificent city in the world in its day and was immensely wealthy. But by this time the irrigation system upon which Shensi primarily depended had begun to deteriorate, soil erosion and deforestation had begun to be problems, and the productivity of the area declined. The maintenance of a huge metropolis of more than 1,000,000 people in the area consequently necessitated the difficult and costly transportation of vast quantities of grain and provisions from the eastern plains and the Yangtze Valley. The capital remained in Shensi largely because the area (known as Kuan-chung—literally Within the Passes) was easily defended and was of crucial importance as a frontier with China's neighbours. After the sack of Ch'ang-an in 882, however, no dynasty ever again had its capital in the Northwest, and the area rapidly declined in importance as the economic centre of the empire gradually gravitated toward the Yangtze Valley and the South. During the next millennium Shensi became one of the poorest and most backward of China's provinces.

The early modern period. Under the Mongols, from 1279 onward, Shensi as a provincial unit assumed approximately its present form, incorporating the area formerly known as Shan-nan (literally South of the Mountains), or Li-chou. During this era, however, Shensi underwent many changes. In the course of the Yüan dynasty (1279 to 1368), the province was devastated and largely

Ancient construction projects

depopulated as a result of the Mongol conquest. Subsequently there emerged a large Muslim element in the population. The area suffered badly from rebellion and disorders following the collapse of Mongol rule after about 1340, when two independent regimes—those of Chang Ssu-tao in the Northwest and of Li Ssu-chi around Ch'ang-an—controlled most of Shensi. Later it was one of the areas in which disaffection with Ming rule (which began in 1368) first appeared in the late 1620s, and it was somewhat badly damaged in the fighting leading up to the Ch'ing conquest in 1644. Under Ming rule Shensi Province also incorporated Kansu, but under the Ch'ing dynasty (1644–1911) the two were separated once more.

The 19th and 20th centuries. By the 19th century Shensi was seriously impoverished. Although only marginally affected by the Taiping Rebellion (1850 to 1864) in its last stages, eastern and southern Shensi were slightly disturbed by the Nien Rebellion between 1853 and 1868. It then suffered the terrible Muslim Rebellion of 1862 to 1878, which affected much of the western and northern parts of the province. Although the effects of the rebellion and its savage suppression were not as terrible as in Muslim Kansu, about 600,000 were killed in Shensi, and the resulting destruction left the province in a serious plight.

As this rebellion was coming to an end, Shensi was also affected by one of the worst drought famines of modern times. It had virtually no rain from 1876 to 1878, and, when the government tried to remedy the situation in 1877, poor transport facilities prevented effective relief. Perhaps 4,000,000 or even 5,000,000 people died in Shensi alone, with some single counties in the fertile Wei Ho Valley losing more than 100,000 dead. As a result of the terrible death toll in the last decades of the 19th century, Shensi became a haven for a wave of land-hungry immigrants from Szechwan and Hupeh provinces.

The end of the empire in 1911 brought yet further deterioration in living conditions. In 1912 the governors of Shensi and Kansu became engaged in a destructive civil war of an unusually brutal and violent character; the war, often affecting the whole province, continued until 1921, after which the province became involved in a still larger war between Yü-hsiang Feng and the Chihli warlords. In 1926 the capital, Sian, was besieged and badly damaged; the death toll numbered nearly 100,000 from starvation alone.

In the earlier years of the 20th century, Shensi also suffered badly from periodic famines, which occurred in 1915, in 1921, and finally in 1928. This last famine was as severe as that of 1877–78; it is estimated that at least 3,000,000 people died of starvation, after which a wave of epidemics increased the death toll still further. Whole counties were virtually depopulated. This time, however, some measures of relief were forthcoming. The International Famine Relief Organization began to rehabilitate the derelict irrigation system of the Wei Ho Valley, while the extension of the Lunghai Railway into the province meant that, if in the future famine should threaten, relief supplies could quickly be moved into the province.

A further political upheaval followed in 1936, when Communist armies, driven out of their bases in Kiangsi, passed through the western parts of Shensi. They then established themselves in Yen-an in northern Shensi, which was to be the base from which they conducted their war of resistance against the Japanese and from which, after the end of World War II, they successfully undertook the conquest of all China. In Shensi itself they controlled the territory of the present Yen-an and Yü-lin, special districts from 1937 onward.

Southern Shensi. The history of the southern part of the province has been more placid. Until the late 17th century the area was very sparsely peopled, and much of it, apart from the Han-chung basin, is still virgin forest. In the period after about 1680, the introduction of maize (corn) and sweet potatoes, followed in the 18th century by the Irish potato, made upland farming possible. A pattern emerged of growing rice in the valley bottoms, maize on the lower mountain slopes, and Irish potatoes on the higher land. Southern Shensi, with its great

amounts of vacant land, attracted immigrants on a large scale after severe famines and crop failures had occurred in Hupeh and Szechwan provinces in the 1770s. In the early 19th century, immigrants from central and southern China constituted as much as 90 percent of the population in some parts.

Rapid and often reckless development of the uplands, however, often led to soil erosion, rapid loss of fertility, and declining crop output. Local disaffection broke out in the so-called White Lotus Rebellion of 1796–1804, which was centred in the Szechwan–Shensi–Hupeh–Honan border regions. After its suppression, however, the area remained generally peaceful: in the 20th century it escaped the worst excesses of the northwestern warlords' civil wars, as well as of the repeated famines that occurred in northern Shensi.

LANDSCAPE AND ENVIRONMENT

Relief. Shensi Province comprises three distinct natural regions—the mountainous southern region, the Wei Ho Valley, and the northern upland plateau.

The mountainous southern region forms the drainage area of the upper Han Shui, which is a northern tributary of the Yangtze. The Han Shui flows between two great mountain complexes that structurally form part of a great, single fold zone. These complexes are the Ta-pa Shan, forming the boundary with Szechwan Province to the south, and the Tsinling Shan—the major environmental divide between northern and central China—to the north. The Ta-pa Shan is an impressive range, 5,000 to 6,000 feet (1,500 to 1,800 metres) in height, with individual peaks reaching altitudes of up to 8,000 feet (2,400 metres). Its northern flank in Shensi is very heavily dissected by the complex pattern of the Han Shui's southern tributaries. There is only one major break in this mountain chain; it occurs in the far southwest of the province where the Chia-ling Chiang, which rises to the north in the Tsinling Shan, cuts through the Ta-pa Shan chain to flow into Szechwan on its way to join the Yangtze at Chungking. This valley forms the major communication route from the Wei Ho Valley in central Shensi to Szechwan and the southwest.

The Han Shui Valley itself broadens out near the city of Han-chung into a fertile and densely cultivated basin about 60 miles (100 kilometres) long and 10 miles (16 kilometres) broad. Further downstream the valley again narrows, after which the river flows between mountains and through deep gorges, only emerging into the plain once more in Hupeh Province.

The Tsinling Shan to the north of the Han Shui Valley forms an even more impressive barrier than the Ta-pa Shan. Structurally a continuation of the great K'unlun Mountains to the west, it runs continuously across Shensi from west to east at an average height of some 8,000 feet, with individual peaks, such as T'ai-pai Shan, reaching 13,500 feet. East of Sian the Hua Shan branches off the main range to the northeast, running eastward to the south of the Wei Ho and Huang Ho valleys into Honan. The main range, however, merges into the Fu-niu Shan (which has a northwest to southeast axis) and the Hsiung'erh Shan (which has a southwest to northeast axis) in Honan.

The Tsinling Shan forms a very broad mountain belt, divided into three parallel west to east zones. The northern and highest zone consists of ancient metamorphic rocks with massive intrusions of granite. It is divided from the Wei Ho Valley to the north by a line of faults that make its northern face rise abruptly in clifflike ranges from the plain. The middle zone is composed of intensely folded younger rocks. The southern zone, again, consists of metamorphic rocks that are younger than those of the northern range and mostly consist of metamorphic limestones and granite intrusions. The main watershed is in the highest northern zone. The southern slope of the range, draining into the Han Shui, is deeply sculptured by an extremely complex drainage pattern.

Only three passes of any importance cross the Tsinling Shan. These are the San-kuan Shan-k'ou (San-kuan Pass) south of Pao-chi, which leads to the Chia-ling Chiang

The three natural regions

Periodic famines

Valley and thus into Szechwan; the Kao-kuan Shan-k'ou south of Sian, which leads to the Han-chung Basin; and the Lan-t'ien Shan-k'ou southeast of Sian, which affords a route to the town of Shang-hsien and thence to Nan-yang in Honan on the way to northern Anhwei Province. The second major region is the Wei Ho Valley, a tributary of the Huang Ho, which flows from west to east across the province from its headwaters in Kansu to join the Huang Ho at Tung-kuan. This valley is a major geological trough, bounded on the south by a vast complex of faults and fractures along the base of the Tsinling Shan. This is a zone of considerable seismic instability, especially vulnerable to earthquakes. The northern border of the Wei Ho trench is less abrupt, and the large northern tributaries of the Wei Ho, the Ching Ho and Lo Ho, have themselves formed quite extensive alluvial plains in their lower courses that are continuations of the Wei Ho plain. The plain consists largely of loess (which also mantles parts of the northern face of the Tsinling Shan), as well as of redeposited loess washed off the plateau to the north. The rivers are heavily silted.

The third region, to the north, is the great upland plateau of northern Shensi. Structurally this is a basin of largely undisturbed sedimentary rocks of immense thickness. Its raised western rim forms the Liu-p'an Shan, which extends from the far west of Shensi northward into Kansu and the Ningsia Hui Autonomous Region. A minor northwest to southeast axis forms the Ta-liang Shan and Huang-lung Shan, which constitute the watershed between the Lo Ho system and the northern part of the province, which drains directly into the Huang Ho. On the eastern border of the basin the Huang Ho flows from north to south through a narrow, gorgelike trough. In this section it falls some 2,000 feet in less than 500 miles, and it is mostly unnavigable, with frequent rapids, culminating in a very deep, narrow gorge and falls at Lung-men.

The whole of this basin plateau, which is mostly above 3,000 feet, is a peneplain (a region reduced almost to a plain by erosion) covered with a deep mantle of loess, blown from the Gobi and the Ordos Desert by the prevailing northwesterly winds of the winter season. Much of the area is covered to a depth of 150 or even 250 feet, and the loess completely masks the original relief and structure of the region. The loess, in turn, has been heavily eroded, leaving a characteristic landscape of almost vertical walls, cliff faces, and deep ravines. This erosion has been intensified by the effects of human occupation, which have destroyed the natural vegetation cover.

Climate. The Tsinling Shan is not only a physical divide, but it also divides Shensi into two sharply differentiated climatic regions. The southern mountain area has a subtropical climate, similar to that of the Middle Yangtze Basin or of Szechwan. Mean temperatures in January are from 37° to 39° F (3° to 4° C), and the frost-free growing season is from 260 to 280 days, although the summer and autumn are not so hot as in the Middle Yangtze region. Total precipitation is between 30 and 40 inches (750 and 1,000 millimetres), falling mostly between May and October. The driest part of the year is spring and early summer, when irrigation is necessary. But in general the climate is hot and moist. Needless to say, in an area of such rugged and varied topography, there are great local variations.

The Wei Ho Valley has a much drier and somewhat colder climate. Average winter temperatures are about 32° F (0° C), and the frost-free period lasts for about 240 days. Total precipitation is between 20 to 25 inches, mostly falling between May and October, with a sharp peak in September and October. Rainfall is generally deficient in spring and early summer, but the climate is not seriously dry. It is, however, an area subject to severe and prolonged droughts. On the Loess Plateau further north and west the climate grows progressively drier and colder. The extreme north and west have only about 10 inches of annual precipitation, most of which occurs in late summer and autumn, when evaporation loss is at its maximum. The growing season and frost-free period become progressively shorter until in the north the former is only about 190 days. In this area agriculture depends on

techniques for minimizing evaporation losses and in conserving moisture in the soils. The northern frontier with the Inner Mongolian Autonomous Region, roughly coinciding with the line of the Great Wall, remains an important cultural divide. Beyond it conditions for agriculture become precarious in the extreme.

Vegetation and animal life. The vegetation in the northern and southern zones is also sharply differentiated. The southern mountain area forms a part of the mixed deciduous broad-leaved and evergreen forest zone that formerly covered the Lower Yangtze and Han Shui basins; this region is characterized by a very rich variety of vegetation that includes more than 50 broad-leaved genera and a dozen or more coniferous genera. Owing to the difficulty of access, large areas of natural timber remain standing.

The northern slopes of the Tsinling Shan and the lower Wei Ho Valley were originally covered with deciduous broad-leaved forest. The bulk of northern Shensi, except for the pure steppe (treeless plain) of the northern and western borders, was originally part of the so-called northwestern forest steppe area, where deciduous broad-leaved woodland grows only on the highest ground and around watercourses, most of the area being covered by grass or low, drought-resistant scrub. This northern area has been intensively cultivated since the first millennium BC, and its natural vegetation has been virtually destroyed.

POPULATION AND ADMINISTRATION

The people and their settlement patterns. The people are nearly all Chinese and speak a local dialect of Mandarin. There are no ethnic minorities or minority languages. Some Chinese Muslim (Hui) communities remain in the south and northwest of the province. Most of the population is settled in the Wei Ho and Han Shui valleys; the uplands are more sparsely settled. The chief cities are Sian, with a population estimated at 2,500,000 in the mid-1970s; Pao-chi, with about 376,000 in 1980; and Hsien-yang, Tung-ch'uan, and Han-chung, each with between 50,000 and 100,000 in the mid-1970s. An-Pang, San-yiian, Yen-an, Wei-nan, and Yi-lin in the mid-1970s all had populations between 10,000 and 50,000. Most of the province's county seats are very small. Sian is the provincial metropolis besides being the main communication centre and chief industrial city; it is also an important administrative, educational, and cultural centre. It has an important university, a medical college, and an institute of art and music, as well as libraries and museum collections. Pao-chi is an important road and rail transportation centre. San-yiian and Hsien-yang are both satellite cities of Sian, as well as rail and road transport centres. Han-chung is the main communication and administrative centre for the southern region.

Administration. Sian, the provincial capital, Tung-ch'uan, and Pao-chi are independent municipalities directly subordinated to the province. The rest of the province is organized into seven prefectures (*ti-ch'ü*); the northern plateau area is divided between the Yü-lin Prefecture in the far north and the Yen-an Prefecture further south; the central and eastern Wei Ho Valley area is divided into the prefectures of Hsien-yang and Wei-nan; and the mountainous southern area is divided into the Han-chung, An-k'ang, and Shang-lo prefectures. At the second administrative level, the province is divided into 102 counties (*hsien*) and three county-level municipalities (*shih*)—Hsien-yang, Yen-an, and Han-chung. For purposes of economic planning, the province, together with Kansu and Sinkiang Uighur Autonomous Region, forms part of the northwestern economic region.

ECONOMY AND TRANSPORTATION

Resource exploration. Agriculture. The southern part of the province forms a portion of the southwestern highland and basin area, which is characterized by double cropping, wet-field agriculture, and forestry production. Most of the cultivated land is below 3,000 feet. The Han-chung Basin grows rice intensively, followed by winter wheat, but in the mountain zones of the Ta-pa Shan and Tsinling Shan the main cereal crops are maize and winter

Vegetational
zones

The
special
districts

wheat. Such subtropical crops as tea, tung oil, and citrus fruits are grown. Apples, pears, apricots, and grapes are also widely produced, but only in the Han-chung Basin is more than 20 percent of the land under cultivation.

The Wei Ho Valley area is very intensively cultivated. As described above, it was the first area of China to be irrigated on a large scale. Well over half of the total area is under cultivation, and it supports a dense agricultural population. The valley area produces some rice, good winter wheat, tobacco, and cotton, but millet, barley, and corn are also increasingly important crops, as is kaoliang (a variety of grain sorghum). On the higher ground, millet, oats, and buckwheat are common. Hemp and sesame are important subsidiary crops, particularly in the upper Wei Ho and the Ching Ho valleys; in the latter area oats are an important fodder crop. Normally three crops are raised every two years.

The northern plateau is too cold in the winter for winter wheat to survive. It forms a part of the Inner Mongolian dry agricultural and pastoral zone. Spring-sown wheat and millet are the main grain crops, and these depend largely on the availability of irrigation water. Grazing becomes particularly important toward the northern and western borders, and the growing season is so short that only one crop yearly is possible. Over most of the northern region less than 25 percent of the land is cultivated, and in the north and west it is less than 10 percent.

Conservation and reclamation. The whole of Shensi, north of the Tsinling Shan, had in the past suffered badly from soil erosion as a result of the destruction by man of natural vegetation. As a part of the very large-scale Huang Ho multipurpose conservancy scheme, first decided upon in 1955, it was judged essential to reduce the enormous silt load discharged into the Huang Ho by the Wei Ho and its other west-bank tributaries. As a result, a great effort has since been made to spread terraced cultivation in Shensi. The plan also calls for the construction of great numbers of dams in the loess uplands to retain silt before it reaches the Huang Ho. These small dams quickly silt up, forming new farmland. At the same time, ambitious projects have been begun to sow grass on denuded land, to plant trees to protect the new terraced fields and slopes, and to prevent gullying. An even more ambitious plan is the planting of a belt of trees a mile or more wide, mostly consisting of drought-resistant poplar, elm, or willow, in an attempt to contain the spread of sand dunes from the Ordos Desert. This belt extends southwestward for about 375 miles from Yii-lin Special District in northern Shensi across the Ningsia Hui Autonomous Region and into Kansu, skirting the edge of the desert.

The irrigation system has also been greatly extended. The ancient irrigation systems of the Wei Ho and Ching Ho valleys, restored (after centuries of neglect) following the famine of 1932, have been extended, while great numbers of small dams and wells have also been constructed to increase the irrigated area.

Mineral resources. The basin in the north of the province has enormous coal reserves, second in size only to those of Shansi. In the early 1970s, however, the only important modern mines were those at T'ung-ch'uan, on the border of the Wei Ho Valley. The whole basin is also an area with good prospects as an oil-producing district, but again production in the early 1970s was limited to Yen-ch'uan and Yen-ch'ang, near Yen-an, and the exploitation of these was hampered by lack of adequate transportation. There are minor coal and oil-shale deposits in the Han Shui Basin in the south, where there are also iron-ore deposits. The Tsinling Shan contains some minor gold-producing areas (mostly in the west), as well as some minor deposits of manganese and other minerals. But, in general, coal and oil form the only major resources of the province.

Power resources. The coal produced at T'ung-ch'uan feeds two large thermal generating plants at Sian (both generating more than 100,000 kilowatts), as well as a smaller plant at Pao-chi. Pao-chi, Sian, and T'ung-ch'uan are linked by a power grid that extends to the unfinished hydroelectric station at San-men on the Huang Ho, from

where it is also linked to Lo-yang and Cheng-chou in Honan and the industrial centres of T'ai-yüan and Yang-ch'üan in Shensi. This will form the most extensive power grid in China outside the Northeast region.

Industry. The only major industrial area in Shensi is that centred around Sian. Both Sian and the nearby cities of Hu-hsien and Hsien-yang are centres for the cotton-textile industry, with large modern plants. Sian is also an important centre for the production of electrical equipment and for engineering and chemical manufacturing. The first heavy industry in the province was the large iron and steel plant set up at Sian in 1958; in 1960 it was reported to have an annual capacity of 500,000 tons of pig iron. This was temporarily shut down in 1962, following the failure of the Great Leap Forward. It was brought into production again in 1971.

There are minor centres of industry at Pao-chi and at Shih-ch'üan in the Han Shui Valley, near An-Pang, and Yao-hsien, near T'ung-ch'uan, has a large and important cement plant. Also, a small petrol refinery is located at Yen-ch'ang. But, apart from Sian, which ranks 15th among Chinese cities in industrial capacity and which since 1949 has become a regional industrial metropolis, the province remains virtually unindustrialized.

Transportation. The Wei Ho Valley since prehistoric times has formed part of the main east-west route running from the North China Plain in the east to the Kansu Corridor and the steppelands in the west. Sian is a natural route centre, where the great east to west route meets the routes that cross the Tsinling Shan to the south and southeast, an alternative route to the northwest via the Ching Ho Valley, and routes to the Ordos region in the north and to the Fen Ho Valley and Shansi to the northeast. All these routes are now followed by modern highways. In the south a highway crosses the province from east to west, joining Han-chung, in southwest Shensi, with Wu-han, in Hupeh Province to the east, and Lan-chou, in Kansu Province to the west. In the far southwestern corner of Shensi, a main highway follows the route of the ancient Man Post Road from Pao-chi southwestward to Ch'eng-tu in Szechwan. Apart from these trunk routes, only the Wei Ho Valley has an adequate road network.

The first railway to reach Shensi was the Lunghai line, the great east-west trunk line from the sea at Lien-yün-kang in Kiangsu, via the industrial centres of K'ai-feng, Cheng-chou, and Lo-yang in Honan. This line was extended to T'ung-kuan in 1932, to Sian in 1934, and to Pao-chi in 1937. Much of the railway was destroyed during the war with Japan but was reconstructed in the late 1940s and extended westward to T'ien-shui, in Kansu. Also at this time a branch was constructed from Hsien-yang, near Sian, to T'ung-ch'uan, the site of the only large coalfield in the area. Construction of another line from Sian to cross the Huang Ho near Lung-men and join the main trunk line through Shansi at Ch'ü-wu was still incomplete in the early 1970s. A second major new rail link was the line from Pao-chi southwest to Ch'eng-tu in Szechwan, where it links with various lines to the southwest. The northern part of the province is still without adequate communications. Sian is an important centre of air traffic, with regularly scheduled flights to Peking, T'ai-yüan, Lan-chou, Pao-t'ou, and Central Asia, and to Ch'eng-tu, Chungking, and Wu-han.

BIBLIOGRAPHY. The best available description of the physical features and natural environment of the province in a Western language remains that in *China Proper*, ed. by PERCY M. ROXBY, 3 vol. (1944-45). For the climatic regime of the area, see the excellent study by CHU PING-HAI, *The Climate of China* (1968; orig. pub. in Chinese, 1962). An incomplete description of soils and other physical factors is included in VIKTOR A. KOVDA, *Soils and Natural Environment of China*, 2 vol. (1960; orig. pub. in Russian, 1959); while a general and not entirely reliable picture is given in V.G. KALMYKOVA and I.K. OVDIYENKO, *Geographical Survey of North-West China*, 3 vol. (1958; orig. pub. in Russian, 1957). Some economic and social information is included in THEODORE SHABAD, *China's Changing Map*, rev. ed. (1972); in T.R. TREGGAR, *A Geography of China* (1965), and in his more specialized *Economic Geography of China* (1970). On the historical geography of the area, there is a wealth of information on the

Road
and rail
routes

The
irrigation
system

earliest periods in K.C. CHANG, *The Archaeology of Ancient China*, rev. ed. (1968). There also are some good materials in the imaginative historical geography by Y.F. TUAN, *China* (1969); and a great deal of information in the classical work on Chinese economic and social history by P.T. HO, *Studies on the Population of China, 1368–1953* (1959). There is an excellent political-administrative map in the C.I.A. publication, *Communist China Administrative Atlas* (1969).

Sheridan, Richard Brinsley

Richard Brinsley Butler Sheridan, though best remembered as the author of brilliant comedies of manners, was also important as an English politician and orator. His genius both as dramatist and politician lay in humorous criticism and the ability to size up situations and relate them effectively. These gifts were often exercised in the House of Commons on other men's speeches and at Drury Lane Theatre in the revision of other men's plays. They are seen at their best in *The School for Scandal*, in which he shaped a plot and dialogue of unusual brilliance from two mediocre draft plays of his own. In person he was often drunken, moody, and indiscreet, but he possessed great charm and powers of persuasion. As a wit he delivered his sallies against the follies of society with a polish that makes him the natural link in the history of the British comedy of manners between William Congreve and Oscar Wilde.

BY courtesy of the Lord Plunket

Sheridan, oil painting by Sir Joshua Reynolds, 1788–89, in the Lord Plunket Collection.

Formative years. Sheridan's birth date is not known, but he was baptized (mistakenly as "thos. Brinsley") at St. Mary's Church, Dublin, on November 4, 1751, the third son of Thomas and Frances Sheridan. His grandfather Thomas Sheridan had been a companion and confidant of Jonathan Swift; his father was the author of a pronouncing dictionary and the advocate of a scheme of public education that gave a prominent place to elocution; and his mother gained some fame as a playwright.

The family later moved to London, and Sheridan never returned to Ireland. He was educated (1762–68) at Harrow, and in 1770 moved with his family to Bath. While there he corresponded with a school friend then at Oxford, and together they wrote *Jupiter*, a farce, which, after revision, Sheridan renamed *Ixion*. They also collaborated (1771) in a metrical version of the epistles of the fifth-century writer Aristaenetus who compiled two books of love stories taken from Plato, Lucian, and Plutarch. Sheridan's poems *The Ridotto of Bath* and "Clio's Protest" also date from this period.

In Bath Sheridan fell in love with Elizabeth Ann Linley (1754–92), whose fine soprano voice had, from an early age, delighted audiences at the concerts and festivals conducted by her father, Thomas. In order to avoid the unpleasant attentions of a Welsh squire, Thomas Mathews

of Llandaff, she decided to take refuge in a French nunnery. Sheridan accompanied her to Lille in March 1772, but returned to fight two duels that same year with Mathews, in London in May, where he disarmed Mathews, and at Bath in July, where he was bodily wounded. Meanwhile, Elizabeth had returned home with her father, and Sheridan was ordered by his father to Waltham Abbey, Essex, to pursue his studies. He was entered at the Middle Temple in April 1773, but after a week broke with his father, gave up a legal career, and married Elizabeth at Marylebone Church, London.

Dramatic career. After his marriage Sheridan turned to the theatre for a livelihood. His comedy *The Rivals* opened at Covent Garden Theatre, London, in January 1775. It ran an hour longer than was usual, and, because of the offensive nature and poor acting of the character of Sir Lucius O'Trigger, it was hardly a success. Drastically revised and with a new actor as Sir Lucius, its second performance nine days later won immediate applause. The situations and characters were not entirely new, but Sheridan gave them freshness by his rich wit, and the whole play reveals Sheridan's remarkable sense of theatrical effect. Characteristic is the genial mockery of affectation displayed by some of the characters. Even the "malapropisms" that slow down the play give a proper sense of caricature to the character of Mrs. Malaprop.

Some of the play's success was due to the acting of Lawrence Clinch as Sir Lucius. Sheridan showed his gratitude by writing the amusing little farce *St. Patrick's Day; Or, The Scheming Lieutenant* for the benefit performance given for Clinch in May 1775. Another example of his ability to weave an interesting plot from well-worn materials is seen in *The Duenna*, produced the following November. The characters are generally undeveloped, but the intrigue of the plot and charming lyrics and the music by his father-in-law Thomas Linley and his son gave this ballad opera great popularity. Its 75 performances exceeded the 62, a record for that time, credited to John Gay's *The Beggar's Opera* (1728), and it is still revived.

Thus, in less than a year Sheridan had brought himself to the forefront of contemporary dramatists. David Garrick, looking for someone to succeed him as manager and proprietor of Drury Lane Theatre, saw in Sheridan a young man with energy, shrewdness, and a real sense of theatre. A successful physician, Dr. James Ford, agreed with Garrick's estimate and increased his investment in the playhouse. In 1776, Sheridan and Linley became partners with Ford in a half-share of Drury Lane Theatre. Two years later they bought the other half from Willoughby Lacy, Garrick's partner. Sheridan had put only £1,300 into the enterprise; the transaction had been possible only because Garrick and Ford had backed him with mortgages in the belief that Drury Lane would flourish under his direction.

In fact, Sheridan's interest in his theatre soon began to seem rather fitful. Nevertheless, he was responsible for the renewed appreciation of Restoration comedy that followed the revival of the plays of William Congreve at Drury Lane. In February 1777 he brought out his version of Vanbrugh's *The Relapse* (1696) as *A Trip to Scarborough*, again showing his talent for revision. He gave the rambling plot a neater shape and removed much indelicacy from the dialogue, but the result was disappointing, probably because of the loss of much of the play's former gusto.

What Sheridan learned from the Restoration dramatists can be seen in *The School for Scandal* produced at Drury Lane in May 1777. That play earned him the title of "the modern Congreve." Although resembling Congreve in that its satirical wit is so brilliant and so general that it does not always distinguish one character from another, *The School for Scandal* does contain two subtle portraits in Joseph Surface and Lady Teazle. There were several Restoration models (e.g., Mrs. Pinchwife in Wycherley's *The Country-Wife* and Miss Hoyden in Vanbrugh's *The Relapse*) for the portrayal of a country girl amazed and delighted by the sexual freedom of high society. Sheridan softened his Lady Teazle, however, to suit the more refined taste of his day. The part combined innocence and

The Rivals

Drury Lane Theatre

The School for Scandal

Education and marriage

sophistication and was incomparably acted. The other parts were written with equal care to suit the members of the company, and the whole work was a triumph of intelligence and imaginative calculation. With its spirited ridicule of affectation and pretentiousness, it is often considered the greatest comedy of manners in English.

Sheridan's flair for stage effect, exquisitely demonstrated in scenes in *The School for Scandal*, was again demonstrated in his delightful satire on stage conventions, *The Critic*, which since its first performance in October 1779 has been thought much funnier than its model, *The Rehearsal* (1671), by George Villiers, the 2nd duke of Buckingham. Sheridan himself considered the first act to be his finest piece of writing. Although Puff is little more than a type, Sir Fretful Plagiary is not only a caricature of the dramatist Richard Cumberland but an epitome of the vanity of authors in every age.

Political career. Sheridan continued to adapt plays and to improvise spectacular shows at Drury Lane, but as a succession of acting managers took over the burden of direction his time was increasingly given to politics. His only full-length later play was the artistically worthless but popular patriotic melodrama *Pizarro* (1799), based on a German play on the conquest of Peru. Sheridan had become member of Parliament for Stafford in September 1780 and was undersecretary for foreign affairs (1782) and secretary to the treasury (1783). Later he was treasurer of the Navy (1806–07) and a privy councillor. The rest of his 32 years in Parliament were spent as a member of the minority Whig party in opposition to the governing Tories. His critical acumen and command over language had full scope in his oratory and were seen at their best in his speeches as manager of the unsuccessful impeachment of Warren Hastings, governor general of India.

He was recognized as one of the most persuasive orators of his time but never achieved greater political influence in Parliament because he was thought to be an unreliable intriguer. Some support for this view is to be found in his behaviour during the Regency Crisis (1788–89) following the temporary insanity of George III when Sheridan acted as adviser to the unpopular self-indulgent Prince of Wales, later George IV. He encouraged the Prince to think that there would be a great majority for his being regent with all the royal powers simply because he was heir-apparent. In the country at large this was seen as a move by Charles James Fox and his friends to take over the government and drive out Prime Minister William Pitt. Sheridan was also distrusted because of his part in the Whigs' internecine squabbles (1791–93) with Edmund Burke over the latter's implacable hostility to the French Revolution. He was one of the few members courageous enough openly to defend those who suffered for their support of the French Revolution. Indeed, Sheridan liked taking an individual stand, and although he supported Fox in urging that the French had a right to choose their own way of government, he broke with Fox once the French became warlike and threatened the security of England. He also came out on the side of the Tory administration when he condemned mutineers who had rebelled against living conditions in the British Navy (1797). Much to Fox's disgust, Sheridan, although a Whig, gave some support to the Tory administration of Prime Minister Henry Addington, later 1st Viscount Sidmouth (1801–1804).

In November 1806, Sheridan succeeded Fox as member for Westminster—although not, as he had hoped, as leader of the Whigs—but he lost the seat in May 1807. The prince of Wales then returned him as member for the "pocket borough" of Ilchester, but his dependence on the prince's favour rankled with Sheridan, for they differed in their attitude on Catholic emancipation. Sheridan, who was determined to support emancipation, stood for election as member from Stafford again in 1812, but could not pay those who had previously supported him as much as they expected and as a result was defeated.

Last years. Sheridan's financial difficulties were largely brought about by his own extravagance and procrastination, as well as by the destruction of Drury Lane Theatre by fire in February 1809. With the loss of his parliamenta-

ry seat and his income from the theatre, he became a prey to his many creditors. His last years were beset by these and other worries—his circulatory complaints and the cancer that afflicted his second wife, Esther Jane Ogle. She was the daughter of the dean of Winchester, whom he had married in April 1795, three years after Elizabeth's death. Pestered by bailiffs to the end, Sheridan died in London on July 7, 1816. Even in decline, he had made a strong impression on Byron, who wrote a *Monody on the Death of the Right Honourable R.B. Sheridan* (1816), to be spoken at the rebuilt Drury Lane Theatre.

MAJOR WORKS

PLAYS: *The Rivals*, 1775; *St. Patrick's Day; Or, The Scheming Lieutenant*, 1775; *The Duenna*, 1775 (comic opera); *A Trip to Scarborough*, 1777 (Sheridan's version of Sir John Vanbrugh's *The Relapse; or, Virtue in Danger*); *The School for Scandal*, 1777; *The Critic; or a Tragedy Rehearsed*, 1779; *Pizarro* (1799) (adapted from August von Kotzebue's *Die Spanier in Peru*).

POEMS: *The Ridotto of Bath*, 1771; *The Rival Beauties. A poetical Contest*, 1772 (including "Clio's Protest"); *Verses to the Memory of Garrick Spoken as a Monody*, 1779.

BIBLIOGRAPHY

Editions and bibliography: *The Plays and Poems*, ed. by R. CROMPTON RHODES, 3 vol. (1928, reprinted 1962), is the standard text. It should be supplemented by RICHARD L. PURDY's excellent edition of *The Rivals: A Comedy As It Was First Acted at the Theatre-Royal in Covent-Garden* (1935); and by GEORGE H. NETTLETON's texts of *The Rivals*, *The School for Scandal*, and *The Critic*, in *British Dramatists from Dryden to Sheridan*, ed. by Nettleton and A.E. CASE (1939). Annotated editions of *The Rivals* (1968) and *The School for Scandal* (1971), have been prepared by C.J.L. PRICE, who is also responsible for a critical edition of all the plays (1973). No full bibliography of Sheridan's work has been published; valuable bibliographical material may be found in J.P. ANDERSON'S lists in L.C. SANDERS, *Life of Sheridan* (1890); in *Sheridan's Major Dramas*, ed. by GEORGE H. NETTLETON (1906); in the works by SICHEL (see below) and RHODES (see above); in IOLA A. WILLIAMS, *Seven XVIIIth-Century Bibliographies* (1924, reprinted 1968); and in the critical edition of the plays, ed. by Price.

Bibliography and criticism: THOMAS MOORE, *Memoirs of the Life of the Right Honourable Richard Brinsley Sheridan*, 5th ed., 2 vol. (1827, reprinted 1971), is indispensable. WILLIAM SMYTH, *A Memoir of Mr. Sheridan* (1840), is a brief but vivid account from personal acquaintance. W. FRASER RAE, *Sheridan*, 2 vol. (1896); and W. SICHEL, *Sheridan*, 2 vol. (1909), are full accounts, printing much new material, but are not altogether reliable. R.C. RHODES, *Harlequin Sheridan* (1933, reprinted 1969), provides a scholarly review of evidence about disputed passages in Sheridan's life; LEWIS GIBBS, *Sheridan* (1947, reprinted 1970), gives a useful summary of accepted material. JEAN DULCK, *Les Comedies de R.B. Sheridan* (1962), is a close examination of Sheridan's achievement from the French point of view. *The Letters of Richard Brinsley Sheridan*, ed. by C.J.L. PRICE, 3 vol. (1966), prints 972 letters in detail; they are mainly concerned with his life in politics and the theatre, but they also include some delightful ones to his second wife.

(C.J.L.P.)

Sherman, William Tecumseh

An American Civil War general, William Tecumseh Sherman became one of the chief architects of modern warfare when he combined with Gen. Ulysses S. Grant in unified campaigns to crush the Confederate armies and destroy the South's resources for waging war.

Born February 8, 1820, at Lancaster, Ohio, and named Tecumseh in honour of the famous Shawnee chieftain, he was one of eight children of Judge Charles R. Sherman, who died when the boy "Cump" was only nine. Thomas Ewing, a warm family friend and a Whig political force in Ohio, adopted Cump as "the brightest of the lot." His foster mother, a devout Catholic who feared that no priest would baptize a child with a heathen name, added William to the boy's name. When Sherman was 16, Ewing obtained an appointment to West Point for his adopted son, whom Eastern relatives saw as "an untamed animal just caught in the Far West." Cadet Sherman excelled in engineering, geology, rhetoric, and philosophy. He also did well in collecting demerits.

After graduation Sherman was sent to fight Seminole

Early years

Indians in Florida; he encountered no Indians but was delighted with the young ladies of St. Augustine. Transferred to Ft. Moultrie, South Carolina, within easy reach of Charleston, he enjoyed four years of "horse-racing, picnicking, boating, fishing, swimming, and God knows what not." He also thought of becoming an artist.

The Mexican War, in which so many generals of the Civil War received their experience, passed Sherman by. He was stranded in California as an administrative officer. In 1850 Sherman married Ellen Ewing, daughter of his adoptive father, who was then serving as secretary of the interior in Washington. They settled in St. Louis.

He was bored by his commissary duties of purchasing cattle in Kansas and Missouri. The lure of gold in California led him to resign from the army on September 6, 1853, and join the St. Louis banking firm of Lucas, Turner and Co. as its representative in San Francisco. In the collapse of the gold rush, he had accumulated a debt of \$13,000; he thereupon declared himself "the Jonah of banking." Other disappointments followed. As a self-taught lawyer his legal career came to an end in Leavenworth, Kansas, with his first case—proving anew, as he declared, that he had become "a dead cock in a pit." The army would not reinstate him.

Old friends, Southerners Braxton Bragg and P.G.T. Beauregard, found Sherman employment as superintendent of a Southern military college (now the University of Louisiana). He loved being a schoolmaster, but with Louisiana's secession from the Union he returned north and became president of the Fifth Street Railroad in St. Louis. The war, he told one of his daughters, demonstrated that "men are blind and crazy." He distrusted Pres. Abraham Lincoln yet used the influence of his younger brother, Senator John Sherman, to obtain appointment in the U. S. Army as a colonel in May 1861.

Raised to a generalship after the first Battle of Bull Run (July 21, 1861), Sherman begged Lincoln not to trust him in an independent command. Nevertheless, he was placed in charge of troops in Kentucky until his hallucinations concerning the Confederate force opposing him caused him to ask for so many reinforcements that he was publicly called insane. He then served as a commander under Generals Henry Halleck and Grant.

Grant had a calming influence upon Sherman. Together they fought brilliantly to capture Vicksburg (1862–63), shattering the Confederate defenses and opening the Mississippi River to Northern commerce once more. When, in 1864, Grant went east to fight Confederate general Robert E. Lee, Sherman led three armies in the invasion of Georgia that brought the fall of Atlanta. Both Grant and Lincoln doubted the wisdom of Sherman's celebrated "March to the Sea" from Atlanta to Savannah with 60,000 men. But a cocky Sherman reached the Atlantic coast in time to offer President Lincoln the city of Savannah

for a Christmas present. Grant plunged into the Wilderness to trap Lee in Virginia; Sherman marched north through the Carolinas; and the war entered its climactic phases.

Sherman declined all opportunities to run for political office, saying he would not run if nominated and would not serve if elected. When Grant became president in 1869, he made Sherman commanding general of the army, a post he held until 1884. Sherman remained a soldier until the end, though he expressed his view of warfare in the often-quoted phrase, "War is hell." His friends accused him of keeping a carpetbag packed so that he could leave at an instant's notice upon invitation to address an audience. He died in New York City on February 14, 1891.

BIBLIOGRAPHY. The definitive biography of Sherman is LLOYD LEWIS, *Sherman: Fighting Prophet* (1932). **SHERMAN'S** own *Memoirs*, 2 vol. (1875), are charming, straightforward, and highly critical of numerous Confederate heroes. **EARL SCHENCK MIERS**, *The General Who Marched to Hell* (1951), depicts Sherman's temperament and fighting style. Collections of Sherman's letters have been ed. by RACHEL SHERMAN THORNDIKE, *The Sherman Letters: Correspondence Between General and Senator Sherman from 1837 to 1891* (1894); and M.A. DE WOLFE HOWE, *Home Letters of General Sherman* (1909). Some glimpses of the Sherman whom soldiers and southerners knew are given in the diaries of **HENRY HITCHCOCK**, *Marching With Sherman*, ed. by HOWE (1927); and **EMMA LECONTE**, *When the World Ended*, ed. by MIERS (1957).

Shinran

Shinran was an important Japanese philosopher and religious reformer who insisted on the salvation of all human beings, poor and rich, low and high, and who, to achieve these aims, established the Jbdo *Shinshū* ("True Pure Land School") sect of Buddhism in 1224. Historically speaking, this school of Buddhism retained Indian devotionism and provided it with a Buddhistic foundation of compassion (*maitrī-karūṇā*) in contrast to the self-disciplined Buddhism (Tendai, Zen) that concentrated on wisdom (*prajñā*), and had few effective means of saving less well-endowed human beings. Shinran took seriously the salvation of the masses. His belief was that perfect intercommunion of Amida Buddha (the Buddha who ruled over the Western Paradise) and all sufferers and, thus, the salvation of all could be achieved through the mere calling of the name of Amida Buddha (*Namu-Amida-Butsu*).

Shinran, ink on paper by Sen-ami, middle of the 13th century. In the Nishi-Hongan-ji, Kyōto, Japan.

Shinran was born to **Hino** Arinori near Kybto in AD 1173. Orphaned at an early age, he entered the Tendai priesthood when he was nine and was given the name Hannen Shbnagon-no-Kimi in 1182 by the priest Jichin (Jien), the head of Shbren-in. For 20 years Shinran studied Buddhism on Mt. Hiei, where an eminent Bud-

Early life
and career

dhist monk, Dengyō Daishi, had established the centre of the Tendai school, which taught that the Buddha uses skillful means to enlighten men.

Despite the most rigorous asceticism, Shinran failed to find the assurance of salvation. A long spiritual struggle in quest of salvation had occupied his early years as a monk of the Tendai school, which had been weakened by its political affiliation with the aristocracy. Moreover, at the beginning of the Kamakura period (1192–1333), the decline of the aristocratic class and its fierce struggles with the military class for political supremacy brought so much confusion and distress that the people began to accept a pessimistic view of history, according to which, with the passage of time after the Buddha's death, the world would gradually become degenerate and the Buddha's teaching would become decadent.

Shinran then came down from Mt. Hiei for 100 days to continue his quest for salvation in the Rokkakudō, in Kyōto (the "Hexagonal Temple"). It was at this time that he met the Buddhist saint Hōnen, founder of the Jōdo ("Pure Land") sect, who had been preaching to the masses the message: "Anyone who only calls Amida's Name shall be saved without fail, for the Name-Call is not a human contrivance, but the select way given in Amida's Original Vow." This practice of calling Amida's name is known as nembutsu. In his 29th year, "Shinran abandoned ascetic practices and took refuge in the Original Vow." In his 33rd year, Shinran was allowed to copy Hōnen's main work, *Senchaku-shū* ("Book on the choice of nembutsu"), and drew a portrait of Hōnen. The *Senchaku-shū* was a great source of inspiration to Shinran, for copies of the document were entrusted only to a few close disciples. Shinran's study under Hōnen came to an end in 1207, when the government issued an edict against Hōnen's nembutsu movement (focussed on the invocation of the Buddha's name). The oppression had its centre in Kōfuku-ji at Nara and at Enryaku-ji on Mt. Hiei. As a result, Hōnen was exiled to Tosa Province, Shinran to Echigo, and two other nembutsu teachers were decapitated. Soon after his arrival in Echigo, Shinran married Eshinni, in violation of the Buddhist precept of celibacy for the priesthood.

Shinran's biography *Denne*, written by Kakunyo in 1295, ascribes a strong evangelistic impulse to his move to Kanto in eastern Japan, where, between 1212 and 1235 or 1236, he lived an academic and missionary life. In this period he compiled a monumental anthology, *Kyōgyōshinshō* ("Teaching-Action-Faith-Attainment," in six volumes), around 1224. In this work Shinran made an original contribution to Buddhist philosophy with the interpolation of faith between action and attainment. His ministry also had great success. Leaving behind a body of devoted believers, he had sown seeds that were later to bear fruit when ecclesiastical institutions were set up.

After 20 years he left Kanto for Kyoto, where his fellow believers were in a miserable plight from constant oppression after Hōnen's death. Moreover, in 1256 Shinran had to disown Zenran, his oldest son, who tried to control the community with a heretical interpretation of the faith. This was the most tragic experience in Shinran's long life. Despite spiritual depressions and economic difficulties, he completed his *Kyōgyōshinshō* and compiled a number of derivative works to make his teachings accessible to the masses. Among these writings, *Wasan* ("Poems"), *Gutokushō* ("An Exposition of Buddhism and Amida's Vow"), and *Yuishinshōmon* ("A Commentary on Saichō's Book of Faith") are regarded as important books.

Shinran died quietly on November 28, 1262, in Kyōto, where he had been born 90 years before. Shinran's teaching of justification by faith alone, and especially his teaching concerning the spiritual priesthood of all devotees, contained democratic implications that the mass of the people were later to apply in the service of a social and religious reformation. Shinran's religion, Jōdo Shinshū, has become the largest school of Buddhism in Japan today.

Shintō

Shintō is the name given to indigenous religious beliefs and practices of Japan. The word Shintō literally means "the way of kami" (kami means "mystical," "superior," or "divine," generally sacred or divine power, specifically the various gods or deities) and came into use in order to distinguish indigenous Japanese beliefs from Buddhism, which had been introduced into Japan in the 6th century AD.

NATURE AND VARIETIES

Shinto consists of the traditional Japanese religious practices as well as the beliefs and life attitudes which are in accord with these practices. Shintō is more readily observed in the social life of the Japanese people and in their personal motivations than in a pattern of formal belief or philosophy. Shintō remains closely connected with the Japanese value system and the Japanese people's ways of thinking and acting.

Shintō can be roughly classified into the following three major types: Shrine Shintō, Sect Shintō, and Folk Shintō. Shrine Shintō (*Jinja Shintō*), which has been in existence from the beginning of Japanese history to the present day, constitutes a main current of Shintō tradition. Shrine Shintō includes within its structure the now defunct State Shintō (*Kokka Shintō*)—based on the total identity of religion and state—and has close relations with the Japanese Imperial Family. Sect Shintō (*Kyōha Shintō*) is a relatively new movement consisting of 13 major sects which originated in Japan around the 19th century. Each sect was organized into a religious body by either a founder or a systematizer. Folk Shintō (*Minzoku Shintō*) is an aspect of Japanese folk belief that is closely connected with the other types of Shintō. It has no formal organizational structure nor doctrinal formulation but is centred in the veneration of small roadside images and the agricultural rites of rural families. These three types of Shintō are interrelated: Folk Shintō exists as the substructure of Shintō faith, and a Sect Shintō follower is usually a parishioner (*ujiko*) of a certain Shrine Shintō shrine at the same time.

Three major types of Shintō

HISTORY TO 1900

Much remains unknown about religion in Japan during the Paleolithic and Neolithic ages. It is unlikely, however,

that the religion of these ages has any direct connection with Shintb. Yayoi culture, an early West Japan culture which originated in north Kyūshū around the 3rd or 2nd century BC, is directly related to later Japanese culture and hence to Shinto. Among the primary Yayoi religious phenomena were agricultural rites and shamanism.

Early clan religion and ceremonies. In ancient times small states were gradually formed at various places. By the middle of the 4th century AD a nation with an ancestor of the present Imperial Household as its head had probably been established. The constituent unit of society in those early days was the *uji* (clan or family), and the head of each *uji* was in charge of worshipping the clan's *uji-gami*—its particular tutelary or guardian deity. The prayer for good harvest in spring and the harvest ceremony in autumn were two major festivals honouring the *uji-gami*. Divination, water purification, and lustration (ceremonial purification), which are mentioned in the Japanese classics, became popular and people started to build shrines for their *kami*.

Ancient Shintb was polytheistic. People found *kami* in nature, which ruled seas or mountains, as well as in outstanding men. They also believed in *kami* of ideas such as growth, creation, and judgment. Though each clan made the tutelary *kami* the core of its unification, such *kami* were not necessarily the ancestral deities of the clan. Sometimes *kami* of nature and *kami* of ideas were regarded as their tutelary *kami*.

Two different views of the world were present in ancient Shintd. One was the three-dimensional view in which the Plain of High Heaven (Takama-no-hara, the *kami*'s world), Middle Land (Nakatsu-kuni, the present world), and the Hades (Yomi, the world after death) were arranged in vertical order. The other was a two-dimensional view in which this world and Perpetual Country (Tokoyo), a utopian place of boundless wealth, pleasure, and peace) existed in horizontal order. Though the three-dimensional view of the world (also characteristic of North Siberian and Mongolian shamanistic culture) became the representative view observed in Japanese myths, the two-dimensional view of the world (also present in Southeast Asian culture) was dominant among the populace.

Early Chinese influences on Shintd. Confucianism is believed to have reached Japan in the 5th century AD, and by the 7th century it had spread among the people, together with Chinese Taoism and Yin-Yang (harmony of two basic forces of nature) philosophy, and stimulated the development of Shinto ethical teachings. With the development of centralization of political power, Shintō began to develop as a national cult as well. Myths of various clans were combined and reorganized into a pan-Japanese mythology with the Imperial Household as its centre. The *kami* of the Imperial Household and tutelary *kami* of powerful clans became the *kami* of the whole nation and people, and offerings were made by the state every year. Such practices were systematized supposedly around the Taika Reformation (645). By the beginning of the 10th century about 3,000 shrines were receiving state offerings. As the power of the central government declined, the system ceased to be effective, and after the 13th century only a limited number of important shrines continued to receive the Imperial offerings. Later, after the Meiji Restoration (return to traditional Imperial system) in 1868, the old system was revived.

The encounter with Buddhism. Buddhism was first introduced into Japan in AD 538 and developed gradually. In the 8th century there emerged tendencies to interpret Shinto from a Buddhist viewpoint. Shintb *kami* were viewed as protectors of Buddhism; hence shrines for tutelary *kami* were built within the precincts of Buddhist temples. *Kami* were made equivalent to *deva* (the Buddhist Sanskrit term for "gods") who rank highest in the Realm of Ignorance, according to Buddhist notions. Thus *kami*, like other creatures, were said to be suffering because they were unable to escape the endless cycle of transmigration; help was therefore offered to *kami* in the form of Buddhist discipline. Thus from the mid-8th

century Buddhist temples were even built within Shintb shrine precincts, and Buddhist *sūtras* (scriptures) were read in front of *kami*. By the late 8th century *kami* were thought to be avatars, or incarnations, of Buddhas and *bodhisattvas*. *Bodhisattva* names were given to *kami*, and Buddhist statues were placed even in the inner sanctuaries of Shintb shrines. In some cases also Buddhist priests were in charge of the management of Shintō shrines.

After 1192, during the Kamakura shogunate, theories of Shintb-Buddhist amalgamation were established. Two representative examples of such amalgamation were Shingon Shintb and Tendai Shintd. According to Shingon Shintb—also known as Ryōbu ("Two Aspects") Shintb—the principal source of the whole universe was considered to be the cosmic Buddha, Mahā-Vairocana (the Great Illuminator). According to Tendai Shintb—also called Ichijitsu ("One Reality") Shinto—only the Buddha-nature was the source of all things. These two sects also brought various Buddhist rituals of an esoteric nature into Shintb. Buddhist Shintō was popular for several centuries and influenced the majority of Shintb shrines until its extinction at the Meiji Restoration.

Shintd reaction against Buddhism. Watarai, or Ise, Shinto was the first theoretical school of anti-Buddhistic Shintō in that it attempted to exclude Buddhist accretions and tried to formulate a pure Japanese version. Watarai Shintb appeared in Ise during the 13th century as a reaction against the Shintd-Buddhist amalgamation. Konton (chaos), or Kizen (non-being), was the basic *kami* of the universe for Watarai Shintō and was regarded as the basis of all beings, including the Buddhas and *bodhisattvas*. Purification, which had been practiced since the time of ancient Shintb, was given much deeper spiritual meanings. *Shōjiki* (uprightness or righteousness) and prayers were emphasized as the means by which to be united with *kami*.

Yoshida Shintb, which was started by Yoshida Kanetomo (1435–1511) in Kyōto, inherited various aspects of Watarai Shintb and also showed some Taoist influence. Its fundamental *kami* (the source of all things and beings in the universe) was Taigen Sonjin (the Great Exalted One). According to its teaching, if one is truly purified, his heart can be the *kami*'s abode. The ideal of inner purification was a mysterious state of mind in which one worshipped the *kami* that lived in one's own heart. Although the Watarai and Yoshida schools were thus free of Buddhist theories, the influence of Chinese thought was still present.

Neo-Confucian Shintō. In 1603 the Tokugawa Shogunate was founded in Edo (Tokyo), and contact between Shintb and Confucianism was resumed. Scholars tried to interpret Shintb from the standpoint of Neo-Confucianism, which became an official subject of study for warriors, and from that of the Chinese Wang Yang-ming school of philosophy. Scholars emphasized the unity of Shintō and Confucian teachings. Yoshikawa Koretaru (1616–94) and Yamazaki Ansai (1618–82) were two representative scholars of Confucian Shintb. They added Neo-Confucian interpretations to the traditional theories handed down from Watarai Shintb, and each established a new school. The T'ai Chi ("Supreme Ultimate") of Neo-Confucianism was regarded as identical with the first *kami* of the *Nihon-shoki*, or *Nihongi* ("Chronicles of Japan"). One of the characteristics of Yoshikawa's theories was his emphasis on political philosophy. Imperial virtues (wisdom, benevolence, and courage), symbolized by the *sanshu-no-shinki* ("Three Sacred Treasures"), and national ethics, such as loyalty and filial piety, constituted the way to rule the state. Yamazaki Ansai further developed this tendency and advocated both mystic pietism and ardent emperor worship.

Revival of Shintō. Revival Shintd is one of the Kokugaku ("Japanese studies") movements which started toward the end of the 17th century. Advocates of this school maintained that the norms of Shintb should not be sought in Buddhist or Confucian interpretations but in the beliefs and life-attitudes of their ancestors as clarified by philological study of the Japanese classics. Moto-ori

syncretism

Kami

Yoshikawa
Koretaru
and
Yamazaki
Ansai

Norinaga (1730–1801) represented this school. His emphasis was on the belief in musubi (the mystical power of becoming or creation), which had been popular in ancient Shinto, and on a this-worldly view of life, which expected the eternal progress of the world in ever-changing mutations. These beliefs, together with the inculcation of respect for the Imperial line and the teaching of absolute faith—according to which all problems beyond human capability were turned over to *kami*—exercised great influence on modern Shintō doctrines.

The most important successor of Moto-ori in the field of Shintō was Hirata Atsutane (1776–1843), who showed the influence of Roman Catholic teachings in some respects—derived from the writings of Jesuits in China—and introduced the idea of a creator god and retribution for ethical and religious failings in another world. These doctrines, however, were not accepted into the main current of Shintō. Hirata developed the philological studies started by Moto-ori and trained many capable disciples. He also wrote plays, worked out formulas for family cults of tutelary *kami* and ancestors, and promoted Shintō practices. His criticism of the Tokugawa shogunate, based on the spirit of ancient Shintō, and his call to unite all the people under the emperor enlisted many supporters and served as one of the factors in bringing about the Meiji Restoration in 1868.

Formation of Sect Shintō. From the end of the Tokugawa period to the beginning of Meiji (1867–68), new religious movements emerged out of the social confusion and unrest of the people. What these new movements taught differed widely: some were based on mountain-worship groups, which were half Buddhist and half Shintō; some placed emphasis on purification and ascetic practices; and some combined Confucian and Shintō teachings. New religious movements such as Kurozumi-kyō (*kyō* means "religion," or "religious body"), founded by Kurozumi Munetada (1780–1850), Konkō-kyō (Konkō is the religious name of the founder of this group which means, literally, "golden light") by Kawate Bunjirō (1814–83), and Tenri-kyō (tenri means "divine reason or wisdom") by Nakayama Miki (1798–1887) were based mostly on individual religious experiences and aimed at healing diseases or spiritual salvation. These sectarian Shintō groups, amounting to 13 during the Meiji period (1868–1912), were stimulated and influenced by Revival Shintō. They can be classified as follows:

1. Revival Shintō sects: Izumo-ō-yashiro-kyō (or Taisha-kyō), Shintō-tai-kyō, Shinri-kyō
2. Confucian sects: Shintō-shūsei-ha, Shintō-taisei-kyō
3. Purification sects: Shinshū-kyō, Misogi-kyō
4. Mountain worship sects: Jikkō-kyō, Fusō-kyō, Ontake-kyō (or Mitake-kyō)
5. "Faith-healing" sects: Kurozumi-kyō, Konkō-kyō, Tenri-kyō

SHINTO LITERATURE AND MYTHOLOGY

Shintō has no founder. When the Japanese people and Japanese culture became aware of themselves, Shintō was already there. Nor has it any official scripture that can be compared to the Bible in Christianity or to the Qurʾān in Islām. The Kojiki ("Records of Ancient Matters") and the Nihongi or Nihon shoki ("Chronicles of Japan") are regarded in a sense as sacred books of Shintō. They were written in AD 712 and 720 respectively and are compilations of the oral traditions of ancient Shintō. But, they are also books about the history, topography, and literature of ancient Japan. It is possible to construct Shintō doctrines from them by interpreting the myths and religious practices they describe.

Stories partially similar to those found in Japanese mythology can be found in the myths of Southeast Asia; and in the style of description in Japanese myths, some Chinese influence is detectable. The core of the mythology, however, consists of tales about Amaterasu Ō-mikami ("Sun Goddess"), the ancestress of the Imperial Household, and tales of how her direct descendants unified the Japanese people under their authority. In the beginning, according to Japanese mythology, a certain number of kami simply emerged, and a pair of kami,

Izanagi and Izanami, gave birth to the Japanese islands, as well as to the kami who became ancestors of the various clans. The "Sun Goddess," the ruler of Takama-no-hara, the Moon Ruler (Tsukiyomi-no-mikoto), and the ruler of the nether regions (Susanowo-no-mikoto) were the most important among them. A descendant of the "Sun Goddess," Jimmu Tennō, is said to have become the first emperor of Japan. Japanese mythology says that the Three Sacred Treasures (sanshu-no-shinki; the mirror, the sword, and the jewels), which are still the most revered symbols of the Imperial Throne, were first given by the "Sun Goddess" to her grandson. The Grand Shrine of Ise is dedicated to this ancestral goddess and is the most highly respected shrine in Shintō.

The Japanese classics also contain myths and legends concerning the innumerable kami (yaho-yorozu-no-kami; literally, yaho=800, yorozu=10,000, no=of). Some of them are the tutelary deities of clans and later became the tutelary kami of their respective local communities. Many others, however, were not enshrined in sanctuaries and have no direct connections with the actual Shintō faith. Little attention had been paid to Shintō mythology until the development of Revival Shintō, and even today it is not really well known except by Shintō priests and scholars.

DOCTRINES

Concept of the sacred. At the core of Shintō are beliefs in the mysterious power (musubi, creating and harmonizing power) of kami and in the way or will (makoto, truth or truthfulness) of kami. The nature of kami cannot be fully explained in words because kami transcends the cognitive faculty of man. Devoted followers, however, are able to understand kami through faith and usually recognize various kami in polytheistic form.

Parishioners of a Shintō shrine believe in their tutelary kami as the source of human life and existence. Each kami has a divine personality and responds to truthful prayers. Kami also reveals makoto to men and guides them to live in accordance with it. According to the traditional Japanese way of thinking, truth manifests itself in empirical existence and undergoes transformation in infinite varieties in the empirical conditions of time and space. Makoto is not an abstract ideology. It can be recognized every moment in every individual thing in the encounter between man and kami.

In Shintō all the deities are said to cooperate with one another, and life lived in accordance with kami's will is believed to produce a mystical power that gains the protection, cooperation, and approval of all the particular kami.

Precepts of truthfulness and purification. As the basic attitude toward life, Shintō emphasizes *makoto-no-kokoro* (heart of truth) or *magokoro* (true heart), which is usually translated as "sincerity, pure heart, or uprightness." This attitude follows from the revelation of kami's truthfulness in man. It is, generally, the sincere attitude of a man in doing his best in the work he has chosen or in his relationship with others, and the ultimate source of such a life-attitude lies in man's awareness of the divine.

Although Shintō ethics do not ignore individual moral virtues such as loyalty, filial piety, love, and faithfulness, it is generally considered more important to seek for *magokoro*, which constitutes the dynamic life-attitude that brings forth these virtues. *Magokoro* was interpreted as "bright and pure mind" or "bright, pure, upright, and sincere mind" in ancient scriptures. In other words, it is the pure state of mind. Purification, physical and spiritual, is stressed in Shintō even today to produce such a state of mind. It is a necessary means to make communion between kami and man possible and to enable man to accept kami's blessings.

Nature of man and other beliefs. In Shintō it is commonly said that "Man is kami's child." First, this means that man was given his life by kami and that his nature is therefore sacred. Second, it means that daily life is made possible by kami, and, accordingly, the personality and life of man are worthy of respect. Man must revere the basic human rights of everyone (regardless of

Kami and
makoto

Kojiki
and
Nihongi
("Nihon
shoki")

race, nationality, and other distinctions) as well as his own. The concept of original sin is not found in Shinto. On the contrary, man is considered to have a primarily divine nature. In actuality, however, this sacred nature is seldom revealed in man. Purification is considered symbolically to remove the dust and impurities that cover man's inner mind.

Role of the individual in the history of his family

Shintō is described as a "religion of tsurtagari" (continuity or communion). The Japanese, while recognizing each man as an individual personality, do not take him as a solitary being separated from others. On the contrary, he is regarded as the bearer of a long, continuous history that comes down from his ancestors and continues in his descendants. He is also considered as a responsible constituent of various social groups.

Moto-ori Norinaga stated that the human world keeps growing and developing while continuously changing. Similarly Japanese mythology speaks of an eternity of history in the divine edict of the "Sun Goddess." In its view of history, Shintō adheres to the cyclical view, according to which there is a constant recurrence of historical patterns. Shintō does not have the concept of the "last day": there is no end of the world or of history. One of the divine edicts of the "Sun Goddess" says:

This Reed-plain-1,500-autumns-fair-rice-earLand is the region which my descendants shall be lords of. Do thou, my August Grandchild, proceed thither and govern it. Go! and may prosperity attend thy dynasty, and may it, like Heaven and Earth, endure forever.

Modern Shintoists interpret this edict as revealing the eternal development of history as well as the eternity of the dynasty. From the viewpoint of finite individuals, Shintoists also stress *naka-ima* (middle present), which repeatedly appears in the Imperial edicts of the 8th century. According to this point of view, the present moment is the most valuable of all conceivable times. In order to participate directly in the eternal development of the world, it is required of Shintoists to live fully each moment of life, making it as worthy as possible.

Historically, the *uji-gami* of each local community played an important role in combining and harmonizing different elements and powers. The Imperial system, which has been supported by the Shinto political philosophy, is an example of unity and harmony assuming the highest cultural and social position in the nation. After the Meiji Restoration (1868), Shinto was used as a means of spiritually unifying the people during repeated wars. Since the end of World War II the age-old desire for peace has been restressed. The General Principles of Shintō Life proclaimed by the Association of Shinto Shrines in 1956 has the following article: "In accordance with the Emperor's will, let us be harmonious and peaceful, and pray for the nation's development as well as the world's co-prosperity."

RITUAL PRACTICES AND INSTITUTIONS

Shintō does not have a weekly religious service. People visit shrines at their convenience. Some may go to the shrines on the 1st and 15th of each month and on the occasions of *matsuri* (rites or festivals), which take place several times a year. Devotees, however, may pay respect to the shrine every morning.

Matsuri

Rites of passage. Various Shintō rites of passage are observed in Japan. The first visit of a newborn baby to the tutelary kami, which will be between 30 and 100 days after his birth, is to initiate the baby as a new adherent. The Shichi-go-san festival on November 15 is the occasion for children of three, five, and seven years old respectively to visit the shrine to give thanks for *kami*'s protection and to pray for their healthy growth. January 15 is Adults' Day. Youth in the village used to join the local young men's association on this day. At present it is the commemoration day for those Japanese who have attained their 20th year. The Japanese usually have their wedding ceremonies in Shintō style and pronounce their wedding vows to *kami*. Shinto funeral ceremonies, however, are not popular. The majority of the Japanese are Buddhist and Shintōist at the same time and have their funerals in Buddhist style. A traditional Japanese house

has two family altars: one, Shintō, for their tutelary *kami* and the goddess Amaterasu Ō-mikami, and another, Buddhist, for the family ancestors. Pure Shintō families, however, will have all ceremonies and services in Shintō style. There are other Shinto *matsuri* (rites) concerning occupations or daily life, such as a ceremony of purifying a building site or for setting up the framework for a new building, a firing or purifying ceremony for the boilers in a new factory, a completion ceremony for a construction works, or a launching ceremony for a new ship.

Varieties of festival, worship, and prayer. Each Shintō shrine has such grand festivals every year as the Spring Festival (Haru-matsuri, or Toshi-go-i-no-matsuri; prayer for good harvest), Autumn Festival (Aki-matsuri, or *Niiname-no-matsuri*; Shinto thanksgiving), Annual Festival (reisai) and Divine Procession (shinkd-shiki). Divine Procession usually takes place on the day of Annual Festival, and sacred palanquins (*mikoshi*, miniature shrines carried on the shoulders) are transported through the district. The order of rituals at a grand festival is usually as follows: (1) Purification rites (*harai*)—commonly held at a corner of the shrine precincts before participants come into the shrine, but sometimes held within the shrine before beginning a ceremony. (2) Adoration—the chief priest and all the congregation bow to the altar. (3) Opening of the door of the inner sanctuary (by the chief priest). (4) Presentation of food offerings—rice, sake wine, rice cake, fish, bird, seaweed, vegetables, salt, water, etc., are offered, but not animal meat, because of the taboo on shedding blood in the sacred area. Generally, cooked food used to be offered to *kami*, but nowadays uncooked food is more often used. In accordance with this change, the idea of entertaining *kami* changed to that of thanksgiving. (5) Prayer—the chief priest recites *norito* (prayers). The models for *norito* are ancient Shintō prayers that were compiled in the early 10th century, based on the old belief that spoken words would have spiritual potency. (6) Sacred music and dance. (7) General offering—participants in the festival make symbolic offerings using little branches of the evergreen sacred tree with strips of white paper tied on them. (8) Taking offerings away—food and symbolic offerings are taken away. (9) Shutting the door of the inner sanctuary. (10) Final adoration. (11) Feast (*naorai*).

Ritual at festivals

Bob and Ira Spring

In the olden days *naorai*, a symbolic action for participants to hold communion with *kami* by having the same food offered to the deity, came in the middle of the festival ceremony. The custom is still observed sometimes at the Imperial Household and some old shrines. Most of the shrines, however, today have communion with *kami* by drinking the wine that was offered to *kami* after the festival instead. Since World War II it has be-

come popular to have a brief sermon or speech before the feast.

Most **Shintō** festivals are observed generally in accordance with the above-mentioned order. On such occasions as the Annual Festival, various special rites may be held; e.g., special purification (misogi) and abstinence (*o-komori*), a divine procession of a sacred palanquin (*o-miyuki*) or of boats (*funa-matsuri*), a ceremonial feast (*tōya-matsuri*), sumo wrestling, horseback riding (*kwabe-uma*), archery (*matoi*), a lion dance (*shishi-mai*), and a rice planting festival (*o-taue-matsuri*).

Types of shrines. A simple torii gate stands at the entrance of the shrine precincts (see illustration). After proceeding on the main approach, a visitor will come to an ablution basin where he is to clean his hands and rinse his mouth. Usually he will make a small offering at the oratory (*haiden*) and pray. Sometimes a visitor may ask the priest to conduct rites of passage or to offer special prayers. The most important shrine building is the inner sanctuary (*honden*), in which a sacred symbol called *shintai* (kami body) or *mitama-shiro* (divine spirit's symbol) is enshrined. Usually it is a mirror, but sometimes it is a wooden image, a sword, or some other object. In any case, it is carefully wrapped and placed in a container, and it is forbidden to see it. Only the chief priest is allowed inside the inner sanctuary.

In the beginning Shintb had no shrine buildings. At each festival people placed a tree symbol at a sacred site or built a temporary shrine to invite kami. Later they began to construct permanent shrines where kami were said to stay permanently. The *honden* of the Grand Shrine of Ise and Izumo Shrine (in Shimane Prefecture) illustrate two representative archetypes of shrine construction. The style of the former probably developed from a storehouse for crops, especially for rice, and that of the latter from ancient house construction. In the course of time, variations of shrine architecture were adopted and additional buildings were attached in front of the *honden*. The *honden* and *haiden* are in many cases connected by a hall of offering (*heiden*) where prayers are usually recited. Large shrines also have a hall for liturgical dancing (*kagura-den*).

Other practices and institutions. Uji-gami belief is the most popular form of **Shintō** in Japan. The term uji-gami originally referred to the kami of an ancient clan. After the 13th century the term was used in the sense of the tutelary kami of a local community, and all the members in the community were considered to be that kami's adherents (*ujiko*). Even today a *ujiko* group will consist of the majority of the residents in a given community. A Shintbist, however, can believe at the same time in shrines other than his own local shrine. It was only after World War II that some large shrines also started to organize believers' groups (*sūkeisha*). The Believers' Association of the Meiji Shrine, for instance, has approximately 200,000 members living around Tokyo.

Kokugakuin University and Kōgakkan University are the primary training centres for **Shintō** priests. Though anyone who goes through certain training processes may be a priest (or a priestess), many priests are, in fact, from the families of hereditary **Shintō** priests.

SHINTO RELIGIOUS ARTS

The Japanese from ancient times have valued emotional and aesthetic intuitions in expressing and appreciating their religious experiences. They found symbols of kami in natural beauty and the forces of nature, and they developed explicitly religious poetry, architecture, and visual arts. Shrine precincts are covered with green trees and are places of a serene and solemn atmosphere, which is effective in calming worshippers' minds. In the larger shrines, surrounded by expansive woods with mountains as their background, a harmony of nature and architecture may be achieved. The Grand Shrine of Ise and Izumo Shrine still retain the ancient architectural styles. After the 9th century an intricate form of shrine construction was developed adopting both Buddhist and Chinese architectural styles and techniques. The curving roof style is one example. Unpainted timbers are most

frequently used, but wherever Buddhist Shintb was popular, Chinese vermilion-lacquered shrines were also built. A torii gate always stands in front of a shrine. Various kinds of torii can be seen in Japan, but their function is always the same: to divide the sacred precincts from the secular area. A pair of sacred stone animals called *koma-inu* (dogs of Kokuryū, an ancient Korean kingdom) or *karajishi* (lions of Tang) are placed in front of a shrine. Originally they served to protect the sacred buildings from evil and defilements. After the 9th century they were used for ornamental purposes on ceremonial occasions at the Imperial Court and later came to be used at various shrines generally. Some of the stone lanterns (*ishi-dōrō*) used at the shrines are works of art. The dedicatory name and the year are inscribed on the lanterns to inform viewers of the long tradition of faith and to urge them to maintain it.

Compared with the Buddhist statues, images of kami are not outstanding either in their quality or quantity. Images of kami were, in fact, not used in ancient Shintb until after the introduction of Buddhism into Japan. These are placed in the innermost part of the *honden* and are not the objects of direct worship by the people. Kami icons are not worshipped at shrines.

The history of the shrine, its construction arrangements, and ritual processions are recorded in picture scrolls (*emakimono*), and at the older shrines there are many votive pictures (*emu*)—small wooden picture plaques—that have been dedicated by the people from former times. Other articles, such as specimens of calligraphy, sculpture, swords, and arms, dedicated by the Imperial families, nobles, or feudal lords, are also kept at shrines. Several hundred such items and shrine constructions have been designated by the Japanese government as national treasures and important cultural properties.

The traditional religious music and dance of shrines were performed for the purpose of entertaining and appeasing kami, rather than to praise them. *Gagaku* (literally "elegant music") involves both vocal and instrumental music, specifically for wind, percussion, and stringed instruments. *Gagaku* with dance is sometimes called *bugaku*. *Gagaku* was patronized by the Imperial Household as court music and was much appreciated by the upper classes from the 9th to the 11th century. Later some of the more solemn and graceful pieces were used as ritualistic music by shrines and temples. Today *gagaku* is widely performed at larger shrines. The authentic tradition of *gagaku* has been transmitted by the Institute of Music of the Imperial Household (established in 701).

Apart from *gagaku* there are also *kagura* (a form of indigenous, religious music and dance based on blessing and purification), *ta-asobi* (a New Year's dance-pantomime of the cycle of rice cultivation), and *shishi-mai* (lion dance), which developed originally from magico-religious dances, and are now danced for purification and as prayers. *Matsuri-bayashi* is a gay lively music with flutes and drums to accompany divine processions. Some organizations of both Shrine and Sect Shintb have recently begun to compose solemn religious songs to praise kami, making use of Western music. It is expected that such songs will be used in the future along with the traditional music. (See also VISUAL ARTS, EAST ASIAN; MUSIC, EAST ASIAN; DANCE AND THEATRE, EAST ASIAN.)

POLITICAL AND SOCIAL ROLES

Until the end of World War II, Shintb was closely related to the state. Offerings to kami were made every year by the government and the Imperial Household, and prayers were offered for the safety of the state and people. The *matsuri-goto* (the affairs of worship) offered by the emperor from olden days included not only ceremonies for kami but also for ordinary matters of state. "Shintb ceremonies and political affairs are one and the same" was the motto of officials. Administrators were required to have a religious conscience and develop political activities with *magokoro*.

This tradition was maintained as an undercurrent throughout Japanese history. Villagers prayed to the tutelary kami of the community for their peace and wel-

Torii: the sacred gates

Religious music and dance

Shintai and mitama-shiro

fare, and promoted unity among themselves with village festivals. After the Meiji Restoration, the government treated Shintō like a state religion and revived the system of national shrines, which dated from the 10th century. In order to propagate Revival Shintō as the foundation of the national structure, they initiated the "great promulgation movement" in which the emperor was respected like *kami*. Although the Japanese constitution enacted in 1889 guaranteed freedom of faith under certain conditions, priority was, in fact, given to Shintō. In elementary schools Shintō was taught to children, and most of the national holidays were related to Shintō festivals. Shintō of this nature was called State Shintō and came under the control of the Bureau of Shrines in the Ministry of Home Affairs.

Relation of State and Sect Shintō

State Shintō was regarded as a state cult and a national ethic and not as "a religion." The free interpretation of its teachings by individual Shintō priests was discouraged. Priests of the national shrines were prohibited from preaching and presiding over Shintō funerals. By 1945 there were 218 national and approximately 110,000 local shrines. The number of Sect Shintō groups was limited to 13 after the organization of Tenri-kyō. Legally these 13 sects were treated as general religious bodies, similar to Buddhism and Christianity, and came under the supervision of the Ministry of Education.

After the end of World War II, the Supreme Commander for the Allied Powers ordered the Japanese government to disestablish State Shintō. All financial support from public funds and all official affiliation with Shintō and Shintō shrines were also discontinued. State rites performed by the emperor were henceforth to be regarded as the private religious practices of the Imperial family. These rulings were carried into the new Japanese constitution in 1947. Presently, Shrine Shintō is faced with two serious problems. The first is determining how the traditional unifying function of Shintō can be promoted in local communities or in the nation without interfering with freedom of faith. The second is the necessity of harmonizing Shintō with rapid modernization, especially in organizing believers and dealing with human problems or the meaning of life.

The number of Shintō shrines has been decreasing since the beginning of the Meiji era, in part because a municipal unification plan in 1889 called for the shrines of tutelary *kami* to be combined with the municipality. As of 1968, there were about 80,000 shrines, most belonging to the Association of Shintō Shrines, established in 1946. Another 1,000 shrines are independent or belong to small groups. Shintō believers number about 60,000,000.

About 15 percent of 16,251 Sect Shintō churches were damaged during World War II. Although they were not affected by the occupation policies after the war, many sects, in fact, went through difficult years because of unrest among the people and disunion within their own organizations. At present, Tenri-kyō in particular is most active among the Sect Shintō groups and is extending its missionary activities overseas to East Asia, North and South America, etc. As of 1968 the number of some of the major sects is approximately as follows: Izumo-ō-yashiro-kyō—1,530,000; Shinri-kyō—688,000; Shinshū-kyō—523,000; Ontake-kyō—655,000; Kurozumi-kyō—605,000; Konkō-kyō—521,000; Tenri-kyō—1,846,000.

PLACE OF SHINTO IN JAPANESE AND WORLD RELIGION

Shintō together with Buddhism is closely related both culturally and socially to the life of the Japanese people. Its relationships to other religions in Japan are generally cooperative and harmonious. Most Shintōists believe that cooperation between different religions could contribute to world peace, but this is not to imply a facile religious syncretism. Shintōists insist on maintaining their own characteristics and inner depth while working toward the peaceful coexistence of human beings.

Ship

A ship is a relatively large floating vessel capable of operating in the deep ocean. In modern times the term usually applies to vessels of over 500 tons that can negotiate the open seas, as opposed to "boat," a term reserved for smaller craft. Submersible ships are an exception to this convention in that regardless of their large size and unlimited operational ability they are generally called boats. The same is true of ore-carrying vessels on the U.S. Great Lakes, which are always called ore boats. In reference to sailing vessels, the word ship signifies three or more masts with square rigging.

A fuller history of sailing ships will be found in SAILS AND SAILING SHIPS. The present article briefly treats the historical development of all types of ships, oared, sailed, and combinations of the two, before the advent of steam propulsion; traces the development of the metal-hulled steamship; and describes the various types of modern ships and propulsion systems. Air-cushion vehicles are described in the article AIR-CUSHION MACHINES.

This article is divided into the following sections:

I. Ships of oar and sail

- Ancient ships
 - Egyptian and Minoan ships
 - Phoenician merchant ships
 - Greek and Roman ships
 - Oriental ships
 - Northern ships
- Rigging
 - Medieval developments
 - The full-rigged ship

II. The age of steam and iron

- From sail to steam
 - The first steamboats
 - Development of steam power
 - Developments in hull design and propulsion systems
 - Hull materials and fabrication
 - The screw propeller

III. The modern ship

- Developments in shipbuilding
 - The "Great Eastern"
 - The transatlantic liners
 - World War II ships
 - Postwar developments
- Special types of ships
 - Container ships
 - Roll-on-roll-off
 - Ferryboats
 - Icebreakers
 - Tankers
 - Nuclear ships
 - Hydrofoils
 - The LASH ship
 - Ferrocement boats

IV. Ship maintenance

I. Ships of oar and sail

Historians are not unanimous in their determination of the birth of ships, but from the evidence it is safe to conclude that man ventured on water before 6000 BC, probably at first on a log, later on logs tied together. It has been argued that a raft is not technically a ship, because it depends for support on the buoyancy of its material rather than on the displacement of water. Prehistoric man, however, used primitive tools or fire to hollow out logs to form the earliest displacement vessel, the dugout canoe, still in use in some corners of the Earth. Other forms of early floating devices were fashioned from hides of animals inflated with air and sealed or stretched over branches to make lighter and faster canoes. The North American Indian's birchbark canoe is a similar device, using bark instead of hides.

Propulsion for the earliest craft was by hand or leg paddling, later by a flattened piece of wood, which evolved into the canoe paddle. The sequence of improved technology, improved tools, and availability of better materials and fastening methods, resulting in lighter and stronger hulls and more efficient propulsion, was repeated many times in the history of the ship.

ANCIENT SHIPS

Many of the most primitive types of ships still exist for special purposes. Log rafts are used in some regions in which seas are so rough that stiffer structures would be beaten to pieces. The efficiency of the outrigger canoe in giving the least possible frictional surface to the water for the most support against tipping under sail is still widely used by natives in the South Pacific and in Hawaii. Other surviving ancient types include the Arab dhows and the Chinese junk.

Egyptian and Minoan ships. From rock drawings dating from 6000 BC in Egypt and from descriptions in legends and stories, it is known that relatively large ships were developed in the eastern Mediterranean; and on the Nile River in Egypt, ships were built of bundles of reeds, the ends of which were bound together and bent upward to form the bow and stern of the ship so that in profile the ship was crescent shaped. This kind of construction was dictated not by choice but by the lack of large trees suitable for making dugouts or straight, heavy-strength members. Further to the east, across the Red Sea, where there were trees, early shipbuilders used a different method. They started with a canoe dug out from a stout log and graduated to building slanted sides fastened to a bow and stern boards to keep out the water and increase the carrying capacity. The result was a flat-keeled boat with square comers at the ends. These ships were also immortalized in rock drawings. By 3000 BC the reed boats of Egypt were venturing into the Mediterranean as far as Crete and Lebanon to bring back logs and other materials. Because these ships had no keel, they were held in shape by a taut cable, running on deck from the bow to the stern, which could be tightened as required. They were rowed and were steered by long oars over the stern. Later, sails were devised to move the ships when the wind was from the stern, which in the Nile was an advantage, because the wind normally blew upriver, so that the ships could sail up against the current and either pole or row down with the current. As successful and numerous as the Egyptian ships were, had not others invented a ship built around a sturdy log, ship development would have ceased, because without the strength and stiffness of a central structural member such as a keel or keels, larger and faster ships would have been impossible.

By about 2000 BC in Crete, the Minoans had developed ships using a log keel with ribs and planking on the sides joined at the stem and stern. To protect the bow against damage from waves, the heavy keel was bent upward and forward of the joint between the two sides of the ship, thus giving the ship a double, or bifid, bow.

During this period, nearly all ships were narrow beamed for their length to facilitate rowing. In the absence of navigational devices, the ships were restricted to moving on rivers, along coasts, or in narrow seas. Merchant ships and warships were very similar, although a warship development of the bifid bow became the sharpened ram projecting forward near the waterline. When the ram was used, it produced a great stress on the bow of the galley. In order to overcome this, heavy timbers were fastened lengthwise along the sides of the galley to help support the bow from damage. These timbers were known as whales (wales). Later, in addition to their original purpose of attacking other war vessels, it was found that they stiffened the ship so it did not have the unpleasant habit of bending in the middle when a wave passed under. In more modern times the strength members have been put inside the hull and are called longitudinals. To conserve the energy of the crew, these galleys included one or more large, square sails. Such galleys could not sail into the wind, and in battle the sail was never used; to set sail was a sign of defeat.

Phoenician merchant ships. The great merchants of the Mediterranean world, the Phoenicians of Tyre and Sidon, found that galleys were inefficient for trading voyages, because the large crews needed were expensive to feed, and the long narrow hull provided little space for cargo. The first merchant ships were descendants of the old Egyptian reed boats in that their hull form was broad and short, earning them the nickname of the round ship. They were built up from a heavy keel with ribs and a stem and stern post. A single large square sail furnished propulsion (see Figure 1). Such ships may have sailed around Africa. It is known that they sailed in the Atlantic as far north as Britain to trade for tin.

Figure 1: Model of a Phoenician ship, 13th century BC. In the Museum of the Philadelphia Civic Center.

Greek and Roman ships. In the Greek era the galley developed from an open, undecked craft up to 100 feet (30 metres) long and driven by a single row of oars 25 on a side to the ships used in the Battle of Salamis in 480 BC, about 150 feet (45 metres) in length with an outrigger (*parado*) on which the oarlocks were fixed. Width including outrigger was 20 feet (six metres). The oars were arranged in two banks (biremes) or three banks (triremes). In the next few hundred years larger galleys were tried but were found to be too cumbersome to manoeuvre, and so the final development of the war galley produced a ship of about 150 feet with a full deck or decks and a strong ram. They were called quinquiremes, a term the meaning of which is still in dispute. Some authorities believe it refers to a ship having five banks of oars, and others interpret it to mean five men to each oar. While the galley was the predominant military ship, the vast Mediterranean commerce in the Greek era was carried on with the round ships of Phoenician design.

The Romans brought little change in ships except the addition of the *corvus*, a bridge at the bows of a war galley to accommodate boarding parties. Roman grain ships grew to new sizes, measuring some 90 feet (27 metres) in length and 28 feet (nine metres) in beam, capable of carrying about 250 tons of cargo and over 300 passengers. Such heavy oared ships required more sail to drive them as well as to help in manoeuvring. Though they could still not sail into the wind, they were able to hold a course with their sails hauled around to take the wind on the quarter (about 45° from dead astern), an important step forward. These ships proved their seaworthiness in regular commerce with the British Isles.

Oriental ships. While the peoples of the Mediterranean were developing ships from those of the Egyptians, at about the same time China, with its vast land areas and poor road communications, was turning to water for transportation. The development in China followed a slightly different pattern from that of the Mediterranean. Starting with a dugout canoe, the Chinese joined two canoes with planking, forming a square punt, or raft. Next, the side, the bow, and the stern were built up with planking to form a large, flat-bottomed wooden box. The

The Phoenician round ship

The Chinese junk

Flat-keeled boats

bow was sharpened with a wedge-shaped addition below the waterline. At the stern, instead of merely hanging a steering oar over one side as did the Western ships, Chinese shipbuilders contrived a watertight box, extending through the deck and bottom, that allowed the steering oar or rudder to be placed on the center line, thus giving better control. The stern was built to a high, small platform at the stern deck, later called a castle in the West, so that, in a following sea, the ship would remain dry, and when hove to or anchored she would turn with her bow to the wind. Thus, in spite of what to Western eyes seemed an ungainly figure, the Chinese junk was an excellent hull for seaworthiness as well as for beaching in shoal (shallow) water. Her principal advantage, however, not apparent from an external view, was great structural rigidity. In order to support the side and the bow planking, the Chinese used solid planked walls (bulkheads), running both longitudinally and transversely and dividing the ship into 12 or more compartments, producing not only strength but also protection against damage.

In rigging the Chinese junk was far ahead of Western ships, with sails made of narrow panels, each tied to a sheet (line) at each end so that the force of the wind could be taken in many lines rather than on the mast alone; also, the sail could be hauled about to permit the ship to sail somewhat into the wind. By the 15th century junks had developed into the largest, strongest, and most seaworthy ships in the world. Not till about the 19th century did Western ships catch up in performance.

Meanwhile, in the island kingdom of Japan, little other than river or coastal dugouts and small ships were developed until about 81 BC, when the Emperor decreed that each province must build a ship. From this time until the early 17th century, when Japan closed its ports to the world, Japan developed its ships rapidly. From drawings in the 15th century, Japan had ships comparable to the best Western vessels. But soon after, the closure of Japanese ports halted progress until the mid-19th century, when Japan recommenced building ships.

Northern ships. In the European north, where the seas were cold and unfriendly, the peoples of the Scandinavian countries developed still another form of ship. Because they also started from the log, some authorities hypothesize that in early times Minoans fleeing invaders had taught the northern people how to build ships. In any case, the first northern ships were very similar to the Minoan ships with the bifid bow. Because these ships had to weather higher seas, the bifid was not developed into a ram, for in pitching in a heavy sea the ram put great stress on the ship and tended to break her back. Instead, the Vikings developed double-ended ships, having both a sharp bow and a sharp stern, built high against following seas. To survive in the strong gales of the northern waters, the single large square sail on the Viking ship was made of leather or cloth with reinforcing leather strips. Over the stern a long oar was suspended from one side, extending below the bottom of the keel, to improve stability. The hull form in the centre (amidships) was much broader than that of the galleys of the south, and overall there was a smooth, flowing curve from the high bow through the well-rounded midships to the high stern, a good design still used in lifeboats and whaleboats today. Another feature was the covering of the oar ports with sliding plugs to keep out the water when the oars were not in use. Many pictorial representations of Viking galleys show shields slung over the oar ports, which may be the locations they were placed when the ship was in port, but at sea this placement would have interfered with the operation of the oars. The planks were fastened to the ribs by lashings rather than by bolts or pegs, giving the ship a flexibility that reduced the stress in heavy seas. Even more important was a northern merchantman, the knorr, broader and deeper-hulled than the long ships and the first northern ships to sail into the wind. In about the 14th century the knorr developed into a standard merchant ship, the design of which governed north European shipbuilding for over 400 years. This later version, called the cog, was given a true stern rudder for better handling and a long spar extending forward

called a bowsprit. Modified by a built-up castle in the stem or stern to provide a platform for soldiers, the cog became the standard man-of-war.

RIGGING

Medieval developments. Meanwhile, in the Mediterranean a change in rigging had permitted ships to sail closer to the wind. Traders may have observed Chinese junks with their lug rig or the Arab dhows of the Indian Ocean. In the Indian Ocean the monsoon winds blow toward India in the summer and Africa in the winter. For this situation the Arabs developed the dhow, with a long stem and a sharp bow to run well before the wind and a square sail with only a top spar. It could be placed so that the spar was nearly vertical, allowing the rest of the sail to lie nearly in the fore and aft plane of the ship for sailing with the wind and could be placed horizontal to support the square sail for sailing before the wind.

To summarize the problem of a rig to permit sailing before or into the wind, it may be noted that, when the simple square sail is placed 90 degrees to the centreline of a ship with the wind coming from directly astern, the force of the wind literally blows the ship along at a speed somewhat less than that of the wind. If the wind is from the side of the ship, however, the sail must be placed at an angle to the wind. In this case, the phenomenon known as aerodynamic lift, which supports aircraft in flight, comes into play and produces a force nearly perpendicular to the surface of the sail, driving the ship forward and simultaneously causing her to drift to leeward (downwind), depending on how deep the ship is. As the ship begins to move forward in the water, the sail reacts not directly to the direction and velocity of the wind but to the force that is the sum of the wind and the motion of the ship (the vector), producing a greater force at the sail. For this reason, a ship can sail faster than the prevailing wind, a common characteristic of well-designed racing ships. In iceboats where resistance to motion is small this effect can build up to high speeds (90 to 100 miles [145 to 160 kilometres] per hour). To work this way a sail must have a tight, straight luff (edge facing the wind) and a gentle curve from the luff to leach (edge further from the wind) resembling the upper surface of an airplane wing (see SAILS AND SAILING SHIPS).

The first attempts at sailing into the wind of the Chinese and the Norsemen were made simply by attaching ropes (sheets) to the ends of the top and bottom spars and leading these sheets one forward and the other aft, to hold the spars at a desired angle to the wind, permitting sailing within 80 degrees of the wind. The Arabs found that, by leaving off the bottom spar, tilting the top spar nearly vertical, and varying the tension on the sheets, the best curve of the sail could be obtained. This rig became known as the lateen after an innovation that eliminated the luff and produced a triangular sail.

About the 9th century the Byzantines built carvel-planked (smooth-sided) ships with the new lateen rig that could sail to within about 60° of the wind, giving them a great manoeuvring and navigational advantage over earlier ships. Their round form helped their sailing qualities, and the smooth carvel sides offered less skin friction to the water, giving at once a commodious ship with good sailing qualities and the ability to sail generally in the desired direction without too much concern for the wind direction. This development was the final stage of the southern ship, which had inherited 6,000 years of Mediterranean experience. These ships grew over the next two to three hundred years to large and cumbersome ships called nefs, which had two and three masts, all lateen rigged, and displaced over a thousand tons.

the full-riggedship. In about the 13th century the sturdy square-sailed cogs of the north appeared in the Mediterranean and met the lateen-rigged nefs of the south. Over the next few years the features of the two types merged in the carrack, which became the prototype for the western European ocean ship. The carrack was a three-masted ship with carvel hull planking and external whales for strengthening. It had the centreline rudder and the graceful rounded lines of the northern parent. Its rig

Problems of sailing into the wind

Viking ships

was a mixture of north, south, and ancient Roman. By happy coincidence, at nearly the same time, the magnetic compass made its appearance, equipping the carrack with a fundamental navigational aid.

The swift evolution of the carrack into the classic ship that served as both warship and merchantman for the Western world consisted mostly of details. The drudgery of handling the large square sails brought forth sets of smaller sails on the forward masts, with the lower being the driving sail, called the course sails, then upper and lower topsails, resulting in the full-rigged ship.

Copper cladding. From the beginning there had been a problem of bottom fouling and attacks by a boring worm called *Teredo navalis*. These had been dealt with by coating with tar or other substances or sheathing with lead, with indifferent success. Ships had been small enough so that their crew either could careen them (tip them over with weights in the water until most of one side of the bottom showed) or could haul them out on a gently sloping beach and clean and treat their bottoms. As sails became more efficient and ships became larger, these practices were not nearly as practical. During the late 18th century the British tried coating the bottoms with sheets of copper, which at first caused severe corrosion of the iron fastenings but later proved to be very effective with bronze fastenings, and by the end of the 18th century most ships of any significance had copper-clad bottoms to protect them.

Ships grew with the efficiency of their sailing rigs from the 80- or 90-foot (24- or 27-metre) lengths of the 15th century to the 2,000- and 3,000-tonners of the early 19th century.

The clippers. The last period of the wooden sailing ships produced some of the fastest and most beautiful ships of the entire era. The Industrial Revolution brought pressure for speed in shipping, while trade among Europe, North America, and the Orient was blossoming, particularly in tea, which had become the staple beverage in England. Grown almost solely in China, tea was a seasonal crop, its leaves being picked each summer. Rivalry developed between ships to bring the first shipments each year to England and North America. As a result, the sailing ship achieved its finest development, in the form of the China clipper, just as the steamship matured to displace it.

The term clipper, first applied to a class of small, swift Chesapeake Bay schooners and brigs (Baltimore clippers), was given in 1833 to a larger ship, built in Baltimore, named the "Ann McKim," which became the prototype of a new type of ship for the North Atlantic packet service. Built for speed and stability to handle the greatest possible area of sails and to offer the least resistance to the water, the clippers had a radically new set of hull lines, a sharp cutwater at the bow widening very gradually toward the midship section, giving actually a concave shape to the waterlines. This conformation still is a very popular form for the underwater portion of a fast ship—V sections forward and U sections aft. The hull was designed to give minimum weight with adequate strength, another modern principle for a fast ship. The first ship built to the new design, the "Rainbow," made a round trip from New York to Canton, China, in six months, 14 days, a new record, on her maiden voyage. In the 1840s and 1850s the demand for clipper ships was so great that the shipyards on the East Coast of the United States were mass producing them. British shipbuilders and owners quickly joined the competition. The Civil War in America ended American supremacy and left the field to the British; competition between the Clyde builders and the Aberdeen builders produced the finest clippers of all. The British clippers were built of hardwoods that lasted much longer and remained dryer than the American clippers. In the 1860s the British used composite structure to insure that their ships would be as dry as possible. Their ribs were formed of iron, on which the hull planks were fastened. These ships were very strong, and at least one, "Cutty Sark," launched in 1869 and sailed in commerce for over 30 years, is still preserved in a dry dock in Greenwich. Some of the clippers reached speeds of 21

knots (21 nautical miles per hour) and even averaged 16 to 18 for a full day's sailing.

By the 1870s the Suez Canal had been opened, the trans-continental railroad was opened across North America, and steamships were gaining dependability and acceptance. The day of the clipper ship thus ended barely 30 years after it started, and with it ended the age of sail.

II. The age of steam and iron

FROM SAIL TO STEAM

The first steamboats. Though Robert Fulton is generally credited with the invention of the steamboat, it is well known that he had been preceded by several others. Salomon de Caus of France experimented with steam power for a boat as early as 1615, as did Denis Papin, a French Huguenot physicist, a century later. The first steam-powered boats to actually run followed James Watt's improvement of the steam engine in 1775. Among others, John Fitch demonstrated one in the United States in 1787 and by 1790 had built several. Fitch was unlucky in attracting backers and lacked the funds to continue development. His original model was powered by a set of six paddles suspended from either side of the boat and moved forward and aft by the action of the steam piston. He later built a craft with three paddles in the stern that attained a speed of eight miles (13 kilometres) per hour. All of these earliest steamboats used chains attached to ratchet wheels or other crude methods to convert the reciprocating motion of the piston rod of the single steam piston. In Scotland, however, William Symington aroused interest with his use of a crank, the capacity of which to convert linear to rotary motion is still the basic principle of reciprocating steam machinery. With the crank device, Symington built the 56-foot (17-metre) "Charlotte Dundas," named after the daughter of his financial backer, in 1801. Its piston developed ten horsepower and enabled it to act as a tug in the canals of Scotland, probably the first commercially successful steam-driven vessel.

Robert Fulton developed a steamboat that he demonstrated on the Seine in 1803 with indifferent success, but, undaunted, he had the "Clermont" built and shipped to the United States, where it was demonstrated on the Hudson River in 1807. The "Clermont," nearly three times the length of the "Charlotte Dundas," steamed up the Hudson under its own power at an average speed of five miles (eight kilometres) per hour. After a few improvements it was renamed the "North River" and went into regular service between New York and Albany. Highly successful financially, it enabled Fulton to continue his work and produce many more ships.

A contemporary of Fulton's, John Stevens, in 1804 applied the principle of the Archimedes screw, a rotating helix, to drive a ship. His boat ran, but insufficient skill of the workmen who fabricated the propeller prevented him from perfecting his device. Stevens, however, formulated lasting principles in steam engineering. He said that a ship, to be successful, should have a multitube boiler, high-pressure steam, direct connection of the steam engine to the propeller, and a short, four-bladed, helical propeller. Although the number of blades has varied, Stevens' predictions have been remarkably accurate. While development continued in the United States, a number of shipbuilders on the Clyde River in Scotland, close to large foundries and machine works, led steamboat building in Europe.

For its first 50 years, steam power was looked on with mistrust, not totally unfounded in view of the wooden construction of the ships, yet the steam engines themselves were remarkably dependable, perhaps because of their simplicity. Nearly all ships of this period were equipped with sails as well as steam and relied mainly on sail to conserve their wood fuel supply. Such was the case with the "Savannah," built by Moses Rogers, a sea captain and engineer, who interested backers in Savannah, Georgia, in developing a steam-equipped ship to cross the Atlantic. Purchasing an unfinished sailing packet in New York, Rogers added a two-boiler reciprocating steam engine. The ship was about the size of a modern seagoing tug. The engine produced at most 75 horsepower, equalled

John
Fitch's
paddle
boat

Moses
Rogers'
"Savan-
nah"

by some modern outboard motors. Among noteworthy characteristics of the engine and propulsion system were the use of seawater for boiler feed; coal-fired instead of wood-fired boilers, collapsible paddle wheels to be stowed on deck in severe storms, and a full set of sails.

Although the "Savannah" was especially outfitted for passenger comfort, people were apprehensive of taking passage in it, and in 1819 it sailed with no passengers and no cargo. Rogers took it all the way to Russia with no mechanical troubles reported, but the vessel remained a financial failure and in the end was stripped of its power plant and sold as a sailing packet. Despite its own fate, the "Savannah" was followed by many successors; by 1839 there were 776 steam-propelled ships registered in the British Isles alone. A series of Atlantic crossings under sail and steam culminated in 1827 in the all-steam crossing by the British-built Dutch ship "Curaçao," a ship of 438 tons with steam-driven paddle wheels capable of 50 horsepower each. A short time later the "Royal William," a Canadian ship of 830 tons and 200-horsepower engines, made regular scheduled crossings.

An important contribution to the success of the new ships came from Robert Napier, a British ship designer who observed that the bluff bows of old-fashioned sailing ships caused considerable turbulence. Experimenting in a model tank, Napier developed a sharp cutwater bow that allowed easier passage of the steamship, thus improving its speed. One of Napier's associates was a merchant named Samuel Cunard, who with several others formed a company that obtained a subsidy from the British government to carry mail. With this help they built the four ships that began the famous Cunard Line, the "Britannia," the "Acadia," the "Caledonia," and the "Columbia." They were not large, being about 200 feet (60 metres) long with 34-foot (ten-metre) beam and displacing 1,150 tons. Their power of 750 horsepower enabled them to cross the Atlantic on a regular basis, the "Britannia" doing it in 14½ days.

In the United States in 1850, a new line called the Collins Line was formed with the purpose of surpassing the Cunard ships. This line built five large paddle-wheel steamers of 1,000 horsepower using a cylinder of eight-foot (2.4-metre) diameter with a nine-foot (2.7-metre) stroke. The Collins ships displaced 2,860 tons and carried extensive sail. Their speed of about 13 knots won them temporary dominance in the Atlantic trade.

Development of steam power. In all these early steamships the steam pressures were very low, at first as little as three to five pounds per square inch above atmospheric pressure. To grasp the problem confronting the marine engineers of the 19th century, a brief description of the low-pressure steam engine is necessary. In it, wood or coal was burned in proximity to water in a square boiler, causing the water to boil and form steam at a pressure above atmospheric. This steam was led into the cylinder, in which its expansive force pushed the piston to the end of the cylinder; valves then opened to allow the steam to escape to the condenser and be returned to the liquid state. The water, pressurized by pumps to a pressure slightly higher than that existing in the boiler, was reintroduced into the boiler to continue the cycle. Where water was plentiful, the cycle could be even further simplified by exhausting the steam from the engine directly to the atmosphere and pumping in new water to the boiler.

The expansive force, or pressure, of steam depends upon its temperature. In the low-pressure cylinder, during the stroke, the steam expanded to at or below atmospheric temperature and pressure. Because this represented only a relatively modest drop, the power generated was weak. After 50 years of steamboats, maximum steam pressure possible was about 20–30 pounds per square inch at the boiler. To increase power output, the size of the pistons was increased, or more were added. The largest pistons could deliver up to 1,000 horsepower. By the 1860s the boxlike low-pressure boiler had reached the limit of its potential. In the 1870s a new approach was tried. A British warship, HMS "Iris" was given a boiler built in the form of a cylinder. The experiment was a success; a much

higher steam pressure was achieved without structural failure of the boiler. Within a decade, steam pressures multiplied six times.

With this increased pressure available, a further refinement could be introduced. The hot, high-pressure steam could be used more than once. It could be expanded through the original high-pressure cylinder and discharged to power a second, lower pressure but larger cylinder (double expansion) and even a third (triple expansion). Improved condensers brought the exhaust of the last cylinder to well below atmospheric pressure. With these improvements, the reciprocating steam engine approached the peak of its development by the turn of the 20th century, producing better than 20,000 horsepower per engine from an initial steam pressure of slightly over 200 pounds per square inch. Engines such as these drove the North Atlantic liners of the day, but the size of the reciprocating engine was placing a limit on its further development, because at these powers the lowest pressure cylinders were nearing ten feet (three metres) in diameter, and, with their large structural foundations and braces to take the load of the tons of metal reversing every stroke, they were becoming extremely heavy.

The turbine. A continuing demand for greater speed and power brought the adoption of a newer form of engine, the turbine. Reciprocating machinery remained in vogue for moderate powered ships, however, and many still remain in service because of their simplicity of operation and maintenance, their long life, and dependability, ideal qualities for merchant ships relying on low-cost operation. One of the added advantages of the reciprocating engine was that it could be timed to turn at the relatively slow speed that is required of an efficient ship propeller, thus removing an added complication arising with the turbine.

The principle of the turbine, which is the reaction or impulse or both of a current of pressurized water, steam, or gas against a series of curved blades on a central rotating spindle, had been known for some time when, in 1884, an English engineer, Charles A. Parsons, patented a turbine in which the rotor wheel was driven by the reaction of a steam jet from its periphery (reaction turbine), and shortly afterward a Swedish inventor, Carl de Laval patented a turbine in which the jet of steam impinged on the turbine blade (see also TURBINE). Because these turbines were inherently efficient devices that were not limited in size, they developed rapidly, and by the start of the 20th century they were in service. Initially, the real advantages of the turbines, high efficiency and light weight, were not exploited; directly connected to the relatively slow-turning propellers, they had to be made large and inefficient. The first solution for faster ships was to use several propellers (multiple screws) and turn them at higher than optimum speeds and to divide the turbines into several units, the lowest pressure units becoming very large in diameter.

Reduction gearing. About 1910 the real solution to the problem appeared in the form of new transmissions. These took three forms. The solution in Germany was to provide a hydraulic speed-reducing coupling in the propeller shaft so that the turbine could run at its more efficient high speed while the propeller could run at its slower optimum speed. In Britain a similar result was achieved by fitting mechanical reduction gearing between the turbine and the propeller shaft; and in the United States the turbines were used to drive electric generators, which in turn drove electric motors attached to the propeller shaft, and, by motor control, the best speed for each could be obtained. The net result of any of these systems was to open the way for rapid development of high-powered fast ships with improved range of operation, because these devices allowed the turbine and propeller designers to achieve about 25 percent improvement in overall efficiency. Ultimately, most ships adopted mechanical gearing. Electric drive, because of its lower efficiency and higher cost, is usually reserved for ships requiring very fine control of engines from the bridge or ships such as dredges in which there are high requirements for electric power. Because of poor efficiency, hy-

draulic couplings have almost disappeared except for certain specialized uses.

In the early cylindrical boilers the fire was still brought through the water in tubes, as in the old box types. The system was perpetuated in the so-called Scotch boiler widely used with reciprocating machinery in merchant ships requiring only moderate pressures; above a certain point such a boiler becomes too massive to be practical. Shortly after the introduction of the Scotch boiler, its successor, the water-tube boiler, was invented. Its perfection took several years because of difficulties in circulation and watertightness, but in the end it supplanted the fire-tube boiler in all high-powered ships. As the name implies, the water-tube boiler uses a furnace in which the fire is contained and through which water is passed in tubes between upper and lower cylindrical drums. Water-tube boilers originally employed natural circulation, using the lower density of hot water to keep the water flowing through the tubes. Later, in order to increase efficiency further and reduce size and weight, pumping was introduced to force circulation, thus achieving faster heating rates.

DEVELOPMENTS IN HULL DESIGN AND PROPULSION SYSTEMS

Hull materials and fabrication. From earliest times the custom was to build the hull from the most readily available natural material. In Egypt this meant reeds; in Crete it meant wood; and so it went for most of the shipping nations until the early and middle part of the 19th century. When iron first became available, the concept of putting to sea in a vessel built of a material heavier than water was not accepted by shipbuilders any more than by the general public. The fact that the ship is supported by the water it displaces rather than by the buoyancy of its material could not overcome the fear of sinking should the hull be ruptured. The beginning of iron shipbuilding was the construction by an iron founder in Scotland of an iron barge in 1787, a venture that met with ridicule. But in 1818 Thomas Wilson, also of Scotland, built an iron sailing ship, the "Vulcan," to haul coal in coastal and river traffic; the vessel proved so durable that it was still in service 60 years after its launching. In 1821 the "Aaron Manby," with a hull of iron, made the passage from Birmingham, where it was built, to France, where it entered service on the river Seine. There followed several smaller iron ships built in England and Scotland. Most were sailing craft and designed for service on inland waterways, a use that did not arouse popular apprehension over sinking so much as for oceangoing service. A significant event in 1834 helped to change the image of iron ships, when a number of wooden ships and one iron steamer, the "Garryowen," were driven ashore in a storm. After the storm the "Garryowen" was able to refloat itself and proceed, while the wooden vessels were either badly damaged or lost. This graphic demonstration of the superior hull strength of iron over wood quickly led to the widespread adoption of iron as a hull material. From 1850 through about 1880, iron was the principal material for ships' hulls.

Wood was finally abandoned for other reasons. In 1853 Russia first used explosive shells in warfare at sea, and the wooden ships that had resisted solid shot well splintered and came apart with exploding shells. Another reason was economic. The wooden ship cost more to build and maintain than her iron successor. Finally, because of difficulty in fastening and inherent strength, the size of ships built from wood was limited to about 300 feet (100 metres). Iron plates formed to the shape of the ship, joined by rivets to each other and to the frames of the ship, produced a more homogeneous structure than wooden hulls, which had a weakness wherever the ends of planks were connected. After 1880, steel offered superior ductility and strength to produce lighter and stronger hulls and soon replaced iron.

In the 20th century, engineers were long aware of the possible superior strength of welding over riveting, but the problems of incomplete welds or of cracking kept widespread use of welding for hulls from developing until

nearly World War II, when welding's advantages in mass production became an overriding consideration. Great numbers of ships were then built with all of the connections in their hulls welded. During the latter part of the war and shortly thereafter, several mysterious ship losses occurred. In a few cases, tankers with all-welded hulls cracked in two while riding at anchor. The problem of welding ships was studied by metallurgists and shipbuilders, and it was found that some steels at low temperatures, such as are found in the wintertime in the North Atlantic, became very brittle and so sensitive to small cracks and notches that under the right conditions they cracked with almost explosive speed and violence. Remedies for these weaknesses were found by inserting riveted joints in these ships at critical points, a practice that stopped the running of cracks. For later ships a change in the composition and treatment of the steel was made to avoid the notch sensitivity. The episode was a good illustration of the unsuspected problems that have made shipbuilders and designers traditionally conservative.

With the solution of the cracking problems, all-welded ships became the rule. As the search for higher speeds continued, newer hull materials were introduced. In the case of very high speed cutters and hydrofoils or air-cushion ships, almost exclusive use has been made of high-strength alloys of aluminum. Investigations continue in even higher strength materials, such as titanium, for highly stressed elements.

The screw propeller. From the introduction of steamships, both the paddle wheel and the screw propeller were available for propulsion, and at first the paddle wheel predominated. Of itself, the paddle wheel is a very efficient device and is competitive with even modern propellers. The drawbacks that led to its being replaced include its vulnerability to damage; its unhappy trait of coming out of the water when the ship rolls violently in a heavy sea, complicating steering; and the fact that, because it operates close to the surface of the water, it is susceptible to excessive slipping under heavy load at slow speed and high thrust (driving power). The propeller, on the other hand, is well submerged and if well designed can have good low-speed thrust as well as high-speed efficiency. Its disadvantages are underwater resistance of shafts and struts, the need to make the penetration of the hull by the shaft watertight, and vulnerability to underwater obstacles. In 1845 the British Admiralty staged a tug-of-war between HMS "Rattler," a screw-propelled ship designed and built by Isambard Kingdom Brunel, and a merchant ship equipped with paddle wheels, the "Alecto." Both ships were about 800 tons and about equal power. The event was held on a calm sea, and the "Rattler" towed the "Alecto" away at about two to two and a half knots. This test was hailed as a proof that the screw propeller was superior to the paddle wheel, because it was under those conditions of very slow speed and high thrust. Whether the paddle wheel would fare so badly at speed in an efficiency run was not determined, but from that day forward the screw propeller was favoured, and nearly all ships are fitted with propellers today, except for river steamers that are faced with shoal-water operation and some ships operating on sheltered lakes.

Other forms of propulsion have developed to fill various specialized needs, such as the air propeller to supply thrust for high-speed boats designed to traverse swamps and for some air-cushion vessels. The simple air screw seems to have many advantages for propulsion, but its prohibitive size for larger powers at the relatively slow speed of ships has restricted its use.

III. The modern ship

The changes in the early steamships during the age of iron ships followed the developments in power, propulsion, and hull materials already discussed. A typical ship of the 1840s was the "Sarah Sands," 186 feet (57 metres) long, 33-foot (ten-metre) beam, 1,400 gross tons, equipped with 300 horsepower in two cylinders. The Inman Line built a succession of ships of iron with screw propellers that set a new standard. For example, the "City of Washington" was 2,870 tons and 358 feet (109

metres) long with a 40-foot (12-metre) beam. In 1852 the last Cunard wooden ship was built, the "Arabia," with a sea speed of 13 knots on 3,250 horsepower.

DEVELOPMENTS IN SHIPBUILDING

The "Great Eastern." In nearly every development of ships, the fundamental motive that brought on the building of a better ship was economic need. So, too, was the case of the largest ship of its time and perhaps the most revolutionary single step in shipbuilding—the "Great Eastern." It was conceived in the mind of one of the great builders of his time, the "Little Giant," Isambard Kingdom Brunel, also an outstanding bridge and railroad builder. From his knowledge of naval architecture Brunel realized that, the larger a ship is, the less power it takes to drive it; or, stated another way, the longer the ship, the faster it will travel with about the same power. At the time, the mid-19th century, steamships were just beginning to come of age and compete with sailing ships. Their weakest feature was their lack of sufficient fuel for long voyages, and in the 1850s the most lucrative employment was the China tea trade, in which round-trip speed was important. Putting these factors together, Brunel sold the idea to a syndicate of building, with existing technology, a steamship five times as large as the largest ship then afloat. The result was a remarkable ship, over 690 feet (210 metres) long, of nearly 19,000 gross tons. To give adequate strength, it was fashioned out of $\frac{7}{8}$ -inch (22-millimetre) iron plates and was the first ship to have a double bottom. In addition, it was divided into 22 massive compartments by fore and aft- and transverse-subdivision bulkheads, making it comparable to modern ships in strength and capacity to survive damage. It was powered by three separate means of propulsion, a pair of 58-foot (18-metre) paddle wheels, a 28-foot (nine-metre) screw propeller driven by a separate steam engine, and, as an additional safety measure and to conserve fuel, the enormous spread of 6,500 yards of sail. Its fuel capacity gave it sufficient endurance to make the round trip of 22,000 miles (35,000 kilometres) from England to Ceylon and return without refueling.

Launching a ship of such unprecedented size created unprecedented problems, and the launch effort ended in failure. The ship was stuck on the ways for almost four months, bursting some of the most powerful hydraulic jacks in the country before it was finally set afloat in 1858. By this time the original £780,000 cost had been exceeded, and, because there was no government subsidy, the backers went bankrupt. After several changes of ownership and more difficulty, it finally went on an unprofitable voyage to the United States and was put on exhibition in several places to attempt to gain funds for its owners. It never was sent on the route for which it was designed, or it might have set records; but instead it gained a measure of fame for laying the transatlantic cable and the cable to India. It was a technical marvel, but, because financing and other problems did not permit it to perform its design mission, it was an economic failure. Not approached in size or efficiency for over 50 years, the "Great Eastern" led the way to the ship revolution of the second half of the 19th century.

The transatlantic liners. The rivalry for the record for the fastest passage of the Atlantic by steam spurred most of the developments in shipbuilding during this period, each company adopting new technology as fast as it was proved practical. By 1874 the ocean liners had reached the speed of 16 knots and had cut the Atlantic crossing time to seven days. Their displacement had risen to over 5,000 tons. By 1881, ships of 7,000 to 8,000 tons and steam pressures of over 100 pounds brought speeds of 20 knots. Steel had arrived as a hull material, and double, triple, and quadruple expansion engines rapidly reduced fuel requirements by nearly 50 percent. Finally, in 1899 the "Oceanic" was built, measuring 704 feet (215 metres) in length, after a half century, the first ship to exceed the size of the "Great Eastern." German shipbuilders of this time took command of the Atlantic speed records with the "Deutschland," which raced across the ocean at from 22 to 23 knots.

Another event in this great change in the face and power of ships was the demonstration of Parsons' "Turbinia." Parsons experimented with a turbine-driven boat in secret, and, when he had achieved a reasonable balance between turbine speed and propeller speed, he took his boat to Queen Victoria's Diamond Jubilee Review of the Fleet. Before the large crowd of onlookers, he proceeded to weave his way in and out between the ships of the fleet at a previously unheard of speed of 34½ knots. After this unorthodox demonstration, the turbine was accepted as a means of propulsion for the future high-speed ships. About the same time, Rudolf Diesel in Germany was discovering the principles of the diesel cycle, which was to result in one of the most economical means of marine propulsion.

Between 1900 and 1914, all of the innovations in technology seemed to come into focus with the age-old principle that a larger, longer ship was easier to drive and more comfortable to ride. Ships grew to gigantic proportions. Geared turbines had made high powers easier to produce, and steam pressures were in the area of 300 pounds per square inch. The largest of the prewar monsters was the German "Vaterland," of 904-foot (276-metres) length and 54,000 tons.

During World War I the "Vaterland" was seized by the U.S., used as a troop transport, and later refurbished under the direction of William Francis Gibbs, a New York naval architect, who was to become for the United States what I.K. Brunel was to the 19th century in England. It was converted to oil, and many structural changes were made to improve its resistance to damage. Renamed the "Leviathan," for years it dominated the Atlantic. Shortly after its refit, it set a new speed record of 27.48 knots average speed for over 25 hours.

In 1929–30 the Germans launched the "Bremen" and the "Europa," which, while moderate in size, had better engineering and hull design and thus gave them the transatlantic speed record. These ships exploited a new hull-design idea, the bulbous bow, in which the bow of the ship was made sharp at the waterline to cut the waves but flattened out further down, giving greater buoyancy, and easier changes of direction to the water. In addition, this greater buoyancy below the water reduced pitching of the ship and made it ride easier.

The next record holder was the giant 79,280-ton "Normandie," which in 1935 reduced the transatlantic record to four days, three hours, and two minutes at an average speed of over 30 knots. It used a turbo-electric drive.

In the 1920s and 1930s the world's commerce was being hauled in many less glamorous ships, some with Scotch boilers and reciprocating engines, about 400 feet (120 metres) long and steaming at an economical 13 to 14 knots. The diesel engine had started to displace steam, because the fuel consumption and the crew requirements of the diesel made it more economical to operate, even though its maintenance costs were higher.

World War II ships. World War II, with its tremendous production of new tonnage of all types, brought several new standards. In steamships, superheated steam (600 pounds per square inch and 850° F [450° C]) became nearly a standard for high-powered ships, some going as high as 1,000 pounds per square inch. In the light of boiler-maintenance problems, some engineers considered that a more modest pressure might have been more prudent, but "higher, lighter, and faster" was the watchword of the times. A military type of ship developed from a British prototype was introduced in several sizes during the course of the war. Its most widely used version was labelled the LST (landing ship tank), which could load or unload wheeled vehicles through a bow door, could transfer them to another deck through a ramp device, and could turn them around on a turntable. The great utility of this slow-moving, pedestrian-looking ship caused it to inspire many changes in ships of the postwar period.

In World War II, as in its predecessor, the momentum of war and the necessity of speed produced building programs that are unequalled in peacetime. Shortly after the start of the war, a British purchasing mission came to the

Specifications of the "Great Eastern"

The "Vaterland"

World War II Liberty ships

United States to contract for 60 ships, 441 feet (134 metres) long, of 10,490 tons displacement, with reciprocating steam engines and coal-fired Scotch boilers, as simple and rugged a merchant ship as could be devised. Shortly afterward, the same designers redesigned this ship for the U.S. war effort, giving it oil-fired watertube boilers, but otherwise left them identical to the British ships. The U.S. program to produce emergency ships got under way in April 1941, when the first keel was laid; the "Patrick Henry" was launched on September 27, 1941. In all, 2,610 Liberty (or Ec-2) ships were built. Many records were set in this effort, including the launching of a ship within ten days of the laying of the keel, with completion and delivery four days later. Altogether, the U.S. shipbuilding effort in World War II produced 5,874 merchant-type ships of 57,205,407 deadweight tons, over one-third of the world tonnage at the beginning of the war. As in World War I, the tonnage was of mixed types and quality. Barracks, barges, and drydocks were built of iron-enriched concrete. Few if any wooden ships were built, but some older wooden hulls were converted to war service. Mass production of ships, the coming of age of welded steel as a hull material, standardization of machinery components and plants, and the many special-purpose ships and craft that were developed during the war left an important heritage in design and construction.

Postwar developments. After World War II, the arrival of fast, dependable air travel across the oceans signalled the beginning of the end of the era of the super passenger liners. The speed differential between a jet aircraft and even the swiftest liners made performance differences between ships somewhat irrelevant, but even toward the end of the superliner era new records were set. In the 1970s France has in service the longest passenger ship in the world, the "France." It is 1,035 feet (315 metres) long, aluminum in its superstructure lightens its displacement, and it is equipped with fin stabilizers protruding from its sides below the water to reduce roll. Its modern plant is powered by 1,000-pounds-per-square-inch steam at 1,052° F, and 175,000 horsepower drives it at a speed of slightly over 35 knots. This combination of improvements, however, did not gain for the "France" the speed record, which belongs to a ship ten years its elder, the 1952-launched "United States," the holder of the Atlantic records for both east and west crossings. The "United States," the personal project of noted designer William Francis Gibbs, on its maiden voyage set a record of three days, ten hours, and 40 minutes. The record is likely to stand, because the competition of air travel makes it improbable that the expense and effort required to build a superliner to surpass it will be economically feasible (see Figure 2).

Two noteworthy technical developments of the postwar period were nuclear propulsion and hydrofoils (both

From Laurence Dunn, Passenger Liners

Figure 2: Silhouettes of several post-World War II passenger liners.

discussed below). Far more significant in its impact on merchant shipping was the advent of containerization, a revolution that began in the late 1960s.

SPECIAL TYPES OF SHIPS

Container ships. The military success of prepackaged shipments to overseas points during World War II and the rising costs of stevedore services and labour in general stimulated consideration of the use of standardized containers for shipping materials. At first, the relatively poor volumetric efficiency in the stowage of the ship delayed acceptance of the concept. Studies of the savings available in turnaround time, lower insurance rates because of reduced pilferage and damage, better customer satisfaction, and the greater facility of transshipping from sea terminal to land transportation slowly made their weight felt.

Figure 3: Profile and section of a typical container ship.

Standard containers that fitted into cells created in container ships, on trailer trucks, and on rail cars were adopted (20 by eight by eight feet (about six by 2.5 by 2.5 metres). The containers were fabricated of light, strong aluminum alloys, usually of corrugated construction to provide requisite stiffness. They were provided with lifting pads to allow easy hoisting and with fittings to permit them to be fastened to truck beds. They became the unit of transit in a complete transportation system from point of origin to destination. Packed and sealed at the warehouse, the container is transmitted by road or rail to a port, at which specially designed high-speed lifting cranes take it from the carrier either to temporary pier-side stowage or directly to the container ship. The ship is equipped with a cellular grid of belowdecks compartments opening to the weather deck, designed to receive the containers and hold them in place until unloading at the port of destination. The ship is filled to the deck level with containers, the hatches are closed, and one or two layers of containers, depending upon the size and stability of the ship, are loaded on the hatch covers on deck. Upon arrival at the port of destination, specially designed lifting gear removes the containers in a matter of hours and loads them to trucks or trains or to temporary terminal stowage. In another few hours, the ship can be filled with containers for another port and can be under way. An additional economy is the low cost of the crew of the ship while in port awaiting loading or unloading. Further, because each ship can make more trips than before, container fleets require fewer vessels. There is also less pilferage and, hence, lower insurance rates and, finally, the assurance to the shipper that his shipment will not require any further handling until it arrives at its designation (see Figure 3).

Among the disadvantages is the fact that each ship does not carry quite as much total volume of cargo with containers as with regular bulk stowage, because the containers themselves take space and, since they are square in shape, do not fill in all the nooks and crannies created by a ship-shaped hull form. Further, a rather substantial capital investment is needed in port facilities, such as special berths, weight-handling equipment, storage areas, and links to land transportation, all of which must be made by the ports that receive or ship via container ship if its full potential savings are to be realized.

Since 1965 there has been a worldwide upsurge in port development, spurred by the adoption of container shipping. As early as 1967, 20 percent of all tonnage from New York was in containers. In the early 1970s several weekly scheduled container-ship lines were operative between European and American ports, as well as on the longer routes to the Mediterranean and Far Eastern ports.

Advantages of container ships

Developments in containers include an increase in maximum size to 40 feet (12 metres) in length, with several ships able to carry large or small containers interchangeably. There are also refrigerated containers for perishables, open-top containers, and many other improvements.

The "Elbe Express"

The newer ships being built or converted to this service are moderate-sized merchant ships but of a higher average speed than in the past; in fact, few modern ships are built for speeds of less than about 20 knots. Greater use is being made of small, compact power plants to provide more space for containers. One new ship of the more common variety is the "Elbe Express." Built in 1969, it is equipped with fin stabilizers to help prevent damage to containerized cargo, and its nine-cylinder Diesel engine, giving 15,750 horsepower, drives it at 20 knots with good efficiency. It can carry either 786 standard 20-foot containers or 300 40-foot containers and 136 20-foot containers. Twenty-one 40-foot refrigerated containers can be accommodated. Special equipment includes six mooring winches to insure accurate positioning of the ship under cranes in port and special tanks to list (tip) and trim (level) the ship to permit a symmetrical loading or unloading without excessive list or trim. Its crew numbers only 33, including two stewardesses. Its route is from the continent of Europe via Britain to the United States East Coast ports.

Roll-on-roll-off. Another offspring of the specialized ships of World War II is the so-called roll-on-roll-off ship, which uses the general principles of the landing-ship tank but on a much larger scale. The ship is equipped with bow or stern openings (ports) and in most cases with side ports from which ramps can be extended to shore. Through these ports, vehicle traffic is efficiently ramped to the many decks within the ship. In essence, the inside of the ship is arranged to resemble a seagoing parking garage. Large sliding or folding watertight doors preserve the integrity of watertight bulkheads within the ship by giving sufficient compartmentation to withstand some flooding. Sealing the large doors that cover the openings in the hull offers a certain problem but one that modern mechanisms have satisfactorily solved. The general outline of the ship, in view of its relatively low density of cargo, is rather beamy, with a high deckhouse covering much of the ship's superstructure, to afford more parking decks. To insure stability, fixed ballast is usually included in these ships, along with water ballast to adjust load and stability. The engineering plants of these ships are commonly twin engines of compact variety, such as geared diesel, so arranged that the engine spaces are at either side of the ship, allowing valuable free space between them for vehicle passage.

The "Aoi Maru"

An example of such a ship is the Japanese "Aoi Maru," designed for the Japanese coastal trade. It has four car decks above the weather deck and three within the hull itself, giving it a capacity of 737 cars (Japanese compact-size), but its areas can also accommodate moderate-sized buses and trucks. To avoid the problem of bow sealing, no port is included in the bow. Its speed is 19.5 knots.

Ferryboats. A close kin to the roll-on-roll-off ship is the ferryboat, built for protected waters over a predetermined, usually short route. Ferries have been in existence for hundreds of years. Some of the earliest were unpowered rafts towed back and forth across a stream by ropes pulled by men or horses. In other cases, the barges or rafts were towed by small boats or tugs. The modern powered ferryboat is usually relatively small—100 to 200 feet (30 to 60 metres) in length—and broad in the beam to accommodate two to four lanes of vehicles on either side of a narrow centre section containing access and exhaust systems. The ships are usually double-ended, with propellers and rudders at both ends and separate sets of controls in pilothouses at the top of both ends of the ship. At each terminal a specially devised slip is built so that the ship can, in any condition of tide or current, dock end first, with almost no manoeuvring. A shore-based bridge is lowered to the deck to allow the vehicles to discharge and another load to come aboard.

Much larger ships have been used to carry trains across

bodies of water such as the English Channel, although, because of their seaworthiness requirements, these might better be classed as seagoing ships than ferries. Ferries on longer inland routes, such as Puget Sound, in the northwestern United States, are of much more conventional hull form. In fact, the "Chinook," a Puget Sound ferry, somewhat resembles a destroyer; its propulsion plant is a wartime diesel destroyer escort plant, its bow is conventional, and with its 4,800-horsepower twin screws it makes over 17 knots.

Since World War II, construction of bridges over waterways that interrupt heavily travelled routes has considerably reduced the need for ferries.

Icebreakers. Many ports and harbours of the world are above the latitudes that provide ice-free navigation year around; consequently, ships that can break ice to provide lanes for other ships have been a necessity. These ships do not rush into ice and break it up by the impact of their hull against the edge of the ice, although this is possible with very thin ice of only a few inches thickness. Rather, the ship is designed to ride up over the ice as it proceeds along its path, and then, when the ice by a wedging action has picked up more of the weight of the ship than it can support by its shear strength, the hull falls through the ice, leaving a hole slightly larger than the ship's width. Thus, the hull lines of the icebreakers are broad, with very shallow draft at the bow and stem and gentle increases in draft to the midship section. The waterline of the ship must be reinforced with layers of plating and supported by a close-knit grill of stiffeners to protect against the constant collisions with solid ice. Because propeller damage is an obvious hazard, an icebreaker is usually provided with three screw arrangements, with the centre screw protected by a tunnel or flute in the bottom of the ship. It is also common practice to provide propellers at both ends of the ship, so that, if one end is imprisoned by ice, the other may be able to move the ship enough to get free. The propellers are built with large hubs to which each blade is individually bolted, so that single blades that are broken or bent can be replaced.

How an ice-breaker operates

While sailing ships operated in ice at times, and some were strengthened to withstand the squeeze of the ice, the first genuine icebreaker that deserves the name was the "Ermak," built in Britain for the Russian government in 1899. It had 1½-inch (38-millimetre) steel plating on its waterline, displaced 10,000 tons, and had over 10,000 horsepower in steam engines. As today, it had three screws aft and an additional one in the bow. It was so successful at its task that it has served as a prototype of nearly all following icebreakers. One of the outstanding differences that has developed is in the propulsion. Modern ships have used electric drive extensively to obtain the fine control of the propellers needed, and, because the centre screw is the most protected, the propulsion system is so balanced that the centre screw carries 50 percent of the power, with the other 50 percent divided between the two outer propellers. Because many of their ports are icebound, the Russians are perhaps the world's leading users and builders of icebreakers. The world's largest icebreaker is also the world's first nuclear surface ship—the "Lenin," built in Leningrad in 1957. Displacing 16,000 tons, it is 440 feet (134 metres) long and 90½ feet (27½ metres) in beam, with a maximum draft of 30 feet (nine metres). It has three screws with a total of about 44,000 horsepower from an atomic-steam-turbine-electric power plant. Its free route speed is 18 knots. It is protected at the sides by a stiffened ice belt of 1.5 to 2 inches (four to five centimetres) of high-strength steel. While the best weight-to-horsepower ratio would be obtained by using one large atomic reactor, the "Lenin" is fitted with three, two of which can carry the ship's load, leaving the third as a reserve reactor. The principal advantage of the nuclear reactor is that it imparts an almost unlimited cruising range to the ship. In heavy ice an icebreaker must do a huge amount of work, expending large amounts of fuel, to make a few miles a day. In conventional ships, the fuel supply is limited, and operations must at some times be curtailed to insure that fuel will not be exhausted, while on the "Lenin," with for

practical purposes an unlimited fuel endurance, power can be used in whatever amounts the situation demands. Next to the submarine, in which nuclear power makes possible almost an entirely new type of ship, the icebreaker represents the most advantageous marine use of nuclear power. The overall cost of nuclear-power installation, however, has discouraged construction of more such icebreakers.

Tankers. Perhaps the simplest ship to build and operate is the tanker. In essence, the tanker is a floating group of tanks contained in a ship-shaped hull, propelled by an isolated machinery plant at the stern. Each tank is substantially identical to the next throughout the length of the parallel-sided middle body of the ship. The tanks are fitted with heating coils to facilitate pumping in cold weather. Within the tanks are the main, or high-suction, pipes, running several feet from the bottom to avoid sludge. Below them, low-suction piping, or stripping lines, removes the lowest level of liquid in the tank. Tanks are filled either through open trunks leading from the weather deck or from the suction lines with the pumps reversed. Because tankers, except for military-supply types, usually move a cargo from the source to a refinery or other terminal with few manoeuvres en route, the machinery plant is called on only to produce at a steady rate the cruise power for the ship; consequently, considerable use of automatic controls is possible, thus reducing the size of the crew to a minimum. In view of the simplicity of inner arrangement, the tanker lends itself to mass production perhaps more than any other ship type. Because of the limited crew requirements and the low cost per ton for initial building and outfitting, the tanker has led the way in rapid expansion in the size of ships (see Figure 4).

For reasons already stated, larger ships are superior to smaller ones. The interaction of the wave train set up by the passage of the bow and that from the passage of the stern establishes a relationship between the speed of the ship and its length, such that, at a critical speed-to-length ratio, the addition of great amounts of power result in little if any increase in speed, while, below this ratio, the power requirements of a ship drop off radically, till, at low speed-to-length ratios, very small powers are required. Simply put, the longer the ship, the less power is required to drive it at a given speed. Hence, when ships of very high speed are desired, such as ocean passenger liners, lengths of up to 1,000 feet (300 metres) were used. In the case of the tanker, where economy is paramount, and speeds in the order of 15 to 18 knots are sufficient, the greater length of the ship reduces power requirements to very low amounts.

Early in the history of merchant ships, the carrying of oil was viewed with caution. Before the 1880s, oil transported across the seas was carried by loading it in barrels

and stowing it in ordinary merchant ships. In 1886, however, a 300-foot (90-metre) German ship, the "Gluckauf," was launched, designed to carry oil in tanks against the ship's hull plating. By 1900 the idea of the tanker was so well established that 99 percent of the oil carried at sea was carried in tankers. Originally about the same size as other merchant ships, tankers were designed differently. For safety, the machinery was placed aft, with only enough superstructure forward to provide protection for the decks from water washing across and an elevated platform for ship control. The caution about the carrying of oil at sea has persisted to this day in that passengers are never carried in the same ship as cargo oil. Gradually, the size of oil tankers increased as the demand for the service grew, and the need for economical operation to compete for cargo continued, until those of the 1970s nearly stagger the imagination. The Universe-class tankers, built in Japan, the largest in service in the early 1970s, are of 326,000 tons deadweight. Dimensions are 1,132 feet (345 metres) in length and 175 feet (53 metres) in beam, with a loaded draft of 81 feet (25 metres), dwarfing the largest of the old-fashioned ocean liners. Such a ship is able to average over 15 knots on only 37,400 shaft horsepower. Complications arose with the introduction of such large ships; most of the harbours of the world are dredged to no more than 50 feet (15 metres) in the main channels, and special port facilities had to be arranged. One solution that is used in Kuwait, where much oil is shipped, is to build an artificial island in deep water, connected to shore by a pipeline, to load and unload tankers.

Presumably, the length of tankers will ultimately be limited only by the strength of available materials, for in the 1970s the monstrous Universe ships were surpassed by a new class of tankers ordered from Japan by a British corporation and designed for 477,000 deadweight tons. A Dutch company has developed an offshore buoy mooring and servicing system that will handle all ships now building or contemplated, up to and including ships of 1,000,000 deadweight tons or three times as large as the largest now afloat.

Along with the great increase in numbers and size of tankers have come specialized uses of tankers for products other than oil. A major user is the natural-gas industry, which ships natural gas by tanker to areas such as the British Isles. For shipment, gas is cooled and converted to liquid at -260°F (-162°C), pumped aboard the tanker for transit in aluminum tanks surrounded by heavy insulation to prevent absorption of heat and keep the liquid from evaporating during the voyage. So popular was this type of tanker that in 1970 orders were placed for 46 such ships, more than doubling the capacity of the existing fleet. The cost of these ships is rather high, because steel cannot be used for the containers. The cold liquid

The first tanker

gas, in contact with steel, would make the steel as brittle as glass. Aluminum is therefore used, sometimes backed by balsa wood, backed in turn by steel. A special nickel-steel alloy known as Invar has been used in this application.

Other materials, such as iron ore, can be carried in a tanker in the form of slurry. The bulk dry cargo is mixed with high-velocity water jets, forming a pumpable mixture to load the tanker; at the other end of the voyage, jets in the bottom of the tankers again mix the cargo with water to permit pumping ashore. The ships using this system have been reported to be much more economical to operate than ordinary dry bulk cargo ships.

Other cargo that has been shipped by tankers includes wine, molten sulfur, and methane gas. A novel type of tanker is the Mobil *Pegasus*, by today's standards moderate-sized, only 1,017 feet (310 metres) long and 63 feet (19 metres) in draft for a total deadweight of 212,000 tons. The innovative feature of this ship is the fact that it is the first tanker to be built with a second bottom inside the hull. In this space is run all the piping to the tanks and to controls. The bottoms of the tanks above this are smooth so that no pockets of oil are formed when pumping out, and, since the tanks drain through a hole in the bottom, no stripping pipes are needed. In addition, the double bottom space allows what ballasting is necessary to be done outside the cargo oil tanks, reducing the possibility of polluting cargo.

A noteworthy tanker exploit was the voyage of "Manhattan," a 150,000-ton ship refitted with a heavily reinforced bow, that with the aid of two icebreakers was able to force her way through the Northwest Passage from Alaska to the Atlantic coast in 1969, breaking ice floes as thick as 15 feet and ridges as high as 40 in the process. This voyage, a first for a merchant ship, may foretell a new profitable route to extract oil from the newly discovered rich Alaskan fields later in the 1970s.

Nuclear ships. From the end of World War II, when the power generation capability of nuclear power was being developed, it was realized that, if a practical nuclear-power plant could be fitted into a submarine, a new type of ship could at last be realized—a true submarine instead of merely a short-term submersible. A large number of such submarines were ultimately built, with virtually unlimited underwater cruising range (see SUBMARINE). A few nuclear-powered surface naval ships have also been built. Civil applications of marine nuclear power have so far been limited. As mentioned above, the Soviet Union built a successful icebreaker, the "Lenin," in 1957, and in 1962 the potential of nuclear power for an ordinary merchant ship was explored when the "Savannah," sponsored by the United States Atomic Energy Commission and Maritime Commission, was delivered. A modern shelter-deck ship of 12,220 gross tons with accommodations for 60 passengers, "Savannah" made about 20 knots on her 22,000-horsepower nuclear-powered geared steam-turbine plant. Named for the ocean-steam pioneer of 1818, it was designed to demonstrate the feasibility of nuclear-power plants, as the first "Savannah" had done for steam power. "Savannah" represented a reversal of the usual progression to higher temperatures and pressures, because it produced steam at 480 pounds per square inch for its turbines. "Savannah" performed its function reasonably well in that it was a ship around which many of the regulatory and procedural problems could be solved and in which the technical feasibility of this type of ship could be demonstrated. But it could not compete with other dry-cargo ships and was never used commercially.

Another nuclear ship being evaluated for commercial service in 1970s was the "Otto Hahn," operated in Germany by the Society for the Evaluation of Nuclear Energy in Shipbuilding and Navigation. It is reported to have a smaller and more compact power plant than the "Lenin" or "Savannah," giving it a better safety factor against collision. To date, no nuclear ship has been produced and operated by a commercial enterprise, because of the high initial costs and the difficulties in crew training. As nuclear cores become longer lasting and conse-

quently reduce fuel costs and downtime (for overhaul and repair), and as other factors become more favourable, it is not considered impossible that this source of power could be important in ships.

Hydrofoils. The search for speed on water has been frustrated by the combination of the resistance created by the ship in making waves and by the friction of water flowing past the hull. The combination of these factors makes the power demands of a ship at very high speed prohibitive. One method of overcoming this situation is offered by the hydrofoil. This craft is so designed that the hull of the ship is lifted entirely out of the water as it gains speed and is supported on hydrofoils, wings shaped like those of an aircraft but made much stronger and smaller; because the density of water is about 600 times that of air, a relatively small lifting surface in water will lift as much as a large wing in air.

The mode of operation of these craft is for the hull to support its weight, when at rest or steaming slowly, by its own buoyance. As speed is increased, the foils pick up more and more of the weight until at "takeoff" all of the weight is transferred to the foils and the ship is "flying."

The likeness to an aircraft is more than one of nomenclature. The problems of weight control are critical; because the same laws apply in foils as in aircraft, every pound of weight creates drag that must be supported by power. Thus, the hulls are built of light alloys and the foils of such materials as high-strength steel or titanium. Power is supplied by the lightest possible source, such as aircraft-type gas turbines. Propulsion is a special problem, because the power in a ship is normally generated in the hull and must be transmitted a considerable distance to the water. For this reason, several early hydrofoils used air-screw propulsion. Later, a water jet in which water is pumped out of the stern at high velocity was developed to provide low-weight propulsion.

Control and stability of foils is similar to that of aircraft, except that the control of altitude must be much more precise, for the range of motion can be only the distance from the surface of the water to the foil submergence, usually not over ten feet (three metres). All of the early foils relied on their geometry for control. The most prevalent foil system is the surface system, in which the foil surface intersects the surface of the water at an angle, so that, when more lift is needed, the foil simply submerges farther and with more surface in the water produces enough lift to regain equilibrium. These types have been arranged in single Vs or in a ladder pattern, with several foils one above the other to increase the lift faster as more submergence is attained. All the early systems relied on the surface of the water for control and consequently produced a rather rough ride. Later developments produced electronic means of sensing the clearance of the hull from the water and signalling control-surface changes to fully submerged foils that operate nearly independent of the surface and hence provide both a smoother ride and greater seakeeping ability.

The first hydrofoil may have been a French patent application in 1897 by the Comte de Lambert, who drove a catamaran hull fitted with four transverse "hydroplanes." There is some doubt that this boat actually used the hydrofoil principle at all; it may have been only a specialized planing boat. The first true hydrofoil was operated by an Italian inventor, Enrico Forlanini, between 1898 and 1905 and was supported by a set of hydrofoils. While little is known of the performance of this craft, another Italian inventor operated a craft of this type at 50 miles (80 kilometres) per hour.

Hydrofoils reached a pinnacle of performance and publicity when a boat built by Alexander Graham Bell and Casey Baldwin set the world's water speed record in 1918 with a speed of 60 knots. The craft, the HD 4, was powered by two Liberty aircraft engines of 350 horsepower each and was equipped with a set of ladder-type foils. While the boat was far ahead of its time, its efficiency by later standards was rather low. In the early 1930s several effective surface-piercing foil boats were developed, and World War II gave a major stimulus. In Germany, craft of up to 80 tons and speeds of nearly 60

dry
cargo
by
tanker

The
nuclear
ship
"Savannah"

knots were built, but Allied bombs prevented this effort from reaching operational status. After the war the United States, Canada, the Soviet Union, Britain, and Germany all launched development efforts. A boat developed by a U.S. windmill builder was supported by four V foils, one at each corner of the boat, that gave excellent stability. Because there was no supporting structure in the water, only lifting surface, it was most efficient, having the highest lift-to-drag ratio attained up to that time.

A breakthrough came in the early 1950s, when the laboratories of Massachusetts Institute of Technology in conjunction with the ship-designers firm of Gibbs and Cox developed a sonic device to measure the distance from the bow of the ship to the water and to use this measurement to control fully submerged foils. The new device was tried on a standard power yacht converted to a set of tandem, fully submerged foils with great success. The speed of the boat was more than tripled and its seakeeping ability in heavy seas greatly enhanced.

By the early 1970s the technology was available to construct and operate hydrofoils of up to 500 tons with speeds from 40 to 50 knots. Several passenger ferries employed the hydrofoil principle; one in the Soviet Union, the "Meteor," had a capacity of 150. The U.S. Navy's "Plainview," of about 300 tons, had speed in excess of 40 knots, and test craft have reached speeds in excess of 80 knots on foils under controlled conditions.

The LASH ship. A recent development in shipping is the LASH (lighter-aboard-ship) vessel, designed to carry nearly any cargo in steel lighters or barges, each about 60 feet (18 metres) long and 30 feet (nine metres) wide and capable of handling 500 tons of cargo (see Figure 5).

From *Business Abroad* (January 1971)

Figure 5: A group of lighters (small cargo vessels) loaded aboard a specially designed cargo ship. The combination is referred to as LASH (lighter aboard ship).

The hull of the ship is generally conventional except that its superstructure is dominated by a large travelling crane supported by legs from each side of the ship. At the stern the tracks for the crane extend well aft of the deck, so that barges that are picked up from the deck may be lowered directly into the water, or, in reverse, barges can be picked up directly from the water and placed in their stowage position aboard. The ship can also carry containers (for a complete description of LASH ships and some other recent developments in this area, see MATERIALS HANDLING AND TRANSPORTATION, WATER).

Ferrocement boats. Ferrocement construction, under development since 1965, involves the use of common waterproof cement or concrete applied over a metal rod or lath (wire-mesh) core to form the hull and subdivisions of a boat hull. The low cost of the materials (portland cement, metal lath, reinforcing rods, and wooden forms) is somewhat offset by the relatively high amount of labour involved in plastering the successive layers required for the completed hull. In underdeveloped countries, however, where labour is plentiful and inexpensive, this material is widely used. Its resistance to rot and corrosion and ease of repair offer some of the advantages of plastic construction, while the weight of the hull is

considerably greater than that of aluminum or plastics. Its cost to the private boat builder who is furnishing his own labour is undoubtedly the lowest of any material now used. For further information on shipbuilding, see SHIP DESIGN AND CONSTRUCTION.

IV. Ship maintenance

When ships were small, the ship's crew was able to perform not only routine maintenance but also major repairs. As ships grew larger and more complicated, they came to require specialized facilities. Such facilities are collectively called a shipyard. A shipyard consists of one or more dry docks or marine railways to expose the bottoms of the ships for cleaning and painting (normally every 18 or 36 months) and a series of long, high-reach cranes to take loads in and out of ships for repair. Water-front facilities are supplemented by shops for shipfitting, machining, electric and electronic work, carpentry, pipe welding, painting, and rigging.

Conventional ships are sent into shipyards on a regular schedule for bottom cleaning and overhaul. Though schedules vary among ship types and services, vessels are generally sent to shipyards once in every one to three years. A considerable amount of preplanning is required before the ship's entry to the shipyard. The operators of the ship and representatives of the shipyard meet, usually three to six months in advance of the overhaul, to determine needed repairs and other work. The owners and the repair yard then arrange the ordering of the necessary materials to perform the repairs.

Since modern ships have become more and more complicated advance planning in maintenance is vital. Electronic parts and control devices may need to be ordered several months in advance; the owner cannot afford to leave his vessel idle. In the case of submarines or nuclear-powered vessels, planning for repair may start from 18 months to two years in advance.

In addition to formal overhaul in the yard, ships require day-to-day cleaning, lubrication, adjustment, and minor repairs to continue to operate during their time at sea. This work is normally done by the crew, using onboard supplies. Since a ship at sea is dependent on itself for all such services as fresh water, heat, light, and refrigeration, the responsibility of the crew members is a great and personal one.

A new approach to maintenance, intended to increase the time that the ships are in service and to reduce the direct labour required of the crew, has recently appeared. Machinery components small enough and so packaged that they can be removed from the ship easily and replaced by new or overhauled components are provided. Even those parts that may be replaced at sea are installed in modules that can be stored and installed easily when needed. Although the initial cost of the ship may be increased, this is offset by savings in maintenance.

An extreme example of this modular concept of ship maintenance is the adoption of gas-turbine power for some of the newer high-speed container ships. The principle advantage of this type of power has been its very low weight per horsepower, which made its use attractive in hydrofoils and high-speed boats. Gas turbines are now used in many aircraft installations and thus are mass produced. Even more important from the economic viewpoint, they are mass serviced. In addition, the gas-turbine installation is more compact than any other type of power, permitting more room for cargo, and is light enough to be removable from the ship for servicing. Replacement of units, which can be accomplished in less than 12 hours in some installations, permits ships to remain in service without extended stays in port. In a container ship, for example, engines can be replaced while the ship is being loaded for her turn around, without any loss in time at sea. These advantages have overcome the disadvantages of higher fuel costs of gas turbines. The "Adm. William Callaghan," the largest roll-on-roll-off ship afloat in the early 1970s, was powered by a combination of gas turbines totalling 50,000 horsepower.

While the use of gas turbines increases the amount, weight, and cost of fuel needed, the reduction in crew

Ship-

facilities

Gas-
turbine
power

and ease of maintenance (a gas turbine is so light and compact that it can be hoisted out of the ship and replaced within a few hours) tip the economic balance. The same procedure is used in modular electronic units, complicated control units, and even in the electrical-generating units themselves. Of course, the new method of overhaul and repair by module requires a much more sophisticated planning and control system ashore to ensure that a new or repaired unit is available when and where it is needed without an excessive inventory of parts being accumulated. Computers are used to assist in such control.

Ship Design and Construction

Ship design and construction is a complicated compound of art and science. In the great days of sailing, vessels were designed and built on the basis of practical experience; ship construction was predominantly a skill. With the rapid growth and development of the physical sciences, beginning in the early 19th century, it was inevitable that hydrokinetics (the study of fluids in motion), hydrostatics (the study of fluids at rest), and the science of materials and structures should be utilized to augment the skill of the shipbuilder. The consequence of this was a rapid increase in the size, speed, commercial value, and safety of ships.

HISTORY

From antiquity until the 19th century. People have been building boats since remotest antiquity. It is quite probable that primitive peoples first took to the water on a log or on a raft. Later, the invention and application of paddles enabled them to progress from rafts to dugout canoes. The paddle led eventually to the lever and so to the use of oars. Much later came the harnessing of wind and the application of sails. Excavations in Crete have shown that seagoing craft were constructed in the eastern Mediterranean as long ago as 5000 BC. In ancient Egypt, ships built of planks were used on the Nile. By about 2800 BC the basic principles of boatbuilding had evolved, with transverse and longitudinal strengths being provided by different parts of the structure. The largest Roman ships, which exceeded 100 feet (30 metres) in length, were carvel-built; that is, the oak planks were laid flush at the seams over closely spaced ribs. These craft were propelled by oars and by a primitive form of rectangular sail. Later, the triangular lateen sail on its long slantwise yard appeared on Roman ships; this type of rigging had first been used by Arab dhows sailing the Red Sea and the Indian Ocean. A striking development that appeared in Scandinavian waters was the Viking ship, of fine form, but clinker-built—that is, with the planks that formed its sides overlapping, and propelled mainly by oars and carrying a simple sail. The ship was of wood—plank construction with cross beams—of the open-boat, undecked type. A seagoing ship peculiar to Chinese and Japanese waters was the junk, a flat-bottomed boat with square sails that were made of matting (see also SAILS AND SAILING SHIPS).

Progress continued from the Middle Ages onward, with considerable advances in sail design. Sails entirely supplanted oars in all large European vessels, except in the Mediterranean. As ships grew larger, they were decked over, and more decks were fitted with "castles" at bow and stern. In Portugal, Henry the Navigator (1394-1460) encouraged the building of new types of ships. Portugal's achievements in navigation were due in part to Henry's enlightened policy of experiment on actual vessels. Sporadic attempts to test ship forms were made in Italy, France, Sweden, and England but to little practical effect. Ships remained essentially unchanged from the 15th to the 19th century, when a fast new vessel of revolutionary design was constructed in North America in 1812. The clipper ship followed, a triumph of empiricism and craftsmanship; it was capable of very high speeds, the result of hulls designed for minimum water resistance, and greater sail area.

Developments since the 19th century. A more profound revolution in shipbuilding followed the substitution of steam engines for sails and the substitution of iron for wood in hull construction. Iron, in turn, was replaced by steel, with a substantial saving in weight. In the decades-long period of transition from sail to steam, side-paddle wheels were first used but were gradually ousted by the screw propeller. The first propeller-driven ship was put into service in 1839, but it was not until about 1850 that steam navigation entered upon its era of unprecedented development, during which the steam engine evolved into a propulsive force of great power and economy. At the beginning of the 20th century, the steam turbine appeared and soon became a rival to the reciprocating steam engine, eventually supplanting it. More powerful than even the largest of the reciprocators, the steam turbine, because of its comparatively small size, greatly changed the size and proportions of ships and cut the cost of operating them.

During the first decade of the 20th century the heavy-oil engine also came into use. Though the first of these was not notably successful, by 1912 the marine diesel engine was established. From that time onward, the steam turbine and the heavy-oil engine enjoyed a keen rivalry. They were joined later by the gas turbine and the nuclear power plant.

Impact of science and technology. From early days shipbuilding was practiced in most of the maritime Eu-

ropean nations, notably in Britain, The Netherlands, Germany, Italy, and in the countries of the Baltic Sea. Before 1850, U.S. shipbuilders were supreme in the building of sailing vessels. The U.K. industry was at that time handicapped by the shortage of suitable timber supplies; moreover, it could not compete in price with either U.S. or Baltic shipbuilders. The introduction and development of iron and steel ships, however, gave the U.K. an enormous, if temporary, advantage because of Britain's wealth of coal and iron, together with its early and successful application of steam propulsion.

Modern
shipbuild-
ing

For a time old and new practices were mingled; sails were used to drive iron ships, wooden hulls were propelled by steam engines, and composite ships—framed with iron sections and planked with wood—were driven by both systems. The size of wooden ships had been limited by timber's inherent shortcomings as a structural material; ships made of iron and steel could be larger.

Despite the rapid progress in the design and construction of ships, the greatest technical innovations were in their engines; **After** a century of development, the steam engine was eclipsed by the direct-driven steam turbine, at first, only for the largest and fastest vessels; later, by the aid of gearing, for vessels of moderate size and speed. It was natural that in Britain, the **home** of steam, the steam turbine should be the favoured engine. In Europe, notably in Germany, Switzerland, and Denmark, the heavy-oil engine was preferred.

In the period from 1850 to 1890, the shipbuilding industry in Britain grew so rapidly that for a time it produced more than 80 percent of the world output of ships, and even from 1910–14, 60 percent. Over the next half century other countries increasingly moved into the world's shipbuilding industry, notably Japan and the U.S.S.R.

Since World War II, scientific research has resulted in a general improvement, both in the propulsive performance of ships and in their structural qualities. The widespread adoption of welding, the introduction of prefabrication, as well as technical planning and improvements in managerial efficiency, have combined to revolutionize the industry.

Trend to larger ships. Since the early 1960s, the dimensions and complexity of ships have increased remarkably. By the end of the 1960s, oil tankers of about 325,000 tons deadweight had been built and much larger hulls were under construction. Ore carriers and other types have also grown in size, while specialized ships have replaced the general bulk-cargo vessels. Probably the most significant innovation has been the container ship, which carries prepacked cargo in standard containers eight feet square (2.4 metres) in cross section and 20 feet (6.1 metres) or 40 feet (12.2 metres) in length. The governing principle has been that the cost of transportation decreases as ship size increases. The unit cost of carrying oil in a 200,000-ton tanker is 25 percent lower than in a 16,000-ton vessel. Moreover, a larger ship requires a proportionally smaller crew than does a smaller ship and, in the early 1970s, the wages bill for a ship greatly exceeded the cost of fuel, a predominant item for all ships until the late 1950s. In addition to larger size, modern ships are capable of attaining higher average service speeds, which permit these ships to spend more days out at sea and fewer days in port.

Ship design

PRINCIPLES OF NAVAL ARCHITECTURE

Naval architecture is the branch of engineering concerned with the design and construction of ships. Merchant vessels range in size from mammoth tankers to tugs and trawlers; naval ships range from aircraft carriers to patrol craft. The basic principles of naval architecture apply to all vessels, irrespective of size and type: a ship design must guarantee safety, stability, strength, and speed completely adequate for the requirements and conditions of the vessel's operations.

The measurements of ships are given in terms of length, breadth, and depth. The length, *L*, between perpendiculars, is the distance on the summer (maximum) load waterline, from the forward side of the stem at the ex-

treme-forward part of the vessel to the after side of the rudder post at the extreme rear, or to the centre of the rudder stock, if there is no rudder post. The beam, *B*, is the greatest breadth of the ship. The depth, *D*, is measured at the middle of the length, from the top of the keel to the top of the deck beam at the side of the uppermost continuous deck. Draft is the summer draft, measured from the keel. These terms, together with several others of importance in ship design, are illustrated in Figure 1.

Figure 1: Terms used in ship construction.

Certain form coefficients are useful as indications of a vessel's shape characteristics. The commonest is the block coefficient, which is the ratio of the actual displacement of the vessel to the displacement of a rectangular block with the same length, breadth, and draft as the vessel. The block coefficient thus indicates the relative fineness or slenderness of the vessel and varies from about 0.5 in a fine, fast ship to 0.85 in a full, slow-speed oil tanker. The midship area coefficient is the ratio of the immersed area of a vessel's midship section (the transverse section at the middle of the length) at any draft to the area of a rectangle of which the breadth is equal to the breadth of the vessel and the depth is equal to the given draft.

The prismatic coefficient is the ratio of the actual displacement of a vessel to the displacement of a prism of length equal to the vessel's length and of the same cross section as the vessel's immersed midship area. The water plane of a ship is the horizontal section of the ship at the waterline. The water plane area coefficient is the ratio of the actual area of a vessel's water plane to the area of a rectangle having the length of the ship and a breadth equal to the widest part of the water plane.

Form
coefficients

HYDRODYNAMICS AND HYDROSTATICS

When a body is immersed in a liquid, the upthrust of the water that holds up the body equals the weight of the fluid displaced by the body; this is Archimedes' principle. This upthrust is called buoyancy. Hence, when a body is floating freely in a fluid, the weight of the body equals the buoyancy, which equals the weight of the fluid displaced. The watertight volume of a ship above the waterline is called the reserve buoyancy. This is important in the assignment of the minimum service freeboard, freeboard being the distance between the waterline and the deck below which all bulkheads are made watertight. Minimum service freeboard determines the maximum permissible draft, the vessel's ability to survive flooding after damage, and its weather qualities in a seaway. The centre of gravity of the volume of water displaced by a ship floating at rest is called the centre of buoyancy. Its position is largely determined by the underwater shape of the vessel and is specified by its distance above the keel and from amidships. For equilibrium, the centre of gravity of the ship and its contents must lie in the same vertical plane as the centre of buoyancy. If a weight already on board is moved aft, for example, the ship's centre of gravity will move aft, but for equilibrium the vessel will adjust its position until the new centre of buoyancy is in the same vertical plane as the new centre of gravity.

Stability and trim. Figure 2 shows a transverse section of a ship floating at a waterline W_1L_1 , displaced from its

Figure 2: Stability shown in a transverse section of a floating ship (see text).

original waterline WL. One condition of equilibrium has been defined above. A second condition is that the centre of gravity of the ship must be in such a position that, if the vessel is inclined, the forces of weight and buoyancy tend to restore the vessel to its former position of rest. At small angles, vertical lines through B_1 , the centre of buoyancy when the vessel is inclined at an angle θ , intersect the centre line at M, the metacentre, which means "change point." If M is above G (the centre of gravity of the ship and its contents), the vessel is in stable equilibrium. When M coincides with G, there is neutral equilibrium. When M is below G, the forces of weight and buoyancy tend to increase the angle of inclination, and the equilibrium is unstable.

The distance GM is termed the metacentric height and the distance GZ, measured from G perpendicular to the vertical through B_1 , is termed the righting level or GZ value. Weight and buoyancy are equal and act through G and B_1 , respectively, to produce a moment (tendency to produce a heeling motion) ΔGZ , where A is the displacement or weight in tons.

Stability at small angles, known as initial stability, depends upon the metacentric height GM. At large angles, the value of GZ affords a direct measure of stability, and it is common practice to prepare cross-curves of stability from which a curve of GZ can be obtained for any particular draft and displacement.

Transverse stability should be adequate to cover possible losses in stability that may arise from flooding, partially filled tanks, and the upward thrust of the ground or from the keelblocks when the vessel touches the bottom on being dry-docked.

The case of longitudinal stability, or trim, is illustrated in Figure 3. There is a direct analogy with the case of

Figure 3: Longitudinal section of floating ship showing change in stern trim as deck load W is shifted from position A to position B (see text).

transverse stability. When a weight originally on board at position A is moved a distance d, to position B, the new waterline W_1L_1 intersects the original waterline WL at the centre of flotation (the centre of gravity of the water

plane area WL), the new centre of buoyancy is B_1 and the new centre of gravity is G_1 .

For a small angle of trim, signified by the Greek letter theta (θ),

$$\theta = (a + f)/L$$

$$wd = \Delta GM, (a + f)/L$$

Thus if $(a + f) = 1$ inch $= 1/12$ foot, $wd = \Delta GM/12L$ and this represents the moment to change trim one inch.

The inclining experiment. A simple test called the inclining experiment provides a direct method of determining GM, the metacentric height, in any particular condition of loading, from which the designer can deduce the position of G, the ship's centre of gravity. If a weight w (tons) is transferred a distance d (feet) from one side of the ship to the other and thereby causes an angle of heel ϵ (theta) degrees, measured by means of a pendulum or otherwise, then $GM = wd/\Delta \tan \epsilon$ (see Figure 2).

For any particular condition, KB and BM can be calculated, GM is found by the inclining experiment, whence $KG = KM - GM$. It is simple to calculate the position of G for any other condition of loading.

Ship motions. Ship motions are defined by the movements from the equilibrium position of the ship's centre of gravity along the three axes shown in Figure 4 and by

Figure 4: Coordinate axes of ship motions (see text).

rotations about axes approximately parallel to these. The linear displacements along the horizontal (x), lateral (y), and vertical (z) axes are termed surge, sway, and heave, respectively. The rotations about the corresponding body axes are respectively termed roll, pitch, and yaw (veering off course). Roll, pitch, and heave are oscillatory because hydrodynamic forces and moments oppose them.

Ship motions are important for many reasons. A ship should be able to survive any sea that may be encountered and, in addition, to behave well and to respond to control. In brief, a ship should respond to the action of the sea in such a manner that the amplitudes of its motions and its position never become dangerous, and so that the accelerations it undergoes are kept within reasonable limits. Propulsive performance always deteriorates when a vessel is rolling, pitching, or heaving. Hence these motions are made as small as possible.

Ship motions are excited by waves, whose growth is governed by the wind velocity at the sea surface, the area of water, or distance, over which the wind blows (the "fetch"), and the length of time during which the wind has been blowing (the "duration"). Any seaway is always a complex mixture of waves of different lengths, as wind itself is a complex mixture of gusts. All wave components do not travel in the same direction, but the directions of most of them in a single storm lie within 30° of each other. Regular trains of waves of uniform height and length are rarely, if ever, encountered. Most seas are confused and can be considered as made up of many separate component waves that differ in height and length. Pitching, rolling, and heaving are all excited by the changing pattern of surface waves in relation to the speed and course of the ship. In practice, it is possible to damp one motion only—that of rolling. The fitting of bilge keels (finlike longitudinal projections along the part of the underwater body of a ship between the flat of the

Rolling,
pitching,
heaving

bottom and the vertical topsides) has this effect, and still more effective means are the activated fin stabilizer (a device along the side of a ship activated by a gyroscope and used to keep the ship steady) and the passive or flume stabilizing tank, filled with water inside the ship.

Ship vibration. Vibration is undesirable in any ship, and especially in passenger vessels. The main causes of vibration are: (1) unbalanced forces and couples (or moments) in main machinery, auxiliary machinery, and propellers; (2) propeller-excited forces and moments arising in the wake of the ship; (3) impacts from sea waves. Vibration may be local, occurring in structural parts or members only; or it may be general, arising when the hull vibrates like a girder. Though the local type is almost impossible to predict when the ship is being designed, it can usually be cured at little expense, often by the addition of local stiffening or pillar support. Though general vibration can be avoided in many instances by careful design, alleviation presents formidable difficulties in a completed vessel.

The hull of a ship is a girder that varies in cross section, sometimes with large openings in the decks, and is subjected to nonuniform loads arising from the distributions of weight and buoyancy. Additionally, the hull is subjected to acceleration forces arising from the ship's motions in a seaway and from wave impacts. Forces and moments from the main and auxiliary machinery that cause vibration can be made as small as possible, but forces and moments from the propellers and from waves are inevitable. Furthermore, this circumstance holds for each condition of loading—intermediate between-load draft, when the ship is fully loaded with cargo, and ballast draft, when the ship is empty of cargo, but the ballast tanks (which are filled with water to give the ship stability when it is empty of cargo) are full. Though it is almost impossible to calculate all of the possible modes and frequencies of vibrations to which a ship will be subjected, it is possible to compute with some reasonable degree of accuracy the fundamental modes of vertical and horizontal vibrations. Though the accuracy of calculated results for higher modes decreases as the order of vibration increases, reasonable approximations can be obtained. The results of such calculations are sometimes presented to indicate the ranges of engine revolutions per minute at which vibration difficulty may occur.

Resistance and propulsion. The motion of a surface vessel, whether towed or propelled, is characterized by three effects. They are: resistance to motion, formation of a wave pattern, and change of both draft and trim, as compared with draft and trim at rest.

When a vessel is in motion, friction exists between the hull surface and the water touching it; the vessel's motion also causes pressure between the hull surface and the adjacent fluid. These two forces cause waves. The relation of these forces to various ship designs is often studied on small models in experimental tanks.

Any propelling device operates by accelerating, and so increasing the momentum of, the fluid that passes through it. For the great majority of surface vessels, the screw propeller provides an efficient and convenient method of propulsion. The propeller may be described as a device for obtaining a propulsive thrust from a rotary motion.

Ships are usually propelled by one or more propellers situated at the stem. Thus the propeller works in a region where water flow is disturbed by the hull—i.e., in the "wake," where the water has already been set in motion by the passage of the ship.

The action of the propeller increases flow velocities over the hull near the stem and thus reduces fluid pressure in this region. Consequently, there is in effect an addition to the resistance of the hull, commonly termed resistance augment or thrust deduction.

Efficiency of propulsion is generally defined at any speed as the ratio between the power required to tow the vessel and the power absorbed by the propeller(s). The propulsive qualities of a vessel are ascertained by means of: (1) resistance tests with the naked hull; (2) resistance tests with the hull, plus any appendages that affect propulsion (e.g., the struts that support the propeller); (3)

self-propulsion tests. The optimum hull has the minimum increase of resistance in waves; hence further tests may be made in waves.

Propellers for high-speed vessels present special difficulties, notably cavitation, which may be described as the formation and collapse of cavities in a stream of flowing liquid as a result of pressure changes within the stream caused by changes in the velocity of flow. Cavitation tunnels are employed for the appropriate propeller investigations. Cavitation is overcome by increasing the propeller blade area and by modification of the blade section shape.

Manoeuvrability. Increases in the size and speed of ships bring problems of safe operation in congested waters and control at high speed in waves. Therefore, designs necessarily represent a compromise between manoeuvrability and course-keeping ability. Ship operators desire maximum manoeuvrability in port to minimize the need for assistance from tugs and to reduce delays in docking. They also desire a ship that can hold a steady course at sea with the minimum use of helm. These aims, however, are mutually conflicting.

A ship is steered by means of one or more rudders arranged at the stern or, in rare cases, at the bow. There are many types and shapes of rudders, depending upon the type of ship, design of stem, and number of propellers. When a yaw—that is, a change of angle about a vertical axis through the centre of gravity—is started, a turning moment is set up and the ship swings off course unless the swing is corrected by rudder action. This turning effect arises because the hull's centre of lateral resistance is much nearer the bow than the ship's centre of gravity.

Good course keeping demands directional stability. This is aided by design features that bring the centre of lateral resistance nearer to the ship's centre of gravity. These measures, however, increase the diameter of the ship's turning circle, requiring a design compromise. In warships, in vessels operating in confined waters, and in tugs, a small turning circle is essential. In merchant ships, rapid manoeuvring is required only in port; accordingly, the everyday function of the rudder is to ensure the maintenance of a steady course with the minimum use of helm. In this sense, turning circle properties are of less practical significance than the effect of small rudder angles.

STRUCTURAL STRENGTH

In still water, the loads acting on a hull include weight, fluid pressure, and buoyancy. In a seaway, additional forces arise from the wave-induced alteration of buoyancy distribution, from the ship's motions, from vibration, and from static and dynamic fluid pressures, including wave impact and slamming. The resultant loading on the main hull girder can be resolved into distributions along the length of shearing force, the bending moment in both vertical and horizontal planes, and the twisting moment.

The maximum stresses usually arise from the longitudinal vertical bending moment when the vessel is moving at right angles to a train of waves. As indicated above, this bending moment is considered as the sum of two components: first, the still water bending moment, due to the unequal distribution of weight and buoyancy along the ship length; and, second, the wave bending moment, which arises from differences in buoyancy distribution between the still-water and wave surfaces. The first of these components is governed by the disposition of weights within the ship and can often be minimized by skill and ingenuity at the design stage. The second is governed by the shape of the hull and the length and height of waves encountered. The length of a wave is the horizontal distance from the lowest point of one wave (the trough) to the lowest point of the next, or from the highest point of one wave (crest) to the highest point of the next. The height of a wave is measured vertically from the trough to the crest of any single wave. It is customary to assume that the worst conditions are when the length of the wave equals the ship length or when the midpoint of the ship is either at the crest or in the trough. Height of wave was formerly taken to be $1/20$ of its length, but

Location
of
vibration
symptoms

Rudders
and
steering

Stresses
acting
upon the
ship

a common present-day practice is to assume that height h is the square root of the length l times the factor 1.1 ($h = 1.1\sqrt{l}$).

With the wave crests at the ends of the ship, the supporting buoyancy is mainly at the ends of the ship, while with the wave crest at amidships the support is mainly at amidships. In the former case the greatest bending moment acting on the structure will occur when there is a concentration of weight amidships. Similarly, with a wave crest at amidships, the greatest bending moment will occur when there is concentration of weight toward the ends. The former case is known as sagging and the latter case as hogging.

In addition to stresses arising from the vertical forces which tend to bend the hull and which have their origin in heavy seaways and in engine pulsations, shear stresses are often investigated, notably in the longitudinal bulkheads of oil tankers. In container ships, where there is little actual deck area because of the large hatchways, special structural reinforcement is required to obtain the necessary strength. High superstructures, extending over a large fraction of the length, are a characteristic feature of passenger liners; and the design of such superstructures presents special problems. Transverse strength also poses difficult problems, notably in oil tankers, container ships, and bulk carriers.

The design of all structures is based upon experience, and experience is nowhere more requisite than in the design of ships. The great majority of ships are built according to the requirements of the classification societies of their countries, which publish rules and regulations for the construction of ships. To build a vessel of the classification specified by the owner, the shipbuilder must conform to these rules and regulations; he is thereby spared much difficult and tedious calculation work.

Steel is the main structural material in shipbuilding. The permitted types, composition, and qualities of mild and high-tensile steel, together with the approved manufacturing and the requisite tests, are specified in the classification society rules. The rules also cover the composition, manufacture, and tests appropriate to castings, forgings, and other manufactured components. Aluminum alloys, with good resistance to corrosion and the necessary strength properties, are used for the construction of erections on deck, notably in the superstructures of passenger ships, where their relative lightness makes ship stability properties more easily attainable. In the early 1970s it was thought that no new material was likely to replace steel as the main structural material within that decade, although composite materials might do so eventually. High-tensile steels were increasingly being used in the construction of very large tankers, bulk carriers, and container ships. Wood and wood substitutes are often employed for the sheathing of weather decks. Various synthetic materials with good fire-resisting properties can be used in accommodation spaces.

Spacing of watertight bulkheads. Typical ship hazards are stranding—when the bottom may be holed—and collision, when spaces within the hull may become flooded. Dry-cargo ships are protected against stranding by their double bottom construction. All ships must have a collision bulkhead, bulkheads to enclose the machinery space, and others—the number of which depends, in cargo and passenger ships, on their length. Oil tankers are well subdivided by both transverse and longitudinal bulkheads because a large number of separate tanks is required. In all vessels, but especially in passenger ships, the number and spacing of transverse watertight bulkheads must be adequate for safety under specified conditions of flooding. The extent to which a compartment open to the sea will flood depends on the permeability of its contents, this being defined as the ratio of the volume that can be occupied by water to the total volume. Formulas for the permeability of different compartments are laid down by governments, according to international agreement. Calculations to determine the floodable length—that is, the length at any point in the ship that may become flooded, without resulting in the immersion of any part of the margin line, which is three inches (76 millimetres) below

the deck to which the bulkheads extend—are made on the basis of an assumed permeability. The rule book also specifies formulas which ensure that one, two, or three adjacent compartments may be flooded before the margin line is immersed. Ships are thus described as having one-, two-, or three-compartment standards. The product of the floodable length and the factor of subdivision gives the permissible length of compartment. In the case of passenger ships, calculations must be made to discover whether their stability remains adequate under flooding.

Safety. In most maritime countries, a government department assumes responsibility for specifying and enforcing standards of safety in merchant vessels relating to maximum allowable draft, lifesaving appliances, stability, bulkhead subdivision, carriage of dangerous cargoes, lights and signals, and so on. These departments employ surveyors who supervise the testing, fitting, and inspection of all lifesaving appliances and other equipment essential for the safety of passengers and crew. Official inquiries are made into accidents, strandings, collisions, or wrecks, when loss of life is incurred.

The classification societies, such as Lloyd's Register of Shipping in England, the American Bureau of Shipping, Det Norske Veritas, Bureau Veritas, Registro Italiano Navale, Germanischer Lloyd, and Nippon Kaiji Kyokai, undertake the task of determining appropriate technical standards in ship construction and classification. Standards are laid down in the rules and regulations published by these societies, together with detailed specifications for the composition, quality, and testing of all materials of construction. The societies' surveyors are responsible for the testing of materials and for supervising the construction and repair of ships and their machinery. An owner specifies that a ship built to his order obtain a certain classification-society class because, for insurance purposes, this ensures a definite standard of strength and workmanship and a minimum freeboard. In the U.K., Lloyd's Register of Shipping is empowered by the Board of Trade to assign freeboards. Lloyd's also publishes annually its register book, which gives technical information for all merchant ships in service throughout the world and is kept up-to-date by the regular issue of supplements.

THE NAVAL ARCHITECT

A naval architect asked to design a ship may receive his instructions in a form ranging from such simple requirements as "an oil tanker to carry 100,000 tons deadweight at 15 knots" to a fully detailed specification of precisely planned requirements. He is usually required to prepare a design for a vessel that must carry a certain weight of cargo (or number of passengers) at a specified speed with particular reference to trade requirements; high-density cargoes, such as machinery, require little hold capacity, while the reverse is true for low-density cargoes, such as grain.

Deadweight is defined as weight of cargo plus fuel and consumable stores, and lightweight as the weight of the hull, including machinery and equipment. The designer must choose dimensions such that the displacement of the vessel is equal to the sum of the deadweight and the lightweight tonnages. The fineness of the hull must be appropriate to the speed. The draft—which is governed by freeboard rules—enables the depth to be determined to a first approximation.

After selecting tentative values of length, breadth, depth, draft, and displacement, the designer must achieve a weight balance. He must also select a moment balance because centres of gravity in both longitudinal and vertical directions must provide satisfactory trim and stability. Additionally, he must estimate the shaft horsepower required for the specified speed; this determines the weight of machinery. The strength of the hull must be adequate for the service intended; detailed scantlings (frame dimensions and plate thicknesses) can be obtained from the rules of the classification society. These scantlings determine the requisite weight of hull steel.

The vessel should possess satisfactory steering characteristics, freedom from troublesome vibration, and should

Classifica-
tion
societies

Materials
in
ship-
building

Major
design
factors

comply with the many varied requirements of international regulations. Possessing an attractive appearance, the ship should have the minimum net register tonnage, the factor on which harbour and other dues are based. (The gross tonnage represents the volume of all closed-in spaces above the inner bottom. The net tonnage is the gross tonnage minus certain deductible spaces that do not produce revenue. Net tonnage can therefore be regarded as a measure of the earning capacity of the ship, hence its use as a basis for harbour and docking charges.) Passenger vessels must satisfy a standard of bulkhead subdivision that will ensure adequate stability under specified conditions if the hull is pierced accidentally or through collision.

Compromise plays a considerable part in producing a satisfactory design. A naval architect must be a master of approximations. If the required design closely resembles that of a ship already built for which full information is available, the designer can calculate the effects of differences between this ship and the projected ship. If, however, this information is not available, he must first produce coefficients based upon experience and, after refining them, check the results by calculation.

Training. There are four major requirements for a good naval architect. The first is a clear understanding of the fundamental principles of applied science, particularly those aspects of science that have direct application to ships—mathematics, physics, mechanics, fluid mechanics, materials, structural strength, stability, resistance, and propulsion. The second is a detailed knowledge of past and present practice in shipbuilding. The third is personal experience of accepted methods in the design, construction, and operation of ships; and the fourth, and perhaps most important, is an aptitude for tackling new technical problems and of devising practical solutions.

The professional training of naval architects differs widely in the various maritime countries. University degrees in naval architecture are offered by many universities and polytechnic schools; such academic training must be supplemented by practical experience in a shipyard.

Trends in design. The introduction of calculating machines and computers has facilitated the complex calculations required in naval architecture and has also introduced new concepts in design. There are many combinations of length, breadth, and draft that will give a required displacement. Electronic computers make it possible to prepare a series of designs for a vessel to operate in a particular service and to assess the economic returns to the shipowner for each separate design. Such a procedure is best carried out as a joint exercise by owner and builder. As ships increase in size and cost, such combined technical and economic studies can be expected to become more common.

Shipbuilding

THE SHIPYARD

The wooden ship was constructed on a building berth, around which timbers and planking were cut and shaped, and then fitted together on the berth to form the hull. A similar practice was followed with iron vessels and, later, with the earlier steel ships, as these tended to be replicas of wooden hulls. Gradually iron came to be used more effectively in its own right, rather than as a substitute for timber. The berth or slipway from which the vessel is launched is an assembly area, rather than a ship construction site. In many shipyards the number of launching berths has been reduced to increase the ground area available for prefabrication sheds. Greater ease of fabrication means that, despite the reduction in the number of berths, more ships can be built and construction costs lowered.

Organization. A shipbuilder undertakes to deliver to the client by a certain date and for a stated sum a vessel with specific dimensions, capabilities, and qualities, a vessel that has been tested on trial and is ready for service. The function of a shipyard is the production of completed ships in accordance with the shipbuilder's undertakings. The raw materials for construction and finished items to be installed on board are delivered there. The labour force in the yard consists of various workmen—

steelworkers, welders, shipwrights, blacksmiths, joiners, plumbers, turners, engine fitters, electricians, riggers, and painters.

Management is headed by a chairman and a board of directors, consisting usually of about 6 to 12 members from the technical, commercial, and secretarial departments, with one or more representing outside interests. The chief departments are the design, drawing, and estimating offices, planning and production control, the shipyard department—responsible for construction up to launching—and the outside finishing department, which is responsible for all work on board after launching. Other departments are responsible for buying and store-keeping and the yard maintenance.

The construction of the hull is only one of a shipbuilder's responsibilities. As soon as a contract is placed, he must negotiate with subcontractors for the supply of items that shipyards do not produce—the electric power plant, propulsion machinery, shafting and propellers, engine-room auxiliaries, deck machinery, anchors, cables, and furniture and furnishings. Production planning and control is therefore a complex undertaking, covering subcontracts, assembly, and installation, in which costs must be kept as low as possible.

Layout. In the early 1970s, shipyard practice was to have few building berths and extensive areas around them for the construction of large components of the steel hull. Building berths slope downward toward the waterway, to facilitate launching. Building basins, or dry docks, are sometimes used for the construction of very large vessels, because it is convenient to lower, rather than to lift, large assemblies, and this method also eliminates problems associated with launching. Extensive water frontage for the building berths is unnecessary. The main requirement is a site of considerable depth, rather than width, with a large area extending inland from the berths. Steel plates and sections are delivered to the shipyard at the end of the area farthest from the berths. There they are stored in a stockyard and removed, as needed, for cleaning, straightening, shaping, and cutting. Separate streams of plates and rolled sections converge toward the prefabrication shop, where they are used to build structural components or subassemblies. The subassemblies are transported to an area nearer the berths, where they are welded together to form large prefabricated units, which are then carried by cranes to the berth, to be welded into position on the ship.

In practice, there are many variations in this general procedure. At the Gotaverken shipyard at Arendal, Norway, for example, partly fitted-out sections of the ship are fabricated in sheds and welded to sections already completed. As the vessel becomes built up with component sections, it is moved out of the covered area into a building dock and further sections are attached until the ship is complete. Water is then admitted to the dock and the ship is floated out for completion in the fitting-out basin. An example of an outstanding shipbuilding facility is the Harland and Wolff building dock in Belfast, Northern Ireland, completed in 1970, then the largest of its kind in the world: 1,825 feet (556 metres) long, 305 feet (93 metres) wide, and 38 feet (12 metres) deep. It is large enough for the construction of a 1,000,000-ton dead-weight tanker. The dock is spanned by a travelling crane capable of lifting prefabricated structures of 840 tons maximum weight.

PLANNING

Delivery of a completed ship by a specified date requires careful planning. Following the introduction of the critical path method of planning and control by the U.S. E. I. du Pont de Nemours & Company about 1959, new techniques were adopted in many shipyards.

The critical path method is the basis of network analysis, which is used in planning complex production projects. The network, and information derived from it, is used for overall planning of a project and also for detailed planning with production progress control. The network gives a logical, graphical representation of the project, showing the individual elements of work and

Prefabrication

The building berth

Critical path method

their interrelation in the planned order of execution. Each element of work is represented by an arrow, the tail of which is the starting point of activity and its head the completion. The arrows are drawn to any suitable scale and may be straight or curved. An event, which represents the completion of one activity and the beginning of another, is usually indicated by a circle and described further by a number within the circle. But each activity need not be completed before the next activity is begun. The logical order of steelwork in a hull, for example, is: (1) detailed drawings of steelwork; (2) ordering of steel; (3) manufacture and delivery of steel; (4) storing of steel material in stockyard; (5) shotblasting, cleaning, and forming operations; (6) subassembly work; and (7) erection of structure on berth. These operations can be represented on a ladder type of diagram. Many such diagrams—ladder and other types—go toward making up the complete aggregate operation of building a ship. When the proper sequence of operations is decided upon, times must be allocated to each operation to ensure that the men in charge understand their obligations. Planning, based on realistic estimates of times and costs, must begin at the precontract stage, so that, throughout the building program, a clear plan, with scheduled dates for each major section, is available. Detailed networks must be prepared for each of the major sections, showing dates for completion. The earliest and latest permissible starting and finishing times are indicated for each activity.

The critical path of a project is a series of activities whose duration cannot be increased without delaying the completion of the project as a whole. In large networks there may be more than one critical path. Up to about 100 activities can be dealt with manually but, for more complex cases, the numerical work is done by computer. The spare time available for a series of activities; *i.e.*, the maximum time these activities can be delayed without retarding the total project, is aggregated into a "total float." This is regarded as a factor of safety to cover breakdowns, mishaps, and labour troubles. Intelligent and experienced use of critical path methods can provide information of great value. Savings in production costs depend upon the use that management makes of this information.

From contract to working plans. Before an order is placed, the main technical qualities of the ship are decided upon and a general-arrangement drawing of the vessel, showing the disposition of cargo, fuel, and ballast, and crew and passenger accommodation is prepared. This plan provides a complete picture of the finished vessel. It is accompanied by detailed specifications of hull and machinery. This general-arrangement plan and the specifications form the basis of the contract between shipowner and shipbuilder.

As soon as an order is confirmed, drawing offices and planning departments produce working plans and instructions. Since ships are usually constructed according to the rules of a classification society, the stipulated structural plans are normally submitted to the society for approval. The spacing of bulkheads in passenger ships, for example, must be approved by the appropriate authority. For all ships, passenger and cargo, the approval of the maximum permissible draft must be sought from the classification society. Necessary working drawings include the lines plan and detailed plans of the steel structure—shell plating, decks, erections, bulkheads, and framing—as well as accommodation spaces, plumbing, piping, and electrical installations, and main and auxiliary machinery layout. The planning and production department prepares a detailed progress schedule, fixing dates for the completion of various stages in the construction. A berth in the yard is allocated to the ship, arrangements for the requisite materials, labour, personnel, and machines are made, and precautions are taken to ensure that the many interrelated operations will progress according to the timetable.

The lines plan; fairing. A lines plan, usually a $\frac{1}{48}$ life-size scale drawing of a ship, is used by designers to calculate required hydrostatic, stability, and capacity conditions. Full-scale drawings formerly were obtained from

the lines plan by redrawing it full size and preparing a platform of boards called a "scribe board" showing the length and shape of all frames and beams. Wood templates were then prepared from the scribe board and steel plates marked off and cut to size.

An alternative to the full-scale scribe board is a photographic method of marking off, introduced about 1950 and widely adopted. The lines plan is drawn and faired (mathematically delineated to produce a smooth hull free from bumps or discontinuities) to a scale of one-tenth full-size by draftsmen using special equipment and magnifying spectacles. The formerly used wood templates are thus replaced by specially prepared drawings, generally on one-tenth scale. Photographic transparencies of these drawings are then projected full size from a point overhead onto the actual steel plate. The plate is then marked off to show the details of construction, such as position of stiffening members, brackets, and so on. This optical marking-off system is much more economical in terms of space and skilled labour than the older method.

By the 1960s, digital computers were being used to fair the preliminary lines plan by a numerical method. Faired surfaces can be produced to a specified degree of accuracy and the lines can be drawn by a numerically controlled drawing machine, bringing the process under continuous scrutiny. Tapes can be produced for use in numerically controlled plate-burning machines, which cut plates to shape, and for the automatic cold bending of frames and curved girdeis. Fairing calculations produce data that can be fed back into a computer, and programmed to generate hydrostatic and stability data and other information.

FABRICATION AND ASSEMBLY

Since 1930, rivetting has been progressively supplanted by welding. This has proved more than a mere alteration in the method of connecting structural components because welding facilitates prefabrication of large component parts of the main hull structure.

Before welding came into wide-scale use every ship was constructed on the building berth. The keel was laid, floors laid in place, frames or ribs erected, beams hung from the frames, and this skeleton, framed structure was held together by long pieces of wood called ribbands. Plating was then added and all the parts of the structure were rivetted together. In other words, the ship was built from the keel upward.

The modern method is to construct large parts of the hull, for example, the complete bow and stern. Each of these parts is built up from subassemblies or component parts, which are then welded together to form the complete bow or stern. These sections of the ship are manufactured under cover in large sheds, generally at some distance from the building berth, before being transported to the berth and there fitted into place and welded to the adjacent section. The advantages of this procedure are that work can proceed under cover, unhampered by bad weather, and the units or component parts can be built up in sequences to suit the welding operations—not always possible at the building berth itself.

A number of techniques can be used to weld together two pieces of the same metallic material. The ideal weld is a continuity of homogeneous material, with the same composition and the same physical properties as the parts being joined. In steel shipbuilding, metal arc welding is produced by an electric arc formed between the parts to be joined; the fusion material is supplied by a coated electrode. The welding electrode consists of a core rod that is deposited as weld metal; it is flux coated to protect the molten metal from the atmosphere during deposition and to supply certain metallurgical properties to the weld. A great deal of research has gone into the production of the best possible coated electrodes for specific duties. The main advantages of welding over rivetting are: (1) a lighter structure (because overlaps are eliminated), (2) improved watertightness and oiltightness, (3) smoother surfaces, and (4) reduced hull upkeep. Certain precautions, however, are necessary. The design of the structure must be adapted for welding because structural details

The
welding
electrode

General-
arrange-
ment
drawing

which can be rivetted are seldom suitable for welding. The joints must be carefully prepared beforehand for welding. Incomplete penetration, lack of fusion, porosity, and cracking are typical weld defects that must be avoided. Hard spots must be avoided and gradual tapering off of stiffness is necessary if defects in service are to be minimized (see also WELDING, BRAZING, AND SOLDERING).

LAUNCHING, OUTFITTING, AND TRIALS

Launching. Apart from certain small craft built on inland waterways, which are launched sideways, the great majority of ships are launched stern first from the building berth. Standing structures called ways, constructed of concrete and wooden blocks, spaced about one-third of the vessel's beam apart, support the ship under construction. The slope of the standing ways—which are often cambered (slightly curved upward toward the middle or slightly curved downward toward the ends) in the fore and aft direction—ranges from one-half to three-quarters of an inch per foot of length (from 42 to 62 millimetres per metre of length); ways extend from a position near the bow to past the stern and for a certain distance into the water. Over these standing ways is built the launching cradle, which consists of sliding ways on which are built poppets, or supporting structures, of timber to provide support for the hull. Between standing ways and launching ways is a layer of lubricant.

During construction the ship is supported by at least one line of blocks under the keel, with side supports and shores as necessary. As the vessel nears completion, the standing ways are built under it, the sliding ways are superimposed, and the cradle is built up. The weight of the vessel is transferred gradually to the standing ways. The full weight must not be supported by the ways for too long because the thickness of lubricant would be reduced by squeezing and its properties would be adversely affected. It is common to fit launching triggers which, when released at the moment of launching, permit the sliding ways to move over the standing ways.

As a vessel moves down the ways, the forces operating are: its weight acting down through the centre of gravity, the upward support from the standing ways, and the buoyancy of the water. As it travels further, the buoyancy increases and the upthrust of the ways decreases, with the weight remaining constant. As the centre of gravity passes the after end of the standing ways, the moment of the weight about the end of the ways tends to tip the ship stern first. At this position and for some time later, it is essential that the moment of buoyancy be greater than the moment of weight about the after end of the ways, thus giving a moment to keep the forward end of the sliding ways on the standing ways; otherwise there would be concentration of weight at the end of the ways, causing excessive local pressure. Calculations are made to determine the most important factors in launching, namely, the moment at which the stem lifts, the difference between weight and buoyancy when the stern lifts, the existence of a moment against tipping, and the equality of weight and buoyancy before the vessel reaches the after end of the ways to ensure that the cradle will not drop off the end of the standing ways.

The launching of a vessel into a restricted waterway requires the application of a retarding force. Usually piles of chains are laid alongside the sides of the ship to act as drags, and these are secured to chain plates by wire cables, fixed temporarily to the hull. As the vessel slides down the launching ways, the drags come serially into operation after, or sometimes before, the bow has cleared the after end of the ways. Launching can be a hazardous operation. If the lubricant is ineffective, the vessel will not move. If the stem does not lift as the vessel slides down the ways, the ship may tip about the way ends. The bow may sustain damage when it drops into the water at the end of the ways and may damage the slipway when the stem lifts. Excessive loads on the poppets may cause their collapse.

Outfitting. After launching, the ship is berthed in a fitting-out basin for completion. The main machinery, together with auxiliaries, piping systems, deck gear, life-

boats, accommodation equipment, plumbing systems, and rigging are installed on board, along with whatever insulation and deck coverings are necessary. Fitting out may be a relatively minor undertaking, as with a tanker or a bulk carrier, but in the case of a passenger vessel, the work will be extensive. Although fitting-out operations are diverse and complex, as with hull construction there are four main divisions: (1) collection and grouping of the specified components, (2) installation of components according to schedule, (3) connection of components to appropriate piping and/or wiring systems, and (4) testing of completed systems.

In the early 1970s, the tendency in planning was to divide the ship into sections, listing the quantities of components required and times of delivery. Drawings necessary for each section are prepared and these specify the quantities of components required. A master schedule is compiled, specifying the sequences and target dates for completion and testing of each component system. This schedule is used to marshal and synchronize fitting work in the different sections and compartments.

Trials. As the vessel nears completion a number of tests are made. The naval architect makes a careful assessment of the weight of the finished ship and checks its stability and loading particulars by reference to data for the ship's lightweight and centre of gravity, obtained from a simple inclining experiment. The inclining test also provides a check on calculations.

Before the official sea trials, **dockside** trials are held for the preliminary testing of main and auxiliary machinery. Formal speed trials, necessary to fulfill contract terms, are often preceded by a builder's trial. Contract terms usually require the speed to be achieved under specified conditions of draft and deadweight, a requirement met by runs made over a measured course.

It is usual to conduct a series of progressive speed trials, when the vessel's performance over a range of speeds is measured. The essential requirements for a satisfactory measured course are: adequate depth of water; freedom from sea traffic; sheltered, rather than exposed waters; and clear marking posts to show the distance. Whenever possible, good weather conditions are sought. With a hull recently docked, cleaned, and painted, sea-trial performance can provide a valuable yardstick for assessing performance in service. Ideally, the ship should be run on trial in the fully loaded condition; but this is **difficult** to achieve with most dry-cargo ships. It is, however, comparatively simple to arrange in oil tankers, by filling the cargo tanks with seawater. Large vessels with a low displacement-power ratio must cover a considerable distance before steady speed is attained; hence they need to make a long run before entering upon the measured distance.

Speed trials

MODERN TRENDS

The rapid expansion of world trade, combined with the closure of the Suez Canal in 1967, has created a great demand for shipping of all types, but particularly for large vessels to carry bulk raw materials, such as oil, ore, and grain. The number of ships above 50,000 tons gross more than trebled in the succeeding years, and a tanker of 476,000 tons deadweight was on order at the end of 1970. Almost 90 percent of the ships on order were either tankers or bulk cargo carriers. Simultaneously, there has been a rapid expansion of the container ship fleet which, because of these ships' greater productivity, is likely to supersede much of the existing dry-cargo ship fleet, leading to a net reduction in the number of ships in service. Ship passenger transport continues to decline as air transport becomes relatively cheap, but passenger vessels continue to find employment in the tourist and cruise fields.

The effect of these changes on the shipbuilding industry has been profound. Shipyards have had to be reorganized and, in many cases, rebuilt to cope with the demand for very large ships. This has necessitated vast capital expenditure, and in a period of fierce world competition there have been amalgamations of small firms into large shipbuilding groups. In Britain, for example, in the 1960–70 decade the number of shipbuilding companies producing

Launching into a restricted waterway

ships over 400 feet (120 metres) in length declined from 36 to about 12, while the output remained substantially the same.

By concentrating on the construction of large tankers and bulk carriers, Japan has become the leading ship-building nation, with an annual output of about 9,000,000 tons—nearly half the world total. At the beginning of the 1970s, only three shipyards in Britain were capable of producing very large tankers. West Germany specialized in container-ship production and now has a large share of that trade. Thus, increasingly, the trend was for particular shipyards to specialize in certain types of vessels, and the day of the shipyard with facilities to build practically any type of vessel was over.

Propulsion

Marine engineering is a branch of mechanical engineering. Its distinctiveness lies in the special features of engine design and operation that are necessary for ship propulsion. Otherwise, production processes, organization, and other matters have a similar basis.

A shipowner considers the following factors before ordering a ship: (1) capacity and deadweight on suitable draft, (2) speed, (3) first cost, (4) running and maintenance charges, and (5) general suitability. Items (1) and (2) indicate the purchaser's requirements. Items (3), (4), and (5) are computed by the engine builder.

The choice of propelling machinery is influenced by the engine power necessary for the required ship speed; the effects of the weight and space of engines plus fuel bunkers on the dimensions of the ship; fuel costs; upkeep costs—including overhaul, replacements, and consumable stores; and special considerations, such as personnel required. The choice of alternatives in marine propulsion may be grouped into two basic classes: diesel engines and geared steam turbines. The diesel engine is available in double-acting two-stroke; single-acting two-stroke or single-acting four-stroke direct drive; and in indirect drive systems, such as geared diesel engines and diesel-electric systems. It is usually possible to determine, without elaborate analysis, which type of machinery is most suitable for a particular vessel engaged in a particular trade. Occasionally, however, detailed investigation is necessary.

STEAM INSTALLATIONS

Steam generators. Immediately after World War II general mercantile practice favoured boiler pressures of 450–600 pounds per square inch (psi) with steam temperatures of 750–825° F (400–440° C). Occasionally, installations were built with levels as high as 850 psi and 900° F (480° C). In the early 1970s, pressures of 600–800 psi and temperatures of 800–900° F (425–480° C) became general; but higher ranges (e.g. 900–1200 psi and 1,000° F [540° C]) were accepted.

The following design data apply to a typical steam generator: normal evaporation, 180,000 pounds (82,000 kilograms) of water per hour; steam pressure/temperature, 880 psi, 990° F (530° C); feed temperature, economizer inlet, 280° F (140° C); temperature air heater outlet, 250° F (120° C); carbon dioxide in funnel gases, 15 percent; boiler efficiency, 86.8 percent. Such a generator normally would be provided with four fuel injectors, directed downward, arranged in the combustion chamber roof. Combustion air from the atmosphere is delivered by motor-driven fans. The furnace is surrounded by a wall of water-filled tubes, to which the heat of combustion is transmitted. The steam thus generated rises to a horizontal steam drum and from there it flows through pipes to the superheater, to be further heated by combustion gases. Finally, it is conveyed to the turbine. Hot gases rising from the superheater flow to the economizer, through which feedwater is circulated on its way from the feed heating system to the boiler. The products of combustion finally rise to the funnel and thence into the atmosphere (see STEAM POWER).

Steam turbines. A succession of evolutionary changes has brought steam-turbine practice to its present level. Two-turbine units are now standard for all except low-

power installations, and these are single-turbine sets (see TURBINE).

Gearing. Reduction gearing between the steam turbines and the propeller enables the prime mover to rotate at speeds sufficiently high to ensure maximum thermal efficiency, while propeller revolutions are low enough to realize the maximum propulsive efficiency. In this respect the geared turbine has an advantage, compared with the direct-driven diesel engine.

Double-reduction gearing is the most widely applied arrangement, the ratio of reduction ranging between 30 to 1 and 60 to 1; the lower values are for low-pressure turbines and the higher values for high-pressure turbines. Single-reduction gearing, in which the ratio may be from 12 to 1 up to 20 to 1, has only limited applications.

For twin-screw ships, the propeller revolutions are usually of the order of 110 to 120 per minute (rpm). For single-screw vessels, the propeller may revolve at 90 to 100 rpm. Where the ship form permits, propellers of large diameter may be installed, as in single-screw ships with a large cross section (e.g. tankers); in such ships the revolutions may be as low as 80 per minute, to the great advantage of propulsive efficiency.

INTERNAL COMBUSTION ENGINES

Diesel engines. Heavy-oil engines, commonly termed diesel engines, operate on a cycle comprising four phases: suction, compression, expansion, and exhaust. Fuel is injected at the end of the compression stroke. In the so-called four-stroke cycle, each of the phases occupies one stroke; that is, the complete cycle extends over two revolutions. The earliest marine engines were of this form and were heavy and costly. The next step was to complete the four-phase cycle in one revolution, hence the term two-stroke cycle. In this cycle, the revolution is divided into three approximately equal periods, for compression, combustion and expansion, exhaust and scavenge. In all the early engines, combustion air was drawn from the atmosphere and the engines were termed atmospheric induction engines. Air density determines the maximum fuel weight that can be burned; it therefore determines the power that can be developed. If the charge-air density is increased by the interposition of a compressor between the atmosphere and the cylinder, then the weight of air is increased and a greater weight of fuel can be burned, with a proportionate increase in power output. The compressor, or blower, is driven by a gas turbine utilizing the heat energy of the exhaust gases. This is the principle of exhaust turbocharging. Single-acting, two-stroke, exhaust turbo-pressure-charged engines are almost standard in marine practice (see DIESEL ENGINE).

Geared engines. When engine powers were moderate, there was little or no need for geared engines. With the trend to larger direct-coupled engines, the scope for geared units, as an alternative method of propulsion, has widened. Moreover, there is greater opportunity for variation with geared engines than with direct-coupled engines. In general terms, the advantages of geared drive are: (1) greater reliability, by having more than one engine per screw; (2) when the ship is running light or partly loaded, one or more of the engines can be shut down and the others operated at their most efficient ratings; (3) maintenance is easier because the engines are of more manageable size; (4) engines can be overhauled one after the other at sea; (5) by modifying the number of engines per ship and cylinders per engine, the propelling machinery of a fleet of vessels of different sizes and powers can be standardized upon a single cylinder size, with advantage to initial cost, delivery time, and replacements.

Geared engines occasionally have been made with a heavy flywheel as the only damping agent between engine and gearing. More commonly, however, a flexible coupling of some kind is interposed between engine and gearing: to serve as a cushion, preventing the transmission of detrimental torque pulsations from engine to gearing; to function as a quick-disconnecting clutch for use when manoeuvring; and to limit the transmissible torque to, say, 1.5 to 2.5 times its normal value and thus obtain a

Double- and single-reduction gearing

Factors affecting choice of engine

Flexible couplings

measure of protection should one of the engines stop suddenly.

A flexible coupling can be mechanical, electrical, hydraulic, or pneumatic. A mechanical coupling cannot easily be made to serve as a clutch. Cost, weight, space, and reliability are the factors to be considered when comparing forms of coupling. The gearing is always **single-reduction**. The efficiency of the energy transmission, from engine to propeller, is approximately 92 percent for a geared installation and about 97 percent for a direct-coupled engine.

Diesel-electric drive. An alternative to geared engines is the diesel-electric drive, in which a diesel engine powers an electric generator and the propellers are powered by electric motors. Its advantages are similar to those of the geared arrangement. With the exception of small powers, however, direct-current machinery is too heavy and too costly to compete with geared systems; and alternating current and high voltages are accompanied by certain problems, especially those associated with manoeuvring and reversing.

GAS TURBINES

The gas turbine has not fulfilled the expectation at the beginning of the 1940s that it would become popular as a marine prime mover. By the 1970s, it was being applied to certain types of naval vessels, but it has seldom been used for mercantile ship propulsion. One of its basic problems is the low efficiency of the compressor; moreover, the metallurgical problems associated with the very high temperatures required for efficient operation are difficult to surmount (see also TURBINE).

NUCLEAR PROPULSION

In principle, the difference between a conventional steam installation and a nuclear power plant is that the combustion chamber in the former is replaced by a reactor using enriched uranium, the process of nuclear fission being utilized as the source of heat (see NUCLEAR REACTOR). The steam produced is fed into a normal set of steam turbines. The essential part of the reactor system is enclosed within a sealed, shielded structure capable of containing the products of any possible rupture in the reactor when in service. The weight of the shielding structure is more than three times that of the reactor system itself. The thickness of the surrounding concrete wall may vary from 30 to 48 inches (760 to 1,200 millimetres).

Many types of reactors are in use or are under investigation in land plants. There are approximately 25 possible types of ship reactors. Nuclear plants for merchant-ship propulsion ultimately may take the form of a direct-cycle reaction gas turbine, thus eliminating steam and other forms of intermediate heat exchange. Such a cycle may be a pressurized gas reactor coupled directly to a gas turbine. In the early 1970s pressurized water was preferred as the primary coolant-moderator medium in marine installations; it was a logical development from high-pressure marine boilers.

The first nuclear-propelled merchant vessel, the 21-knot **NS "Savannah,"** which was launched in 1959, made clear the great potentialities of the system. This vessel is propelled by a single-screw, two-cylinder geared turbine arrangement delivering 21,000 shaft horsepower (shp). Steam pressure is only 460 psi, 475° F (245° C)—considerably below the usual level, 650 psi, 875° F (470° C), of conventional marine boilers.

A conventional steamer of the same size and power as the "Savannah" is limited in its steaming range to 13,000 nautical miles before refuelling. The nuclear-powered ship can travel 350,000 nautical miles before fuel renewal is necessary. Whereas fuel for a fuel-oil-fired ship is paid for when purchased at routine intervals, in a nuclear ship the first fuel charge must be built-in. Thus the initial capital cost is high.

THE ENGINE ROOM

Engine-room auxiliary machines. In addition to the main propulsion machinery, an engine room contains a number of auxiliary machines. These auxiliaries fall into

two groups: (1) those needed for ship services, and (2) those attendant upon the propulsion machinery. In the first group are the bilge, ballast, sanitary, freshwater, and general-service pumps. The bilge pump deals with leakage water, and the ballast pump is used to empty the double-bottom ballast tanks before cargo is shipped.

In steam installations, pumps are required for main condenser circulation and water extraction, boiler feed, and fuel-burning equipment. There are also evaporators, feed heaters, forced- and induced-draft fans, soot collectors, an auxiliary condenser with circulating pump, forced lubricating pumps, and oil purifiers. Pumps needed for diesel propelling engines include water-circulating pumps for cylinder jackets, lubricating oil pumps, filters and purifiers, oil transfer and surcharging pumps, and an auxiliary boiler for fuel heating and other services. Water pumps are almost invariably of the vertical, motor-driven, centrifugal type. Cogwheel or screw pumps, as well as reciprocators, are commonly used for pumping fuel (see also PUMP).

Electric power for all purposes is provided by **turbogenerators** or by diesel-driven generators. Some of the auxiliaries run continuously at full load; others run intermittently, often at reduced load. To determine the total power requirements of the electric generators, the rated horsepower of the various units are added and multiplied by a diversity factor that may vary between about 0.60 and 0.75. On deck there are cargo winches, capstan machinery, anchor winches, steering gear, and, perhaps, stabilizers. Although operated by the deck department, this equipment is kept in working condition by the engineering staff.

The piping systems for bilge, ballast, fuel oil, and other services, although out of sight under the floorplates, are elaborate and costly. In cargo liners and tankers, the total weight of piping is 20 to 27 percent that of the main engines; the cost of **pipework** can be 35 to 45 percent that of the main engines.

Engine-room automation. Automation, to a greater or lesser degree, is standard. The makers of proprietary engines have their own characteristic systems. There are differences of opinion regarding the extent to which propelling engines and auxiliary equipment should be automatically and remotely controlled, and the number of engineers that should be available at a central console. The American Bureau of Shipping, Lloyd's Register of Shipping, Bureau Veritas, and Det Norske Veritas have each published memoranda and guidance notes; but none has issued mandatory regulations.

Shock, Electrical

An electrical shock is the perceptible and physical effect of an electrical current that enters the body. The shock may range from an unpleasant but harmless jolt of static electricity, received after one has walked over a thick carpet on a dry day, to a lethal discharge from a power-line. The present article is focussed primarily upon the dangerous and often lethal shocks from house currents.

In the middle of the 18th century, after the invention of the electrical condenser, also called a capacitor (a device for the accumulation and storage of electrical charges), numerous experiments were carried out to discover the physical effects of electricity and its effects on animals. In one such experiment by Benjamin Franklin, the American editor, scientist, and statesman, a pullet was "struck dead" by an electric shock through the head and was revived by someone's repeatedly blowing into its lungs. It is important to note that in that experiment the current was passed directly through the pullet's head. Two years later, during a similar experiment with lightning in St. Petersburg (Leningrad), the investigator accidentally received a heavy discharge along the same current pathway and was killed. This difference in effect is just one example of the variability of the effects of electricity. Some of these variations are discussed in the paragraphs that follow (see also LIGHTNING).

The advent of town electrical-distribution systems, toward the end of the 19th century, may be said to have made electric shock a hazard of everyday life. From the beginning of the 20th century to the present, deaths from electric shock have increased manyfold in industrially developed countries. The consumption of electricity has meanwhile increased even more rapidly, so that the average number of deaths per gigawatt-hour (million kilowatt-hours) is actually falling (see Table).

Deaths Due to Electric Shock				
year	country	number of deaths per annum	average consumption (gigawatt-hour)	deaths per gigawatt-hour
1910	England and Wales	26
	Sweden	5
1950	England and Wales	89	42	2.1
	Sweden	41	18	2.3
	France	181	29	6.2
	U.S.	955	329	2.9
1960	England and Wales	117	93	1.3
	Sweden	30	35	0.9
	France	184	65	2.8
	U.S.	989	753	1.3
1965	England and Wales	126	149	0.8
	Sweden	28	49	0.6
	France	203	94	2.2
	U.S.	1,071	1,055	1.0

Type of current responsible for most deaths

The great majority of deaths occur from alternating current at house-current frequencies of 60 hertz (cycles per second) in North America and 50 hertz in Europe, and it is shocks from this type of current that will be considered in the present article. Most of the deaths occur from contact with conductors at less than 500 volts. That is not to say that high voltages are less dangerous, but they are generally present only on apparatus and supply lines operated by utility companies, which try hard to ensure that only trained and authorized persons have access to them.

The effects of electric shock on the human body depend on the current that flows—the amperage—rather than on the force of the current, or voltage. The electrical resistance of the human body is variable and may in fact alter considerably during the passage of an electric shock. Therefore, except in broad terms, applied voltage is not a consideration. This leads to difficulties in the investigation of accidents, for the electrical engineer is often able to state only the voltage applied, but the physician thinks in terms of the current that flowed.

Another important consideration is the path that the

current takes through the body. Looked at as an electrical conductor, the body behaves as a solution of electrolytes in a leathery container. The greatest current density therefore occurs along the axis joining the two points of contact. As the distance perpendicular to the line of current flow increases, the density of current rapidly falls off. Thus, those organs most likely to be affected are those that lie close to the direct path of the current. As the great majority of electrical fatalities are due to currents passing between an arm (usually the right) and the legs, the current passes through the chest and affects the organs within it. Except in those extremely unusual accidents in which the head makes one of the points of contact, the brain does not lie on or near the pathway of the current.

Causes of death. An electric shock may directly cause death in three ways: asphyxia, 'persistent respiratory arrest, and ventricular fibrillation.

Asphyxia. A person may be unable to let go of a conductor of electrical current because of the uncontrollable contraction of the forearm muscles. In the same way a current traversing the body through the chest holds the chest muscles in an uncontrollable contraction and the victim is unable to breathe. Unless he is freed or manages to release himself, he will die within a few minutes.

Persistent respiratory arrest. The early experimenters directed electric currents through the heads of the experimental animals and produced persistent arrest of respiration. From this, and similar evidence, arose the widely accepted belief that restoration of breathing by artificial respiration was the correct and sufficient first-aid treatment for all victims of electric shock. As has been said above, accidents in which currents pass through the head are quite uncommon, but in such instances artificial respiration by itself would be an appropriate treatment. During electroconvulsive therapy (electric shock treatment), used for treatment of some psychiatric illnesses, an electric current is passed across the head, and respiratory arrest is an extremely rare complication.

Ventricular fibrillation. At the end of the 19th century it was shown that an electric shock can cause the heart to function in such an uncoordinated fashion that the circulation stops. This condition, called ventricular fibrillation, is not peculiar to electric shock and may occur in a number of other conditions. Untreated, ventricular fibrillation results in death within three to five minutes; only rarely in human beings does the heart revert spontaneously to a normal rhythm.

An electric shock will cause ventricular fibrillation only if the current passes through the heart at the moment when the ventricles (the main pumping chambers of the heart) are starting to relax. It has been shown that, during this vulnerable period, the greater the current the shorter the time it takes to cause ventricular fibrillation. It is generally believed that ventricular fibrillation is the most common cause of death in electric shock.

First-aid treatment. It has been seen that, although electric shock may bring about death in a number of ways, all of these result in either the arrest of respiration or the arrest of the circulation (due to disordered heart action) or both. First aid is therefore directed at treatment of these conditions. Arrest of respiration is now almost universally treated by mouth-to-mouth artificial respiration, and circulatory arrest by external massage of the heart (cardiac massage). Both of these are effective if started promptly within three minutes of the accident—and if applied correctly. There is no time to learn these techniques from books or posters after the accident, and persons who are likely to be first on the spot in an emergency should have a thorough practical training beforehand. This is particularly the case with external cardiac massage, which may itself cause death or serious injury if carried out incorrectly. Because of these dangers, external cardiac massage should be used only when it is really necessary as a life-saving procedure. Not only should the potential rescuer know how to carry out external cardiac massage, but he must be able to recognize quite clearly the indications for starting.

Aftereffects. Although the great majority of victims of electric shock, excluding those who have been burned,

Artificial respiration and cardiac massage

either die or recover completely, a very small number suffer from aftereffects, which may be temporary but are sometimes permanent. These may include cataract of the eye, a form of angina (attacks of pain beneath the breast-bone), or various disorders of the nervous system. All sorts of conditions that might have started in any event are commonly attributed by uncritical observers to an electric shock that occurred perhaps weeks or months earlier. Such tendencies lead one to skepticism, but careful study of accident records including the current pathway and the clinical details have convinced a number of observers that some manifestations actually are sequelae. Nevertheless, it must be emphasized that such after-effects of accidental electric shock are extremely rare.

Shock, Physiological

Physiological shock may be defined as acute progressive circulatory failure in which defective tissue perfusion occurs. This definition is derived from the one constant feature of physiological shock, the failure of adequate blood flow through the capillaries, the smallest of the blood vessels. As a result of this failure, an inadequate supply of oxygen and nutrients is delivered to the tissues, and the removal of metabolic waste products from the tissues is incomplete.

All, or some, of the following features may be present: a raised pulse rate, each pulse being diminished in strength, or "thready"; diminished arterial blood pressure; a cold, sweaty skin; rapid, deep respirations (breathing called air hunger in this context); mental confusion; dilated pupils; a dry mouth; and diminished flow of urine.

Many classifications of various types of shock have been developed, the most popular being one that relates the state to its cause; e.g., hemorrhage (bleeding) or sepsis (invasion by pus-forming organisms). This classification has the advantage of possessing diagnostic and therapeutic implications, but unfortunately the cause of shock is often uncertain. Alternatively, the state may be called hypovolemic if it is associated with a reduction in blood volume or normovolemic if no blood-volume diminution has occurred. Shock can also be subdivided into "warm hypotension," if the sufferer has lowered blood pressure and warm dry skin, and "cold hypotension," if the skin is cold.

In order to comprehend the various mechanisms associated with the onset of shock, it is necessary to understand the functioning of the normal circulation, as it is described in detail in the article CIRCULATION AND CIRCULATORY SYSTEMS. Essentially there are five circulatory components: (1) the heart, whose muscle, called the myocardium, pumps blood around the circulatory system; (2) the arteries; elastic-walled vessels whose final subdivisions are the arterioles, which act as sluice gates to regulate both the flow of blood into the capillary bed and the pressure in the arterial tree; (3) the capillaries; tiny, thin-walled vessels at which vital metabolic exchanges between blood and tissues occur; (4) the veins; large, relatively thin-walled vessels conducting blood back to the heart; and (5) the blood, comprised chiefly of plasma fluid and red blood cells. Malfunction of any one of these can lead to inadequate blood flow and permeation of the tissues, and thus cause shock.

THE TYPES OF SHOCK AND THEIR RECOGNITION

Shock due to inadequate blood volume. Hemorrhage is the commonest cause of shock. In the "average man" (weighing 70 kilograms, or about 154 pounds) the blood volume is about five litres (about 5.3 quarts), and the loss of any part of this will initiate certain cardiovascular reflexes. Hemorrhage results in a diminished return of

venous blood to the heart, the output of which therefore falls, causing diminution of the arterial blood pressure. When this occurs pressure receptors (baroreceptors) in the aorta and carotid arteries will initiate remedial reflexes either through the autonomic (nonvoluntary) nervous system by direct neural transmission or by epinephrine (adrenaline) secretion into the blood from the adrenal gland. The reflexes comprise increase in the rate and power of heart beat, increasing its output; constriction of arterioles leading to nonessential capillary beds (notably the skin and some viscera); and constriction of the veins, diminishing the large proportion of the blood volume normally contained therein. By these means arterial blood pressure will tend to be maintained, thus preserving blood flow to the vital areas such as the brain and the myocardium. After continued acute blood loss of 20-30 percent of the blood volume, the compensatory mechanism will begin to fail, the blood pressure will begin to fall, and shock will ensue.

Increased sympathetic (autonomic) nervous activity thus accounts for the fast pulse rate, pallor, and coldness of the skin in shock and, in addition, is the cause of increased sweating and dilation of the pupils of the eyes. Air hunger and mental confusion are caused by the inadequate carriage of oxygen, and decreased urine flow stems from a diminution in the renal (kidney) blood flow. This diminution, if severe, can lead to kidney failure. If acute blood loss continues beyond about 50 percent, the inadequacy of flow through vital circulations will lead to death.

Loss of whole blood is not necessary for the blood volume to be low, for plasma loss through burnt areas of the skin, or dehydration following inadequate intake of fluid, or exceptional fluid loss can lead to contraction of the blood volume to levels capable of causing shock (see DEHYDRATION).

Shock due to inadequate cardiac output. *Cardiogenic shock.* Sudden interference with the blood supply to the heart muscle, as by a thrombosis (clotting) in a coronary artery, causes damage to the muscle with resultant diminution in its contractile force. The output of the heart falls; if the decline is severe, a fall in blood pressure stimulates the baroreceptors and, in the way just described, shock results. This occurs in a substantial number of myocardial infarcts (death of sections of heart muscle). But low heart output alone may not account for the shock, for in chronic heart failure the cardiac output may be low without such a response in the peripheral circulation.

Pulmonary embolus. A thrombus is a blood clot that remains fixed to the blood vessel wall at its point of origin. The clot is called an embolus if it breaks loose from its point of origin. A pulmonary embolus results when a venous thrombus breaks loose from its original site (usually in a pelvic or leg vein), passes along the veins to the heart, and on to a pulmonary artery or subdivision. By the bulk of the clot or because of reflex constriction of the remainder of the pulmonary arterial tree, blood flow through the lung is obstructed. This reduces cardiac output, and shock may follow; in addition breathing is noticeably faster and deeper.

Dissection of the aorta. Degenerative changes in the lining layer (intima) of an artery can lead to the stripping of this layer from the vessel wall (dissection) by the flow of the blood, which works into the interstices of the arterial wall. Thus the passageway of the vessel (lumen) is effectively blocked, and, should this occur in the thoracic aorta—usually at the site of a localized dilation (aneurysm)—diminished cardiac output leads to shock.

Cardiac tamponade. The heart is enclosed in a membranous sac (the pericardium) whose lubricated smooth inner layer facilitates unimpeded movement during the heart's contraction and refilling. The thin layer of pericardial fluid may suddenly increase or a hemorrhage into the sac may occur, which can compress the heart, preventing adequate filling between contractions. This compression of the heart by surrounding fluid, a condition called cardiac tamponade, causes diminution in cardiac output that can lead to shock.

Shock from functioning of heart

Components of normal circulation

Shock due to increased circulatory capacity. If widespread dilation of the veins or of the capillary beds occurs, the blood volume is no longer sufficient to fill the larger space and shock ensues.

Bacteremic shock. Infection anywhere in the body may spread to the circulation, and the presence of organisms in the blood stream—bacteremia—may lead to shock. Bacteria are conveniently divided into "gram-positive" and "gram-negative" grouped according to their reaction to a special gram stain.

Gram-negative bacteremia, the more common and more lethal type, is frequently caused by *Escherichia coli*, *Proteus*, *Pseudomonas*, or *Klebsiella* organisms; the first of these normally inhabits the intestine. The clinical picture of gram-negative bacteremia is much like that of hemorrhage, although no blood has been lost, with a rapid, thready pulse; a cold, sweaty skin; and low blood pressure. A fever may occur, in addition to the local signs of the associated infection. The cause of the type of reaction is uncertain.

The response to bacteremia from gram-positive organisms such as *Staphylococcus* and *Streptococcus* is different. Widespread dilation of the blood vessels results in a warm, dry skin and a full volume pulse in spite of lowered blood pressure.

In both types of bacteremia the condition may be exacerbated by contraction in blood volume. This follows fluid loss, e.g., that lost in the peritoneal cavity in peritonitis—inflammation of the peritoneum, the membrane that lines the abdominal cavity; in the tissues in streptococcal infection; or through the intestine in enteritis (inflammation of the intestine).

Anaphylactic shock. Anaphylactic shock is discussed in detail in the article ALLERGY AND ANAPHYLACTIC SHOCK. An anaphylactic reaction follows the entrance of a specific foreign material into the bloodstream of a person whose body has become sensitized against it by previous contact. When this happens, intense constriction of the lung bronchi occurs, interfering seriously with respiration; blood pressure may fall precipitously because of the release of substances (serotonin, histamine, and bradykinin) that cause dilation of the arterioles and venules with increase in the capillary-wall permeability. Thus the circulatory capacity is increased, and fluid is lost into the tissues.

Psychogenic shock. Psychogenic shock causes fainting, probably by initiating dilation of the vessels of the muscles. Blood pressure falls, the skin becomes cold and sweaty, and the pulse rate increases. Decrease in blood flow to the brain leads to light-headedness and loss of consciousness. As soon as the affected person is prone cerebral blood flow improves and the circulation recovers.

Drugs and shock. Most anesthetic drugs—nitrous oxide is a notable exception—have a profound effect on the circulation, decreasing contractility of the heart muscle and increasing circulatory capacity by dilating the blood vessels. In addition, the normal postural circulatory reflexes are lost, so that pooling of blood in the legs is liable to occur if the affected person is tilted to a head-up position. This is of particular importance after an operation, when sitting up too soon can lead to low blood pressure and insufficient blood flow to the brain.

Overdosage of certain drugs, notably barbiturates, narcotics, and tranquilizers, blocks normal circulatory reflexes and causes dilation of the blood vessels, leading to a fall in blood pressure that often is accompanied by a slow, full-volume pulse.

Neurogenic shock. The maintenance of the tone of the blood vessels by the autonomic nervous systems may be affected by severance of one of these nerves or by its interruption of the flow of nervous impulses. Thus, spinal anesthesia—jection of an anesthetic into the space surrounding the spinal cord—or severance of the spinal cord results in a fall in blood pressure because of dilation of the blood vessels in the lower portion of the body and a resultant diminution of venous return to the heart.

Endocrine causes of shock. The endocrines play a vital role in the regulation of normal metabolic processes, and it is not surprising that part of the picture in malfunction

relates to the circulation. Detailed description is found in ENDOCRINE SYSTEM DISEASES AND DISORDERS.

Inadequate secretion by the adrenal cortex, the outer substance of the adrenal gland, leads to shock both by diminution of myocardial efficiency and by decrease in the blood volume. Functional disorders of the pituitary, the adrenal medulla (the inner substance of the adrenal gland), the thyroid, and the parathyroids can all lead to circulatory upset and shock.

Refractory and irreversible shock. The terms refractory shock and irreversible shock are widely used in professional literature. Refractory shock exists when in spite of apparently adequate therapy the shock state continues. Commonly the treatment proves later to have been inadequate, in which case the shock was not true refractory shock. This often occurs after a major injury in which there is internal bleeding, leading to underestimation of true blood loss and therefore to inadequate transfusion.

In certain cases, though the therapy actually is appropriate, shock persists; if patients in such cases respond to further special treatment, then this is true physiologic refractory shock. If the patient fails to respond, and death follows, then the diagnosis of irreversible shock is made retrospectively.

The concept of refractory and irreversible shock can be clarified by reference to animal experiment. If a tube is inserted into the femoral artery of a dog and about 20 percent of the dog's blood volume is removed, the animal goes into shock. If the blood is immediately replaced, the animal recovers. If replacement of the blood is delayed, then reinfusion later on may not result in reversal of the shock state, which is thus refractory; infusion of additional intravenous fluid will cause pulse and blood pressure to return to normal. If the dog is allowed to remain in the shock state for too long before reinfusion, no therapeutic measure will result in more than transient recovery and death will be inevitable. This is therefore irreversible shock. Clearly fundamental change must occur in the circulatory components to cause the refractory, or irreversible state, but, in spite of extensive research, it is not yet clear where the defect lies. The possibilities are:

The heart. It is possible that in severe or prolonged shock states the myocardial blood supply is diminished sufficiently to damage the heart's pumping action temporarily or permanently. Alternatively it may be that noxious products of inadequately perfused tissues may circulate and affect the heart muscle.

The peripheral circulation. While the flow of blood through major vessels is under the control of the nerves, circulation through the capillary beds is of a more primitive type and is under the influence of local metabolic products. In this way local tissue requirements control the microcirculation by effecting the capillary sphincters and by shunts between the small artery, or arteriole, and the small vein, or venule. Normally only one third of the capillaries, containing about 5 percent of the blood volume, are open at any given moment. In shock, arteriolar constriction causes inadequate flow through the tissues and local waste products increase. These cause dilation of the capillary sphincters and opening of the whole capillary bed, which thus contains an increased proportion of the blood volume. Further, the post-capillary sphincter (being less sensitive to lack of oxygen) is less widely dilated than the precapillary one so that the capillaries become further engorged with slowly flowing blood, and fluid leaks through the vessel walls into the tissues. Thus the body is further deprived of circulating blood volume.

Disseminated intravascular coagulation. It has been suggested that widespread clotting of the blood occurs during capillary stagnation. This leads to severe damage to the cells unsupplied by flowing blood. Later, when the clot is dissolved under the influence of enzymes that dissolve the fibrin of the clots, the flow through these areas carries toxic metabolic products to vital organs such as the heart, kidney, or liver, and the ensuing damage leads to irreversibility of shock.

Endotoxin. In experiments on dogs, hemorrhage leads to diminution of blood flow to the bowel to such a

Definitions of refractory and irreversible shock

Reaction to foreign material in blood-stream; fainting

Possibility of clotting in capillaries

degree that damage to its lining results. Intestinal bacteria, or their products, may then breach this unhealthy mucous membrane and enter the circulation, perpetuating the shock state. Though other experimental evidence lends support to this theory, there is little evidence that this sequence of events occurs in man, in whom the changes in blood flow to the bowel are much less severe.

Reticuloendothelial system. Spread throughout the body is a system of cells, called reticuloendothelial cells, whose function is to absorb toxins from the bloodstream. It seems possible that these may be incapacitated by the shock state and may thus permit the accumulation of substances that contribute to prolongation of the state. This may be particularly true of the reticuloendothelial cells of the liver, since a period of low blood pressure may deprive them of the ability to absorb noxious substances arriving in the blood from the intestine. These substances are normally filtered out in the liver.

Identification of the causes of shock. It must be emphasized that although the types of shock have been categorized for clarity of description, several causes may actually be present in any given instance. For example, in peritonitis—inflammation of the lining membrane of the abdominal cavity—bacteria enter the bloodstream as a result of the infection, and fluid loss into the peritoneal cavity leads to a low blood volume. In pancreatitis, inflammation of the pancreas, the cause of shock may be threefold: bleeding and escape of fluid into the tissues may lead to diminished blood volume; there may be increased release of the vasodilator bradykinin, leading to increased circulatory capacity; and bacteremia, the presence of bacteria in the bloodstream, may exist. In severe infection with *Streptococcus* organisms, there may be bacteremia, a low blood volume from loss of fluids into the tissues, and toxic damage to the heart muscle.

Hemorrhage may present no recognition difficulties, since losses of blood from the intestine or from wounds and fractures are usually apparent, but the bleeding may not be evident if it occurs in the chest or abdomen after trauma or if the blood fails to drain from deep-seated operative wounds.

When bacteremia occurs there is often an obvious source of infection such as peritonitis, pneumonia, or urinary tract infection, but such loci of infection may be small or deep-seated, so that final proof of cause has to be determined from culture of the blood.

Cardiogenic shock usually occurs only along with typical features of coronary thrombosis—severe central chest pain perhaps radiating to the arm or neck and showing typical changes on an electrocardiogram (ECG). Myocardial infarction, the death of a section of heart muscle, can occur without causing any signs; it may happen while a person is under anesthesia, for example, and it does not always produce typical changes in the ECG at first. Furthermore, low blood pressure from any cause can result in ECG changes, further obscuring the cause of shock.

Lodging of a clot in a pulmonary blood vessel—pulmonary embolus—often occurs without clinical evidence of formation of the clot in a vein of the leg or pelvis but is usually distinguishable by a severe shortness of breath in the absence of pulmonary physical signs. It may be difficult, however, to differentiate pulmonary embolus from pneumonia with bacteremia.

MANAGEMENT AND PROGNOSIS

Treatment is directed at the specific cause, when the cause is known.

Shock due to inadequate blood volume and cardiac output. *Hemorrhage.* When it is possible to anticipate blood loss, and to measure it accurately—e.g., during an operation—losses may be immediately replaced before significant volume depletion can occur.

More often, however, hemorrhage is unexpected; it may not be possible to measure the amount of blood lost. If shock occurs in an otherwise healthy person weighing 70 kilograms, or about 154 pounds, then at least one litre of blood (or slightly over one quart) has been lost and generally is replaced by transfusion into a vein. But since a preliminary matching between recipient serum and donor

cells must be carried out, and cannot be done in less than twenty minutes, other fluid is usually given intravenously during the delay. The fluid chosen, such as plasma or a solution of the carbohydrate dextran, must contain molecules large enough to keep the solutions within the blood vessels.

The doctor judges the adequacy of the volume given from the rising blood pressure and falling pulse rate with increasing pulse volume. Monitoring central venous pressure (CVP) helps in accurate volume replacement.

Burns. Since the main loss from burns is plasma and electrolytes, these require replacement in proportion to the area of the burn and the size of the patient and are calculated from a suitable formula.

Dehydration. Pure water loss rarely occurs. Thus, low blood volume is treated by intravenous infusion of a balanced salt or electrolyte solution, though an initial circulatory boost with a large-molecule solution may be required.

Dissection of the aorta. Major arterial dissections are treated where possible by removal of the section of diseased artery. When this is not possible an opening is made in the loosened intima at the far end of the dissection, to allow blood to return to the main channel.

Cardiac tamponade. Usual emergency treatment is by removal of the fluid that is compressing the heart. If there is a wound in the heart muscle, allowing leakage of blood from the heart into the pericardium, the opening must be closed.

Shock due to increased circulatory capacity. *Bacteremic shock.* Bacteremic shock, exceeded in frequency only by cardiogenic and hemorrhagic shock, is most often caused by gram-negative organisms. There are three aspects of treatment: collections of pus are drained as soon as possible; the circulatory volume is increased to compensate for enlargement of the vascular bed; and appropriate antibiotics are administered.

Anaphylactic shock. The essence of treatment of anaphylactic shock is the injection of epinephrine (adrenaline), whose effects include an increase in the heart rate and constriction of the blood vessels, followed by an antihistamine, to counteract the reaction to the foreign substance, and a bronchodilator, to ease breathing.

Psychogenic shock. Persons suffering from psychogenic shock are placed flat or with head slightly lower than the rest of the body, to restore a good flow of blood to the brain and bring about recovery from the fainting.

Shock from drug use. Dangerously low blood pressure may be raised by decreasing the dose of the drug (such as an anesthetic agent), by speeding its elimination from the body, or by the administration of a substance that constricts the blood vessels.

Neurogenic shock. Neurogenic shock does not usually require specific therapy; indeed, spinal anesthetics may be given with a view to producing a low blood pressure so as to diminish bleeding during an operation. If blood pressure becomes critically low, the legs are sometimes elevated and a vasoconstrictor administered.

Undiagnosable and refractory shock. A major problem in the treatment of shock occurs when the doctor cannot be sure of its cause, either because of a lack of diagnostic criteria or because failure to respond to specific therapy has placed the diagnosis in doubt. In particular, the doctor must differentiate between shock that results from inadequate cardiac output and shock due to absolute or relative blood volume deficiency. The latter type improves when measures are taken to increase blood volume, while in the former type such treatment overloads the failing heart, giving rise to edema of the lungs, which can cause death.

In cases in which there is doubt about the volume of intravenous replacement or the rate at which it should be given, a long, fine tube may be threaded through a peripheral vein until its tip lies in the superior vena cava, the last venous channel before the heart. Although the pressure in this vein—central venous pressure (CVP)—does not give an accurate measure of the blood volume, it does give an indication of the ability of the heart to deal with returning venous blood. Thus, broadly speaking, if intra-

Measures taken when cause is undetermined

Monitoring effective-ness of treatment

venous fluids are given, with clinical improvement and no gross change in the CVP, a volume deficiency is deemed to be present and treatment is by further volume replacement. If rapid rise in CVP follows intravenous fluid administration, then a cardiac deficiency is present and no further intravenous volume therapy is given.

Other measures that may be taken in addition to a trial of volume therapy include administration of wide-spectrum antibiotics (antibiotics effective against a wide range of bacteria), oxygen, and, if there is evidence of failing heart, digitalis. Any tendency toward a decline in blood alkalinity is corrected.

If the shock remains undiagnosed and refractory, the effectiveness of further treatment can sometimes be checked by such direct measurements as of the blood volume, the cardiac output, and the blood pressure in the pulmonary artery. If such measurements are not possible, the doctor may have some indication of progress by observation of the physical signs and response to therapy listed in the accompanying Table.

Clinical Indicators of Circulatory Dynamics	
indicator	significance
Pulse volume	Cardiac output
Skin temperature	Arteriolar constriction
Urine output	Visceral perfusion
CVP upper normal range	Adequate circulatory volume

In the past, drugs such as norepinephrine have been used to constrict the arterioles in an attempt to elevate blood pressure. Because arteriolar spasm resulting from such measures prevents adequate flow to the capillaries and results in tissue damage, modern therapy utilizes agents that diminish constriction of the arterioles and thus improve blood flow and tissue perfusion. This type of therapy increases the overall circulatory capacity and consequently may need to be accompanied by further volume replacement therapy, the actual amount being controlled by reference to the CVP.

Prognosis. During the course of treatment, some indication of outlook may be had from measurement of the lactic acid in the blood. The higher its level, the greater is the chance of irreversibility.

The outlook may also depend on the cause of shock and the speed and vigour with which it is treated. At one end of the scale the mortality of immediately treated shock following hemorrhage is small, while at the other, severe cardiogenic shock carries a mortality rate of about 80 percent. In septic shock the mortality is about 50 percent.

SALIENT FEATURES OF PHYSIOLOGIC SHOCK

Shock is a failure of blood flow through the tissues and is most commonly seen after hemorrhage, myocardial infarction, sepsis, or pulmonary embolus. Clinically it is characterized by fast, thready pulse, low blood pressure, and cold sweaty skin, though many variants are found. Treatment usually involves elimination of blood volume deficiency and sepsis and improvement of myocardial action. When therapy initially fails, additional treatment with arteriolar dilators sometimes improves perfusion of the tissue with blood. Blood flow is seen to be more important than blood pressure.

Shooting

Shooting, as the subject of this article, is the sport--or art--of firing at targets of various kinds with rifles, shotguns, or handguns (pistols and revolvers) as an exercise in which accurate marksmanship is the goal.

Rifles may be divided into four subclasses: modern cartridge rifles (big bores and small bores), muzzle-loading rifles, benchrest rifles, and air rifles. (Benchrest rifles are heavy target guns that in competition are cradled, usually on a sandbag rest on a solid platform called a benchrest.)

Shotguns for competition shooting consist of two basic classes: guns for trap shooting, frequently with one barrel only; and shotguns of several gauges for skeet shooting, a fairly modern clay bird sport developed about 1924. (For the use of modern shotguns and rifles in taking big and small game, flying wildfowl, and upland birds, see HUNTING, SPORT.)

Handguns used in competitive target shooting include local police and armed forces service weapons and, more frequently, small-calibre pistols of various types; rifled air pistols now are also used. Air rifles and rifled air pistols are new in formal competition, having been introduced in 1966 at the world championship matches held in Wiesbaden, West Germany.

This article covers the history of target shooting, its development as an organized sport, and the principal competitive events that have evolved for the various firearms. For the history and development of firearms and for technical information, see GUNS, SPORTING AND TARGET. See also SMALL ARMS, MILITARY.

HISTORY

Shooting at a mark as a test of skill had its beginnings long before the advent of firearms (c. AD 1300). It seems reasonable to assume that the first archers, some 50,000 years ago, may have loosed their arrows at a practice target, perhaps a large stone, to prove the accuracy of their equipment and their ability. Certainly target archery with the longbow and the crossbow was a widespread sport in much of Europe, Asia, and the Far East as early as the 15th century. Because the origin of firearms is still uncertain, it is not known whether sport shooting existed coevally with the use of guns in warfare, but game shooting with firearms is recorded as early as the 16th century, by which time matchlock guns had been in use almost 100 years. The matchlock, fired by a match, or wick, controlled by a trigger, at last allowed the shooter to take and sustain aim at birds on the wing. Soon thereafter, toward the end of the 16th century, the rifled wheel lock, fired by a spark, appeared, and formal target shooting, particularly in the German areas of central Europe, became popular. Rifling--the spiral or helical grooves cut into a smoothbored barrel to impart spin to the bullet and thus improve its accuracy--existed at least by 1480 if not earlier, though instances of it were vastly outnumbered by barrels of smooth, uncut interiors, suitable for firing both solid ball and small shot.

Target shooting with rifles. The history of target shooting with guns is largely the history of shooting at targets with rifles. Elaborately decorated Germanic wheel locks, profusely engraved and inlaid with gold and silver, appeared in the late 16th century. These had rifled bores and, sometimes, quite sophisticated peep or aperture rear sights that were fully adjustable. Since such guns were probably too valuable to have been hunting arms, it has been assumed they were intended for target shooting.

Early evidences. It is generally held that rifled shoulder arms of finest quality were made throughout Europe,

Origins in archery

especially in Germany, by 1525. The Turin armoury is known to have owned at least one rifled iron gun in 1476. A shooting match was held in Eichstätt in 1477 in which participants, probably matchlock shooters, competed at a range of 200 metres (220 yards). This is the earliest known recorded instance of shooting at a mark.

Shooting in Switzerland. Target rifle shooting certainly took place early in Switzerland. A painting from 1506 depicts target shooting with the crossbow; another shows a rifle shooting setup that is quite modern. Three enclosed and covered shooting booths are pictured, the contestants firing at targets in the background. Each target frame is flanked by a small hut, inside which a target marker is concealed during the actual shooting; after the shot the marker indicates to the marksman and the judges the value of the hit via a staff or pole. The judges and scorekeepers are seen in the right foreground, seated at a table under a roof. Several wind flags are shown flying, and spectators are seen watching the shooting. This shooting took place at Ziirich in 1504.

If shooting facilities and range appointments of such advanced degree were extant in 1504, then it can easily be argued that target shooting with firearms had existed in Switzerland in the 15th century, most likely as early as 1450–75. Shooting at a mark with the crossbow had been a popular sport in that country for at least 100 years earlier, so the sporting use of the rifle followed naturally.

Popularity in Europe and Great Britain. By the 16th century target shooting with rifled arms was a popular pastime in much of Europe, especially in the Germanic countries. In 1517 the cardinal Luigi d'Aragona wrote: . . . every place and every village (in Germany) has its shooting park, where anyone interested in crossbow or rifle shooting—or in any other weapon—may go to practise.

Many museums in Germany possess wooden targets dating from as far back as 1540. These were special targets, made to honour such occasions as marriages, and were painted in a large range of subject matter—portraits, scenics, and so on. Such targets were shot at by the assembled guests sometime during the ceremonies and then given to the host as a memento.

From that time on, target rifle shooting grew rapidly until, by the end of the 18th century, the sport was enjoyed over most, if not all, of Europe. In Spain the use of the rifle—and its problems—was thoroughly understood as early as 1644, when Alonso Martinez de Espinar wrote at length in his *Arte de Ballesteria y Monteria* (Madrid; 1644) on the details and peculiar aspects of rifling, including the rates of twist and number of spiral grooves. In Great Britain target rifle shooting was a popular and refined sport before 1800. In 1776 an English patent was granted to Patrick Ferguson (1744–80) on a breech-loading, flintlock, single-shot rifle, an arm that was to see some service in the American Revolution. Ferguson was a dedicated rifleman; in the 1750s, having been posted to the Caribbean as a young subaltern, his personal luggage on arrival included some dozen rifles.

The first book in English on target rifle shooting was published in London in 1808: *Scloppetaria: Or considerations on the Nature and Use of Rifled Barrell Guns . . . by a Corporal of Riflemen* (pseudonym of Capt. Henry Beaufoy). The contents are advanced and knowledgeable, while the illustrations show intricate and useful gun sights and other accoutrements of the serious rifleman. Some of the aperture sight designs are quite modern.

Sport rifle shooting in Russia. While hunting for sport had existed in Russia from the 16th century, shooting at a mark did not, apparently, make a start until the early 18th century.

A.A. Yuriev, in *Sporting Rifle Shooting* (Moscow; 1957), says that the first recorded instance of target shooting was in 1737, when the empress Anna ordered the establishment of a target-shooting range at the imperial court. The marks shot at were, in fact, live birds, not paper targets, but the object of these competitions was not the obtaining of game for the table. The marksmen were given valuable awards—gold- and diamond-studded cups—and the royal shooting contests soon became a tradition.

In 1806 the Society of Shooting Amateurs was formed in St. Petersburg (modern Leningrad), largely by army and guard officers. Their chief interest was in handgun shooting, which, at that time, would have been with flintlock pistols.

In that same city the first public shooting range, or club; was founded in 1834. Shooting could be done with rifles, smoothbores, or handguns on payment of a nominal fee. Many more such public shooting grounds had appeared in various Russian cities by the 1850s.

In the 1890s several other shooting societies were established: among these were the Russian Athletic Society, with a shooting range on club property; the St. Petersburg Club of Sports Amateurs; the St. Petersburg Society of Salon Shooting; and the Riga Shooting Society.

In 1897 the Imperial Society of Reglemented Hunting published rules for rifle-shooting competitions, particularly for military-style rifles. The next year in the society's first formal tournament, in Khabarovsk, some 130 competitors, using the Berdan Mark II rifles of 1870, shot at 466 feet (142 metres). The bull's-eye of the target was 28 inches (70 centimetres). A second contest the same year brought out over 200 participants.

In 1899 the Southern Russian Shooting Society, just formed, offered for the first time gold and silver award badges, in two categories, to successful sharpshooters.

The first All-Russian Championship-drawing shooting competition, from all over Russia, was held at Kiev in 1913. A like event took place at Riga in 1914.

After World War I—and in part, perhaps, because of its stimulus, as was the case in the U.S. and elsewhere in the West—organized target shooting grew rapidly, especially small-bore-rifle shooting. Following World War II the interest in sport shooting expanded greatly, more so than anywhere else, probably, except for the U.S.

The continuing successes of Soviet marksmen in the Olympic Games and World Championship events need little elaboration.

The American frontier. Rifle shooting in the North American colonies was a way of life on the frontier and in the farming settlements west of the Atlantic seaboard. The flintlock Kentucky rifle, so-called, appeared about 1750. Most were made then, and for many years thereafter, in the Lancaster area of Pennsylvania. Most of the gunmakers were of German extraction, and the rifle they had evolved differed greatly from its central European ancestor. Since shots at relatively long range were common, the new rifle was long in the barrel, up to 48 inches (122 centimetres) and longer, its diameter, or calibre, averaging about one-half inch (1.3 centimetres), compared to its forebear, the jäger (hunter) rifle, of Europe. These were often heavy and bulky looking, of calibres as large as .80 inch (20 millimetres), their barrels some 30 inches (76 centimetres) long.

Because the Kentucky rifle barrels were long, a larger charge of powder could be used, thereby imparting to the smaller round lead ball a much increased velocity, which in turn meant a flatter shooting trajectory and greater accuracy, resulting in effective use to 200 yards (180 metres) and more—then considered quite a long range.

Target shooting became common on the frontier and grew in popularity throughout the entire 19th century. Virtually every village and settlement was the scene for a shooting match on weekends and holidays. Some of the larger events attracted an entry list of a hundred or more marksmen. White paper was scarce along the frontier, and a common target was a piece of board blackened in the smoke of a fire or charred. On this a cross was slashed with a knife, and the ball that hit closest to the intersection—or upon it—was the winner. Shooting at a wooden figure of a bird atop a tall pole, after the fashion of crossbowmen in the Middle Ages, was also popular. Live turkey shooting—the bird tethered behind a box or rock, and only his head and neck visible—was a standard event.

By 1830 shooting clubs began to form, particularly in the more heavily populated East but also in many towns and cities in the Midwest. Target shooting from a bench or rest was an old activity before 1840. Between 1840 and 1848 the accuracy level of rifles improved as the result of

Early
targets

The
Kentucky
rifle

two developments: the introduction of a magnifying telescopic sight, probably in the middle 1830s, and the invention in 1840 of a device called the false muzzle or patent muzzle, which was removable from the barrel after loading and permitted an elongated bullet to be seated into the barrel without deformation or distortion. The new bullet was ballistically superior to the round lead ball hitherto in general use, especially for the 40- and 80-rod (220- and 440-yard; 200- and 400-metre) shooting early bench marksmen preferred. The telescope sight, attached to the rifle and carrying crosshairs at its optical centre, was a far better means of sighting and holding the centre of the bull's-eye.

Sometime in the 1850s a benchrest shooting club was formed in Vermont. Called the National Rifle Club—though its annual matches were more regional than nationwide in scope—its members established a high reputation for their skill and their scores in shooting relatively heavy-barrelled muzzle-loading rifles from what were, essentially, shooting platforms or machine rests. In 1871 the National Rifle Association was founded (an organization with well over a million members in the early 1970s.) A weekly paper called *The Rifle* was inaugurated a few years later. Other journals devoted to both target events and hunting came into being.

Long-range shooting. Research on various rifles and projectiles, conducted by the English military from about 1800, focussed interest on long-range shooting at targets of over 600 yards (550 metres). Early in the 1850s volunteer rifle brigades devoted to this kind of shooting were formed. Many of their members were among the finest shots in the United Kingdom, and so popular was the activity and so intense had been the earlier studies of rifles and bullets that, in July 1860, on the occasion of the first prize meeting of the new British National Rifle Association, Queen Victoria had been persuaded to fire the opening shot. Shooting continued with increasing interest at Wimbledon Common (outside London) and at numerous other ranges. A 2,100-yard (1,900-metre) range existed in Scotland.

During the period 1853–77, improvements in firearms included the reduction of bore diameter (from the previously common calibre .58 to .45; i.e., from $\frac{58}{100}$ inch to $\frac{45}{100}$) and a sharp alteration in the rate of twist of the rifling, from a standard twist (in the issue Enfields) of one turn in four feet (1.2 metres) to one turn in 20 inches (51 centimetres). At the same time an elongated bullet was introduced, at first of hexagonal cross section for use in a hexagonal barrel. The longer bullet proved ballistically superior to the bullet of the same weight but reduced length then in common use, requiring much less elevation of the sights at the longer ranges, and at the same time giving far greater accuracy on the 600- to 1,000-yard (550- to 900-metre) targets commonly used by the long-range shooters. W.E. Metford, a civil engineer with a lifelong interest in all that pertained to rifles, demonstrated, in long-range matches, that his design of bullet, a quite smooth cylinder, and his matching rifled bore were superior to the hexagonal bullet. In 1865 he produced his first "small bore" rifle, one of .45 calibre and with a depth of groove only .004 inch (.1 millimetre) deep. That rifling pattern is virtually identical to the rifling used today throughout the world.

During the 1870s and 1880s there was a gradual change-over from the caplock muzzle-loading rifle to the breech-loader. Breechloaders had existed, in fact, from the earliest days of firearms, but none had been fully successful until the advent of the metallic cartridge case, which formed a perfect barrier to leaking burning gases, which had been an early problem with breech-loading rifles.

Nevertheless, the early breechloaders were not yet as accurate as the highly developed muzzle-loaders. In 1873 an Irish rifle team, competing at Wimbledon against the best teams from England and Scotland, won the matches by a substantial margin and then challenged U.S. marksmen to an 800-, 900- and 1,000-yard (700-, 800-, and 900-metre) match to be held at Long Island in September 1874. The U.S. team, however, though it had not shot at distances over 600 yards (550 metres), won the match

by three points, shooting breech-loading rifles against the Irish muzzle-loading caplocks.

Interest in long-range shooting grew greatly in the last third of the 19th century and continued until quite recently. All of the English-speaking countries participated in this essentially military-inspired form of target shooting. International competitions were held frequently, with teams from as far away as Australia and New Zealand making the journeys to England as late as the 1930s.

Schuetzen shooting. Of Germanic-Swiss ancestry, Schuetzen shooting was practiced throughout much of central Europe for centuries and in a practically unchanged manner. Although this form of target shooting had many adherents as early as the 1850s, it was not until the 1880s that Schuetzen shooting became a national sport. Schuetzen shooting was performed in the standing, or offhand, position. Targets were 100 or 200 yards (90 or 180 metres) from the firing points when the matches were held outdoors. In the winter months indoor galleries were used and the ranges were usually 25 yards (23 metres). While the use of any rifle type was generally permitted, the rifle of choice among serious marksmen was a single shot of fairly heavy weight (as much as 17 to 18 pounds [7,700 to 8,200 grams] or more). These carried highly refined sights, capable of minute adjustments, or a telescope. The butt plate was made with long prongs or extensions that went under and over the upper arm and palm rests, a device attached to the underside of the rifle, usually to the fore-end, and held in the shooter's left hand as a means of supporting and directing the muzzle-heavy barrel. Triggers were carefully tuned and adjusted. Superb shooting was done with the Schuetzen rifle in this period. The sport began to decline in Europe and the United States in the 1920s.

The .22 rifle and growth of the sport. Following the end of World War I, interest in target rifle shooting grew rapidly throughout the world. Shooting clubs and associations soon numbered in the thousands. There had been, of course, many such establishments prior to World War I, some of them dating to the mid-19th century, but by the 1930s numerous small villages and hamlets offered public or private facilities where rifles and other firearms could be shot.

Many of these new facilities came into being because of the rapid growth of small-bore—.22-calibre rimfire—shooting. The .22-calibre rimfire cartridge (a cartridge with a firing charge in the rim set off by a blow from the hammer) appeared in the 1870s, but serious match shooting with small-bore rifles had its major beginnings in England only after the Boer War. In that conflict, British military authorities learned that British military marksmanship was poor, especially in comparison with that of the Boers, many of whom were bush dwellers and countrymen long familiar with the hunting rifle. In the resulting push to upgrade military trainees' shooting abilities, it was soon found that the .22 rifle offered many advantages over the much larger and heavier service rifle: rifles, ammunition, ranges (200 yards instead of 1,000 yards), backstops, and other equipment were all less expensive. The shooter's initial equipment costs were thus much lower, and the major component—his rifle—lasted satisfactorily for many thousands of rounds of ammunition, unlike the big-bore rifle, which frequently lost its required accuracy after a thousand or so bullets had gone through its barrel. Interest in target shooting with the small-bore .22-calibre rifle quickly spread to civilian shooters and attracted and held many new marksmen.

Target shooting with handguns. The history of handguns roughly parallels that of long guns, but, perhaps because they are so much more difficult to aim and shoot accurately, they have never been as widely used in warfare or for sport in hunting or target shooting. In the days when men might be challenged to a duel with pistols, they perforce, if prudent, had to practice shooting for accuracy; and a large and romantic role has been ascribed to the six-shooter revolver in the taming of the American frontier in the West. But, aside from widespread use by the police forces in many nations, handguns usually have

Improve-
ments in
bores and
bullets

Breech-
loaders

The
six-shooter

been used as secondary hunting weapons—many sportsmen carry a .22 pistol for use in case of an emergency, and big-game hunters often carry a heavy gun, such as a .44 magnum, as a backup weapon—and for self-defense.

Pistol shooters, nevertheless, are among the most avid devotees of the sport of marksmanship. Evidence of the considerable interest in target shooting with handguns is the fact that pistol shooting was added to the official program of the National Rifle Association national championships in 1900, and three events in target pistol shooting were included in the first of the modern series of Olympic Games held in 1896.

Target shooting with shotguns. The original purpose of shooting at targets with shotguns was to improve the skills required for shooting game, usually upland game birds or ducks or other waterfowl, by simulating the various conditions that occur in actual field shooting. This required moving targets, and for many years live birds, usually pigeons, were used for this purpose. The pigeons were released from simple box traps and, the direction of the birds' flight being unpredictable, served as a challenge to the shooters' skill. In England about the end of the 18th century, pigeon shooting developed into a sport with rules and regulations governing the number of traps, their placement and distances from the shooter, the weight of shot allowed, and so on. In the 19th century pigeon shooting became popular in England and in Europe, and international competitions and sweepstakes were held annually at Monaco and elsewhere.

As pigeon shooting increased in popularity the supply of live birds was soon critical, and a substitute was found in glass balls that were flung out in various directions by spring-loaded devices. Late in the 19th century various types of saucer-shaped clay targets were tried, from which evolved the modern disk-type clay targets called "birds" or "clay pigeons," which are thrown or scaled through the air from mechanical devices called traps (after the box traps from which live pigeons are released).

Trapshooting. The sport was introduced into the United States about 1830 by Cincinnati, Ohio, sportsmen. The evolution of targets followed the same sequence of live birds, glass balls, and clay disks that had occurred in England. The first successful clay target and modern trap in the United States was developed in Cincinnati in 1880. Trapshooting for some years was also known, especially in England, as inanimate bird shooting, the Inanimate Bird Shooting Association being founded there in 1893.

Trapshooting is a long-range, clay-target sport. A single sunken trap house, from which the targets are propelled into the air at varying angles, is 16 yards (15 metres) in front of the shooter's station. The target is usually rising at the time of shooting and, on the average, when hit is about 35 yards (32 metres) from the marksman.

Skeet shooting. In skeet shooting the same targets and traps used in trapshooting are employed, but the pattern of shooting is different. Skeet shooting is a short-range, clay-target sport requiring two trap houses and eight shooting stations. It originated in the United States as a method of informal shooting practice for upland hunters who wanted a greater variety of shooting angles than was possible in trapshooting.

Between 1915 and 1920 definite rules governing the sport were instituted. At that time the shooting area was a complete circle of 25-yard (23-metre) radius, with the stations marked off like the face of a clock. A ground-level trap, located at the 12 o'clock position, threw the targets toward the 6 o'clock point. In 1923 the radius of the circle was reduced to 20 yards (18 metres), and, at about the same time, a second trap was placed at 6 o'clock that threw targets over 12 o'clock, and the 12 o'clock trap was elevated about ten feet (3 metres) above the ground. By shooting from stations in only half the circle and using both traps to throw targets, all of the shooting angles remained, and the range could be set up in a smaller area with no danger to spectators, who formerly had been required to move with the marksmen.

The term skeet, derived from an old Norse word for "shoot," was adopted in the U.S. after a 1925 nationwide contest to name the new sport.

Other events. Other less formal target shotgun events have been devised, usually to simulate the shooting of a particular kind of game. One of these is the so-called grouse walk or quail walk, in which the shooter walks along a woodland path and shoots at clay-bird targets that are released, either singly or in pairs, from traps hidden in the bushes alongside the path. Other events simulate the shooting of "springing teal," "running rabbits," or other small game. Shotguns are also used with paper targets in simulation of old-time live turkey shoots; in one form a small central mark on the target must be struck by a pellet, or, in case it is not hit, the pellet hole nearest the mark is the winner.

Regulation. The governing body for trapshooting in the United States is the Amateur Trapshooting Association, which came into being at the end of the 19th century as the Interstate Association of Trapshooters and conducted tournaments for both live-bird and clay-target shooting. In 1900 the name of the organization was changed to the American Trapshooting Association. It existed as an organization controlled by firearms manufacturers until 1923, when it was decided to make the sport completely independent and the name was changed to its present form, in part because of the increasing numbers of Canadian members.

The National Skeet Shooting Association was organized in 1925, and the first national championships, which are held at a different place each year, were in 1927.

In Great Britain the governing body is the Clay Pigeon Shooting Association of London. With the introduction of the standard clay targets at the close of the 19th century, the name of the Inanimate Bird Shooting Association was changed to the Clay Bird Shooting Association in 1903, and the association became known by its present name in 1928. The association annually awards the Coronation Cup to the best all-round performer in skeet.

Clay-pigeon shooting, the common term for all inanimate-target shotgun shooting in Europe, is popular in most continental nations, particularly the U.S.S.R., Romania, Italy, Belgium, France, Greece, Finland, and Sweden. Live-pigeon shooting is still popular in Italy, France, and Spain.

International organization and competition. Hundreds of local clubs and dozens of state and regional associations and national federations are devoted to one or more aspects of sport shooting. More than 100 federations from 90 countries belong to the International Shooting Union (ISU), with headquarters at Wiesbaden, West Germany. The ISU was founded in 1907 and reorganized after World War I, in 1919. It conducts the world championships and regulates shooting competition in the Olympic Games.

World championship competitions are with the small-bore rifle, free rifle, centre-fire pistol, free pistol, rapid-fire pistol (.22-calibre), air rifle, air pistol, and shotgun. Army rifle matches are fired with a military weapon designated by the International Shooting Union. The running-deer and running-boar matches are fired with relatively light rifles, calibre .22 rimfire or .222 centre-fire, and telescope sights are permitted.

The small-bore rifle competition consists of firing from three positions (standing, prone, kneeling) at a range of 50 metres. Three-position matches are held at 300 metres in the free-rifle (unrestricted as to rifle design and accessories) and army-rifle competitions.

Free-pistol matches are conducted at 50 metres, while centre-fire and rapid-fire competition is at 25 metres.

Running-deer and running-boar competition is conducted at 100 metres, with the shooters firing at rapidly moving silhouette targets. Clay-pigeon (trapshooting) and skeet matches are also conducted.

Except as noted, only metallic sights are permitted in ISU competitions.

Shooting has been a recognized Olympic sport since the first modern Olympic Games in 1896. In addition to the more regular events of shooting competition, however, Olympic shooters have also taken part in such events as live-pigeon shooting and competition with duelling pistols. One of the five events in the modern, or military,

pentathlon, included in the Olympic Games since 1912, is shooting a pistol or revolver at a 25-metre standing silhouette target. In the winter Olympic Games the biathlon is a combination of cross-country skiing and rifle shooting.

Growth of interest and participation. Interest in competition shooting under International Shooting Union rules and auspices—and participation therein—has grown tremendously over the past 20 years or so. The first post-World War II World Shooting Championship matches were held at Stockholm in 1947. Sixteen different events were staged, with marksmen from 11 countries entered in the various contests. At that time this was considered an excellent turnout and the shoot a highly successful affair.

In the intervening years these world matches (now held every four years) became successively more popular, both in number of events scheduled and in entries, until in 1966 the World Shooting Championships took place at Wiesbaden, in West Germany. This 39th running of the matches saw 52 nations participating in 37 shooting contests for rifle, shotgun, handgun, and air-arm awards. Competitors numbered 1,390, a new record.

In October of 1970 the 40th World Shooting Championship matches were held at Phoenix, Arizona, the various events spanning 13 days. This was the first time these matches had been held in the United States since 1923. The latter contest was something of a fiasco—only two countries took part, the U.S. and Canada, shooting for seven events.

The number of competitors at Phoenix fell to 704, about half the number appearing at Wiesbaden, but an even 50 nations were represented. The United States is a long way from Europe, where the majority of those who enter the ISU matches live and where most of the World Shooting Championships have been held.

Twenty of the 50 countries won at least one gold (first place), silver (second), or bronze (third) medal at Phoenix; but, as has been the case in recent years, the U.S.S.R. and the United States garnered most of the awards. Several world records were toppled at Phoenix, both in individual and team events, and with rifled firearms and smoothbore guns—in the running-boar matches by a Swedish shooter; in the air rifle by a German; in the rapid-fire pistol, individual, by an Italian; in rapid-fire pistol, team, by the Czech team; and in the ladies' air pistol, team (see below).

Women competitors and events. Women may compete as members of men's teams (team scores are derived from the individual's shooting performance), but there were at Phoenix six separate events scheduled for women, including rifle, handgun, and shotgun matches. The most outstanding shooting at Phoenix, and the most surprising, was the winning of a gold medal by Capt. Margaret Murdock (U.S. Army) in the free-rifle matches, a three-position event (40 shots each, while standing, kneeling, and prone) at 300 metres (330 yards). The rifles used in this event are without restrictions except as to weight (not to exceed eight kilograms [18 pounds]) and calibre (not over eight millimetres), and only metallic sights may be used, without optics of any kind. The free rifle, therefore, may be quite a heavy arm, and it usually weighs 13–15 pounds (six-eight kilograms).

Captain Murdock, the only woman among 46 contestants in the match, won her gold medal in the standing position, the first and only woman ever to do so. The standing position is the most difficult of the three, yet Mrs. Murdock's score was only one point under the previous world record. Captain Murdock also won the Ladies Standard Rifle Match, making her the only double gold medalist among the American contingent.

The Soviet women's team took their first gold medal at Phoenix in winning the ladies' air pistol matches (four stages) and established a new world record at the same time.

International-U.S. differences. Participation by American shooters in the World Shooting Championship matches and in the similar Olympic matches has increased more than has ISU-controlled shooting worldwide.

This has come about in spite of two serious problems. One problem has been that, while the considerable costs of hosting a World Shooting Championship program have been underwritten in whole or great part by the host nation virtually without exception in all other countries, in the United States the costs have been met by private and local groups and voluntary contributions, without the aid of government funds.

The second reason why more American shooters, until recent years, have not participated in ISU and Olympic matches lies in the distinctly different modes of shooting in the United States, compared with competition marksmanship under ISU regulations. American shooters, of all classes and types, have long used targets and ranges based on the English systems of measurement—ranges set out in feet and yards, targets designed with, for example, a two-inch ten-ring at 100 yards, and so on. Much of the world's shooting, however, is done under the metric system, and certainly all ISU competitions are so conducted. American shooters generally, and for a variety of reasons, have been reluctant to adopt the metric system for U.S.-held events; this has also meant a lack of facilities available for metric-system practice. In addition to the cost involved in converting scores of targets and thousands of shooting ranges to the metric system, there are the ISU matches themselves, many of them markedly different from U.S.-style events, many others having no full counterpart in American match programs. Another hurdle facing American marksmen—and perhaps the hardest one—has been and is the increasingly more difficult task of scoring well on ISU targets. For example, in the ISU free-pistol match, fired at 50 metres (55 yards) offhand with a .22 rimfire (5.6-millimetre) single-shot handgun (the free pistol is one almost without restrictions as to weight, barrel length, stocks, and trigger pull; the only requirements are that it shall not have optical sights and that the grip or stock may not offer support to the shooter's arm), the target has a ten-ring measuring 1.97 inches (five centimetres); the 50-yard (45-metre) U.S. targets' ten-rings are 3.39 inches (8.61 centimetres) across, and they are five yards closer to the shooter. American marksmen have been shooting "possibles" for many years, which is to say the full score, or 100 out of a possible 100. They are loath to give their own targets up, for in ISU matches the possible are noted for their rarity.

The American clay-bird shooter, long used to breaking 100 and 200 birds without a miss—with much longer "straights" not unusual—in the stiffest competition, finds such ISU events much more difficult. (For further details on this kind of shooting, see below *Shotgun-shooting events*.)

The foregoing account of the differences between ISU and American shooting is, necessarily, simplified. For a detailed analysis and a full explanation of the various ISU matches, plus a comparison of shooting under U.S. rules, see the latest issue of the NRA *Illustrated International Shooting Handbook*, published by the National Rifle Association.

THE SPORT OF SHOOTING

Rifle-shooting events. Marksmanship with rifled arms is commonly practiced with paper targets (fixed or movable) at various distances, from ten metres (11 yards) for air pistols and rifles to 1,000 yards (900 metres) and more with centre-fire rifles. Handgun ranges may be anything from a few yards (combat shooting, quick-draw techniques) to 50 metres (international competition).

Formal match shooting with rifles may call for one or more of several positions to be assumed by the shooter. In the least steady, the standing or offhand stance, the rifleman cradles the butt of the stock into his shoulder, grasping the grip or small of the stock (wrist) with his right hand (if he is right-handed), his forefinger tip pad (usually) touching the trigger. His left hand grasps the fore-end of the rifle, directing his aim at the target. In the case of heavily-recoiling centre-fire rifles, the right hand is also used to press the butt firmly against the hollow of the shoulder in order to better absorb the rifle's thrust on

Reluctance to adopt metric system

Standing, kneeling, sitting, and prone positions

firing. The left elbow is classically held directly under the rifle, for optimum support and steadiness. The offhand rifleman usually stands at or near **90°** to the target, the rifle positioned across his chest, but this classic stance is not mandatory. The shooter's aiming eye is held close to the peep sight (or aperture, a movable disk in the rear sight having a hole in its centre), sighting through this—not at it—to a front sight usually surrounded by a hood to exclude light; this may be a square post or another but larger aperture that encircles the target bull's-eye.

The kneeling position, somewhat steadier than standing, finds the rifleman with his right knee on the ground (or shooting mat). He may sit on his right foot, side or heel, if he wishes to and the rules permit. His left foot is flat on the ground, his left knee supporting his left forearm or, less steadily, his left elbow. His knee and left arm are directly under the rifle for support. The other aspects of hold and aiming are the same as for standing and sitting.

In the sitting position the shooter faces some **45°** to the right of the target, his knees raised and spread, his heels dug into the ground (if permitted by the rules and if feasible). The outside of his upper arms lies against the inside of his knees, his hands supporting and aiming the rifle as described earlier.

The orthodox prone position has the rifleman face down, his body angled about **45°** to the target. His elbows, forming two legs of a tripod, in effect, support the rifle. His left elbow is placed under the rifle for support. His legs are spread apart, flat to the ground. The rifle is aimed and held as before, except that the buttplate impinges to a degree on the shooter's collarbone.

Much freedom of choice is exercised by the shooter in assuming the prone (and other) positions. Often he lies at other than the conventional **45°**, and his legs may be in almost any position—crossed, one knee partially raised, and so on. Individual comfort and a position he has found best for his shooting are the criteria.

In all rifle-shooting positions a sling (usually a strap of leather) is frequently used to further steady the position. The forward sling end is attached to the rifle somewhere toward the front, the rear portion going around the shooter's upper arm or attaching to a leather cuff encircling the left arm above the biceps muscles.

Maintaining sight alignment and trigger control are vitally important in rifle (and handgun) target shooting. While the amount of applied weight against the trigger (pull) to effect its release varies with the style and class of the arm being used, successful shooters train themselves to complete the trigger **letoff** with minimum disturbance of the sight picture. The fleshy pad of the forefinger first joint is usually placed on the trigger, the pressure gradually increased as sight alignment is observed, the shooter holding a part breath during the process.

Under current ISU rules, air rifle shooting is done only in the regular standing position, with the target ten metres away. The only calibre allowed is **4.5** millimetres (**.177** inch); the pellet is of soft lead. Spring-air guns or carbon-dioxide-powered guns may be used. Very light triggers are in common use, so maximum trigger control is a prime requirement. Shooting techniques and the like are the same as with the cartridge rifle.

Handgun-shooting events. Target shooting with handguns has been marked by a gradual decline in popularity of revolvers in favour of autoloading pistols, both **rim-fire** and centre-fire. Most modern revolvers are of **double-action** design; the trigger may be pulled to effect discharge of the gun, but this entails bringing the hammer from rest to full cock and then forward to fire. This technique, which may call for as much as ten pounds (**4.5** kilograms) of effort or more, tends to affect steady aim. As a result, target shooting with revolvers is almost invariably done in single-action form; the hammer is brought to full cock manually, by the thumb in one-hand (extended arm) shooting, the thumb repositioned on the gun, and the much lighter and crisper trigger pulled off. Additional time is needed to thumb-cock the hammer, time the shooter needs in the timed-fire and rapid-fire stages common to formal handgun matches.

With the autoloading pistol the shooter can concentrate on sight alignment and trigger control, or watching the clock or his practiced rhythm in the fast fire courses. The autoloader does as its name implies—chambers a fresh cartridge after a shot is fired, rapidly and without attention.

In conventional paper-target shooting, the handgunner may adopt any standing position that is comfortable. Generally, the right-handed shooter stands at **20°** to **90°** away from the target, facing left, his right arm extended and about level (when ready to fire). His elbow is "locked," particularly when firing centre-fire guns. This carries the recoil straight back and upward, allowing fast and precise return to the shooting position for the next shot. The manner of grasping the handgun may vary with the individual, but maintaining the chosen grip undisturbed is important. Even minor alterations in holding usually impair results at the target. Holding the sights of a handgun in correct alignment is far more important than it is with rifles because of the quite short sight radius; i.e., distance between rear and front sights. Even a slight error in this alignment is magnified many times at the target some ten to **50** yards (nine to **45** metres) away. In slow-fire handgun shooting the marksman generally holds a half breath, too, but that is not so readily done in timed and rapid fire.

For reasons of safety and better control of shooters and their arms, formal handgun competition (and rifle matches as well) is controlled by one or more assigned officials. Shooting commences on signal, the shooters in position, their guns held to point downwards and toward the targets. Another command or signal ends the firing.

Open sights are standard in handgun competition. The usual rear sight carries a square or rectangular notch in a vertical-standing metal leaf, a common width being **.125** inch (**.3** centimetre). A similar flat-topped post is used for the front sight, so dimensioned that a small amount of light may be seen at either side when the post is held central and level with the rear sight opening.

Such "iron," or metallic, open sights on target handguns are invariably capable of being adjusted in precise increments of movement both laterally (commonly called "windage") and vertically. Such movement is frequently by clicks, audible and visual, so that the shooter may make such adjustments in the often-dark confines of a shooting booth. These precise sight movements are a necessity if a given brand or type of ammunition is to print or cut the target at its centre. The individual shooter's particular method of aiming and sighting his handgun adds to the need for controlled sight adjustment. Low-cost handguns usually have fixed (nonadjustable) sights, generally integral with the gun frame or barrel.

Shotgun-shooting events. Formal clay-bird shooting takes place under well-established rules. These regulations differ in Europe and elsewhere from those in force in the U.S. In both straight trapshooting and skeet, international rules require a clay bird to be a bit harder than U.S. targets (thus more difficult to break), to fly at greater velocity from the throwing machines (traps), and thus fly farther. In international shooting the contestant's gun must be held at his side, the butt visible below his bent arm. Under U.S. rules the gun may be fully mounted at the shoulder, ready to fire when the target appears on call from the shooter. International rules also permit an unknown (up to three seconds) delay before the called bird is thrown from the trap house. In the U.S. the clay bird is propelled immediately following the shooter's call or other vocal signal to the referee or trap house attendant.

Formal trapshooting and skeet shooting in the U.S. are team events, teams ordinarily consisting of five shooters (women as well as men, though the latter predominate greatly). Scoring, however, is on an individual basis. In trapshooting each contestant takes his turn at shooting from one of five stations (arranged in a shallow semicircle), these shooting positions being 16 yards (15 metres) from the trap house on single clay birds (see Figure 1) unless the match is a "handicap" type. Shooters are handicapped on the basis of their ability, and **high-**

scoring shooters may have to fire from 18 to 27 yards (16 to 25 metres) away from the trap house. The trap house opening lies at about ground level; the birds are thrown at various lateral angles (up to 22° from either side of the house) away from the shooter—angles unknown beforehand to the contestant.

The usual singles event at trap consists of 100 shots per man, but in "doubles," where two clays are thrown at the same time, 50 to 100 shots are usually fired in one event.

Skeet shooting is similar to trapshooting in that shotguns and the same type of clay target are used and that a round consists of 25 shotshells (the standard box or carton) to be fired by each shooter. The skeet layout (see Figure 2) has eight stations, seven of them arranged in a half-circle; station 8 lies in the centre, between the two trap houses. Station 1 is sited at the "high house," station 7 at the "low house," stations 2 through 6 located at a uniform distance apart on the rest of the quadrant. Both houses in skeet throw targets along fixed lines of flight, thereby differing from trapshooting. These flight paths cross at a point equidistant from each house but six feet (two meters) from the central station.

Figure 2: Layout of a skeet shooting field.

A round of skeet consists of 16 single shots; *i.e.*, eight targets from each house, plus four pair of doubles from stations 1, 2, 6, and 7. If all 24 clay birds are broken (or "dead"), the 25th shot is an "optional" and may be fired at any station. If a bird is missed at any previous station, however, that shot is repeated at that time.

Guns used in skeet are generally open bored; *i.e.*, they throw shot patterns in a larger circle at given ranges than the trap gun does. The skeet target, correctly broken, is hit at closer ranges than is the case with straight trap. Double-barrelled guns are generally thought to be ade-

quate when half of the shot charge hits inside a 30-inch (76-centimetre) circle at 40 yards (37 metres) from one barrel and 55 to 60 percent from the other. Because of the fast gun swinging required in skeet, barrels tend to be short—26 to 28 inches (66 to 71 centimetres)—but any length may be used.

Four gun classes are recognized for skeet shooting. All-bore allows any gauge up to and including 12. Twenty-gauge requires a gun of that gauge or smaller. (The bore or gauge number was originally the number of lead balls, each the diameter of the bore, that would weigh one pound.) Small bore calls for a 28-gauge or .410 (the .410 is calibre .41), while subsmall bore may be shot only with the .410. Shot loads and sizes in these four gauges are restricted, respectively, to: 1½-oz., ¾-oz., ¾-oz., and ½-oz. (32, 25, 21, and 14 g), all shot pellets to be size 9 or larger. All shotgun types are used at skeet except single shots. Autoloading and pump guns (also called slide—or trombone action) are quite popular in the U.S. (and abroad to a somewhat lesser extent), but double-barrelled guns, both side-by-side and over-under forms, are regaining some of their lost popularity. Double guns had all but disappeared from the U.S. market because of high manufacturing cost, until the 1960s saw an influx of European-made models at moderate prices that sold well. Many of these are offered as "skeet specials," which is to say with single trigger, selective automatic ejectors (these propel the fired empty cases forcibly from the chambers and to some distance), with fore-ends "beavertail" style—that is, broad fore-end stocks that let the hand grasp them for better directional control. Both skeet and trap buttstocks are generally of straighter profile and a bit longer than the stocks found on field (hunting) guns. This results in the shot charge being thrown higher at normal target distances. Shotguns ordinarily have only a front sight (on clay target guns there may be a middle sight, placed about halfway along the barrel), the top of the stock (or comb) acting as a rear sight.

BIBLIOGRAPHY

General: Of the many books extant on firearms, relatively few are on shooting as such. JACK O'CONNOR *et al.*, *The Complete Book of Shooting* (1966); LARRY KOLLER, *How to Shoot* (1964), and C.E. CHAPEL, *The Art of Shooting* (1960), cover field and target use of shotguns, rifles, and handguns comprehensively and well.

Rifle shooting: JAROSLAV LUGS, *A History of Shooting* (1968), is what the title implies, with emphasis on marksmanship and exhibition shooting with rifle and handgun. N.H. ROBERTS and K.L. WATERS, *The Breech-Loading Single-Shot Match Rifle* (1967), is an outstanding work on Schuetzen (offhand) and rest shooting in the United States from about 1840 to the 1920s. The NATIONAL RIFLE ASSOCIATION of America publishes books and brochures on target shooting of all types, as does its counterpart, the British NRA. Two titles available from the NRA of America that will be most helpful are the *NRA Shooting Handbook* (1961) and the *NRA International Shooting Handbook* (1960). Some excellent books on rifle shooting, out of print but not yet replaced by studies of equal worth, are T.F. FREMANTLE, *The Book of the Rifle* (1900); and H. OMMUNDSEN and E.H. ROBINSON, *Rifles and Ammunition* (1914). The former is a superb history of British rifles and rifle shooting from the 18th century; the latter a well-illustrated, comprehensive volume on British and continental military rifle shooting. E.C. CROSSMAN, *Small Bore Rifle Shooting* (1927), and *Military and Sporting Rifle Shooting* (1932), both first-rate texts despite their age, are not in print.

Handgun shooting: Target handgunning in its many phases is well treated in P.C. FREEMAN, *Modern Pistol Shooting* (1968); PAUL B. WESTON, *The Handbook of Handgunning* (1968); and C. GAYLORD, *Handgunner's Guide* (1960).

Shotgun shooting: JACK O'CONNOR, *The Shotgun Book* (1965), is an excellent work, with material as well on gun selection, choice of gauges and chokes, and cartridges. A first-class text on target (clay-bird) shooting, from the British viewpoint is PERCY STANBURY and G.L. CARLISLE, *Clay Pigeon Marksmanship* (1964). GOUGH THOMAS, *Gough Thomas's Gun Book* (1969); and MICHAEL BRANDER, *The Game Shot's Vade Mecum* (1965), furnish a wealth of information for the British shotgunning, with good coverage on marksmanship and its attainment. B. HARTMAN, *Hartman on Skeet* (1967); and D. LEE BRAUN, *Trapshooting with D. Lee Braun* (1969), are excellent choices for the clay-bird-shooting aspirant. F.E. SELL,

Shot
patterns
and gun
classes

Sure-Hit *Shotgun Ways* (1967), devotes over a third of its pages to a fast method of learning to shoot the smoothbore gun.

(J.T.A.)

Shorthand

Shorthand is a method of writing rapidly by substituting characters, abbreviations, or symbols for letters, words, or phrases. Other names for shorthand are stenography (close, little, or narrow writing), tachygraphy (swift writing), and brachygraphy (short writing). Because shorthand can be written rapidly, the shorthand writer is able to record the proceedings of legislative bodies, the testimony of law courts, or dictation in business correspondence. In addition, shorthand has been used through the centuries as a cultural tool; for example, George Bernard Shaw wrote his plays in shorthand, and Samuel Pepys recorded his diary in shorthand. Furthermore, Cicero's orations, Martin Luther's sermons, and Shakespeare's plays were all preserved by means of shorthand. Today, in every industrial nation of the world, shorthand is used to conduct operations in business, industry, and the professions.

Background and development. Through the centuries shorthand has been written in systems based on orthography (normal spelling), on phonetics (the sounds of words), and on arbitrary symbols, such as a small circle within a larger circle to represent the phrase, "around the world." Most historians date the beginnings of shorthand with the Greek historian Xenophon, who used an ancient Greek system to write the memoirs of Socrates. It was in the Roman Empire, however, that shorthand first became generally used. Marcus Tullius Tiro, a learned freedman who was a member of Cicero's household, invented the *notae Tironianae* ("Tironian notes"), the first Latin shorthand system. Devised in 63 BC, it lasted over a thousand years. Tiro also compiled a shorthand dictionary. Among the early accomplished shorthand writers were the Emperor Titus, Julius Caesar, and a number of bishops. With the beginning of the Medieval Age in Europe, however, shorthand became associated with witchcraft and magic, and disappeared.

While he was archbishop of Canterbury, Thomas Becket (1118?–70) encouraged research into Tiro's shorthand. By the 15th century, with the discovery in a Benedictine monastery of a lexicon of Ciceronian notes and a Psalter written in Tironian shorthand, a renewed interest in the practice was aroused. Somewhat influenced by Tiro's system, Timothy Bright designed an English system in 1588 (that consisted of straight lines, circles, and half circles. (Tiro's method was cursive, based on longhand script.) Bright's system was called *Characterie: an Arte of Shorte, Swifte, and Secrete Writing by Character*.

The 17th century produced four important inventors of shorthand systems: John Willis, who is considered to be the father of modern shorthand; Thomas Shelton, whose system was used by Samuel Pepys to write his famous diary; Jeremiah Rich, who popularized the art by publishing not only his system but also the Psalms and the New Testament in his method of shorthand; and William Mason, whose method was used to record sermons and to translate the Bible in the years following the Reformation. Mason's system was later adapted and became the official system of the British Parliament.

Several other systems were invented in the next decades, but most of them were short-lived. One of the most successful was that of the British stenographer Samuel Taylor, who invented a system in 1786 that was based on that of one of his predecessors. Taylor's method was adapted into French, Spanish, Portuguese, Italian, Swedish, German, Dutch, Hungarian, and other languages.

The Industrial Revolution brought a demand for stenographers in business. Because the geometric systems then in use required a high standard of education and long training in the system, a need existed for a method that would be easier to learn. The German Franz Xaver Gabelsberger (1789–1849) turned away from geometric methods and developed a simple cursive system. Gabelsberger has been considered by many to have been one of

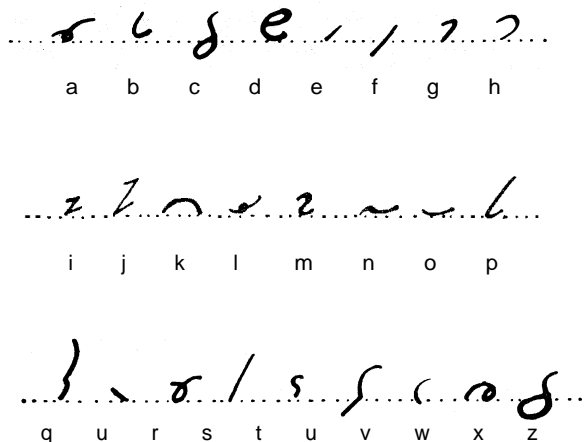

Figure 1—Alphabet of Gabelsberger shorthand, 1834.

From Hans Glatte, *Shorthand Systems of the World*

the world's leaders in the field of shorthand. His system, which he called "Speech-sign art," was based on Latin longhand characters and had a neatness and beauty of outline that is unsurpassed. It enjoyed a spontaneous success and spread to Switzerland, Austria, Scandinavia, Finland, and Russia. Its simplicity made it an easy matter to translate it into other languages, and in 1928 it became the Italian national system.

Modern symbol systems. Sir Isaac Pitman (1813–97), an educator who advocated spelling reform, was knighted by Queen Victoria for his contributions to shorthand. Pitman had learned Taylor's method of shorthand but saw its weakness and designed his own system to incorporate writing by sound, the same principle he advocated in phonetic longhand spelling. He published his system in 1837, calling it *Stenographic Sound-Hand*. It consisted of 25 single consonants, 24 double consonants, and 16 vowel sounds. Similar, related sounds were represented by similar signs, shading was used to eliminate strokes, the shortest signs were used to represent the shortest sounds, and single strokes were used to represent single consonants. At first, the principle of positioning to express omitted vowels—i.e., writing the word above, on, or below the line of writing—was reserved until later lessons, after the theory had been presented. Later, positioning was introduced with the first lesson.

In 1852, Isaac Pitman's brother, Benn Pitman, brought the system to America, where, with several slight modifications, it became the method most extensively used in the United States and Canada. An investigation in 1889 stated that 97 percent of the shorthand writers in America used the Isaac Pitman system or one of its modifications. The percentage is much lower today, but Pitman shorthand is still the major system in New York City, Philadelphia, Chicago, and all of Canada. In addition, Pitman shorthand has been adapted to Afrikaans, Arabic, Armenian, Dutch, French, Gaelic, German, Hebrew, Hindi, Italian, Japanese, Persian, Spanish, and other languages.

The Irish-born John Robert Gregg (1867–1948) taught himself an adaptation of Taylor's shorthand at the age of ten. Fascinated by shorthand, he then studied Pitman by himself but disliked its angles, shading, and positioning. Later, while in his early teens, he read a history of shorthand by Thomas Anderson, a member of the Shorthand Society of London. In his book, Anderson listed the essentials of a good shorthand system, stating that no method then in use possessed them. These essentials, which made a lasting impression on Gregg, included the following: independent characters for the vowels and consonants, all characters written with the same thickness, all characters written on a single line of writing, and few and consistent abbreviation principles.

Gregg was 18 when he invented his own system and 21 when he published it in pamphlet form, *Light-Line Phonography* (1888). The Gregg system was predominantly a curve-motion shorthand with circles, hooks, and loops. Based on the ellipse or oval and on the slope of longhand,

Pitman's system

Gregg's light-line phonography

The "Tironian notes"

its motion was curvilinear. Obtuse angles were eliminated by natural blending of lines, vowels were joined, shading was eliminated, and writing was lineal, or in one position.

PITMAN

GREGG

SPEEDWRITING

Figure 2: Modern systems of shorthand recording the same sentence: "Since the dawn of history man has strived to communicate with his fellows and to record experiences that would otherwise be forgotten."

In 1893 Gregg brought his system to America, and Light-Line Phonography became Gregg Shorthand. The inventor found that, except for the eastern coastal cities, shorthand was virtually unknown. Also, at that time American secondary education had embarked upon a new idea, that of teaching shorthand in the high schools. Gregg travelled through the Midwest, the West, and the South, selling his system and demonstrating his teaching methods with great success. The Gregg system is now taught in over 90 percent of the schools teaching shorthand in the United States. It has also spread to Canada and to the British Isles. Gregg shorthand is published in English, French, Spanish, and Portuguese by the parent company. In addition, other companies publish Gregg shorthand in Hebrew, Russian, Italian, Tagalog, Japanese, Thai, Chinese, Erse (Scottish Gaelic), Esperanto, Sinhalese, and Polish.

A German system of importance is the Stolze-Schrey method. Wilhelm Stolze invented his system at about the same time as Gabelsberger and along similar lines. In 1885, Ferdinand Schrey, a Berlin merchant, attempted to simplify the Gabelsberger system. Sometime later the Stolze and Schrey methods were merged and became the leading system in Germany and Switzerland. Stolze-Schrey shorthand was also adapted to other languages, including Danish, Dutch, English, French, Italian, Norwegian, Polish, Russian, and Spanish.

Modern abbreviated longhand systems. The system of Speedwriting shorthand was created around 1924 by Emma Dearborn, an instructor at Columbia University. Her method was designed to be taken down on the typewriter; but in 1942 it was changed to be written by hand with pen or pencil. Speedwriting shorthand uses the letters of the alphabet and the known punctuation marks to represent sounds. For example, the sound of "ch" is written with a capital C; the word "each" is thus written "eC." Over 20,000 words in the Speedwriting dictation can be written with a total of 60 rules and a list of approximately 100 brief forms and standard abbreviations. Speedwriting shorthand is taught in seven languages—English, Spanish, Italian, Portuguese, German, Flemish, and Afrikaans—in 28 countries. There are an estimated 600 licensed schools throughout the world that are teaching this system.

Forkner Alphabet shorthand was first published in 1952 in the U.S. The author, Hamden Forkner, spent ten years in research before publishing the first edition of the new system, which uses a combination of conventional letters and a few symbols for the hard-to-write letters and sounds. For example, H is expressed by a short dash above the line. This same short dash through the letter C gives the "ch" sound, through the longhand S it gives

"sh," and across the T it designates "th." Abbreviations are used for a number of common words. Forkner Alphabet shorthand is now taught in high schools and business colleges in the U.S.

Another U.S. method, Hy-Speed Longhand, was first published under that title in 1932. Based on Andrew J. Graham's *Brief Longhand*, published in 1857, its principles include the omission of silent letters and most vowels, the substitution of letters, numbers, or signs, and the combination of certain letters.

Stenoscript ABC Shorthand is a phonetic system using only longhand and common punctuation marks. It originated in London in 1607 and was revised by Manuel Claude Avancena, who published a modern edition in 1950. Stenoscript has 24 brief forms that must be memorized; e.g., *ak* stands for acknowledge, *ac* for accompany, *bz* for business, and *gvt* for government.

Stenospeed originated in 1950 in the U.S.; the first publication was called Stenospeed High Speed Longhand, but in 1951 the system was revised under the name of Stenospeed ABC Shorthand. It is used by many schools in 20 states of the U.S. as a standard text. Stenospeed has also been programmed for use with teaching machines.

Other alphabetic or partially alphabetic systems have also been devised since the early 1950s.

Machine shorthand. A method of recording speech by using machines became commercially feasible around 1906, when the Stenotype machine was invented by Ward Stone Ireland, a U.S. stenographer and court reporter.

Stenograph
and
Stenotype
machines

At present, the Stenograph and Stenotype machines are used in offices to some extent, but they are principally employed for conference and court reporting. Both machines have keyboards of 22 keys; they are small, light, and silent. Because the operator uses all fingers and both thumbs, any number of keys can be struck simultaneously. The machines print roman letters on a strip of paper that folds automatically into the back of the machine. The operator controls the keys by touch and is thus able to watch the speaker.

To operate the machine, the fingers of the left hand control the keys that print consonants occurring before vowels. These keys print on the left side of the tape. The thumbs control the vowels, which are printed in the centre of the tape, and the fingers of the right hand control the consonants that follow the vowels, which are printed on the right side of the tape. There are not separate keys for each letter of the English alphabet, thus, those letters for which there are no keys are represented by combinations of other letters. Abbreviations are used for some of the most frequent words, giving the operator the ability to write two or three words in one stroke.

The advantages given for machine shorthand include greater speed, interchangeability of notes, and greater volume, in that other typists familiar with the system can transcribe the notes. Disadvantages include the cost of the machine, the inconvenience of moving the machine from place to place, and the difficulty of revising notes once they have been taken, in addition to reading back dictation when desired. Machine shorthand has proved itself in the reporting field, however. Reporting speeds are attained in less time than is needed with pen shorthand; and machine shorthand reporters now do most of the convention reporting and a large part of the court reporting, legislative reporting, and reporting of hearings in the United States.

Voice
transcrib-
ing
machines

Alternatives to shorthand. Machines for voice transcribing are used in modern offices as an alternative to pen or machine shorthand; in fact, they are found in most offices of any size. The advantages of such dictating equipment include the following: the equipment is always available, even though the secretary may not be; the dictator can dictate his thoughts immediately—in his office, in his home, in his car, or on a plane; he can dictate as rapidly as he wishes, unhampered by his secretary's recording skill; and dictation belts can be mailed back to the typist for transcription. Disadvantages of voice transcribing machines are the impossibility of teamwork during the dictation process and the necessity of a high degree of dictating skill when using dictating equipment. In addition, urgent matters usually cannot be dictated and transcribed without some delay.

Short Story

The short story is a kind of prose fiction, usually more compact and intense than the novel and the short novel (novelette). Prior to the 19th century it was not generally regarded as a distinct literary form. But although in this sense it may seem to be a uniquely modern genre, the fact is that short prose fiction is nearly as old as language itself. Throughout history man has enjoyed various types of brief narratives: jests, anecdotes, studied digressions, short allegorical romances, moralizing fairy tales, short myths, and abbreviated historical legends. None of these

constitutes a short story as the 19th and 20th centuries have defined the term, but they do make up a large part of the milieu from which the modern short story emerged.

Many of the elements of storytelling common to the short story and the novel are discussed at greater length in the article NOVEL. The short stories of particular literary cultures, along with other genres, are discussed in articles such as LITERATURE, WESTERN; and LITERATURE, EAST ASIAN; and in articles on the arts of various peoples—e.g., SOUTH ASIAN PEOPLES, ARTS OF.

Analysis of the genre

As a genre, the short story has received relatively little critical attention, and the most valuable studies of the form that exist are often limited by region or era (e.g., Ray B. West's *The Short Story in America, 1900–1950*). One recent attempt to account for the genre has been offered by the Irish short story writer Frank O'Connor, who suggests that stories are a means for "submerged population groups" to address a dominating community. Most other theoretical discussions, however, are predicated in one way or another on Edgar Allan Poe's thesis that stories must have a compact, unified effect.

By far the majority of criticism on the short story focuses on techniques of writing. Many, and often the best of the technical works, advise the young reader—alerting him to the variety of devices and tactics employed by the skilled writer. On the other hand, many of these works are no more than treatises on "how to write stories" for the young writer, and not serious critical material.

The prevalence in the 19th century of two words, "sketch" and "tale," affords one way of looking at the genre. In the United States alone there were virtually hundreds of books claiming to be collections of sketches (Washington Irving's *Sketch Book*, William Dean Howells' *Suburban Sketches*) or collections of tales (Poe's *Tales of the Grotesque and Arabesque*, Herman Melville's *Piazza Tales*). These two terms establish the polarities of the milieu out of which the modern short story grew.

The tale is much older than the sketch. Basically, the tale is a manifestation of a culture's unaging desire to name and conceptualize its place in the cosmos. It provides a culture's narrative framework for such things as its vision of itself and its homeland or for expressing its conception of its ancestors and its gods. Usually filled with cryptic and uniquely deployed motifs, personages, and symbols, tales are frequently fully understood only by members of the particular culture to which they belong. Simply, tales are intracultural. Seldom created to address an outside culture, a tale is a medium through which a culture speaks to itself and thus perpetuates its own values and stabilizes its own identity. The old speak to the young through tales.

The sketch, by contrast, is intercultural, depicting some phenomenon of one culture for the benefit or pleasure of a second culture. Factual and journalistic, in essence the sketch is generally more analytic or descriptive and less narrative or dramatic than the tale. Moreover, the sketch by nature is suggestive, incomplete; the tale is often hyperbolic, overstated.

The primary mode of the sketch is written; that of the tale, spoken. This difference alone accounts for their strikingly different effects. The sketch writer can have, or pretend to have, his eye on his subject. The tale, recounted at court or campfire—or at some place similarly removed in time from the event—is nearly always a recreation of the past. The tale-teller is an agent of time, bringing together a culture's past and its present. The sketch writer is more an agent of space, bringing an aspect of one culture to the attention of a second.

It is only a slight oversimplification to suggest that the tale was the only kind of short fiction until the 16th century, when a rising middle class interest in social realism on the one hand and in exotic lands on the other put a premium on sketches of subcultures and foreign regions. In the 19th century certain writers—those one might call the "fathers" of the modern story: Nikolay Gogol, Hawthorne, E.T.A. Hoffmann, Heinrich von Kleist, Prosper Mérimée, Poe—combined elements of the tale with ele-

The sketch
and the tale

Modern
fusions

ments of the sketch. Each writer worked in his own way, but the general effect was to mitigate some of the fantasy and stultifying conventionality of the tale and, at the same time, to liberate the sketch from its bondage to strict factuality. The modern short story, then, ranges between the highly imaginative tale and the photographic sketch and in some ways draws on both.

The short stories of Ernest Hemingway, for example, may often gain their force from an exploitation of traditional mythic symbols (water, fish, groin wounds), but they are more closely related to the sketch than to the tale. Indeed, Hemingway was able at times to submit his apparently factual stories as newspaper copy. In contrast, the stories of Hemingway's contemporary William Faulkner more closely resemble the tale. Faulkner seldom seems to understate, and his stories carry a heavy flavour of the past. Both his language and his subject matter are rich in traditional material. A Southerner might well suspect that only a reader steeped in sympathetic knowledge of the traditional South could fully understand Faulkner. Faulkner may seem, at times, to be a Southerner speaking to and for Southerners. But, as, by virtue of their imaginative and symbolic qualities, Hemingway's narratives are more than journalistic sketches, so, by virtue of their explorative and analytic qualities, Faulkner's narratives are more than Southern tales.

Whether or not one sees the modern short story as a fusion of sketch and tale, it is hardly disputable that today the short story is a distinct and autonomous, though still developing, genre.

History of the short story

ORIGINS

The evolution of the short story first began before man could write. To aid himself in constructing and memorizing tales, the early storyteller often relied on stock phrases, fixed rhythms, and rhyme. Consequently, many of the oldest narratives in the world, such as the famous Babylonian tale the *Epic of Gilgamesh* (c. 2000 BC), are in verse. Indeed, most major stories from the ancient Middle East were in verse: "The War of the Gods," "The Story of Adapa" (both Babylonian), "The Heavenly Bow," and "The King Who Forgot" (both Canaanite). These tales were inscribed in cuneiform on clay during the 2nd millennium BC.

The earliest tales extant from Egypt were composed on papyrus at a comparable date. The ancient Egyptians seem to have written their narratives largely in prose, apparently reserving verse for their religious hymns and working songs. One of the earliest surviving Egyptian tales, "The Shipwrecked Sailor" (c. 2000 BC), is clearly intended to be a consoling and inspiring story to reassure its aristocratic audience that apparent misfortune can in the end become good fortune. Also recorded during the 12th dynasty were the success story of the exile Sinuhe and the moralizing tale called "King Cheops [Khufu] and the Magicians." The provocative and profusely detailed story "The Tale of Two Brothers" (or "Anpu and Bata") was written down during the New Kingdom, probably around 1250 BC. Of all the early Egyptian tales, most of which are baldly didactic, this story is perhaps the richest in folk motifs and the most intricate in plot.

The earliest tales from India are not as old as those from Egypt and the Middle East. The *Brāhmaṇas* (c. 700 BC) function mostly as theological appendixes to the Four Vedas, but a few are composed as short, instructional parables. Perhaps more interesting as stories are the later tales in the Pāli language, *The Jātaka*. Although these tales have a religious frame that attempts to recast them as Buddhist ethical teachings, their actual concern is generally with secular behaviour and practical wisdom. Another, nearly contemporaneous collection of Indian tales, *The Pañca-tantra* (c. AD 500), has been one of the world's most popular books. This anthology of amusing and moralistic animal tales, akin to those of "Aesop" in Greece, was translated into Middle Persian in the 6th century; into Arabic in the 8th century; and into Hebrew, Greek, and Latin soon thereafter. Sir Thomas North's English translation appeared in 1570. Another noteworthy collection is

The Ocean of Rivers of Stories, a series of tales assembled and recounted in narrative verse in the 11th or 12 century. Most of these tales come from much older material, and they vary from the fantastic story of a transformed swan to a more probable tale of a loyal but misunderstood servant.

During the 2nd, 3rd, and 4th centuries BC, the Hebrews first wrote down some of their rather sophisticated narratives, which are now a part of the Old Testament and the Apocrypha. The book of Tobit displays an unprecedented sense of ironic humour; Judith creates an unrelenting and suspenseful tension as it builds to its bloody climax; the story of Susanna, the most compact and least fantastic in the Apocrypha, develops a three-sided conflict involving the innocent beauty of Susanna, the lechery of the elders, and the triumphant wisdom of Daniel. The Old Testament books of Ruth, Esther, and Jonah hardly need mentioning: they may well be the most famous stories in the world.

Nearly all of the ancient tales, whether from Israel, India, Egypt, or the Middle East, were fundamentally didactic. Some of these ancient stories preached by presenting an ideal for readers to imitate. Others tagged with a "moral" were more direct. Most stories, however, preached by illustrating the success and joy that was available to the "good" man and by conveying a sense of the terror and misery that was in store for the wayward.

The early Greeks contributed greatly to the scope and art of short fiction. As in India, the moralizing animal fable was a common form; many of these tales were collected as "Aesop's fables" in the 6th century BC. Brief mythological stories of the gods' adventures in love and war were also popular in the pre-Attic age. Apollodorus of Athens compiled a handbook of epitomes, or abstracts, of these tales around the 2nd century BC, but the tales themselves are no longer extant in their original form. They appear, though somewhat transformed, in the longer poetical works of Hesiod, Homer, and the tragedians. Short tales found their way into long prose forms as well, as in Hellanicus' *Persika* (5th century BC, extant only in fragments).

Herodotus, the "father of history," saw himself as a maker and reciter of *logoi* (things for telling, tales). His long *History* is interspersed with such fictionalized digressions as the stories of Polycrates and his emerald ring, of Candaules' attractive wife, and of Rhampsinitus' stolen treasure. Xenophon's philosophical history, the *Cyropaedia* (4th century BC), contains the famous story of the soldier Abradates and his lovely and loyal wife Panthea, perhaps the first Western love story. The *Cyropaedia* also contains other narrative interpolations: the story of Pheraulas, who freely gave away his wealth; the tale of Gobryas' murdered son; and various anecdotes describing the life of the Persian soldier.

Moreover, the Greeks are usually credited with originating the romance, a long form of prose fiction with stylized plots of love, catastrophe, and reunion. The early Greek romances frequently took shape as a series of short tales. The *Love Romances* of Parthenius of Nicaea, who wrote during the reign of Augustus Caesar, is a collection of 36 prose stories of unhappy lovers. *The Milesian Tales* (no longer extant) was an extremely popular collection of erotic and ribald stories composed by Aristides of Miletus in the 2nd century BC and translated almost immediately into Latin. As the variety of these short narratives suggests, the Greeks were less insistent than earlier cultures that short fiction be predominantly didactic.

By comparison the contribution of the Romans to short narrative was small. Ovid's long poem, *Metamorphoses*, is basically a reshaping of over 100 short, popular tales into a thematic pattern. The other major fictional narratives to come out of Rome are novel-length works by Petronius (*Satyricon*, 1st century AD) and Apuleius (*The Golden Ass*, 2nd century AD). Like Ovid these men used potential short story material as episodes within a larger whole. The Roman love of rhetoric, it seems, encouraged the development of longer and more comprehensive forms of expression. Regardless, the trend away from didacticism inaugurated by the Greeks was not reversed.

The didacticism of early tales

The earliest tales extant

Beginnings of the romance

MIDDLE AGES, RENAISSANCE, AND AFTER

Proliferation of forms. The Middle Ages was a time of the proliferation, though not necessarily the refinement, of short narratives. The short tale became an important means of diversion and amusement. From the Dark Ages to the Renaissance, various cultures adopted short fiction for their own purposes. Even the aggressive, grim spirit of the invading Germanic barbarians was amenable to expression in short prose. The myths and sagas extant in Scandinavia and Iceland indicate the kinds of bleak and violent tales the invaders took with them into southern Europe.

In contrast, the romantic imagination and high spirits of the Celts remained manifest in their tales. Wherever the Celts appeared—in Ireland, Wales, or Brittany—stories steeped in magic and splendour also appeared. This spirit, easily recognized in such Irish mythological tales as *Longes mac n-Uislen* (probably composed in the 9th century), infused the chivalric romances that developed somewhat later on the Continent. The romances usually addressed one of three "Matters": the "Matter of Britain" (stories of King Arthur and his knights), the "Matter of France" (the Charlemagne cycle), or the "Matter of Rome" (stories out of antiquity, such as "Pyramus and Thisbe," "Paris and Helen"). Many, but not all, of the romances are too long to be considered short stories. Two of the most influential contributors of short material to the "Matter of Britain" in the 12th century were Chrétien de Troyes and Marie de France. The latter was most gifted as a creator of the short narrative poems known as the Breton lays. Only occasionally did a popular short romance like "Aucassin and Nicolette" (13th century) fail to address any of the three Matters.

Also widely respected was the exemplum, a short didactic tale usually intended to dramatize or otherwise inspire model behaviour. Of all the exempla, the best known in the 11th and 12th centuries were the lives of the saints, some 200 of which are extant. The *Gesta Romanorum* ("Deeds of the Romans") offered skeletal plots of exempla that preachers could expand into moralistic stories for use in their sermons.

Among the common people of the late Middle Ages there appeared a literary movement counter to that of the romance and exemplum. Displaying a preference for common sense, secular humour, and sensuality, this movement accounted in a large way for the practical-minded animals in beast fables, the coarse and "merry" jestbooks, and the ribald fabliaux. All were important as short narratives, but perhaps the most intriguing of the three are the fabliaux. First appearing around the middle of the 12th century, fabliaux remained popular for 200 years, attracting the attention of Boccaccio and Chaucer. Some 160 fabliaux are extant, all in verse.

Often, the medieval storyteller—regardless of the kind of tale he preferred—relied on a framing circumstance that made possible the juxtaposition of several stories, each of them relatively autonomous. Since there was little emphasis on organic unity, most storytellers preferred a flexible format, one that allowed tales to be added or removed at random with little change in effect. Such a format is found in *The Seven Sages of Rome*, a collection of stories so popular that nearly every European country had its own translation. The framing circumstance in *The Seven Sages* involves a prince condemned to death; his advocates (the seven sages) relate a new story each day, thereby delaying the execution until his innocence is made known. This technique is clearly similar to that of *The Arabian Nights*, another collection to come out of the Middle Ages. The majority of the stories in *The Arabian Nights* are framed by the story of Scheherazade in "A Thousand and One Nights." Records indicate that the basis of this framing story was a medieval Persian collection, *Hezar Efsan* ("Thousand Romances," no longer extant). In both the Persian and Arabian versions of the frame, the clever Scheherazade avoids death by telling her king-husband a thousand stories. Though the framing device is identical in both versions, the original Persian stories within the frame were replaced or drastically altered as the collection was adapted by the Arabs during the Muslim Mamlūk period (AD 1250–1517).

Refinement. Short narrative received its most refined treatment in the Middle Ages from Chaucer and Boccaccio. Chaucer's versatility reflects the versatility of the age. In "The Miller's Tale" he artistically combines two fabliaux; in "The Nun's Priest's Tale" he draws upon material common to beast fables; in "The Pardoner's Tale" he creates a brilliantly revealing sermon, complete with a narrative exemplum. This short list hardly exhausts the catalogue of forms Chaucer experimented with. By relating tale to teller and by exploiting relationships among the various tellers, Chaucer endowed *The Canterbury Tales* with a unique, dramatic vitality.

Boccaccio's genius, geared more toward narrative than toward drama, is of a different sort. Where Chaucer usually reveals a character through his actions and assertions, Boccaccio seems more interested in his stories as pieces of action. With Boccaccio, the characters telling the stories, and to a large part the characters within the stories, are of subordinate interest. Like Chaucer, Boccaccio frames his well-wrought tales in a metaphoric context. The trip to the religious shrine at Canterbury provides a meaningful backdrop against which Chaucer juxtaposes his earthy and pious characters. The frame of the *Decameron* (from the Greek *deka*, ten, and *hēmera*, day) has relevance as well: during the height of the Black Plague in Florence, Italy, ten people meet accidentally in a church and agree to amuse and divert each other by telling ten stories each. Behind every story, in effect, is the inescapable presence of the Black Death. The *Decameron* is fashioned out of a variety of sources, including fabliaux, exempla, and short romances.

Spreading popularity. Immediately popular, the *Decameron* produced imitations nearly everywhere. In Italy alone, there appeared at least 50 writers of *novelle* (as short narratives were called) after Boccaccio.

Learning from the success and artistry of Boccaccio and, to a lesser degree, his contemporary Franco Sacchetti, Italian writers for three centuries kept the Western world supplied with short narratives. Sacchetti was no mere imitator of Boccaccio. More of a frank and unadorned realist, he wrote—or planned to write—300 stories (200 of the *Novelle* ["Short Stories"] are extant) dealing in a rather anecdotal way with ordinary Florentine life. Two other well-known narrative writers of the 14th century, Giovanni Fiorentino and Giovanni Sercambi, freely acknowledged their imitation of Boccaccio. In the 15th century Masuccio Salernitano's collection of 50 stories, *Il novellino* (1475), attracted much attention. Though verbosity often substitutes for eloquence in Masuccio's stories, they are witty and lively tales of lovers and clerics.

With Masuccio the popularity of short stories was just beginning to spread. Almost every Italian in the 16th century, it has been suggested, tried his hand at *novelle*. Matteo Bandello, the most influential and prolific writer, attempted nearly everything from brief histories and anecdotes to short romances, but he was most interested in tales of deception. Various other kinds of stories appeared. Agnolo Firenzuolo's popular *Ragionamenti di amore* ("The Reasoning of Love") is characterized by a graceful style unique in tales of ribaldry; Anton Francesco Doni included several tales of surprise and irony in his miscellany, *I marmi* ("The Marbles"); and Gianfrancesco Straparola experimented with common folktales and with dialects in his collection, *Le piacevoli notti* ("The Pleasant Nights"). In the early 17th century, Giambattista Basile attempted to infuse stock situations (often of the fairy-tale type, such as "Puss and Boots") with realistic details. The result was often remarkable—a tale of hags or princes with very real motives and feelings. Perhaps it is the amusing and diverting nature of Basile's collection of 50 stories that has reminded readers of Boccaccio. Or, it may be his use of a frame similar to that in the *Decameron*. Whatever the reason, Basile's *Cunto de li cunti* (1634; *The Story of Stories*) is traditionally linked with Boccaccio and referred to as *The Pentamerone* ("The Five Days"). Basile's similarities to Boccaccio suggest that in the 300 years between them the short story may have gained repute and circulation, but its basic shape and effect hardly changed.

The
framing
circum-
stance

This pattern was repeated in France, although the impetus originally provided by Boccaccio was not felt until the 15th century. A collection of 100 racy anecdotes, *Les Cent Nouvelles Nouvelles*, "The Hundred New Short Stories" (c. 1460), outwardly resembles the *Decameron*. Marguerite de Navarre's *Heptameron* (1559; "The Seven Days"), an unfinished collection of some 70 amorous tales, admits a similar indebtedness.

In the early 17th century Béroalde de Verville placed his own Rabelaisian tales within a banquet frame in a collection called *Le Moyen de parvenir*, "The Way of Succeeding" (c. 1610). Showing great narrative skill, Béroalde's stories are still very much in the tradition of Boccaccio; as a collection of framed stories, their main intent is to amuse and divert the reader.

As the most influential nation in Europe in the 15th and 16th centuries, Spain contributed to the proliferation of short prose fiction. Especially noteworthy are: Don Juan Manuel's collection of lively exempla *El Conde Lucanor* (1328–35; "Count Lucanor"), which antedates the *Decameron*; the anonymous story "The Abencerraje," which was interpolated into a pastoral novel of 1559; and, most importantly, Miguel de Cervantes' experimental *Novelas ejemplares* (1613; "Exemplary Novels"). Cervantes' short fictions vary in style and seriousness, but their single concern is clear: to explore the nature of man's secular existence. This focus was somewhat new for short fiction, heretofore either didactic or escapist.

Despite the presence of these and other popular collections, short narrative in Spain was eventually overshadowed by a new form that began to emerge in the 16th century—the novel. Like the earlier Romans, the Spanish writers of the early Renaissance often incorporated short story material as episodes in a larger whole.

Decline of short fiction. The 17th and 18th centuries mark the temporary decline of short fiction. The causes of this phenomenon are many: the emergence of the novel; the failure of the Boccaccio tradition to produce in three centuries much more than variations or imitations of older, well-worn material; and a renaissance fascination with drama and poetry, the superior forms of classical antiquity. Another cause for the disappearance of major works of short fiction is suggested by the growing preference for journalistic sketches. The increasing awareness of other lands and the growing interest in social conditions (accommodated by a publication boom) produced a plethora of descriptive and biographical sketches. Although these journalistic elements later were incorporated in the fictional short story, for the time being fact held sway over the imagination. Travel books, criminal biographies, social description, sermons, and essays occupied the market. Only occasionally did a serious story find its way into print, and then it was usually a production of an established writer like Voltaire or Addison.

Perhaps the decline is clearest in England, where the short story had its least secure foothold. It took little to obscure the faint tradition established in the 16th and 17th centuries by the popular jestbooks, by the Palace of Pleasure (an anthology of stories, mostly European), and by the few rough stories written by Englishmen (e.g., Barnabe Rich's *Farewell to Military Profession*, 1581).

During the Middle Ages short fiction had become primarily an amusing and diverting medium. The Renaissance and Enlightenment, however, made different demands of the form. The awakening concern with secular issues called for a new attention to actual conditions. Simply, the diverting stories were no longer relevant or viable. At first only the journalists and pamphleteers responded to the new demand. Short fiction disappeared, in effect, because it did not respond. When it did shake off its escapist trappings in the 19th century, it reappeared as the "modern short story." This was a new stage in the evolution of short fiction, one in which the short form undertook a new seriousness and gained a new vitality and respect.

EMERGENCE OF THE MODERN STORY

The 19th century. The modern short story emerged almost simultaneously in Germany, the United States,

France, and Russia. In Germany there had been relatively little difference between the stories of the late 18th century and those in the older tradition of Boccaccio. In 1795 Goethe contributed a set of stories to Schiller's *Journal*, *Die Horen*, that were obviously created with the *Decameron* in mind. Significantly, Goethe did not call them "short stories" (*Novellen*) although the term was available to him. Rather, he thought of them as "entertainments" for German travellers (*Unterhaltungen deutscher Ausgewanderten*). Friedrich Schlegel's early discussion of the short narrative form, appearing soon after Goethe's "entertainments," also focussed on Boccaccio (*Nachrichten von den poetischen Werken des G. Boccaccio*, 1801).

But a new type of short fiction was near at hand—a type that accepted some of the realistic properties of popular journalism. In 1827, 32 years after publishing his own "entertainments," Goethe commented on the difference between the newly emergent story and the older kind. "What is a short story," he asked, "but an event which, though unheard of, has occurred? Many a work which passes in Germany under the title 'short story' is not a short story at all, but merely a tale or what else you would like to call it." Two influential critics, Christoph Wieland and Friedrich Schleiermacher, also argued that a short story properly concerned itself with events that actually happened or could happen. A short story, for them, had to be realistic.

Perhaps sensitive to this qualification, Heinrich von Kleist and E.T.A. Hoffmann called their short works on fabulous themes "tales" (*Erzählungen*). Somewhat like Poe, Kleist created an expression of human problems, partly metaphysical and partly psychological, by dramatizing man's confrontations with a fantastic, chaotic world. Hoffmann's intriguing tales of exotic places and of supernatural phenomena were very likely his most influential. Another important writer, Ludwig Tieck, explicitly rejected realism as the definitive element in a short story. As he noted in his preface to the 1829 collection of his works and as he demonstrated in his stories, Tieck envisioned the short story as primarily a matter of intensity and ironic inversion. A story did not have to be realistic in any outward sense, he claimed, so long as the chain of consequences was "entirely in keeping with character and circumstances." By allowing the writer to pursue an inner, and perhaps bizarre, reality and order, Tieck and the others kept the modern story open to non-journalistic techniques.

In the United States, the short story, as in Germany, evolved in two strains. On the one hand there appeared the realistic story that sought objectively to deal with seemingly real places, events, or persons. The regionalist stories of the second half of the 19th century (including those by G.W. Cable, Bret Harte, Sarah Orne Jewett) are of this kind. On the other hand, there developed the impressionist story, a tale shaped and given meaning by the consciousness and psychological attitudes of the narrator. Predicated upon this element of subjectivity, these stories seem less objective and are less realistic in the outward sense. Of this sort are Poe's tales in which the hallucinations of a central character or narrator provide the details and facts of the story. Like the narrators in "The Tell-Tale Heart" (1843) and "The Imp of the Perverse" (1845), the narrator of "The Fall of the House of Usher" (1839) so distorts and transforms what he sees that the reader cannot hope to look objectively at the scene. Looking through an intermediary's eyes, the reader can see only the narrator's impressions of the scene.

Some writers contributed to the development of both types of story. Washington Irving wrote several realistic sketches (*The Sketch-Book*, 1819–20; *The Alhambra*, 1832) in which he carefully recorded appearances and actions. Irving also wrote stories in which the details were taken not from ostensible reality but from within a character's mind. Much of the substance of "The Stout Gentleman" (1821), for example, is reshaped and recharged by the narrator's fertile imagination; "Rip Van Winkle" (1819) draws upon the symbolic surreality of Rip's dreams.

The short prose of Nathaniel Hawthorne illustrates that

A new type of short fiction

A new concern

Evolving in two strains

neither type of modern story, however, has exclusive rights to the use of symbol. On a few occasions, as in "My Kinsman, Major Molineux" (1832), Hawthorne's stories are about symbolic events as they are viewed subjectively by the central character. Hawthorne's greater gift, however, was for creating scenes, persons, and events that strike the reader as being actual historical facts and also as being rich in symbolic import. "Endicott and the Red Cross" (1837) may seem little more than a photographic sketch of a tableau out of history (the 17th-century Puritan leader cuts the red cross of St. George out of the colonial flag, the first act of rebellion against England), but the details are symbols of an underground of conflicting values and ideologies.

Several American writers, from Poe to James, were interested in the "impressionist" story that focusses on the impressions registered by events on the characters' minds, rather than the objective reality of the events themselves. In Herman Melville's "Bartleby the Scrivener" (1856) the narrator is a man who unintentionally reveals his own moral weaknesses through his telling of the story of Bartleby. Mark Twain's tales of animals ("The Celebrated Jumping Frog," 1865; "The Story of Old Ram," 1872; "Baker's Blue Jay Yarn," 1879), all impressionist stories, distort ostensible reality in a way that reflects on the men who are speaking. Ambrose Bierce's famous "An Occurrence at Owl Creek Bridge" (1891) is another example of this type of story in which the reader sees a mind at work—distorting, fabricating, and fantasizing—rather than an objective picture of actuality. In contrast, William Dean Howells usually sought an objectifying aesthetic distance. Though Howells was as interested in human psychology and behaviour as any of the impressionist writers, he did not want his details filtered through a biased, and thus distorting, narrator. Impressionism, he felt, gave license for falsifications; in the hands of many writers of his day, it did in fact result in sentimental romanticizing.

But in other hands the impressionist technique could subtly delineate human responses. Henry James was such a writer. Throughout his prefaces to the New York edition of his works, the use of an interpreting "central intelligence" is constantly emphasized. "Again and again, on review," James observes, "the shorter things in especial that I have gathered into [the Edition] have ranged themselves not as my own impersonal account of the affair in hand, but as my account of somebody's impression of it." This use of a central intelligence, who is the "impersonal author's concrete deputy or delegate" in the story, allows James all the advantages of impressionism and, simultaneously, the freedom and mobility common to stories narrated by a disembodied voice.

In at least one way, 19th-century America resembled 16th-century Italy: there was an abundance of second- and third-rate short stories. And, yet, respect for the form grew substantially, and most of the great artists of the century were actively participating in its development. The seriousness with which many writers and readers regarded the short story is perhaps most clearly evident in the amount and kind of critical attention it received. James, Howells, Harte, Twain, Melville, and Hawthorne all discussed it as an art form, usually offering valuable insights, though sometimes shedding more light on their own work than on the art as a whole.

But the foremost American critic of the short story was Edgar Allan Poe. Himself a creator of influential impressionist techniques, Poe believed that the definitive characteristic of the short story was its unity of effect. "A skillful literary artist has constructed a tale," Poe wrote in his review of Hawthorne's *Twice-Told Tales* in 1842.

If wise, he has not fashioned his thoughts to accommodate his incidents; but having conceived, with deliberate care, a certain unique or single *effect* to be wrought out, he then invents such incidents—he then combines such events as may best aid him in establishing this preconceived effect. If his very initial sentence tend not to the out-bringing of this effect, then he has failed in his first step. In the whole composition there should be no word written of which the tendency, direct or indirect, is not to the one pre-established design

Poe's polemic primarily concerns craftsmanship and artistic integrity; it hardly prescribes limits on subject matter or dictates technique. As such, Poe's thesis leaves the story form open to experimentation and to growth while it demands that the form show evidence of artistic diligence and seriousness.

The new respect for the short story was also evident in France, as Henry James observed, when in 1844 Prosper Mérimée with his handful of little stories was appointed to the French Academy. As illustrated by "Columba" (1841) or "Carmen" (1845), which gained additional fame as an opera, Mérimée's stories are masterpieces of detached and dry observation, though the subject matter itself is often emotionally charged. Nineteenth-century France produced short stories as various as 19th-century America—although the impressionist tale was generally less common in France. (It is as if, not having an outstanding impressionist storyteller themselves, the French adopted Poe, who was being ignored by the critics in his own country.) The two major French impressionist writers were Charles Nodier, who experimented with symbolic fantasies, and Gérard de Nerval, whose collection *Les Filles du feu* (1854; "Daughters of Fire") grew out of recollections of his childhood. Artists primarily known for their work in other forms also attempted the short story—novelists like Honoré de Balzac and Gustave Flaubert and poets like Alfred de Vigny and Théophile Gautier.

One of the most interesting writers of 19th-century France is Alphonse Daudet, whose stories reflect the spectrum of interest and techniques of the entire century. His earliest and most popular stories (*Lettres de mon moulin*, 1866; "Letters from My Mill") create a romantic, picturesque fantasy; his stories of the Franco-Prussian War (*Contes du Lundi*, 1873; "Monday's Tales") are more objectively realistic, and the sociological concern of his last works betrays his increasing interest in naturalistic determinism.

The greatest French storywriter, by far, is Guy de Maupassant, a master of the objective short story. Basically, Maupassant's stories are anecdotes that capture a revealing moment in the lives of middle class citizens. This crucial moment is typically recounted in a well-plotted design, though perhaps in some stories like "Boule de suif" (1880; "Ball of Tallow") and "The Necklace" (1881) the plot is too contrived, the reversing irony too neat, and the artifice too apparent. In other stories, like "The House of Madame Tellier" (1881), Maupassant's easy and fluid prose captures the innocence and the corruption of human behaviour.

During the first two decades of the 19th century in Russia, fable writing became a fad. By all accounts the most widely read fabulist was Ivan Krylov whose stories borrowed heavily from Aesop, La Fontaine, and various Germanic sources. If Krylov's tales made short prose popular in Russia, the stories of the revered poet Aleksandr Pushkin gained serious attention for the form. Somewhat like Mérimée in France (who was one of the first to translate Pushkin, Gogol, and Turgenev into French), Pushkin cultivated a detached, rather classical style for his stories of emotional conflicts (*The Queen of Spades*, 1834). Also very popular and respected was Mikhail Lermontov's "novel," *A Hero of Our Time* (1840), which actually consists of five stories that are more or less related.

But it is Nikolay Gogol who stands at the headwaters of the Russian short story; Dostoyevsky noted that all Russian short story writers "emerged from Gogol's overcoat," a punning allusion to the master's best known story. In a manner all his own, Gogol was developing impressionist techniques in Russia simultaneously with Poe in America. Gogol published his *Arabesques* (1835) five years before Poe collected some of his tales under a similar title. Like those of Poe, Gogol's tales of hallucination, confusing reality and dream, are among his best stories ("Nevsky Prospect" and "Diary of a Madman," both 1835). The single most influential story in the first half of the 19th century in Russia was undoubtedly Gogol's "Overcoat" (1842). Blending elements of real-

ism (natural details from the characters' daily lives) with elements of fantasy (the central character returns as a ghost), Gogol's story seems to anticipate both the impressionism of Dostoyevsky's "Underground Man" and the realism of Tolstoy's "Ivan Ilych."

Ivan Turgenev appears, at first glance, antithetical to Gogol. In *A Sportsman's Notebook* (1852) Turgenev's simple use of language, his calm pace, and his restraint clearly differentiate him from Gogol. But like Gogol, Turgenev was more interested in capturing qualities of people and places than in building elaborate plots. A remaining difference between the two Russians, however, tends to make Turgenev more acceptable to 20th-century readers: Turgenev studiously avoided anything artificial. Though he may have brought into his realistic scenes a tale of a ghost ("Bezhin Meadow," 1852), he did not attempt to bring in a ghost (as Gogol had done in "The Overcoat"). In effect, Turgenev's allegiance was wholly to detached observation.

Developing some of the interests of Gogol, Fyodor Dostoyevsky experimented with the impressionist story. The early story "White Nights" (1848), for example, is a "Tale of Love from the Reminiscence of a Dreamer" as the subtitle states; the title of one of his last stories, "The Dream of the Ridiculous Man" (1877), also echoes Poe and Gogol. Though sharing Dostoyevsky's interest in human motives, Leo Tolstoy used vastly different techniques. He usually sought psychological veracity through a more detached and, presumably, objective narrator ("The Death of Ivan Ilych," 1886; "The Kreutzer Sonata," 1891). Perhaps somewhat perplexed by Tolstoy's nonimpressionist means of capturing and delineating psychological impressions, Henry James pronounced Tolstoy the masterhand of the disconnection of method from matter.

The Russian master of the objective story was Anton Chekhov. No other storywriter so consistently as Chekhov turned out first-rate works. Though often compared to Maupassant, Chekhov is much less interested in constructing a well-plotted story; nothing much actually happens in Chekhov's stories, though much is revealed about his characters and the quality of their lives. While Maupassant focusses on event, Chekhov keeps his eye on character. Stories like "The Grasshopper" (1892), "The Darling" (1898), and "In the Ravine" (1900)—to name only three—all reveal Chekhov's perception, his compassion, and his subtle humour and irony. One critic says of Chekhov that he is no moralist—he simply says "you live badly, ladies and gentlemen," but his smile has the indulgence of a very wise man.

The 20th century. In the first half of the 20th century the appeal of the short story continued to grow. Literally hundreds of writers—including, as it seems, nearly every major dramatist, poet, and novelist—published thousands of excellent stories. William Faulkner suggested that writers often try their hand at poetry, find it too difficult, go on to the next most demanding form, the short story, fail at that, and only then settle for the novel. In the 20th century Germany, France, Russia, and the U.S. lost what had once appeared to be their exclusive domination of the form. Innovative and commanding writers emerged in countries that had previously exerted little influence on the genre: Sicily, for example, produced Luigi Pirandello; Czechoslovakia, Franz Kafka; Japan, Akutagawa Ryūnosuke; Argentina, Jorge Luis Borges. Literary journals with international circulation, such as Ford Madox Ford's *Transatlantic Review*, *Scribner's Magazine*, and Harriet Weaver's *Egoist*, provided a steady and prime exposure for young writers.

As the familiarity with it increased, the short story form itself became more varied and complex. The fundamental means of structuring a story underwent a significant change. The overwhelming or unique event that usually informed the 19th-century story fell out of favour with the storywriter of the early 20th century. He grew more interested in subtle actions and unspectacular events. Sherwood Anderson, one of the most influential U.S. writers of the early 20th century, observed that the common belief in his day was that stories had to be built around a plot, a notion that, in Anderson's opinion, appeared to

poison all storytelling. His own aim was to achieve form, not plot, although form was more elusive and difficult. The record of the short story in the 20th century is dominated by this increased sensitivity to—and experimentation with—form. Although the popular writers of the century (like O. Henry in the U.S. and Paul Morand in France) may have continued to structure stories according to plot, the greater artists turned elsewhere for structure, frequently eliciting the response from cursory readers that "nothing happens in these stories." Narratives like Ernest Hemingway's "A Clean Well-Lighted Place" may seem to have no structure at all, so little physical action develops; but stories of this kind are actually structured around a psychological, rather than physical, conflict. In several of Hemingway's stories (as in many by D.H. Lawrence, Katherine Mansfield, and others), physical action and event are unimportant except insofar as the actions reveal the psychological underpinnings of the story. Stories came to be structured, also, in accordance with an underlying archetypal model: the specific plot and characters are important insofar as they allude to a traditional plot or figure, or to patterns that have recurred with wide implications in the history of mankind. Katherine Anne Porter's "Flowering Judas," for example, echoes and ironically inverts the traditional Christian legend. Still other stories are formed by means of motif, usually a thematic repetition of an image or detail that represents the dominant idea of the story. "The Dead," the final story in James Joyce's *Dubliners*, builds from a casual mention of death and snow early in the story to a culminating paragraph that links them in a profound vision. Seldom, of course, is the specific structure of one story appropriate for a different story. Faulkner, for example, used the traditional pattern of the knightly quest (in an ironic way) for his story "Was," but for "Barn Burning" he relied on a psychologically organic form to reveal the story of young Sarty Snopes.

No single form provided the 20th-century writer with the answer to structural problems. As the primary structuring agent, spectacular and suspenseful action was rather universally rejected around midcentury since motion pictures and television could present it much more vividly. As the periodicals that had supplied escapist stories to mass audiences declined, the short story became the favoured form of a smaller but intellectually more demanding readership. The Argentine Borges, for example, attracted an international following with his *Ficciones*, stories that involved the reader in dazzling displays of erudition and imagination, unlike anything previously encountered in the genre. Similarly, the American Donald Barthelme's composition consisted of bits and pieces of, e.g., television commercials, political speeches, literary allusions, eavesdropped conversations, graphic symbols, dialogue from Hollywood movies—all interspersed with his own original prose in a manner that defied easy comprehension and yet compelled the full attention of the reader. The short story also lent itself to the rhetoric of student protest in the 1960s and was found in a bewildering variety of mixed-media forms in the "underground" press that publicized this life style throughout the world. In his deep concern with such a fundamental matter as form, the 20th-century writer unwittingly affirmed the maturation and popularity of the genre; only a secure and valued (not to mention flexible) genre could withstand and, moreover, encourage such experimentation.

BIBLIOGRAPHY. Perhaps the most informative recent study of narrative, though not necessarily short narrative, that incorporates both theoretical and historical material is R.E. SHOLES and R.L. KELLOGG, *The Nature of Narrative* (1966). K.P. KEMPTON examines the genre, emphasizing theme and meaning, in *The Short Story* (1947). An excellent analysis of story techniques is offered in SEAN O'FAOLAIN, *The Short Story* (1948). BRANDER MATTHEWS' well-known theoretical discussion, *The Philosophy of the Short Story* (1901, reprinted 1931), is predicated on Poe's theories. A provocative thesis regarding the nature of stories is presented in FRANK O'CONNOR, *The Lonely Voice: A Study of the Short Story* (1963). H.S. SUMMERS has collected some of the more important discussions of the form in *Discussions of the Short Story* (1963). *Storytellers and*

Their Art, ed. by G. SAMPSON and C. BURKHART (1963), contains comments of various authors on the form. More specialized discussions of the form are contained in F.L. PATTEE, *The Development of the American Short Story* (1923); R.B. WEST, *Short Story in America, 1900–1950* (1952); E.K. BENNETT, *A History of the German Novelle*, 2nd ed. rev. by H.M. WAIDSON (1961); and S. TREMKNER, *Greek Novella in the Classical Period* (1958). An important discussion of short narratives from the standpoint of the folklorist is S. THOMPSON, *The Folktale* (1946).

(A.J.H.)

Shostakovich, Dmitry

Dmitry Shostakovich was the most important composer that has emerged in Russia since the beginning of the Soviet period. Though he produced operas, some choral works, a large number of able film scores, and some significant piano music and songs, Shostakovich was primarily a symphonic and chamber music composer, whose 15 symphonies, 13 string quartets, six concerti, piano trio, and piano quintet establish him as the most important Russian composer of instrumental music since Tchaikovsky.

EB Inc.

Shostakovich.

Dmitry Dmitriyevich Shostakovich was born in St. Petersburg on September 25 (September 12, old style), 1906, the son of an engineer. He entered the Petrograd (formerly St. Petersburg, now Leningrad) Conservatory in 1919, where he studied the piano with Leonid Nikolayev until 1923 and composition until 1925 with Aleksandr Glazunov and Maksimilian Steinberg, the latter the son-in-law of Nikolay Rimsky-Korsakov. He participated in the Chopin International Competition for Pianists in Warsaw in 1927 and received an honourable mention but made no subsequent attempt to pursue the career of a virtuoso, confining his public appearances as a pianist to performances of his own works.

Even before his keyboard success in Warsaw, he had had a far greater success as a composer with the *First Symphony* (1924–25), which quickly achieved worldwide currency. The symphony's stylistic roots were numerous; the influence of composers as diverse as Tchaikovsky and Paul Hindemith (and, avowedly, Shostakovich's contemporary Sergey Prokofiev) is clearly discernible. In the music Shostakovich was to write in the next few years he submitted to an even wider range of influences. The cultural climate in the Soviet Union was remarkably free at that time: even the music of Igor Stravinsky and Alban Berg, then in the avant-garde, was played. Béla Bartók and Paul Hindemith visited Russia to perform their own works, and Shostakovich himself openly experimented with avant-garde trends. His satiric opera *The Nose*, based upon Nikolay Gogol's story, displayed a comprehensive awareness of what was new in Western music, although already it seems as if the satire is extended to the styles themselves, for the avant-garde sounds are contorted with wry humour. Not surprisingly, Shostakovich's incomparably finer second opera, *Lady Macbeth of the Mtsensk District* (later retitled *Katerina Izmaylova*),

marked a stylistic retreat. Yet even this more accessible musical language was now too radical for the Soviet authorities.

From 1928, when Joseph Stalin had inaugurated his First Five-Year Plan, an iron hand fastened on Soviet culture, and in music a direct and popular style was demanded. Avant-garde music and jazz were banished, and for a while even the unproblematic Tchaikovsky was out of favour. Shostakovich did not experience immediate official displeasure, but when it came, it was devastating. It has been said that it was Stalin's personal anger at what he heard when he attended a performance of *Lady Macbeth of the Mtsensk District* in 1936 that precipitated the official condemnation of the opera and of its creator.

Shostakovich was bitterly attacked in the official press, and both the opera and the until then unperformed *Fourth Symphony* (1935–36) were withdrawn. The composer's next major work was his *Fifth Symphony* (1937), which he described as "A Soviet artist's reply to just criticism." A trivial, dutifully "optimistic" work might have been expected: what emerged was compounded largely of serious, even sombre and elegiac music, presented with a compelling directness that scored an immediate success with the public and even the authorities.

With the *Fifth Symphony*, Shostakovich escaped from the stylistic instability of his earlier works, finally forging the personal style that he used in his subsequent compositions. Gustav Mahler was a clear progenitor of both the *Fourth* and *Fifth* symphonies, but the latter represented a drastic shift in technique. Whereas the earlier symphony had been a sprawling work, founded upon a free proliferation of melodic ideas, the first movement of the *Fifth* was marked by melodic concentration—certain particles providing the main bases of music that grows organically to a relentless climax. This singlemindedness is reflected elsewhere in Shostakovich's work in his liking for the monolithic Baroque structures of the fugue and chaconne, each of which grows from, or is founded upon, the constant repetition of a single melodic idea. This almost obsessive concern with the working out of a single expressive character can also be seen in the recurrence in his mature music of certain thematic ideas, notably various permutations founded upon the juxtaposition of the major and minor third (already clear in the *Fifth Symphony*), and the four-note cell D-E \flat -C-B derived from the composer's initials in their German equivalent (D. Sch.), interpreted according to the labels of German musical notation (in which "S," spoken as "Es," equals E \flat and "h" equals B).

In 1937 Shostakovich was appointed a teacher of composition in the Leningrad Conservatory, and the German attack on the Soviet Union in 1941 found him still in that city. He composed his *Seventh Symphony* (1941) in beleaguered Leningrad during the latter part of that year, and the work achieved a quick fame, though more because of the quasi-romantic circumstances of its composition than because of its musical quality, which is often banal. Indeed, Shostakovich was always an uneven composer. When some extramusical force conditioned the music, empty rhetoric and impoverished invention all too often had been the result. After the evacuation to Kuybyshev in 1942, Shostakovich settled in Moscow in 1943 as a teacher of composition at the conservatory, and from 1945 he taught also at the Leningrad Conservatory.

Shostakovich's works written during the mid-1940s contain some of his best music, especially the *Eighth Symphony* (1943), the *Piano Trio* (1944), and the *Violin Concerto No. 1* (1947–48). Their prevailing seriousness, even grimness, was to contribute to Shostakovich's second fall from official grace. Under the gathering clouds of the Cold War, the Soviet authorities sought to impose a firmer ideological control, demanding a more accessible musical language than some composers were currently using. In Moscow in 1948, at a now notorious conference presided over by Andrey Zhdanov, a prominent Soviet theoretician, the leading figures of Soviet music, including Shostakovich, were attacked and disgraced.

Seventh
Symphony

First
Symphony

Success of
the 10th
Symphony

As a result, the quality of Soviet composition slumped in the next few years, and Shostakovich produced a number of poor pieces. His personal influence was reduced by the termination of his teaching activities at both the Moscow and Leningrad conservatories. Yet he was not completely intimidated, and in his *String Quartet No. 4* (1949), and especially in his *Quartet No. 5* (1951), he offered a splendid rejoinder to those who would have had him renounce completely his style and musical integrity. His *10th Symphony*, composed in 1953, the year of Stalin's death, flew in the face of Zhdanovism, yet, like his *Fifth Symphony* of 16 years earlier, compelled acceptance by sheer quality and directness.

From that time on, Shostakovich's biography is essentially a catalog of his works. He was left to pursue his creative career largely unhampered by official interference. He did, however, experience some difficulty over the texts (*Babi Yar*) by the poet Yevgeny Yevtushenko on which he based his *13th Symphony* (1962), and the work was suppressed after its first performance. Yet he was undeterred by this, and his deeply impressive *14th Symphony* (1969), cast as a cycle of 11 songs on the subject of death, was not the sort of work to appeal to official circles. The composer had visited the United States in 1949, and in 1958 he made an extended tour of western Europe, including Italy, where he had already been elected an honorary member of the Accademia Nazionale di Sta. Cecilia, Rome, and Great Britain, where he received an honorary doctorate of music at the University of Oxford. In 1966 he was awarded the Royal Philharmonic Society's Gold Medal.

Despite the brooding typical of so much of his music, which might suggest an introverted personality, Shostakovich was noted for his gregariousness. After Prokofiev's death in 1953, he was the undisputed head of Russian music. There was no reason to doubt that he was a sincere Communist, and he even participated in political conferences. Yet as a composer he always refused to be a mere cipher of official politics. Indeed, he appeared to flourish in the tension between his own creative drives and the demands of authority, writing much of his best music when his fiercely independent creative thought, under the abiding pressure from his masters for comprehensible expression, was channelled into a musical language of the utmost directness. Shostakovich died in Moscow on August 9, 1975.

MAJOR WORKS

OPERAS: *The Nose* (composed 1927–28; first performed 1930); *Lady Macbeth of the Mtsensk District* (composed 1930–32; first performed 1934; later renamed *Katerina Izmaylova*, and performed in the revised version, 1962).

BALLETS: *The Golden Age* (1930); *Bol*: (1931); *Bright Rivulet* (1935).

ORCHESTRAL WORKS: 15 symphonies, including *No. 1* (composed 1924–25), *No. 5* (1937), *No. 7* (*Leningrad*, 1941), *No. 10* (1953), *No. 14* (a cycle of 11 songs, 1969).

CONCERTI: (VIOLIN): *No. 1* (1948) and *No. 2* (1967). (CELLO): *No. 1* (1959) and *No. 2* (1965). (PIANO): *No. 1* (1933) and *No. 2* (1957).

CHAMBER MUSIC: 13 string quartets; *Piano Quintet* (1940); two piano trios, the first of which (op. 8) was repudiated by the composer.

PIANO: Two sonatas; 24 *Preludes and Fugues* (1951).

CHORAL: *The Execution of Stepan Razin* (1964).

BIBLIOGRAPHY. DAVID A. RABINOVICH, *Dmitry Shostakovich* (1959; orig. pub. in Russian), is marred by its political bias. The most useful study of the music is contained in NORMAN KAY, *Shostakovich* (1971). Though an older work, GERALD ABRAM, *Eight Soviet Composers* (1943), contains valuable critical comment. ALEXANDER WERTH, *Musical Uproar in Moscow* (1949), is an account of the upheaval surrounding the Zhdanov conference of 1948 and yields valuable insight into the pressures under which Shostakovich had to work.

(D.C.Br.)

Siam and Thailand, History of

The present state of Thailand was officially known as Siam before 1939 and from 1945 to 1949.

The Thai peoples emerged out of historical obscurity about a thousand years ago when they began moving

southward and westward from the China landmass to the northern parts of the Indochinese Peninsula. They moved into lands, from Assam in the west to northern Vietnam in the east, where most of the indigenous peoples were already under the influence of Indian culture.

The Thai culture before this time cannot be precisely delineated, since there are no documents describing it. It was once assumed that the Thai peoples were the founders and rulers of the kingdom of Nanchao, an independent state that flourished from the 8th to the 13th century in Yunnan Province of China, but later studies have indicated that the rulers of this state were not Thai. The culture of the Thai, then, can be inferred only on the basis of elements that continue to exist among most peoples speaking Tai languages today. The Thai language itself, in various dialects, is spoken by a wide variety of people living today in Burma, Thailand, Laos, Vietnam, and southern China. The Thai are people of the lowlands; their homes are in river valleys, and their economy is dependent on river waters. They are subsistence farmers whose principal crop is rice. In the rice fields, their technology includes the use of the plow and the harrow for breaking the land and the hand sickle for harvest. Individual landholdings are typical, but cooperative efforts to build dikes or to harvest fields are common. Animals are domesticated, including the water buffalo and ox for labour and the pig and fowl for food.

Family relationships are important among the Thai, but they have no concept of the extended family or clan and no caste system. Women occupy a high position; they may inherit property, and widows are free to remarry.

The earliest Thai religious beliefs were animistic. Spirits were thought to inhabit various natural sites—large trees, high rocks or mounds, the living quarters of families, and the rice kernel, the habitat of the rice goddess. Other spirits were the ghosts of the dead. Spirits could be benevolent or malevolent; offerings were made to them and ceremonies performed to ensure their favour.

When the Thai settlers in Southeast Asia began to emerge into history, they possessed sufficient social cohesion and political order to establish a number of petty principalities. Thai chronicles, although written long after the events they describe, point to the emergence by the 13th century of several small Thai states in what is now north Burma, Yunnan Province of China, and Assam in India, as well as in Thailand. In the 13th century several of these states rose to prominence, thanks partly to the rise of the Mongols, who sent armies to defeat Burma, Vietnam, and Champa but accepted Thai vassal status, and partly to the weakened condition of the Indianized states that had long been powerful in the area.

In the centre of the Indochinese Peninsula two peoples, the Mons and the Khmers, bore the impress of the culture of India in religion, government, the arts, and literature. The Mons, in Lower Burma and central Thailand, and the Khmers, in the Mekong Valley, had created distinctive and vigorous cultures and powerful political states. By the 13th century, the Mons had suffered from the depredations of the stronger Khmers, retaining political independence only in a relatively small state, Haripunjaya, in what is now northern Thailand. Mon culture, however, continued to be strong throughout central and northern Thailand. Particularly noteworthy was the devotion of the Mon peoples to Theravāda Buddhism. The Khmers, after an extraordinary burst of military and cultural expansionism under King Jayavarman VII (reigned 1181–c. 1219), began to decline in political power. The times were propitious for the emergence of the Thai.

Sukhothai and Chiangmai. Two principal Thai states emerged in what is now Thailand during the 13th century: Sukhothai in the Central Plain and Chiangmai in the north. Sukhothai was founded around 1220 after a Thai revolt against Khmer rule at an outpost of the Khmer empire. Chiangmai was founded in 1296, shortly after the Thai defeat of the Mon state of Haripunjaya.

From the outset, both Thai states showed that the Thai had already absorbed many elements of the cultures of the peoples around them. There are, in fact, reasons to assume that the political emergence of the Thai did not

Early
Thai
culture

Mons and
Khmers

represent any drastic change in the ethnic character of Thailand. It seems likely that the Thai, who for centuries had been filtering into the area, at the time of their rise were a minority of the population but were able to rise to dominance because of superior organizational ability and military prowess. The subsequent expansion of the Thai may reflect their ability to retain social supremacy and to absorb large numbers of non-Thai peoples.

Among the cultural borrowings of the Thai, one of the most profound and important was their acceptance, from the Mon, of Theravāda Buddhism. Thai animistic beliefs did not disappear—they persist even today—but to them were added the humanistic and philosophic concepts of a popular and egalitarian world religion.

Sukhothai
under
King
Ramkham-
haeng

Sukhothai, regarded by the Thai today as their first historical kingdom, achieved a considerable expansion by the end of the 13th century. Little is known of Sukhothai during its first two reigns, but its third king, Ramkhamhaeng (reigned 1279?–1317), has left a remarkable stone inscription that is the earliest example of writing in the Thai language. The Ramkhamhaeng inscription, dated 1292, pictures the Thai state as rich and prosperous, active in trade, and benevolently governed by a paternal monarch. According to the inscription, the state taxed its citizens modestly; treated all citizens, including non-Thai, alike; and provided justice for all. And “all its citizenry, all chiefs and nobles, everyone everywhere, all men and women, all groups, believe in Buddhism.” The kingdom is described as extensive, covering much of central Thailand down to Nakhon Si Thammarat on the peninsula, but excluding the plain of the Chao Phraya River below Nakhon Sawan, a region once dominated by the Khmer but apparently during Ramkhamhaeng's reign governed as an independent state called Lavo.

Allowing for some royal exaggeration of the virtues of the state, much of Ramkhamhaeng's description rings true. It seems clear that the Thai rulers of Sukhothai were proud of the differences between their social order and that of their Khmer predecessors and adversaries. The

emphasis on their human and humane king, on their low tax burden, on their popular Buddhist faith was undoubtedly meant to point out the contrast with the very different “god-king” status of the Khmer monarch, the heavy exactions in taxes and labour of the Khmer state, and the high cost and remoteness of the aristocratically oriented Khmer Hindu cults.

Although much of Sukhothai “high” culture was a result of culture borrowing—Buddhism from the Mon, the system of writing from the Cambodians, art techniques and styles from various sources—many of these cultural borrowings were transmuted into Thai forms. Particularly outstanding were Thai bronze sculptures of the Buddha cast with great skill in distinctive and original forms. Thai ceramics, inspired apparently by Chinese Sung ware, were produced in great quantity at kilns in Sawankhalok; their high quality made them prized in trade.

King Ramkhamhaeng combined the abilities of effective ruler, warrior, and patron of Buddhism and the arts. His successors did not have his range. His son, Loe Thai (reigned 1317?–1347), the fourth king of the dynasty, poured his energies into religion, and a weakening of the state was the eventual outcome. Sukhothai apparently regained some power under King Lu Thai (reigned 1347?–74), but it fell under the domination of a new Thai state to the south in 1378.

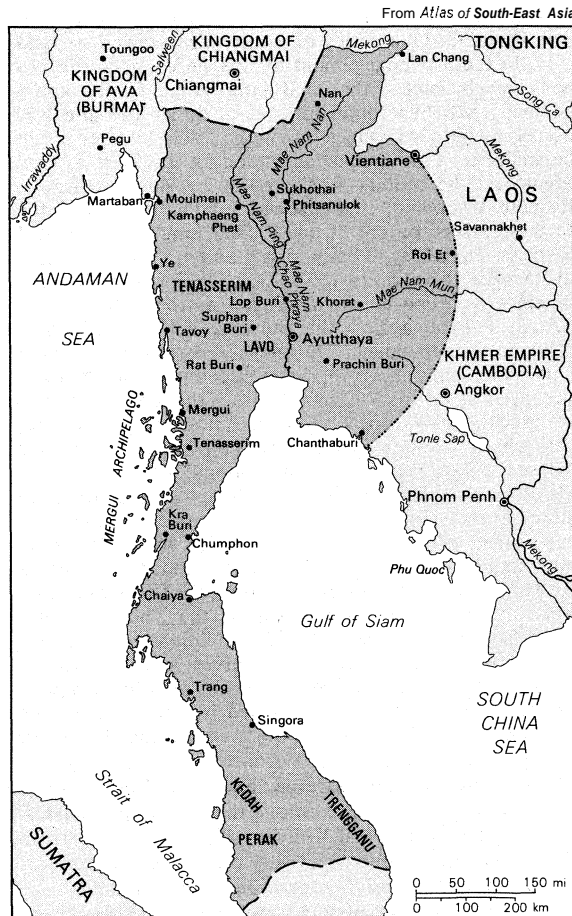

The Ayutthaya Period (1350–1767). The successor state to Sukhothai was the Thai kingdom of Ayutthaya that had emerged around 1350. According to tradition, Ayutthaya's first king, Ramathibodi I, inherited the states of Lavo and U Thong (their capitals correspond to the towns of Lop Buri and Suphan Buri in Thailand today) and combined them into a single strong kingdom. Ayutthaya was located in the centre of the rich rice plains of the Chao Phraya Basin, a region strongly subject to the influences of the Khmer, the Mon, and the Burmese. From the outset it appears to have competed successfully for power with Sukhothai and with the Khmer. By the early 15th century it had absorbed Sukhothai and devastated the eroding Cambodian kingdom.

During the first century after the foundation of Ayutthaya, many changes reflecting the influence of Cambodia occurred in Thai society, particularly on the upper levels. Under King Trailok (reigned 1448–88) further changes were made and former changes were codified; the character of the Thai state was permanently transformed.

The most significant of the changes concerned the nature and organization of government. The self-image of Sukhothai kings had been that of a father bringing riches, justice, and the benefits of Buddhism to his people. In Ayutthaya these ideals were expanded and overlaid with the Khmer view of the ruler as god-king. Court ceremonials and court Brahmins were introduced to bring to kingship the magical attributes of divine intermediary. The court calendar swelled with ceremonies for the manipulation of cosmic forces to promote the success and prosperity of the state. (These ceremonies are described in a voluminous 1718-page 19th-century work in Thai by King Chulalongkorn, “The Royal Ceremonies of the Twelve Months.”) In a practical way, new techniques for centralizing power, including a bureaucratic system of government, were introduced. Members of royalty who had been serving as provincial officials were replaced by appointed nobles. A hierarchy of princes and nobles was established whereby the relative status of each was formalized. A system of patrons and clients extended throughout the population so that, theoretically, every man fulfilled obligations—in loyalty and goods and services—to someone above him and received, in return, protection from a patron. Commoners paid their military service, compulsory labour services, and taxes to local masters who, in turn, were subject to higher masters above them. The apex of the pyramid of patronage was the king himself.

The formal hierarchical system awarded each man *sakdi na*, or “dignity marks,” in which the position of each man was equated with an acreage of land. Ordinary freemen were actually allowed to take possession of twenty-five rai of land, equal to about ten acres, to represent their *sakdi na*. The rank of officials of the government and members

Ayutthayan
government

Ayutthaya kingdom c. 1400.

of the royal family was also expressed in the acreage terms of *sakdi na*; the acreage indicated could number in the hundreds or thousands. But for nobles and princes the term stood for power and position, for "dignity," and not for actual landed estates. High royal and noble officials were, in fact, required to live and work in the capital.

Many of the principles of government were enacted into codes of law, and a large body of law is reputed to date back to the reign of King Ramathibodi I. The basis of law was Hindu, and the codes were probably transmitted to the Thai from Mon sources. These codes were expanded a century later. They included laws on evidence, on slavery, on robbery, on divorce. A Palace Law spelled out the duties of members of the royal family, rules of succession, and court procedures. The institution of the rank of *uparat* also dates back to the mid-15th century. Often inappropriately termed "Second King" by Western visitors to Thailand, this rank was Indian in origin and was, in fact, the highest princely rank awarded to a member of the royal family. The *uparat* functioned as general of the armies and had some claim to being the heir apparent.

By and large, in the context of the times and in comparison with neighbouring states, Thailand in Ayutthaya was a strong and well-governed state. There were, however, periodic internal disorders, products, it would seem, of contests for power between and within the royal and noble elites. In order to retain power a king had to preserve a balance of strength between princes and nobles. The prime ingredient for power was population, for land was plentiful and people were scarce. If a king allowed too many clients to fall under the control of his relatives, the princes, or even of his own bureaucratic officials, the nobles, political conflict would likely ensue. Many such conflicts are recorded—one of the bloodiest resulting from the usurpation of the throne by a high noble early in the 17th century. This noble, whose position was essentially that of minister of the Southern Provinces, paved his way to the throne by putting two kings to death, and after his accession as King Prasatthong, some 3,000 persons, members of the former ruling dynasty and other potential rivals, were executed. One prince who had followed the established practice of seeking sanctuary by becoming a Buddhist monk was first lured out of his monastery and then put to death.

The mass of the people in Ayutthayan times, the peasant farmers, were divided into two main classes: freemen and slaves. Freemen had the right to till an area of land equivalent to ten acres. The obligations of the freemen to government in taxes and labour were paid to local patron-officials. This link was all-important. The way to improve one's status was to gain special favour through a patron or, if he were unable to help, to find a new patron who might give special favour. Exactions on freemen, it would seem, were seldom excessive. The fact of underpopulation meant that freemen could escape onerous obligations or an overly demanding patron by moving and clearing new land; the existence of numerous decrees against this practice testifies to its existence and prevalence. Another "escape" for freemen was slavery. There were many so-called slaves in Ayutthayan times; the term slave, however, is misleading—the great majority of slaves could better be called bondsmen, for the "slave" was usually also a peasant-farmer who could own land and could redeem his status by repayment of his debt.

Theravāda Buddhism in Ayutthayan times continued to supply an element of social cohesion in the Thai state. From king to peasant, all Thai regarded themselves as Buddhists despite the introduction of court Brahmanism on the top levels of society and the continued persistence of animism on all levels. Buddhism, indeed, was thoroughly acculturated in Ayutthayan times. On the popular level, Buddhist amulets and reliance on monks with magic power interpenetrated the more sublime ideas of the doctrine. At court, one king, Trailok, in 1458 cast 500 images of the Buddha in order to prevent repetition of the great famine that had occurred in 1457. The Buddhist monastic establishment itself played an important social role, providing moral and practical education for boys and giving young men who spent some time as monks the opportuni-

ty to "gain merit" for themselves and their parents. For men who chose to remain monks, the monastic order constituted a society parallel to secular society that allowed for considerable social advancement.

In its relationships with outside states, Ayutthayan Thailand was comparatively strong. Warfare was endemic, and the sway, or empire, of Ayutthaya fluctuated considerably during its 400-year history. But Thai dominance of the central Chao Phraya Plain remained unchallenged. Most of the wars were petty campaigns during the dry season, when the terrain permitted the movement of men and the agricultural cycle made their absence from the fields possible. Most of the wars were contests for sovereignty over border principalities. Some were essentially raids to acquire population—i.e., agricultural manpower and skilled artisans—and transportable wealth.

Ayutthaya's emergence in the 14th century in an area once ruled by Cambodia brought on a series of wars with Cambodia. By the early 15th century Ayutthaya had reduced Cambodia to vassal status, and, although Cambodia was frequently able to throw off its dependency, the balance of power between the two states thereafter continued to favour the Thai. Ayutthayan dominance over Sukhothai, achieved early in the 15th century, brought the kingdom into confrontation with the northern Thai states of Chiangmai and Laos. During the reign of King Trailok these wars reached a peak of intensity, and Ayutthaya went to war with Chiangmai seven times. In order to improve his military position with respect to Chiangmai, King Trailok in 1463 moved his capital to the northern town of Phitsanulok, where it remained throughout the rest of the reign. Ayutthaya was unable to retain power over Chiangmai, and Chiangmai had periods of independence and periods of dependency on Burma throughout the Ayutthayan period; it was not until the late 18th century that Thailand finally succeeded in gaining permanent control over Chiangmai.

The most powerful rival of the Thai in the Indochinese Peninsula was Burma. On two occasions when the ethnically diverse area of Burma was welded together into a political whole, Burmese imperial expansion extended into Thailand. One series of campaigns started around 1549. In the first engagement of this series, according to the Thai chronicles, the Thai king Maha Chakkraphat (reigned 1548–69) found himself in difficulties and was rescued by his wife, Queen Suriyothai, who lost her life in the incident. The campaigns ended in 1569 in a Thai defeat, and the country was overrun by Burmese forces. Burmese troops were garrisoned in Thailand, and the Burmese placed on the throne a Thai king who accepted Burmese suzerainty. Thailand remained a Burmese vassal-state for 15 years. In 1584–87, a Thai prince, Naresuan, since regarded by the Thai as a national hero, led a successful revolt against the Burmese and re-established Thailand's independence. In another period of Burmese unity and expansionism in the 18th century, the Burmese succeeded again in 1767 in capturing the Thai capital at Ayutthaya. The Burmese armies did not remain for long; they withdrew after sacking the Thai capital and thus ending the Ayutthaya period of Thai history.

Ayutthaya's relations with most other Asian states were limited to trade and the exchange of occasional embassies. The pursuit of friendly relations with China, started in Sukhothai times, was carried on throughout the Ayutthayan period. These relations were typical of those existing between China and outlying states: the Thai acknowledged the "elder brother" position of China and sent tributary missions triennially to the Chinese court. This formal suzerain-vassal relationship had little political significance but was willingly maintained by the Thai for the very real benefits it brought in the way of trade. Thailand, as a registered vassal, was permitted to send ships to China to purchase silks, pottery, and other luxury goods that were much in demand among the Thai upper classes. Thai trading vessels, and Chinese ships emanating from Thai ports, also conducted a lively trade in such commercial centres as Malacca, Vietnam, Java, and India.

Relations of a different sort were maintained with Ceylon; they were religious contacts. Some of the principal

Ayutthayan–
Burmese
rivalry

religious leaders in Sukhothai had come from Ceylon. Ceylon was looked to in Sukhothai and Ayutthayan times as the font of Theravāda Buddhist knowledge, and several religious missions were sent to Ceylon to obtain religious instruction, religious texts, and religious relics. During the 18th century, Buddhism in Ceylon underwent a serious decline, and a reversal in the religious relationship occurred. Ceylon then turned to Thailand for aid in purifying its ordination and other religious practices. One Thai mission that went to Ceylon in 1753 stayed for three years and performed some 700 ordinations for monks and 3,000 for novices. The Thai missions of this period established a Thai school of Buddhism in Ceylon, called *Syāmvamsa*, that still existed in the 1970s.

European
contacts

In long-range terms the most significant foreign contacts of Thailand—and the rest of Asia—were those with Europeans, who began arriving in the 16th century. By any standard, however, the European impact on Thai society in Ayutthayan times was slight. Portuguese diplomats, traders, and missionaries began arriving at the court of Ayutthaya shortly after the Portuguese capture of Malacca in the Malay Peninsula in 1511. Portuguese trade and missionary activities never became very important; the largest group of Portuguese in Thailand were adventurers who assumed roles as mercenaries in the Thai armies and who introduced some Western military techniques to Thai warfare. In the 17th century the Dutch and English began to arrive and to establish trading centres near the capital and in peninsular Thailand. The growth of Dutch trading interests throughout Eastern Asia was reflected in the emergence of the Dutch as the leading Western traders in Thailand. By 1664 the Dutch, by threatening the use of force, had obtained a treaty giving them monopolies over certain portions of Thailand's external trade. The Thai, seeking to offset Dutch power, welcomed the arrival of French missionaries in the 1660s, and in 1684 initiated a series of diplomatic exchanges between the courts of Ayutthaya and Versailles. The principal French spokesmen for promoting expansion of French interests in Thailand were clerics who, misunderstanding the characteristic Thai attitude of religious toleration, became convinced that the Thai king Narai (reigned 1657–88) could be converted to Catholicism. The arrival in 1687 of a large French mission that included some 600 soldiers aroused Thai fears, and in 1688 a coup by anti-Western Thai leaders led to the expulsion of the French and the beheading of their chief advocate at the Thai court, a colourful Greek adventurer, Constantine Phaulkon, who had become a Thai noble and a leading counsellor of the king. The Thai coup of 1688 inaugurated a new Thai policy of minimizing contacts with Westerners—a policy that was to continue for 150 years.

The Thon Buri and early Bangkok Periods (1767–1868). The Ayutthayan Period in Thai history came to an end as a result of the successful Burmese invasion of 1767. A new period began with the rise of a provincial noble, Phraya Taksin, who succeeded in ousting the Burmese and eliminating Thai rivals to political power. Taksin established a new capital for the kingdom at Thon Buri, on the Chao Phraya River some 40 miles south of the ruined city of Ayutthaya. The new capital was somewhat less accessible to Burmese armies and more accessible to foreign merchants—principally Chinese—who brought desired products and whose trade could be taxed to provide significant revenues for the government. King Taksin followed a policy of political reunification, including the reclaiming of vassal states that had broken off from Thai suzerainty at the time of the Burmese invasion. A campaign in Cambodia led by Thailand's leading general, Chao Phraya Chakkri, was under way in 1781 when a palace coup took place in Thon Buri. Taksin, who had apparently become mad and imagined himself an incarnate Buddha, was deposed. Chakkri hastily returned to the capital, where a group of officials invited him to assume the throne. He did so in 1782, thus establishing a new dynasty, the Chakkri dynasty, that continues to head the Thai state. One of the first acts of the new king was to move the capital across the Chao Phraya River to Bangkok.

There is much continuity in the history of Thailand from

Ayutthaya to Thon Buri-Bangkok. The ethos of the state, the customs and livelihood of the people, underwent no marked change. Taksin and the first Chakkri kings were primarily engaged in a policy of restoration both internally and externally. Law codes, religious works, and literary texts were rewritten. New temples and palaces were built using the patterns, and even the very bricks, of old Ayutthaya. The first three Chakkri kings were all restorers. Rama I (reigned 1782–1809) continued the policy of military reunification and brought Cambodia and other lost territories back into vassal status. He also gathered whatever evidence survived from Ayutthaya to re-establish court rituals and to set down comprehensive law codes and authoritative texts for the Buddhist canon. Rama II (reigned 1809–24) paid much attention to arts and letters. The King himself was an outstanding poet and, together with a team of court poets, wrote definitive Thai versions of the Hindu *Rāmāyana* and other classical works. Rama III (1824–51), during whose reign the British defeat of the Burmese kingdom (1826) ended the Thai–Burmese rivalry, was able to expand the Thai empire in the south and in the north. In the south he strengthened Thai control over vassal states in the Malay Peninsula: in the north he was able to absorb most of the territory of the Lao kingdom of Wiangchan (Vientiane) after he put down a revolt by the leader of that vassal state, Chao Anu. Rama III's armies also fought several campaigns in Cambodia against the Vietnamese, who were extending their power into Cambodian lands during the early 19th century. These campaigns ended in 1845, and negotiations that followed led to an agreement that Cambodia should be a tributary state to both Thailand and Vietnam.

Although restoration of Ayutthayan society was a prime goal during the early Bangkok Period, there were differences between Ayutthaya and Bangkok. For one thing, restoration is conscious traditionalism, which is not quite the same as tradition itself. For another, the restoration policy necessarily led to choices, choices that the Thai may have presumed were made on the basis of authority but in fact were often made on the basis of utility. The reform of the law code in 1805, for example, began after the King discovered in a contested divorce case that the law was not just. In the traditional Thai view, law is of divine origin; it is immutable, and the role of government is not to enact law but to administer it. An unjust law, then, could only be explained as a false law. The reform of 1805 was therefore seen as a work of removing falsifications, although in fact it was a work of reformation.

Some basic social changes in the early Bangkok Period seem also to have been introduced in order to prevent the recurrence of the internal weaknesses and political factionalism that had contributed to Ayutthaya's downfall. Labour-service requirements on freemen were reduced, and payment of obligations in money rather than services was encouraged. These moves can be seen as an attempt by the monarchy to focus greater strength in the royal house, to bring more of the population under the patronage of the king rather than that of the princes.

Other changes in the early Bangkok Period came from the outside and reflect general changes in the Asian scene: the growth of commerce, the great increase in Chinese migration, and the revival of European interest in eastern Asia. In the late 18th and early 19th centuries, trade, primarily with China, seems to have undergone rapid expansion, thanks in part to the growth in numbers of Chinese immigrants acting as merchants and entrepreneurs. The principal Thai export item in the early 19th century was sugar, a new industry that began because of Chinese enterprise.

Chinese immigration assumed the proportions of a flood. By the mid-19th century, approximately half of Bangkok's estimated population of 400,000 were Chinese; these newcomers greatly increased commercial activity in Thailand and came to control much of the country's internal trade.

Revival of Western interest in eastern Asia, which at the start was primarily British interest in China, brought Western traders and diplomats to "rediscover" Thailand in the early 19th century. The Westerners were politely received, and the Thai agreed to sign limited treaties (with

The
early
Chakkri
kings

King
Mongkut's
treaties
with the
West

Britain in 1826 and the United States in 1833).

The acceleration of Western demands for free trade and diplomatic representation in Thailand—emphasized by the British conquests in Burma, expansion in Malaya, and forced opening of China—led to a change in Thailand's foreign policy under King Mongkut (Rama IV; reigned 1851–68). Mongkut signed with Britain (1855), the United States (1856), France (1856), and other Western states treaties that held Thai taxation on imports and exports to a low level and permitted the establishment of foreign consulates with extraterritorial powers. They led to greatly expanded trade with the West, to development of commercial rice farming in the Central Plain, and to expansion of foreign influence.

King Mongkut is noted particularly for his realistic evaluation of Western power and his decision to treat peaceably to gain the best terms possible. Concessions in trade were followed by concessions in territory: Thailand relinquished its rights in Cambodia to the French in 1867. Western influence on internal affairs, however, was limited to the acceptance of some innovations introduced by Western missionaries, including printing and vaccination, and the hiring of some Western technicians and teachers; the latter included Anna Leonowens, whose romanticized report of Mongkut's reign became the basis of a musical comedy, *The King and I*. Perhaps more indicative of the monarch's attitude toward Western culture was his sponsorship of a reformed sect of Thai Buddhism, the *Thammayut*, that aimed at purification of Buddhist practice. This reform reflected the desire to make Buddhism less vulnerable to the criticisms of Western missionaries. In fact, the Thai were (and are) little attracted to Christianity.

King Chulalongkorn and internal reform. King Mongkut was succeeded in 1868 by his 15-year-old son Chulalongkorn (Rama V; reigned 1868–1910), who, after a five-year period of regency, assumed full powers in 1873. Chulalongkorn continued his father's policy of concessions toward the West, and territory was surrendered to the French in Laos and Cambodia and to the British in Malaya. The large concession of all Lao vassal territories east of the Mekong River to France in 1893 was made with extreme reluctance, and the Thai attempted without success to enlist British support against the French. The arrival of French gunboats in the Chao Phraya River with guns trained on the palace gave the Thai little choice. In 1896 the French and British imperial powers agreed to recognize the central part of Thailand as a free neutral buffer zone.

Internal
reform

To the policy of accommodation to the West, Chulalongkorn added the first effective program of internal reform. There were enormous political difficulties in bringing these internal changes about, for many undercut the bases of power of influential men at court. The young King proceeded gradually and was aided by a few gifted and far-sighted leaders of "Young Siam," most notably the King's half brother Prince Damrong. The internal reforms accomplished during Chulalongkorn's reign included the creation of a highly centralized bureaucracy, the strengthening of government revenues, the drawing of vassals and outlying dependencies into the regular provincial administration, the abolition of slavery and labour-service requirements, the end of the formalized system of patron-client relationships, the beginning of new state services such as public education, and the introduction of technical improvements such as railway and telegraph lines. The first tentative move toward internal reform, undertaken in 1873, was aimed at reducing inefficiencies in revenue collection so that a larger share of government revenues would come directly to the King. In 1892 the government was completely reorganized into ministries with functional responsibilities. The model for these reforms was the West; their purpose was to provide Thailand with the internal strength to meet the challenge of the West. The policy was successful: Thailand retained its independence, the country grew stronger, the monarchy retained its leadership.

Chulalongkorn's policies were continued by his sons

Vajiravudh (Rama VI; reigned 1910–25) and Prajadhipok (Rama VII; reigned 1925–35). King Vajiravudh opened (1917) Thailand's first university, which was named after his father; in 1921 he made primary education compulsory. Vajiravudh strengthened the Thai army and navy and created a paramilitary organization, the Wild Tiger Corps, for civil servants. In 1917 he took Thailand into World War I on the side of the Allies, and at the end of the war the Thai won Western assent to new treaties eliminating unequal provisions. King Vajiravudh's major work, however, was the promotion of Thai nationalism; he is best known in Thailand today for a great volume of literary works, much of which stresses the need for the Thai people to be united, to be committed to their nation, religion, and king.

The most notable event during the reign of King Prajadhipok was a coup d'état that brought an end to absolute monarchy in Thailand in 1932. Prajadhipok did not have the inclination to rule that his elder brother and father had had, and he turned many affairs of state over to his royal relatives, who, believing that government expenses were excessive, embarked on a policy of economy. This policy, enlarged during the worldwide depression of the 1930s, adversely affected many government officials, civil and military, and contributed to the disaffection of younger members of the ruling elite.

Thailand since 1932. The coup d'état of 1932 was the work of several discontented elements of the educated ruling class who acted from a variety of motives: unhappiness with Prajadhipok's retrenchment policies, with the domination of government by members of the royal family, with disappointment of personal hopes for position and power, with a monarchic institution that they considered anachronistic, and with the lack, as they saw it, of social and economic progress in Thailand. The intellectuals of the coup, led by a young lawyer, Pridi Phanomyong, made plans for a democratic regime that would enact far-reaching social and economic reforms.

The coup
of 1932

On June 24, 1932, the rebels (the People's Party), without bloodshed, seized control of the army, imprisoned the royal officials, and won the King's acceptance of a constitutional regime.

The disparate elements that composed the coup party soon broke up into factions in the new government: conservative military leaders, on the one hand, and more radical civilians, on the other. When it appeared that the newly appointed parliamentary Assembly, composed of coup members, would accept a socialist economic plan presented by the civilian leader Pridi Phanomyong, the King dissolved it. Fearing that the King would regain control of the government, the military leaders forced the reconstitution of the Assembly. This was followed by an attempted royalist counter coup. By the end of 1933, the government was clearly under the control of the military leaders, and for the most part it has remained so ever since. In 1939 a declaration was issued naming the country Thailand, not Siam.

In 1939 Field Marshal Pibul Songgram became premier and embarked on a strongly nationalistic policy that was chauvinist at home, irredentist and pro-Japanese abroad. Thailand's leaders, whose policy was always to promote Thai independence, appreciated the fact that the country was small and defenseless against a big power. In the 19th and early 20th centuries, when the major power was Britain, the Thai government had been pro-British; in 1941, with Japanese armies at the Cambodian border, the Thai government saw no alternative but to become an ally of Japan.

In 1945 civilian governments headed or supported by Pridi Phanomyong came to power, favoured by the Allied Powers. Problems created by the war, corruption, and the death by gunshot in 1946 of the young king Ananda Mahidol (Rama VIII), who had succeeded Prajadhipok after his abdication in 1935, faced the government, and late in 1947 the army, sensing that Allied interest in Thai internal affairs had declined, removed the civilian government, accusing its leaders of regicide. Pibul Songgram again became premier in 1948.

During the 1950s and '60s, military dominance re-

Sarit as
premier

mained unchanged. For nine years Pibul played the role of arbiter between competing factions, but by 1957 the army faction led by Sarit Thanarat had gained pre-dominance of power and seized control of the government. Sarit became premier in 1958, and, to emphasize his intention of ruling without interference, he abolished the constitution and dispensed with the formality of elections. After Sarit's death in 1963, his successor as commander in chief, Thanom Kittikachorn, assumed the premiership. In 1968 a new constitution was inaugurated, and in 1969 a partly elected National Assembly was re-constituted. Both constitution and assembly were suspended in late 1971.

The autocratic military-dominated regime faced mounting problems in the early 1970s. Internally, while the economy continued to expand, social and regional imbalances grew more marked; externally, American withdrawal from Vietnam stimulated criticism of a long-standing policy of reliance upon the United States. Discontent exploded in late 1973, led by an organized student protest movement. On October 14, in a clash with military units, some 100 student marchers were killed. The discredited government lost army support. King Bhumibol Adulyadej (younger brother of King Ananda and king from 1946) dismissed the government leaders, three of whom fled the country, and launched a process that led to the inauguration of an elected civilian government.

Democratic government lasted three years. In those years censorship of communications media was lifted, trade unionism expanded, and government attempted some programs of economic amelioration. But no national consensus emerged. Polarization of society was evidenced in a plenitude of competing political parties, protest movements, strikes, and virulent leftist and rightist propaganda.

The return of former Premier Thanom late in 1976 set off new student protests and clashes and opened the way on October 6 for the military forces to suppress the students, dismiss the civilian government, and resume power. In November 1977 Supreme Commander Kriangsak Chamanand became premier, promising peace and order, internal reforms, and regularization of relations with Communist neighbours. Parliamentary elections took place in April 1979 under a constitution providing for limited democracy.

BIBLIOGRAPHY. General histories include: WAR WOOD, *A History of Siam*, 2nd ed. (1933), essentially a chronicle of reigns; and CHULA CHAKRABONGSE, *Lords of Life* (1960), a sympathetic account stressing the Bangkok period. A general account of the Chinese minority is G.W. SKINNER, *Chinese Society in Thailand: An Analytical History* (1957). On the Ayutthaya period, see CHARNVIT KASETSIRI, *The Rise of Ayudhya: A History of Siam in the 14th and 15th Centuries* (1977); GEORGE V. SMITH, *The Dutch in Seventeenth-Century Thailand* (1977); and E.W. HUTCHINSON, *Adventurers in Siam in the Seventeenth Century* (1940). The early Bangkok period is discussed in KLAUS WENK, *The Restoration of Thailand Under Rama I, 1782-1809* (1968); WALTER F. VELLA, *Siam Under Rama III, 1824-1851* (1957); and AKIN RABIBHADANA, *The Organization of Thai Society in the Early Bangkok Period, 1782-1873* (1969). Sibelius, Jean

Occupying a special position not only in the music of Finland and Scandinavia but in the development of the symphony, Jean Sibelius possessed the most powerful musical personality to have emerged in any of the Scandinavian countries, and his seven symphonies show an exceptional mastery of form. Two themes run through his art: an overpowering love of nature and of the northern

Sibelius, photograph by Karsh, 1949.

© Karsh

landscape, and a preoccupation with myth, in particular the mythology enshrined in the Finnish national epic, the *Kalevala*.

Born in Hämeenlinna, Finland, on December 8, 1865, Sibelius early showed a talent both for the violin and for composition. After studying in Helsinki, he went abroad to Berlin in 1889 and to Vienna the following year. The first performance of his *Kullervo* Symphony, Opus 7 (completed, 1892), established him as the leading Finnish composer of his generation, a position consolidated by the *Four Legends*, Opus 22 (one of which is the famous "Swan of Tuonela"), and by patriotic works such as *Karelia*, Opus 11, and *Finlandia*, Opus 26, all written during the 1890s. A measure of his success is the fact that the Finnish Senate voted him a small life pension in 1897, before he had composed his Symphony No. 1 in E Minor, Opus 39 (1899). The 1890s show him developing as a nationalist composer, working within the Romantic musical tradition and responding positively to the influence of Tchaikovsky. After the Symphony No. 2 in D Major, Opus 43 (1901), and the Violin Concerto in D Minor, Opus 47 (1903, revised in 1905), there is an undoubted change in his style prompted by discontent with the musical language of post-Romanticism and the development of a stronger sense of classical discipline. The year 1900 marked the beginning of his international career. Championed by conductors, such as his countryman Robert Kajanus, and by several noted European musicians of the day, as well as by such important critics as Rosa Newmarch and Ernest Newman, Sibelius' music gradually won acceptance abroad.

Early
Romantic
works

He made numerous visits to the rest of Europe before World War I and also went in 1914 to the United States, for which country he had written *The Oceanides* (*Aallotarret*), Opus 73 (1914), one of his masterly tone poems. Earlier, in 1909, he was operated on for throat cancer; this experience may account for the greater austerity and depth of the Symphony No. 4 in A Minor, Opus 63 (1911), as well as for the seriousness and concentration of his other music of this period, *The Bard*, Opus 64 (1913), and *Luonnotar*, Opus 70 (1913). During World War I he wrote many lighter instrumental pieces in the hope of repeating the enormous success of *Valse triste*, Opus 44 (1903), the rights to which he had sold outright and which had made his publishers a fortune.

His career during the years up to 1926 is a record of ceaseless creative activity, but after the Symphony No. 7 in C Major, Opus 105 (1924), *Tapiolu*, Opus 112 (1925), and *The Tempest*, Opus 109 (1926), he virtually ceased composing, though promises of an eighth symphony were made to Serge Koussevitzky, Sir Thomas Beecham, and other major conductors. In the 1930s Sibelius' popularity soared to unprecedented heights in England, and the great claims made on his behalf by British musicologist Cecil Gray and other critics doubtless had an

inhibiting effect on a composer who was highly self-critical and given to self-doubt. He lived in quiet retirement until his death from a cerebral hemorrhage at the age of 91, on September 20, 1957, at his home in Jarvenpää.

Personality As a man Sibelius was far more complex than has been generally supposed, and, although his life was outwardly uneventful, he lived it to the full. He was sensitive to criticism, and his keen self-criticism was responsible for the suppression of the early quartet and the *Kullervo Synzphony* as well as the destruction of the *Symphony No. 8*, which he had certainly completed by 1929. He was generous by nature and scarcely recorded an unkind word about his contemporaries. His practical circumstances were not comfortable until the 1920s, although he loved travel almost as much as he did his native Finland and had a love of good wine and cigars.

Each of his symphonies is totally fresh in its approach to structure: one cannot distill from the earlier symphonies any set of rules that can be applied to his later works. It was equally difficult to foresee, from the vantage point of one symphony, the character of the next. The heroism of the *Symphony No. 5 in E Flat Major*, Opus 82 (1915, revised 1916, 1919), is far removed from the quietism of the *Symphony No. 6 in D Minor*, Opus 104 (1923), while the *Seventh Symphony*, a one-movement structure of remarkable unity, seems to explore the epic world of man pitting himself against nature. All show a seemingly infinite capacity for evolving new material from simple germinal ideas.

Sibelius' contributions to the development of the symphonic poem are no less significant. They reveal a power to encompass the imaginative world of Finnish mythology within the strongest formal framework. *Pohjola's Daughter*, Opus 49 (1906), is as perfect an example of the narrative tone poem as any of those written by his German contemporary Richard Strauss, yet it is totally satisfying as pure music to the listener ignorant of its program. *Tapiola* is, however, his most original and awe-inspiring tone poem, for it is here that his vision is most intense. Sibelius, like Hector Berlioz in 19th-century France or Gustav Mahler somewhat later in Austria, was one of the great masters of the orchestra: each line seems conceived directly in terms of the instrumental timbre (tone colour) in which it is cast. So personal is his idiom in *Tapiola* that it is not susceptible of imitation. Sibelius composed prolifically in the smaller orchestral forms, though with varying degrees of success. His incidental music to his contemporary Maurice Maeterlinck's Symbolist drama *Pelléas et Mélisande* or to Shakespeare's *The Tempest* shows with what skill he could communicate atmosphere with so few strokes and the minimum of orchestral means. He composed about 100 songs, mostly to Swedish texts, some of great lyrical power. Though he wrote a great deal of chamber music in his youth, he composed only one quartet in maturity, *Voces intima*, Opus 56 (1909), a work that reaffirms the depth of his classical sympathies as much as it demonstrates his mastery of the medium.

MAJOR WORKS

Orchestral music

SYMPHONIES: Eight symphonies; *Kullervo Symphony*, Op. 7 (1892); *No. 1 in E Minor*, op. 39 (completed, 1899); *No. 2 in D Major*, op. 43 (1901); *No. 3 in C Major*, op. 52 (1907); *No. 4 in A Minor*, op. 63 (1911); *No. 5 in E Flat Major*, op. 82 (1915, rev. 1916, 1919); *No. 6 in D Minor*, op. 104 (1923); *No. 7 in C Major*, op. 105 (1924); *No. 8* (destroyed).

SYMPHONIC TONE POEMS: *En Saga*, op. 9 (1892); "The Swan of Tuonela," No. 3 of *Four Legends*, op. 22 (1893); *Finlandia*, op. 26 (1899, rev. 1900); *Pohjola's Daughter*, op. 49 (1906); *The Bard*, op. 64 (1913); *Tapiola*, op. 112 (1925).

INCIDENTAL MUSIC: *Pelléas et Mélisande*, op. 46 (1905); *The Tempest*, op. 109 (1926).

CONCERTOS: *Violin Concerto in D Minor*, op. 47 (1903, rev. 1905).

Chamber music

String quartet in D Minor (Voces intima), op. 56 (1909); various works for violin and piano.

Piano music

Various sets of *Pieces*; *Sonata in F Major*, op. 12 (1893).

Vocal music

Luonnotar, tone poem for soprano and orchestra, op. 70 (1913); about 100 songs, including *Höstkväll (Autumn Evening)*, op. 38, no. 1, 1903; *Svarta Rosor (Black Roses)*, op. 36, no. 1, 1899; *Våren flyktar hastigt (Spring Flies Speedily)*, op. 13, no. 4, 1891; *Var det en dröm? (Was It a Dream?)*, op. 37, no. 4, 1902; *Flickan kom ifrån sin älskings mote (The Maid Came from Her Lover's Tryst)*, op. 37, no. 5, 1901).

BIBLIOGRAPHY. L. SOLANTERA (comp.), *The Works of Jean Sibelius* (1955); and F. BLUM, *Jean Sibelius: An International Bibliography on the Occasion of the Centennial Celebrations (1965)*, are two bibliographies on the composer. Considerable information may also be found in the Sibelius-museum, Turku, and in the Sibelius family archives. ERIK TAWASTSTJERNA, *Sibelius* (1968), is the first of three volumes (in Finnish, soon to be translated into English) based on hitherto unpublished material, correspondence, and diaries; it is likely to remain the definitive study of the composer. See also KARL EKMÄN, *Jean Sibelius, en konstnärns liv och personlighet* (1935; Eng. trans., *Jean Sibelius: The Life and Personality of an Artist*, 1935; and *Jean Sibelius: His Life and Personality*, 1936), the first comprehensive study of the composer by a Finn; CECIL GRAY, *Sibelius: The Symphonies (1931)*, the most influential study of Sibelius in the 1930s and 1940s; ROBERT LAYTON, *Sibelius (1965)*, a succinct biographical and critical study; SIMON PARMET, *Sibelius symfonier* (1955; Eng. trans., *The Symphonies of Sibelius*, 1959), a study written from a conductor's standpoint; and GERALD ABRAHAM (ed.), *Sibelius: A Symposium (1947)*, predominantly critical and unfailingly illuminating.

(R.Lay.)

Siberian Cultures

Siberia is an immense land area running from the Urals on the west to the Sea of Japan and the Pacific on the east, and from the steppes of Kazakhstan and Outer Mongolia on the south to the Arctic Ocean on the north. It presents a variety of climates and natural habitats but falls into three major zones: a fringe of arid or semi-arid steppe on the south; a wide forested belt in the middle; and, along the northern edge, a band of tundra subject to permafrost and with numerous tidal rivers and lakes.

PEOPLES AND LANGUAGES

Before the large-scale influx of Europeans in the mid-17th century, Siberia was inhabited by a large number of ethnic groups, most of them very small. The culture of these peoples was adapted to the natural and climatic conditions of the three zones mentioned above. In the south were pastoral nomads with herds of sheep and horses. In the forest areas lived hunters and gatherers of wild foods. Most of the latter groups kept some reindeer of a large and sturdy breed for purposes of transport and occasionally milked them but consumed them as food only in case of absolute necessity. The nomads of the northern tundra kept fairly large herds of domestic reindeer, which provided them with their principal means of sustenance and which they drove along fixed routes according to the season. Other parts of the tundra were inhabited by still more primitive nomadic groups who hunted wild reindeer and fished. Finally, the shores of the Arctic Ocean and of the Sea of Okhotsk were settled by groups of maritime hunters living off whales, walrus, and seals.

Agriculture was unknown in Siberia until the beginning of massive Russian colonization in the mid-17th century, and it is even now possible only on the West Siberian plain (Omskaya, Tomskaya, Kemerovskaya, and Novosibirskaya oblasti [regions]) as well as in a relatively few favoured locations in other places—the Khabarovsk and Primorsky (Maritime) kraya (territories), for example. Animal husbandry—dairy farming, beef cattle, and the raising of the Siberian stag, or maral, for meat—is more widely distributed. The Yakut, who are the largest indigenous ethnic group, are raisers of cattle and horses; they represent an incursion of Central Asian pastoral nomads into the northern Siberian environment.

The indigenous population of Siberia before the coming of Europeans was divided into a large number of usually small ethnic groups, the boundaries between which shift-

ed over time and were often arbitrary. The important social unit under Siberian conditions was probably not the tribe but the clan. Instances are known in which members of the same clan belonged to two or even three different tribes but considered themselves bound to each other by clan obligations in respect of marriage and mutual aid. The Siberian ethnic groups belong to a number of different linguistic stocks, the most important of which are: Turkic (Yakut, Siberian Tatars, and a number of small groups along the southern fringe); Tunguso-Manchurian (the numerous and widely scattered groups of Tungus [Evenki] and Evens [Lamuts]); Finno-Ugric (Khanty [Ostyaks], Mansi [Voguls]); Mongolic (Buryats); and the so-called Paleosiberian family (Koryaki, Yukaghirs, Gilyaki [Nivkhi], and some others) consisting of a number of languages that do not fit elsewhere but whose interrelationship has yet to be demonstrated. The shifting and fluid nature of ethnic boundaries resulted in parts of one tribe often engaging in types of economic activity and assuming other cultural patterns characteristic of another tribe. Hence the older ethnographic sources frequently speak of "Yukaghirized Tungus" or the like. Such assimilated groups often acquired a different name from either the main body of their former tribe or from the one to which they were assimilated.

CULTURAL PATTERNS

Social organization. Except for the Yakut, who are considered by Soviet scholars to have been in a stage of incipient feudalism at the time of the first intensive European contact, the Siberian peoples were without exception small, extremely primitive, and loosely organized. The major organizational unit over large parts of the year was the camp group, similar in constitution to the horde among the Australian Aborigines in that it consisted of a core of members of one descent group, with the addition of women from other groups and some male hangers-on. The overall kinship pattern was patrilineal, but Russian and Soviet scholars have identified numerous phenomena that, in their opinion, show the previous existence of a matrilineal pattern. These phenomena include not only the kinship terminology itself but also important elements in the religion, such as the fact that the shaman wore modified female dress and had in certain respects a hermaphrodite personality. The camp group cooperated in economic activity on a regular basis and controlled the important economic resources. The concept of private property in the Western sense was lacking, except among the Yakut and in regard to domestic reindeer.

Social stratification was rudimentary, with one significant exception. For administrative convenience, the Russian authorities appointed certain members of the local ethnic groups to represent these groups in dealings with the Russians. These individuals, referred to in the Russian sources as "princelings," gained opportunities for enrichment and came to form a kind of incipient nobility. In addition, Soviet scholars point to the existence, just prior to the Revolution, of individuals who controlled large herds of reindeer and who could call upon the services of their poorer fellow clansmen—that is, people who were on their way to becoming feudal lords. It is difficult to determine from the sources whether this development was the result of a natural evolution or was due entirely to Russian contact.

As among primitive peoples, the nuclear family (parents and children) among the Siberian tribes was not clearly separated out in its economic and child-rearing functions from the larger kin group. Children were introduced early to economic activities and were taught the basic skills by older relatives. The same skills were also inculcated by special games and contests, some of which are still being used for the same purposes. Such games were a common feature of the rites of passage for both boys and girls. The professions of shaman and blacksmith, which were the only separate professions among most Siberian groups, were acquired by apprenticeship to older practitioners, but these professions called in addition for evidence of special aptitude and election on the part of the apprentice.

Technology and economy. The technology and applied art of the Siberian peoples relied heavily on such materials as horn, mammoth ivory, wood, and the skins of birds, mammals, and fish. The latter were processed in various ways and either tailored into garments or used whole as containers. Iron was obtained by trade with groups close to the sources of supply in the south, or with the Russians. The smelting of iron from ore was unknown, but some groups used a small portable forge to produce such items as smoking pipes (from old gun barrels), stands for storing women's jewelry, and various pieces of harness. The standard weapons before the introduction of firearms were the bow and arrow and barbed spear with a head of mammoth or walrus ivory. The bow in common use was compound, since the wood available was not in sufficiently large pieces to permit the making of a simple bow. Fire was made by the bow-drill method, in which a shaft was spun in a socket by means of tightly wound cords, friction igniting the tinder. In addition to the skin containers mentioned above, many Siberian groups made vessels of wood or birch bark decorated with natural colouring in intricate patterns. Pots for cooking were made of metal and were bought from the Russians. The same was true of small griddles, which were used for preparing unflavoured pancakes of wheat flour; these were considered a delicacy. Clothing was made of cured skins with or without the fur and was elaborately decorated. In certain areas capes and boots were made from fishskin, processed so as to be waterproof. Skins were also used to cover boats and to make bags for clothing and small pieces of equipment.

Aboriginal hunting methods included the use of nets made out of rawhide strips in which reindeer became tangled, to be dispatched with spears. Another favourite device of the reindeer hunter was a movable blind behind which a hunter on skis concealed himself, shooting through a small hole. Nets of rawhide, gut, or string were used for fishing, along with hooks and lines similar to those used by the European peoples.

Means of transport were adapted to the tundra or forest environments: sleds drawn by dog teams, with runners of walrus ivory or metal, sleighs drawn by reindeer, skis, snowshoes, and riding reindeer. In the summer, boats, either of birch bark or covered with skins, were important.

Dwellings were generally portable and made of poles and skins, or (among the more southerly groups) of poles covered with brush and a layer of sod. These latter dwellings were of semi-dugout form. A distinctive type of house was the *balagan*, constructed on runners and moved by means of reindeer. Finally, the maritime sea mammal hunters had more or less permanent dwellings the structures of which were supported on the rib bones of whales. Such houses are very ancient, going back to Paleolithic times.

With the gradual exploration and conquest of Siberian territory by the Russians, various changes took place in the economy of the native peoples. The introduction of firearms, steel spring traps, metal utensils, and the like, led to more efficient hunting and fishing technology. The native peoples were drawn into the ambit of the fur trade and were subject to a special tax, first in furs and later in money. The effect of European contact at this stage, however, was limited and did not affect the basis of the subsistence economy. Other than hunting equipment and supplies needed for the fur trade, only luxury goods—vodka, tobacco, cloth, salt, sugar, tea, and flour in very small quantities—reached the native inhabitants through the trade network.

Religious belief and practice. The religious system of the Siberian peoples was firmly anchored to their subsistence activities. The central figure of their religious life, at least as far as the society as a whole was concerned, was the shaman, who acted as intermediary between the natural and supernatural worlds. The shaman was at once a physician, a counsellor of the community in regard to subsistence activities, and a defender of it by magical means against the attacks of other groups. The shamanistic ritual was embellished with the full skills of the sha-

Kinship
patterns

Types of
dwellings

man in poetry, song, ventriloquism, and magic. The ritual took the form of a dramatic representation of the shaman's journey to the world of the spirits and his return.

The mythical world of the Siberian peoples was conceived of as being on three levels, which were connected either by a "world tree" or by a river, or both (the parallel with ancient Norse mythology is striking). The position of shaman was acquired through a "call," usually during adolescence, that was manifested through a peculiar illness from which the victim could only recover by agreeing to assume the role of shaman. Certain characteristics of a shaman—his hermaphrodite personality, for example, and the fact that he was thought to have organs other than the natural ones implanted in his body—have close parallels among other primitive peoples in widely scattered parts of the world and even in the residual religious phenomena found in more complex societies.

Besides the rites and ceremonies performed by the shaman on behalf of the group at large or of individuals, there were also private ceremonies conducted by individuals in connection with hunting and fishing activities or with important milestones in personal life. On such occasions, the shaman was often not present—perhaps because his participation would have involved an additional expense.

Artistic expression. The folklore of the Siberian peoples includes an origin myth, shamanistic songs, proverbs, and some rudimentary epics. Many groups have a rich tradition of graphic art, in terms both of sculpture in the round and incised drawing on mammoth or walrus ivory. The assortment of musical instruments is meagre: besides the drum (or more accurately tambourine) used by the shaman and as an accompaniment for dancing, there are only a small jew's harp of wood and metal and a few bone and reed pipes. Some of the Far Eastern peoples have primitive stringed instruments, the idea of which was apparently borrowed from the Chinese people.

Russian cultural influence (apart from the mere availability of Western trade goods) was present in various places but was neither universal nor profound. On the southern fringes of the Siberian area—on the Altai upland and in the vicinity of Lake Baikal—there were considerable settlements of Russian peasants, and the native population had begun to acquire agricultural skills. Certain groups—some of them, like the Yakut, fairly large—had been nominally Christianized, and a few individuals attended schools sponsored by the Russian Orthodox Church. Western medicine was available in a few places, but the mortality rate remained extremely high, especially among children. A factor the importance of which was certainly considerable was the tsarist government's policy of exiling political dissidents to remote areas. This affected the type of Russians with whom the native population in many places came into contact. In addition, there were long-established Russian peasant societies in certain parts of Siberia, in many cases the descendants of exiled religious dissidents. Such people, known as Sibiriyaks or "local Russians," have a culture and an outlook differing markedly from those of the people of European Russia. Physical and cultural hybridization with the native population has given rise to a wide range of intermediate groups, some of which still retain their own ethnic identity.

THE SIBERIAN PEOPLES TODAY

After the Revolution of 1917, the Soviet government adopted in principle the goal of comprehensive economic and social development of the Siberian area. Approximately the first 15 years subsequent to the Revolution were devoted chiefly to exploration and planning, and the area was exempted from the requirements of the first five-year plan for the development of the Soviet national economy. Considerable progress was made in education and public health, but these measures were of limited effectiveness among the peoples whose way of life had been and remained nomadic. Institutions such as the Northern Division of the Leningrad Institute of Living

Eastern Languages (established in 1926 and later transformed into the Institute of the Peoples of the North), however, performed an important function, despite the very small numbers of persons involved, in training the first professional cadres of physicians, paramedical workers, and teachers for the northern peoples.

During the 1920s and early 1930s, the languages of a number of small Siberian peoples were reduced to writing for the first time, and elementary school books were published in these languages. In connection with this and other practical tasks, a considerable amount of ethnographic research was undertaken. The publication of books in the languages of some very small groups, and instruction in these languages in the elementary schools, were later abandoned as being uneconomical, or as working counter to the general policy goal of integration of the population of the Soviet Union into a single and unified whole.

Until the end of World War II, however, the basic economic patterns of Siberian native life remained largely unchanged. Collectivization of the hunting, fishing, and reindeer economies (agriculture had been collectivized in the rest of the country during the early 1930s) was hardly even attempted until the end of World War II in most areas, or until the early 1950s in the more remote places. Small cooperative production units of a traditional type, using the native technology and often based on kinship groups, had existed up to that time but represented no sharp break with the pre-Revolutionary situation.

The Soviet policy and practice with regard to the peoples of the Siberian North represent a unique experiment in the integration of small, primitive, formerly tribal groups into a complex modern industrial state. The severity of the climate and the former backwardness of the people, both in a social and a technological sense, are such stubborn factors in the story of cultural change that no serious student of the Soviet Union can fail to admire what has been achieved, notwithstanding serious shortcomings in the planning and implementation of government policy.

In surveying the present situation, a few statistics are in order. According to 1970 census data, there are 151,000 indigenous peoples of the North, Siberia, and the Far East (as against 130,000 in 1959). Native language may be used as an index of ethnic affiliation: in 1970, 67.4 percent of these peoples considered the language of their nationality to be their native language (75.9 percent in 1959). In addition, 52.5 percent were fluent in Russian, and 7.1 percent were fluent in the language of another nationality. There are 26 ethnic groups, all increasing in size, a change from the pre-Revolutionary situation in which most were dying out. There has been a consistent attempt throughout the Soviet period to foster ethnic awareness among the Siberian peoples, even, in some cases, when the awareness had to be created. "National in form, socialist in content" was the slogan created by Soviet premier Joseph Stalin to describe the kind of culture the regime thought appropriate for the Soviet system, and even though Stalin has been discredited, the idea still remains.

Particularly since World War II, the Siberian peoples have been developing under conditions of unprecedented industrialization, almost all of it with labour and tools imported from European Russia. The total population of the Soviet North has risen to 3,000,000. Well into the 1960s, however, the small peoples of the North were predominantly rural, and even urban residency was likely to mean that the family had moved into a large fishing cooperative, or that many young people were away attending school, where for the most part they became doctors, teachers, and cultural or government workers. In some instances the large-scale influx of Europeans has irreparably damaged the traditional way of life of the Siberian peoples, not least because educated young people are unwilling and often physically unable by training or capacities to carry on the occupations of their forefathers. Technological means exist by which reindeer can be herded and waters fished more easily, but the skill to operate and maintain the equipment must be acquired,

affiliation

not, as previously, within the family group but in schools of a radically different type. Change of this type has been slow in coming to the North but will increase in proportion to capital investment in the area.

Soviet policy for the peoples of the Siberian North, particularly with respect to education, faces a dilemma that in the long run is inescapable. This dilemma can be baldly stated as follows: to dismantle the traditional economy, turn the small peoples into an industrial labour force, and supply the North completely from the outside; or to develop the traditional economy and pursue the industrialization of the North exclusively with an imported labour force. No clear choice has yet been made between these two alternatives, and the result is that the educational system is ill-adapted to either one. It goes without saying that if the first alternative is chosen, there will soon be little left of the traditional culture of the small Siberian peoples, and the slogans that have been prevalent up to now will lose their meaning.

Which elements of native Siberian culture can be expected to survive industrialization, urbanization, and the changes in status which accompany them? Certain aspects of material culture will certainly persist for many years to come—native clothing, for example, which is warmer than present synthetics and more readily available. Kinship ties will continue to be important, although the increasing number of mixed marriages may alter the traditional patterns. Other elements of the native culture will have to be nurtured, perhaps artificially. In 1970, for example, there was the premiere of the first Kamchadal (Itelmen) ballet, *Emem Kutkh*, based on a Kamchadal legend of a battle between good and evil and staged in Petropavlovsk-Kamchatsky; the ballet was subsequently sent on tour to the Mongolian People's Republic. The Kamchatka Kamchadals numbered 1,300 by the 1970 census. It should be noted that aside from the ballet's value as an example of Soviet cultural policy, the theme itself is universal enough to appeal to a wide variety of people. Ideally, the unique culture of the Siberian peoples will not be lost but will blend with and enrich Soviet culture as a whole.

BIBLIOGRAPHY. Detailed discussions of Soviet development policy in the Far North, its ethnographic background, and sociological effects may be found in STEPHEN P. and ETHEL DUNN, "The Transformation of Economy and Culture in the Soviet North," *Arctic Anthropology*, 1:1-28 (1963); ETHEL DUNN, "Educating the Small Peoples of the Soviet North: Further Thoughts on the Limits of Culture Change," and "Education and the Native Intelligentsia in the Soviet North: The Limits of Culture Change," *ibid.*, 5:1-31 (1968), *ibid.*, 6:112-122 (1970). TERENCE ARMSTRONG, *Russian Settlement in the North* (1965) and "The Administration of Northern Peoples: The USSR," in RONALD ST. J. MACDONALD (ed.), *The Arctic Frontier*, pp. 57-88 (1966), are historical and political studies by a Canadian scholar, one of the few Westerners dealing with technological development in the Soviet North; V. IANOVSKII, "Man in the North," *Soviet Sociology*, 7:16-26 (1969), gives interesting impressions of "the northern experience" by a prominent Soviet journalist. I.S. GURVICH, "Directions to be Taken in the Further Reorganization of the Economy and Culture of the Peoples of the North," *Soviet Anthropology and Archeology*, 1:22-30 (1962), provides an interesting and important discussion of technical problems and limitations of culture change for northern peoples. V. DIOSZEGI (ed.), *Glaubenswelt und Folklore der sibirischen Völker* (1963; Eng. trans., *Popular Beliefs and Folklore Tradition in Siberia*, 1968), gives interesting data on traditional Siberian ethnography, especially religion and magic, in relation to similar phenomena among other peoples. M.G. LEVIN and L.P. POTAPOV (eds.), *The Peoples of Siberia* (1964; orig. pub. in Russian, 1956), is a semi-popular Soviet book providing detailed information on traditional Siberian culture and economy, with brief sections on modern conditions. W. BOGORAZ, *The Eskimo of Siberia* (1913) and *The Chukchee*, 3 pt. (1904-09), are classic ethnographies of small Siberian groups, reflecting mainly the situation before intensive Russian contact. H.N. MICHAEL (ed.), *Studies in Siberian Shamanism* (1963), contains translations from Soviet literature and gives data on traditional Siberian ethnography, particularly religion and magic, in

relation to similar phenomena occurring among various other peoples.

(S.P.D./E.D.D.)

Sicily

The largest and one of the most densely populated islands in the Mediterranean Sea, Sicily (with several small adjacent islands) is an autonomous region of Italy. Its northern shore, site of the capital, Palermo, is lapped by the Tyrrhenian Sea; to the east it looks across the narrow Strait of Messina to the toe of the Italian peninsula; and it lies about 100 miles (160 kilometres) northeast of Tunisia, in North Africa. The 9,830 square miles (25,460 square kilometres), 9,927 square miles (25,710 square kilometres) with adjacent islands, of Sicily (Italian Sicilia) held a population of 4,582,000 in 1971.

Sicily's strategic location at the centre of the Mediterranean has made the island a turbulent crossroads of history, a pawn of conquest and empire, and a melting pot for a dozen or more ethnic groups whose warriors or merchants sought its shores virtually since the dawn of recorded history. The island and its people have lived much by the sea, flourishing when the Mediterranean traffic was intense and stagnating when it waned. Only a few days' sailing time from the ancient civilizations of Greece and the Aegean, Sicily was at times the major western outpost of the high culture of those regions. Its land also lies open to climatic influences from all directions. In spite of these many forces that so often have reshaped its political and social life and of the economic depression that continues to plague it, Sicily has been able to establish one of the most distinct identities among the Italian regions, a distinctiveness that is guarded jealously by its inhabitants. (For information on related topics, see the articles ITALY; ITALY AND SICILY, HISTORY OF; and MEDITERRANEAN SEA.)

The natural and human landscape. *Surface features.* The landscape of Sicily is mainly one of mountains, sometimes reaching almost to the coasts, and of irregular coastal plains on which all the main cities are located. The present topography is the result of the fact that the rocks erode easily in a climate marked by intense exposure to the sun, persistent drought during the long summers, and the sea winds.

The mountains are continuations of the Apennines of the Italian peninsula and the Atlas Mountains of northwestern Africa, which are parts of the discontinuous Alpine-Himalayan mountain belt circling much of the Earth from Asia to southern Europe and northern Africa. In northeastern Sicily the Peloritani chain rises suddenly from the Strait of Messina and continues the landscape of the Calabrian Apennines of the mainland, though without the typical high plateaus. The higher reaches have little or no vegetation and are deeply scarred by currents that, at lower altitudes, produce frequent flash floods and sweep away both rubble and fertile sediments. Forests of chestnut, beech, or Mediterranean scrub climb above the cultivated lower slopes. Maximum altitudes are about 4,300 feet (1,300 metres).

The Nebrodi and Le Madonie chains to the west are higher, reaching 5,900 and 6,600 feet, respectively. The forms are similar, though in Le Madonie they tend to be stark, standing out like great limestone massifs or peninsulas. Le Madonie is known for its underground drainage, which provides water to Palermo. Inland, the mountains gradually diminish in height toward the south, with great expanses of virtual tableland known for its sulphurous, desolate conditions; grasses and twisted olive trees dominate the landscape. The Iblei chain in the southeast is of volcanic origin and presents a refreshing scene of brightly coloured vegetation.

To the northeast of this chain, the great mass of Mt. Etna rises to 10,703 feet (3,263 metres), the highest point in Sicily which is a region of strong seismic activity. One of the world's most active volcanoes and the biggest in Europe, Mt. Etna covers half the province of Catania and rises above the provincial capital of that name. It is thought that this massive mountain was gradually built by extruded volcanic debris from beneath the sea to its present height. Luxuriant wild and cultivated trees and

Mt. Etna

shrubs cover its sides wherever a cover of decomposed debris occurs. Underground water and springs are plentiful for the many vineyards and citrus orchards of the region.

Climate. Sicily's most notable climatic factors are its southern latitude, its insularity, its elevations decreasing from north to south, and the moderate atmospheric pressure characteristic of the Mediterranean. Latitude and the pattern of winds make it a sun-drenched island, and desert winds from Africa often scourge the southern and central regions during the May to October summers.

Summer temperatures often climb over 85° F (29° C), but the climate is even more influenced by the rainfall, which is irregular in quantity from year to year but regular in its uneven annual distribution, virtually all of it falling in late autumn and winter. Northwestern and central regions receive only about 25 inches (635 millimetres) a year; the south receives about 15 inches; Messina, in the northeast, receives about 39 inches. Much of the fall is lost through deforestation (less than 4 percent of the island is woodland) and the soil's resultant inability to hold the torrents from the mountains; and, though the amounts are similar to those on the Italian mainland at equivalent latitudes, the irregularity of the fall and its concentration in short downpours contributes significantly to the island's agricultural depression and rural poverty. Neither irrigation facilities nor discoveries of underground water have begun to counteract this natural blight.

Vegetation and animal life. Only on the higher slopes does the chestnut replace the laurel, perhaps the most characteristic Sicilian tree. Pines grow on Mt. Etna, on whose upper reaches grow the low, isolated shrubs and grasses of the Alpine zone. Of the cultivated plants, only the flowering ash is native; the olive, grape, almond, pomegranate, hazel, and other fruit and nut trees, however, date from antiquity. Arabs introduced the date palm and citrus trees, though the common orange is of 16th-century Chinese origin, and other species came a century later from the Americas. Of the few animal species, the invertebrates, birds, and fish outnumber mammals, though remains of vanished large mammals occasionally are encountered in caves. Overall, the animal population represents a transitional zone between Italy and Africa.

The people of Sicily. Ethnic composition. Sicily was already inhabited toward the end of the Pleistocene Epoch (more than 10,000 years ago), and throughout its history has received peoples of every coast on the Mediterranean. According to archaeologists, anthropologists, philologists, and historians, the peoples living there in the remotest times, the Sicani, were of Mediterranean origin. Some of the physical features of the present-day population may be traced to them: elongated heads, small stature, and dark pigmentation of the eyes and hair. Interbred with them were the Elimi, who left their mark mainly on the towns of Segesta, Erice, and Entella; they may have come in small numbers from neighbouring Africa.

Then the Siculi, a short-headed Eurasian people who spoke an Italic language akin to Latin, came down the peninsula from the central and eastern Alps; they seem to have infiltrated slowly and in small waves among these ancient Mediterranean peoples. The Siculi and Sicani seem to have formed the most homogeneous group of the island's population. But as early as the transition from the Bronze to the Iron Age, they appear to have been molested by Greek pirates, coinciding and in a sense competing with Etruscan pirates in the lower Tyrrhenian. Some pirate groups appear to have established themselves on the island, forcing the inhabitants to withdraw inland and fortify their new settlements. Later, between the 8th and 6th centuries BC, migrations from Greece seem to have been more frequent and of larger size. The new peoples—among them Ionians from Euboea and Samos, Aeolians and Achaeans from Boeotia, and Dorians from Corinth and other locations—had apparently left their homelands to settle on the island.

At more or less the same time, the Carthaginians, Semites from the North African coast, set up some of their trading posts along the western coast of Sicily. Some of the tyrants then welcomed exiles from the neighbouring continent and recruited labourers to cultivate the land and mercenaries to fight their battles from the Italian peninsula, Greece, Asia, and Africa. These new immigrants remained and merged with their predecessors, an example that was later followed by Romans, Vandals, Goths, and Byzantines, who came for reasons of war or conquest.

From Arabia, Egypt, Syria, and Mesopotamia came the

Diversity of ethnic stocks and physical types

Muslims, who took only 80 years to conquer Sicily, settling mainly in the northern regions, while the Berbers were more predominant in the south. Many Sicilian Christians converted to Islam. Around the year 1000 the Normans arrived and held the island for more than a century; then came the Swabians, who held it for three-quarters of a century. The tall stature, blond hair, blue eyes, and pink colouring of some present-day Sicilians may be traceable to them. The Aragonese also governed Sicily for more than a century.

Demography. The Sicilian population is the most urbanized of the provinces in southern Italy; yet it displays many characteristics of a rural population, a fact attributable primarily to a generally low standard of living. The greatest proportion live in the provinces of Palermo and Catania, and only a small fraction live outside the narrow coastal strip around the island. Migrants long have been driven from the interior not only by the barrenness but also by malaria and by the land-tenure system, *latifundium*, characterized by large estates ruling over great wheat-growing acreages. Contemporary statistics show marriages, live births, and infant mortality to be proportionately greater than throughout Italy as a whole, though overall death rates are lower. Births exceed deaths by about 13 percent.

The region's economy. Incomes. The per capita income of Sicilians is less than three-quarters of that for Italy as a whole. If only employed persons were accounted for, however, the disparity would be less, since, as in all poor regions, the number of dependents per employed worker is higher than in more affluent areas. Only the province of Syracuse approximates the national average, while Agrigento has less than one-half the average.

The tertiary sector of the economy—retailing and services—plus the civil service account for about one-half the island's income. Industry has gradually outstripped agriculture to contribute the greater proportion of the other one-half, especially in Palermo; only in Trapani and Agrigento is agricultural income greater. Much of this industry, moreover, is based on the processing of the products of farm, forest, fishery, and mine.

Components. Agriculture employs about one-quarter of the labour force, and some 95 percent of Sicily's land area is given over to it and to forestry. One-quarter of this is sown in wheat, which does not require great fertility. In ancient Rome, Sicily was known as one of the breadbaskets of the republic and empire. Citrus fruits (including nine-tenths of Italy's entire lemon production) and vegetables, however, provide the largest part of agricultural exports to the peninsula and abroad. Dams, flood- and erosion-control measures, and irrigation canals are among the major projects begun to assist the farmer, but much remains to be done.

Among the more promising aspects of industry, which

employs about one-third of all workers, have been the discoveries of petroleum and the building of refineries to complement the plants producing chemicals, pharmaceuticals, and synthetics. These are in addition to the small-scale food- and sulfur-processing plants and apparel manufacturing. Mineral production also includes limestone, asphalt, and salt.

Virtually all of Sicily's energy is generated in thermal plants; hydro potentiality is nil. The three main ports—Palermo, Catania, and Messina—have extensive shipping facilities and are interconnected by single-track railways. Main highways between cities are adequate, but secondary roads are poor. Many interior communities are reachable only by track.

Governmental involvement. Since World War II, the national government has given Sicily and other areas of southern Italy special funds to improve transportation facilities and other public works and to prepare them for industrial development. In its turn, the regional government took numerous steps to ease the location and capitalization of industry. Years of political instability and shortage of resources, however, have tended to impede even the legislated goals, and observers find it impossible to estimate when the generally backward economy of the region can be given a major stimulus.

Administration and social conditions. Structure of government. An Italian constitutional statute of 1948 made Sicily an autonomous region, divided into nine provinces with 379 communes. Government is parliamentary, with the president elected from among the members of the regional assembly. With the assembly's executive committee, he promulgates laws and may attend meetings of the Italian council of ministers and speak on Sicilian matters. He represents the federal government and is charged with maintaining order with the national police force. A Sicilian separatist movement won minority support after World War II, but faded in the 1950s.

The social milieu. Life in much of the interior remains at a primitive level, with inadequate water supplies and sanitation, and rampant disease. Unemployment is chronic everywhere, except around the developing petroleum-producing and petroleum-processing centres.

The regional government exercises complete control of primary education, but the illiteracy rate remains twice that of Italy as a whole. The universities in Palermo, Messina, and Catania are required to maintain national standards. The well-stocked civil service provides a well-organized system of social services that are generally of low calibre. Good housing and medical services, even in the cities, tend to be in short supply as well.

A peculiar feature of the separateness of Sicilian life from that of mainland Italy is the persistence of the Mafia, an organization dating from the Middle Ages that gradually evolved into a paralegal criminal brotherhood. It gives certain parts of the island virtually a dual government, standard of conduct, and system of enforcement—one is the legitimate regime and the other a shadow but a pervasive social, economic, and political network maintaining its powers through violence. In recent years it has tended to move away from the rural areas, in which it was spawned, to urban Sicily, in which through its traditional code of silence and frequently violent settlement of disputes it directs its activities at legitimate businesses through extortion and terror.

Cultural life. Sicily has made its contribution to Italian literature and art. The poets of the Sicilian school at the court of the emperor Frederick II were important in the development of Italian lyrical poetry in the vernacular early in the 13th century. The Byzantine and Norman architecture of the island with its splendid mosaic murals is celebrated. In the 15th century the great painter Antonella da Messina introduced the Flemish technique of oil painting to Italy.

In more recent times, in the realm of the "fine" arts, Palermo has its opera house and Catania its Bellini Theatre, named in honour of the island's major musical celebrity, the opera composer Vincenzo Bellini. In literature the influences of two Sicilians, the novelist Giovanni Verga and the playwright Luigi Pirandello, have pro-

foundly affected the shape of modern Italian literature and have had great influence far beyond the shores of the Mediterranean. In 1959 the Sicilian poet Salvatore Quasimodo was awarded the Nobel Prize for Literature.

Sicily has been called the cradle of the Italian popular song. Various kinds of song exist locally: love songs are the most numerous, followed by the work songs of such occupations as fishing (the *mattanza*, or tuna fishing song) and by the sung accompaniments to the many children's games. The songs of the beggars and the musical cries of the street vendors are still heard, though they, like much traditional culture, are disappearing under the homogenizing influence of radio and television and of modern life in general.

Sicily has strong traditions of folk art. The elaborately painted carts of the peasants, which are features of the provinces of Catania and Palermo, depict on their sideboards scenes of combat between the Christian knights and the Saracens. Though no extant carts predate the 19th century, their art may commemorate the era of Sicilian prosperity under the Norman kings and the themes of chivalric quest popular in the epic poetry of that time. Similar themes run through many of the puppet dramas, which remain popular on the island. Silver-smiths' and goldsmiths' work, to be seen especially in Palermo, and peasant filigree settings for gems are of the most intricate refinement, and Sicilian embroidery has an uninterrupted tradition many centuries old.

Popular religious festivals make up colourful occasions for the sun-bleached land. The processions of triumphal cars of the feasts celebrating St. Rosalia in Palermo, the Annunciation in Trapani, and St. Lucia in Syracuse, as well as the historical pageants featuring symbolic figures of Christians and Saracens and of Normans and Turks in combat to the accompaniment of fireworks and dancing, represent the gayer sides of Sicilian life.

BIBLIOGRAPHY. ALDO HECORA, *Sicilia* (1968), is an informative, general work. Geography and physical description may be found in OLINTO MARINELLI, *Sicilia* (1968); GUSTAVO CUMIN, *La Sicilia* (1944); and FRANCIS M. GURRO, *Sicily: The Garden of the Mediterranean, the Country and Its People*, 2nd ed. (1954). Land use and economics are covered in FERDINANDO MILONE, *Sicilia* (1960), on the interaction of nature and man; JOHN P. COLE, *Italy* (1964); VERA C. LUTZ, *Italy: A Study in Economic Development* (1962), with an acute understanding of the south; MARGARET CARLYLE, *The Awakening of Southern Italy* (1962); and NUNZIO PRESTIANNI, *L'economia agraria della Sicilia* (1946), which is technical but interesting. Sidney, Sir Philip

Sir Philip Sidney was admired as the ideal gentleman of his age in England, the complete Renaissance man: he was a master of social graces, an idealistic politician, a brave military leader, learned in the arts and sciences of his time, the best writer of English prose, and, after Edmund Spenser, the best English poet of his generation.

He was born at Penshurst, in Kent, on November 30, 1554, the eldest son of Sir Henry Sidney and his wife, Lady Mary Dudley, daughter of the Duke of Northumberland, and godson of King Philip II of Spain. After Elizabeth I succeeded to the throne, his father was appointed lord president of Wales (and later served three times as lord deputy of Ireland), while his uncle, Robert Dudley, was created earl of Leicester and became the Queen's most trusted adviser. In keeping with such a family background, the young Sidney was intended for a career as a statesman and soldier. At the age of ten he entered Shrewsbury School, where his classmate was Fulke Greville (later a court official under Elizabeth), who became his lifelong friend and was his early biographer. In February 1568 he began a three-year period of studies at Christ Church, Oxford, afterward travelling in

Europe, between May 1572 and June 1575, perfecting his knowledge of Latin, French, and Italian. He also gained firsthand knowledge of European politics and became acquainted with many of Europe's leading statesmen.

Sidney, detail of an oil painting by an unknown artist, 1576. In the Warwick Castle Collection.

His first court appointment came in the spring of 1576, when he succeeded his father as cupbearer to the Queen, a ceremonial position. Then in February 1577, when he was only 22, he was sent as ambassador to the German emperor Rudolf II and the elector Palatine Louis VI, carrying Queen Elizabeth's condolences on the deaths of their fathers. But along with this formal task, he also had secret instructions to sound out the German princes on their attitude toward the formation of a Protestant league—the chief political aim being to protect England by associating it with other Protestant states in Europe that would counterbalance the threatening power of Catholic Spain. Sidney apparently brought back enthusiastic reports on the possibilities of forming such a league; but the cautious Queen sent other emissaries to check on his reports, and they returned with less optimistic accounts of the German princes' reliability as allies. He did not receive another major official appointment until eight years later.

He, nevertheless, continued to busy himself in the politics and diplomacy of his country. In 1579 he wrote privately to the Queen advising her against a proposal that she enter into a marriage with the Duke of Anjou, the Roman Catholic heir to the French throne. Sidney, moreover, was a member of Parliament for Kent in 1581 and 1584–85. He corresponded with foreign statesmen and entertained important visitors—including the French Protestant envoy Philippe de Mornay in 1577, the German Calvinist Prince Casimir in 1578, the Portuguese pretender Dom Antônio in 1581, and later a number of Scottish lords. Sidney was among the few Englishmen of his time with any interest in the newly discovered Americas, and he supported maritime explorations by the navigator Sir Martin Frobisher. In 1582 Richard Hakluyt, who published accounts of English explorers' enterprises, dedicated his *Divers voyages, touching the discoverie of America* to him. Sidney later became interested in the project to colonize the American colony of Virginia, sent out by Sir Walter Raleigh, and he intended to set out himself in an expedition with Sir Francis Drake against the Spaniards. He had wide-ranging intellectual and artistic interests, discussed art with the painter Nicholas Hilliard and chemistry with the scientist John Dee, and was a great patron of scholars and men of letters. More than 40 works by English and European authors were dedicated to him—works of divinity, ancient and modern history, geography, military affairs, law, logic, medicine, poetry

Early career and writings

Artistic and intellectual interests

—indicating the breadth of his interests. Among the many poets and prose writers who sought his patronage were Edmund Spenser, Thomas Watson, Abraham Fraunce, and Thomas Lodge.

Sidney was an excellent horseman and became renowned for his participation in tournaments—elaborate entertainments, half athletic contest and half symbolic spectacle, that were a chief amusement of the court. He hankered after a life of heroic action, but his official activities were largely ceremonial—attending to the Queen at court and accompanying her on her progresses about the country. In January 1583 he was knighted, not because of any outstanding accomplishment but in order to give him the qualifications needed to stand in for his friend Prince Casimir, who was to receive the honour of admittance to the Order of the Garter but was unable to attend the ceremony. In September he married Frances, daughter of Queen Elizabeth's secretary of state, Sir Francis Walsingham. They had one daughter, Elizabeth.

Because the Queen would not give him an important post, he had turned to literature as an outlet for his energies. In 1578 he composed a pastorial playlet, *The Lady of May*, for the Queen. By 1580 he had completed a version of his heroic prose romance, the *Arcadia*. It is typical of his gentlemanly air of assumed nonchalance that he should call it "a trifle, and that triflingly handled," whereas it is in fact an intricately plotted narrative of 180,000 words.

Early in 1581 his aunt, the Countess of Huntingdon, had brought to court her ward, Penelope Devereux, who later that year married the young Lord Rich. Some time afterward Sidney fell in love with her, and during the summer of 1582 he composed a sonnet sequence, *Astrophel and Stella*, recounting the first stirrings of his passion, his struggles against it, and his final abandonment of his suit to give himself instead to the "great cause" of public service. These sonnets, witty and impassioned, brought Elizabethan poetry at once of age. About the same time he wrote his *Defence of Poesie*, an urbane and eloquent plea for the social value of imaginative fiction, which remains the finest work of Elizabethan literary criticism. In 1584 he began a radical revision of his *Arcadia*, transforming its linear dramatic plot into a many-stranded, interlaced narrative. He left it half finished, but it remains the most important work of prose fiction in English of the 16th century. He also composed other poems and later began a paraphrase of the Psalms. He wrote for his own amusement and for that of his close friends; true to the gentlemanly code of avoiding commercialism, he did not allow his writings to be published in his lifetime.

The incomplete revised version of his *Arcadia* was not printed until 1590; in 1593 another edition completed the story by adding the last three books of his original version (the complete text of the original version remained in manuscript until 1926). His *Astrophel and Stella* was printed in 1591 in a corrupt text, his *Defence of Poesie* in 1595, and a collected edition of his works in 1598, reprinted in 1599 and nine times during the 17th century.

Although in July 1585 he finally received his eagerly awaited public appointment, his writings were to be his most lasting accomplishment. He was appointed, with his uncle, the Earl of Warwick, as joint master of the ordnance, an office that administered the military supplies of the kingdom. In November the Queen was finally persuaded to assist the struggle of the Dutch against their Spanish masters, sending them a force led by the Earl of Leicester. Sidney was made governor of the town of Flushing and was given command of a company of cavalry. But the following 11 months were spent in ineffective campaigns against the Spaniards, while Sidney was hard put to maintain the morale of his poorly paid troops. He wrote to his father-in-law that if the Queen did not pay her soldiers she would lose her garrisons but that for himself the love of the cause would never make him weary of his resolution, because he thought "a wise and constant man ought never to grieve while he doth play his own part truly, though others be out."

On September 22, 1586, he volunteered to serve in an action to prevent the Spaniards from sending supplies into

the town of Zutphen. The supply train was heavily guarded, and the English were outnumbered; but Sidney charged three times through the enemy lines, and, even though his thigh was shattered by a bullet, he rode his horse from the field. He was carried to Arnhem, where his wound became infected, and he prepared himself religiously for death. In his last hours he confessed:

There came to my remembrance a vanity wherein I had taken delight, whereof I had not rid myself. It was the Lady Rich. But I rid myself of it, and presently my joy and comfort returned.

He died on October 17, 1586, having not yet reached 32 years of age.

Sidney was buried at St. Paul's Cathedral in London on February 16, 1587, with an elaborate funeral of a type usually reserved for great noblemen. The universities of Oxford and Cambridge and scholars throughout Europe issued memorial volumes in his honour, while almost every English poet composed verses in his praise. He won this adulation even though he had accomplished no action of consequence—it would be possible to write a history of Elizabethan political and military affairs without so much as mentioning his name. It is not what Sidney did but what he was that made him so widely admired: he was the embodiment of the Elizabethan ideal of gentlemanly virtue.

MAJOR WORKS

The Countesse of Pembrokes Arcadia (1590, consisting of the revised books i, ii, and part of iii; 2nd ed., "augmented and ended," 1593, adds original books iii–v; 3rd ed., 1598, also includes *Certaine Sonets* and *The Lady of May*); *Syr P.S. His Astrophel and Stella* (1591), an unauthorized corrupt text; a slightly corrected edition of the same year; a better text also contained in the 1598 edition of the *Arcadia*; *The Defence of Poesie* (1595; another edition, of the same year, entitled *An Apologie for Poetrie*); *The Psalmes of David* (first printed 1823—only the first 43 by Sidney, the rest by his sister).

RINGLER, JR. (1962), and *The Countesse of Pembrokes Arcadia (The Old Arcadia)*, ed. by JEAN ROBERTSON (1973), critically reconstructed texts.

(W.A.Ri.)

Siemens Family

Four brothers in the Siemens family made substantial contributions to technology during the last half of the 19th century. Werner and William (later Sir William), in collaboration with Carl and Friedrich, were pioneers in the development and expansion of the electrical and steel industries. The technical advances they achieved, such as the dynamo and the open-hearth process, were all made possible by discoveries in pure science and illustrate the trend—the application of science to technology—that has since characterized the growth of industry.

Werner von Siemens (in full, Ernst Werner von Siemens),

(Left) Sir William Siemens, engraving after a portrait by Rudolf Lehmann. (Right) Werner von Siemens, drawing by Ismael Gentz, 1887.

Werner
and Carl

the eldest son, was born on December 13, 1816, in Lenthe, Germany. He attended grammar school at Lübeck and then joined the Prussian artillery at age 17 for the training in engineering his father could not afford. His next three years at the Berlin Artillery and Engineering School were the happiest of his life. While in prison briefly at Magdeburg for acting as second in a duel between brother officers, he carried out chemistry experiments in his cell. These led, in 1842, to his first invention: an electroplating process. The death of his father in 1840 left him responsible for the bringing up of nine younger children; thus he had to supplement his army pay. His appointment in about 1841 to the artillery workshops in Berlin gave him an opportunity to do research, which in turn set the direction of his life's work. When he saw an early model of an electric telegraph, invented by Sir Charles Wheatstone in 1837, he realized at once its possibilities for international communication and invented improvements for it.

A specialist on the electric telegraph, Werner laid an underground line for the army in 1847 and, at the same time, persuaded a young mechanic named Johann Georg Halske to start a telegraph factory with him in Berlin. In 1848, during hostilities with Denmark at Kiel, he laid a government telegraph line from Berlin to the National Assembly of Frankfurt, as an army officer on loan to the Ministry of Commerce, and supervised the laying of lines to other parts of Germany. In 1849 he resigned his commission to become a telegraph manufacturer; this attracted him more than a career in the army or managing the new Prussian state telegraphs.

The firm of Siemens and Halske prospered rapidly, and in 1852 Werner married Matilda Drumann, a professor's daughter, by whom he had four children. When she died, he married another professor's daughter by whom he had two more children. Werner and his brother Carl von Siemens, who was born on March 3, 1829, established subsidiary factories in London, St. Petersburg, Vienna, and Paris. Under Werner's direction, the firm of Siemens and Halske, with which William was also associated, laid cables across the Mediterranean and from Europe to India. Werner's continued research efforts and his inventions in electrical engineering appeared as new products, including in 1866 the self-excited generator, a dynamo that could be set in motion by the residual magnetism of its powerful electromagnet, which replaced the inefficient steel magnet. In that year he also was a member of the Prussian Chamber of Deputies and, always a Liberal, voted against the increased military budget. Later, he was raised to the rank of nobility and received many honours. Werner died at Charlottenburg, Berlin, on December 6, 1892.

William

William Siemens (christened Karl Wilhelm), who was born at Lenthe, Hanover, April 4, 1823, was first intended by his parents for a business career. After private tutoring he was sent to a commercial school at Lübeck in order to enter his uncle's bank. But Werner, deciding that engineering was more suitable, sent him to a technical school at Magdeburg for three years. Financed by his uncle, he then studied chemistry, physics, and mathematics for a year at the University of Göttingen, where his brother-in-law was a professor of chemistry. Through his brother's influence he became an apprentice-student, without fee, in an engineering factory making steam engines in Magdeburg. While there, he determined to sell Werner's electroplating process; after modest success in Hamburg, William travelled to London, arriving in March 1843 with only a few pounds in cash. He sold the process to Elkingtons of Birmingham for £1,600. He returned to Germany to complete his studies and then went again to England in February 1844 with the intention of selling two further inventions: a chronometric, or differential, governor to control speed in steam engines, invented by Werner and developed by himself; and a copying process improved by the two brothers. But he could not repeat his first success.

Finding that the patent laws in England were encouraging, William boldly decided to settle there as an inventor, but he found it difficult to make a living until his water

meter, invented in 1851, began to earn large royalties. He could now afford an office in London and a house in Kensington, where he lived with Carl and Friedrich until his marriage in 1859 to Anne Gordon, the sister of an engineering professor at the University of Glasgow. The same year he also received British citizenship. Before then, he had developed his life's work, which involved heat and electricity. Beginning in 1847, William and his brother Friedrich (christened August Friedrich), who was born December 8, 1826, attempted to apply to industrial processes the regenerative principle, by which heat escaping with waste gases was captured to heat the air supplied to a furnace, thus increasing efficiency. The technical difficulties of applying it to the steam engine could not be overcome, but Friedrich obtained an English patent in 1856 for a method of heat regeneration in metallurgy. In 1861 William used this principle in his patent for the open-hearth furnace that was heated by gas produced by low-grade coal outside the furnace. This invention, first used in glassmaking, was soon widely applied in steelmaking and eventually supplanted the earlier Bessemer process of 1856. William's achievements were recognized by his membership in the Institution of Civil Engineers in 1860 and by his election as a fellow of the Royal Society in 1862. Tempted by the prospect of profits as well as royalties, he started his own steelworks at Landore, South Wales, in 1869, but, although it flourished for some years, he was losing money by the 1880s.

Meanwhile, William had made yet another reputation and fortune in electric telegraphy. Beginning in 1850, he had acted as English agent for Siemens and Halske of Berlin, a connection he maintained until 1858, when he became managing partner of the separate London firm founded under the same name; the firm was engaged in electrical testing for cable firms and in manufacturing of apparatus. As an expert in electrical cable, he was interested in cable laying. In 1863 he established a factory at Charlton, Kent; in 1865 the name of the London and St. Petersburg branches of the firm was changed from Siemens and Halske to Siemens Brothers (William, Werner, and Carl), while the Berlin branch retained the name of Siemens and Halske. The firm specialized in contracting and manufacturing electrical equipment. After acting jointly with Siemens and Halske, the English firm alone laid, in 1874, the electrical cable from Rio de Janeiro to Montevideo, an operation in which two ships were lost. In 1875, when the firm laid the first direct link from Britain to the United States, William assisted in the design of a new type of ship, the "Faraday."

Thereafter, looking into the future, William worked on electric lighting and electric traction. He invented improvements in arc lights and had them installed in the British Museum and elsewhere. A few months before he died he was responsible for the Portrush electric railway in Northern Ireland. He played a full part in professional life; he acted as president of professional organizations including the British Association for the Advancement of Science, received degrees from various universities and many foreign orders, and was knighted in the year of his death, on November 19, 1883, in London. He left a large fortune but no children. His contributions were commemorated by a window in Westminster Abbey.

BIBLIOGRAPHY. WILLIAM FOLE, *The Life of Sir William Siemens* (1888), is the only book-length biography, written by an eminent engineer. WERNER VON SIEMENS, *Lebenserinnerungen* (1892; Eng. trans., *Personal Recollections*, 1893; *Inventor and Entrepreneur: Recollections*, 2nd ed., 1966), gives interesting details of family relationships and industrial enterprises. The *Dictionary of National Biography*, vol. 18 (1897-98, reprinted 1921-22), contains a scholarly entry that refers mainly to Sir William Siemens.

Siena

Siena was an important commercial city in the Middle Ages. Today it is an agricultural and administrative centre and the capital of the province of Siena in the region of Tuscany in central Italy. Its population was about 64,000 in the early 1980s.

History. The site of Siena was an Etruscan settlement that later became the Roman city of Sena Julia. This colony disappeared, but a new Siena developed on or near the old site, which provided a relatively secure inland refuge from the barbarians who invaded the disintegrating Roman Empire in the 4th and 5th centuries AD.

Thanks to its position on the Via Francigena, the medieval route southward to Rome, Siena flourished under the Lombard kings, who ruled it through royal representatives, or *gastaldi*. The Lombard ruling class gradually fused with the older aristocracy and seized power in the surrounding countryside, or *contado*. These local lords made themselves independent of the Holy Roman emperor, but in the city itself they had, during the 11th century, to share their predominance with the local bishop.

Extensive land reclamation in the fertile *contado*, which produced oil, grain, and wine, increased the total wealth of the area and permitted a growth of urban life. In the 12th century the prospering townsfolk began to replace the rule of local lords and bishops with their own self-governing commune and councils, expanding their hegemony into the countryside and defending it against the emperors, from whom they finally won recognition of their independence. In 1240 the older nobility (the *magnati* or *grandi*) had to accept a governing council with a large measure of popular representation; and in 1277 the *magnati* were completely excluded from government office. Economic rivalry and territorial conflict with neighbouring Florence, which was anti-imperial, or Guelph, made Siena the centre of pro-imperial Ghibellinism in Tuscany. The Sienese reached the peak of political success on Sept. 4, 1260, when their army crushed the Florentines at Montaperti.

This triumph was founded on spectacular economic developments. In the 13th century Sienese merchants were transferring funds for the popes and were trading at the Champagne fairs and in Bruges and London. Siena became a great banking centre, where high interest rates brought great profits. The city, however, lacked both a good local water supply and a maritime port; it developed no real industry and was unable to compete demographically or commercially with its rival Florence. The imperial cause declined, and the popes moved their custom to Florentine banks. Siena suffered from wars and famines and from the general economic decline that afflicted most of Europe. These disasters culminated in the catastrophic visitations of the Black Death, which first reached the city in 1348; the population, perhaps 50,000 within the walls and double that in the *contado*, was probably halved by the plague.

The Ghibelline triumph at Montaperti was short-lived. The popes hit at Sienese business and credit, while the imperialists were decisively crushed at Tagliacozzo in 1268; soon after, Siena itself became Guelph and the Ghibelline nobility lost its share of power. For some two centuries a privileged class of lesser nobles and merchants ruled Siena under various forms of republican government that afforded power to a restricted group of oligarchs, who provided experience, continuity, and stability in public affairs, even if they provoked party strife and endless conspiracy among the many who were excluded. There were repeated and turbulent struggles between representatives of the older aristocracy, the newer rich, many of whom came from the *contado*, and the lesser populace, though class distinctions were seldom clear-cut because the landed nobility often engaged in business while many successful merchants married into the aristocracy and purchased country estates. After 1385 entrance into the governing class was increasingly limited, and the urban ruling elite transformed itself into a new aristocracy based on political privilege and investments in land.

Despite these political and economic problems, the Sienese maintained an overall prosperity that was slow to evaporate and that enabled them to embellish their city. Duccio's great "Maestà," painted (1308–11) to celebrate the victory at Montaperti, adorned the grandiose

Gothic cathedral, schemes for the completion of which were largely abandoned after the Black Death. Beautiful churches, palaces, towers, and fountains reflected the inhabitants' civic pride, while the town centre, the concave Piazza del Campo, was dominated by the Palazzo Pubblico (1297–1310), seat of the government, and by its slender bell tower, the Torre del Mangia (1338–48). The council chambers of the Palazzo Pubblico displayed edifying frescoes of the Virgin, painted by Simone Martini, and of an allegory of good government, painted by Ambrogio Lorenzetti. In the decades of economic and moral depression following the Black Death, Siena entered an era of heightened religiosity, during which the city produced its two great mystic saints, Catherine and Bernardino; this spiritual movement was reflected in the lyrical madonnas painted by Sassetta and a succession of Sienese artists.

Siena retained its independence during the 15th century, but economic stagnation continued as capital was invested in land rather than in commerce, social mobility was reduced to a minimum, and Florence blocked expansion northward toward the main markets of Tuscany and the European lands beyond. In 1487 an exiled aristocrat, Pandolfo Petrucci, seized power and ruled with brutal tyranny through a period of French and Spanish invasions until his death in 1512. His regime was continued by his family until 1524. In 1526 Siena was compelled to seek assistance against the Florentine pope Clement VII from the emperor Charles V, whose protection was subsequently transformed into a Spanish domination that lasted until 1552. Two years later the Spaniards besieged the city; a prolonged and heroic defense drastically reduced the population and ended with the surrender of Siena in April 1555. In 1557 Philip II of Spain ceded the city to Cosimo I de' Medici of Florence. Siena's independence was at an end.

Thenceforth Siena's fortunes followed those of Tuscany and its grand dukes, under whose rule the economy became even more predominantly agrarian. In 1861 Siena, together with the rest of Tuscany, was absorbed into the new Kingdom of Italy.

The modern city. Siena survives as a charming provincial town. It is an archbishopric and a university city. It has some light industry, but it is not on a major national motorway or rail route, although there is a fast road to Florence. Siena thrives on the visitors attracted by its artistic treasures and medieval monuments, by the ancient Palio with horse races in the Piazza del Campo, and above all by its Old-World beauty.

(A.T.L.)

Sierra Leone

Sierra Leone is a sovereign republic in West Africa, bordered on the north and east by the Republic of Guinea, on the south by Liberia, and on the west by the Atlantic Ocean. One of the smaller African countries, it has an area of 27,925 square miles (72,325 square kilometres), and it is larger than Togo and The Gambia but smaller than Dahomey. Its population of about 2,600,000 is large in relation to the nation's size by African standards. The national capital of Freetown commands the third-largest harbour in the world after Rio de Janeiro and Sydney.

The country owes its name to the Portuguese explorer Pedro de Cintra, the first European to sight and map Freetown Harbour, in the 15th century. The original Portuguese name of Serra Lyoa (Lion Mountains) referred to the range of hills that surrounds the harbour.

SIERRA LEONE 12° W

Although most of the nation's population is engaged in subsistence agriculture, Sierra Leone is also a mining centre. Its land yields important quantities of diamonds, iron ore, bauxite, and other minerals. Increasing urbanization has resulted in the gradual depopulation of the rural areas and the growth of a jobless population in the cities. The political troubles of the country after independence in 1961 were perhaps ameliorated by the creation of a republican constitution in 1971. (For history see WEST AFRICA, HISTORY OF.)

THE NATURAL LANDSCAPE

Relief features. The country can be divided into four distinct physical regions. The coastal swamp region extends along the Atlantic for about 200 miles. It is a flat, low-lying, and frequently flooded plain that is between 20 and 40 miles wide and is composed mainly of sands and clays. Its numerous creeks and estuaries contain mangrove swamps. Parallel ridges, often separated by silting lagoons, are common and sometimes form the actual coast. The Sierra Leone Peninsula, which is the site of Freetown, is a region of thickly wooded mountains that

run parallel to the sea for about 25 miles. The Peninsula Mountains rise from the coastal swamps and reach 2,913 feet (888 metres) at Picket Hill.

Inland from the coastal plain is the interior plains region. In the north it is comprised of featureless grasslands (savanna) that are known as "Bolilands" (*Boli* being a Temne word for those lands which are flooded in the rainy season and dry and hard in the dry season, and on which only grass can grow). In the south the plains comprise rolling wooded country where isolated hills rise abruptly to more than 700 feet. The interior contains a variety of landforms ranging from savanna-covered plateau surfaces to rocky scarp and hill country. The region is composed mainly of granite with a thick lateritic (iron-bearing) crust; to the west it is bounded by a narrow outcrop of mineral-bearing metamorphic rocks known as the Kambui Schists. Rising above the plateau are a number of mountain masses; in the northeast the Loma Mountains are crowned by Bintimani Peak at 6,390 feet (1,948 metres), and the Tingi Hills rise to 6,079 feet in Sankanbiriwa.

Drainage and soils. The country's drainage pattern is dense. Numerous rivers rise in the well-watered Fouta Djallon highlands of Guinea and flow in a general northeast to southwest direction across Sierra Leone to empty into the Atlantic Ocean. Their middle courses are interrupted by rapids that restrict navigability to their lower reaches. River levels show considerable seasonal fluctuations. During the dry season, levels generally decrease, and the rivers of the plateau region become mere shallow channels. In the rainy season, however, levels increase and the rivers' lower reaches are usually flooded.

The drainage system has nine major rivers and a series of minor coastal creeks and tidal streams. From north to south, the principal rivers are the Great Scarcies, Little Scarcies, Rokel (known in its lower course as the Sierra Leone River), Gbangbaia, Jong, Sewa, Wanje, Moa, and Mano. The Mano forms the country's frontier with Liberia. The river basins are small compared to the major basins of Africa; the largest is the Sewa River Basin, of over 5,000 square miles.

In most areas, the dominant soils are of the weathered and leached ferrallitic (iron-bearing) type. Red to yellowish-brown in colour, they contain much oxide of iron and aluminum, and are acid. Kaolin (China) clays are important, but under cultivation a light, readily workable, free-draining soil is available, whose productivity depends largely on the nutrients provided from the vegetation previously cleared and burned. In the coastal plains ferrallitic soils, developed on sandy deposits, are poor, but slightly better results are obtained where the soils derive from basic igneous rocks. At the foot of the main escarpment, on the Sula mountain plateau, and elsewhere an iron-rich crust forms a surface that is intractable for agricultural production. In the northeast, ferrallitic soils have been modified to produce a "grit" soil with a relatively high clay and silt content. Swamp soils occur over large areas. In coastal and estuarine areas where mangrove is the natural vegetation, productive soils can be acquired by clearance, but careful water control is sometimes needed to prevent toxicity.

Climate. The climate is tropical and is characterized by the alternation of the wet and dry seasons. Conditions are generally hot. Mean monthly temperatures range from 77° F (25° C) to 83° F (28° C) in low-lying coastal areas; inland the range may be from 73° F (23° C) to 82° F (28° C). In the northeast, where extremes of temperature are greater, mean daily minimums fall to 56° F (13° C) in January, and mean daily maximums rise to 90° F (35° C) in March. During the rainy season, from May to October, the dominant humid air masses blow from the Atlantic. The sky is cloudy, the winds are southwesterly, sunshine is minimal, and rainfall is almost a daily occurrence, especially during July and August. The rainy season usually begins with a series of violent line squalls marked by thunder and lightning. Precipitation is greater on the coast than inland; over 150 inches of rain falls annually on the Peninsula Mountains, while the northeast receives about 80 inches a year.

The major rivers

The dry season, from November to April, is characterized by the dry harmattan wind that blows from the Sahara. Conditions are hazy and dusty, with prevailing northeast winds of low relative humidity. The sky is often clear and blue, and rainless weather is common.

The rainy season tends to be cooler than the dry season by about 10° F (6° C). The relative humidity during the rains may be as high as 90 percent for considerable periods, particularly during the wettest months, from July to September.

Vegetation and animal life. The distribution of plants and animals has been influenced by such factors as relief and soil types and, perhaps more importantly, by farming methods. Remnants of the extensive original forest cover remain in the Gola Forest reserve in the southeastern hill country near the Liberian border. Secondary forest is now dominant, and valuable timber species, such as *Khaya* (African mahogany) and African teak, that were common in the original forests are now rare. The secondary forest is characterized by other tree species, such as the prevalent fire-resistant palm tree, which is a valuable source of palm oil and kernels.

The prevalence of savanna vegetation increases to the north as rainfall decreases. The savannas owe their present extent and character largely to the erosion produced by farming, grazing, and the use of fire. There are some small areas of climax savanna (a closed woodland of broad-leaved, low-growing trees) and tall tussocky grasses, but these are only remnants of a much wider spread. Other savannas are derived from forest, and are characterised by fire-resistant savanna trees with tall grasses. Tracts of tall-grass savanna also occur. Along the coast, mangrove swamps constitute the main vegetation community, especially in the saline tidal areas of river estuaries. These swamps are being extensively cleared for rice cultivation. Piassava, a kind of raphia palm, is common in the swamps of the south.

Large game animals, such as elephants, leopards, lions, wolves, and buffalo, are rarely seen. Various species of monkeys and chimpanzees are common in the forest zones, while tiger cats, porcupines, antelope, and bush-pigs are more generally distributed. There is a wide variety of insects, including the malaria-carrying mosquito and the tsetse fly, a carrier of trypanosomiasis (sleeping sickness). Hippopotamuses, crocodiles, and alligators occupy the rivers. The coastal waters, estuaries, and rivers such as the Sierra Leone and Sherbro, also contain a wide variety of fish, such as tuna, barracuda, and mackerel, and lobsters and sharks. Bird life includes parrots, owls, kingfishes, green pigeons, African magpies, vultures, and many other species.

The human imprint. Villages of about 35 buildings and 300 inhabitants dominate the rural landscape. Modernization is slowly altering the traditional pattern of rural settlement; the old circular village form with a tight cluster of houses is rapidly yielding to the linear village along a road or the regular gridiron pattern with adequate spacing between houses. Economic activity still centres largely around rice farming. The extended family provides farm labour both for rice farming and cash crop production. Fishing is becoming increasingly important. The rearing and herding of cattle is largely confined to the north and to groups of pastoral Fulani. The small shopkeeper is typical of the villages, as are the tailor and carpenter. Traditional crafts, such as metalworking, cloth dyeing and weaving, and woodworking, are rapidly disappearing with the increased importation of cheap manufactured goods.

Except for Freetown, the development of large towns occurred only after World War II. Because of the incipient nature of urbanism, functional specialization is rudimentary and occurs mainly in the development of the small, central business district, the most prominent feature being the daily market of petty traders, the majority of whom are women.

Freetown is a long, narrow city of about 200,000 inhabitants. Central Freetown—the administrative and commercial hub of the city—houses government buildings and embassies, the law courts, hotels, and the Roman

Catholic and Anglican cathedrals. Eastern Freetown is mainly residential, with retail trading concentrated along major roads; there are also a few impressive mosques in the area. Further east is the port area. Western Freetown is functionally similar to the east; it also contains the nation's main stadium, the central prison, and the administrative offices of New England Ville. On Mount Aureol, overlooking the city, is Fourah Bay College, black Africa's first institution of higher learning.

Bo, located in the southeast on the railway, is the second largest town, with a population of 30,000. An early administrative and educational centre, it has shown rapid expansion and has engulfed several surrounding villages. Commerce and retail trade are located in the centre of town near the important daily market. Its role as an educational centre has increased steadily, and Bo now contains many schools, including the famous Bo Government Secondary School, founded in the early 20th century.

Other important towns include Kenema, east of Bo, which has grown as a result of diamond mining, and Makeni, in the north, which is a provincial capital and major commercial centre. Mining has also been important to Koidu, Sefadu, Yengema, and Jaiama in the east and Lunsar in the north. Port Loko, Kabala, Bonthe, Moyamba, Kailahun, Kambia, Pujehun, and Magburaka are administrative centres that have also developed such functions as retail trading and produce marketing.

PEOPLE AND POPULATION

Population groups. There are about 18 ethnic groups that exhibit similar cultural features, such as secret societies, chieftaincy, patrilineal descent, and farming methods. The Mende, found in the east and south, form the largest group; they numbered almost 673,000 in 1963. They are closely followed by the Temne (649,000) in

Sierra Leone, Area and Population

the north. Other major groups include the Limba (183,000), Kuranko (81,000), Susu (67,000), Yalunka (15,000), and Loko (64,000), in the north; the Kono (105,000) and Kissi (49,000) in the east; and the Sherbro (75,000), in the southwest. Minor groups include the coastal Bullom, Vai, and Krim and the Fulani and Malinke (Mandingo), who are immigrants from Guinea concentrated in the north and east. The 42,000 Creole—descendants of freed slaves who colonized the coast in the 19th century—are found mainly in the Western Area and Freetown. Ethnic complexity is further enhanced by the presence of Lebanese and Indian traders in urban centres.

Krio, a language derived from English and a variety of African languages, is the mother tongue of the Creole and the country's lingua franca. Among the indigenous languages, the Mande group is the most widespread; it includes the Mende, Kuranko, Kono, Yalunka, Susu, Vai, and Malinke languages. The Mel group, which is similar to the Bantu languages of Central and eastern Africa, includes the Temne, Krim, Kissi, Bullom, Sherbro, and Limba languages. English is the official language and is used extensively in administration, education, and commerce. Arabic is used among Lebanese traders and adherents of Islām.

(Left) A.F. Kersting, (right) Camera Press—Publix

In the late 1960s about two-thirds of the population practiced a variety of animist religions. About 28 percent of the people were Muslims and 6 percent Christians. *Islām* is most influential in the north, and Christianity is more prevalent in the southern and western cities.

Demography. Fertility and mortality rates are high; the crude birth and death rates approximate 45 and 23 per 1,000 population, giving a natural rate of increase of 22 per 1,000. The population is young, with more than 50 percent under 25 years and only 8 percent over 60 years. Emigration from rural areas to the urban centres is common; immigrants are particularly attracted to Freetown and the diamond-mining areas. There is also a floating immigrant population of Ghanaian fishermen along the coast. Areas of predominant emigration tend to show an excess of females, since migrants are usually men. Areas of predominant immigration, such as Freetown, show an excess of males.

The average population density of more than 92 persons per square mile (1970 estimate), far higher than the average for Africa as a whole, is exceeded only by a few countries, such as Nigeria. Areas of sparse population are found in the mountainous and infertile north and the swampy coastal areas of the south and southwest. Population is dense in the west, particularly in the Kambia and Port Loko districts, where intensive swamp-rice cultivation has produced a rural population distribution sometimes as high as 250 per square mile. In the east profitable cash crop production and diamond mining have created dense population patterns. The Western Area has the highest density, almost 1,000 per square mile, largely as a result of immigration to Freetown and its suburbs. Separating the eastern and western high-density zones is a middle belt of moderate population density. There is a similar moderate zone in the southwest.

Future population trends indicate increasing emigration to the urban centres from rural areas as well as an appreciable increase of the rural population in the southwest following advances in the mechanical cultivation of swamp-rice.

THE NATIONAL ECONOMY

The economy is dominated by mining industries, which account for 85 percent by value of the nation's total exports, while agriculture accounts for about 15 percent. Minerals are fairly widespread and include iron ore, diamonds, chromite, and reserves of rutile (titanium dioxide) that are among the world's largest. Other minerals include bauxite, columbite (a black mineral of iron and columbium), pyrochlore, gold, platinum, monazite, corundum, cassiterite, talc, and vermiculite. Major concentrations of those minerals have been found in the Kono and Kenema districts, along the Sewa River Val-

ley, on the western coastal plain, along a central axis stretching south of Kabala to Mongeri, and in the Peninsula Mountains.

Forest covers almost 1,160 square miles, the most important area of which is the Gola Forest. Biological resources include about 240,000 head of tsetse-resistant *Ndama* cattle, mainly in the savanna belt. The coastal waters provide rich fishing grounds for bonga, herring, snappers, tuna, shrimps, and lobsters. The hydroelectric power potential is appreciable, although none of the country's rivers had been harnessed for electricity by the early 1970s.

Sources of national income. Agriculture is carried out largely by traditional methods. About 75 percent of the population are engaged in production for the domestic and export markets. Rice, the main food crop, is widely cultivated on swampland and upland farms. Swamp-rice cultivation is concentrated in the lower reaches of river basins, of which the Scarcies is the most important. Efforts are being made to reduce upland-rice farming with its attendant soil erosion in favour of swampland farming with its superior yields. Other food crops include millet, peanuts, cassava, sweet potatoes, and oil palms. Vegetable gardening is important around the major urban centres, where markets are available to farmers.

The major cash crops are palm kernels, cocoa, coffee, piassava, and ginger. Production is carried out entirely by small-scale farmers. Timber (which includes *Guarea cendmta*, a cedar-scented, pink, mahogany-type wood, and the *Lopjara plata* variety *procera*, or red ironwood) is produced for the domestic market; there are major sawmills located in the Gola Forest; the main furniture factory is in Kenema.

Mining is the most important industry in terms of employment in the modern sector and in exports, and is second only to agriculture in its contribution to the national economy. Diamonds are mined by the National Diamond Mining Company (Diminco), which is jointly owned by the government (51 percent) and the Sierra Leone Selection Trust (SLST), a subsidiary of a London mining firm, the Consolidated African Selection Trust (49 percent), and also by a few private companies, and vast numbers of private prospectors. Mining methods range from mechanical grab lines with washing and separator plants to crude hand digging and panning. About half of the diamonds are gem stones found in river gravels, especially along the Sewa-Bafi river systems. In 1935 the SLST obtained an initial 99-year concession covering virtually the whole country; in 1956 the lease area was renegotiated and reduced to the Yengema and Tongo fields. The surrendered SLST areas were opened to licensed diggers, and the government opened diamond-buying offices in

The mining industry

Mineral resources

Koidu, Kenema, and Bo, partly as a measure against smuggling.

The Sierra Leone Development Company (SLDC) has been mining iron ore at Marampa since 1935. Mining is open-cast (open-cut) and completely mechanized. The ore is processed and taken about 50 miles by the company's railway to the port of **Pepel** for shipment abroad. During 1963 the Sierra Leone Ore and Metal Company (Sieromco) opened open-cast bauxite mines at **Mokanji Hills**. The ore is shipped to Europe for reduction and refining into aluminum. **Rutile** is found in the southwest; in 1965 rutile production was begun, and production and prospecting activities were in progress in the early 1970s.

Industrialization is restricted largely to import substitution. Manufacturing is concentrated in Freetown, and production is mainly of consumer goods, such as cigarettes, sugar, alcoholic beverages, soap, tires, textiles, mineral fuels, and lubricants. Although factories are small and employ less than 1,000 workers each, their role in economic diversification is important. In the provinces industries are concerned exclusively with the processing of agricultural and forest produce, such as rice, timber, and palm oil. Traditional industries, such as fish curing and leatherwork, continue.

Electricity is provided by thermal power stations with a combined installed capacity of 76,000 kilowatts. Power-development plans centre upon Bumbuna Falls on the Rokel or Seli River.

Financial
services

The Bank of Sierra Leone is the nation's central bank; it issues currency, maintains external reserves, and acts as banker and financial adviser to the government. The National Development Bank is charged with providing finances to investors within the country. In 1971 a National Co-operative Bank was established, and a National Commercial Bank and an Agricultural Co-operative Development Bank are to be established in the future. Their function will be to provide credit and technical assistance to farmers. Commercial banking is handled by **Barclays Bank of the United Kingdom** and the **Standard Bank of Sierra Leone**. Post Office Savings banks are found in all main towns, and there are also various kinds of thrift and credit societies.

Foreign trade is expanding substantially, although its character still reflects the colonial nature of the economy. An excessive reliance is placed upon a few primary products, most of which go to the United Kingdom and western Europe. Minerals and agricultural products account for the bulk of exports. Imports, however, are becoming more diversified; they include machinery, textiles, vehicles, fuel, and food products. Japan, Hong Kong, and Burma are new significant trading partners, while trade with other African countries is small.

Transportation. A 311-mile government railway was completed in 1916 as a means of opening the country to commerce and of ensuring effective British occupancy. The railway runs east from Freetown to Pendembu; the branch line from Bauya to Makeni in the north is now closed. The entire line is being phased out because of its limited carrying capacity and inability to meet the needs of an expanding economy.

Roads, originally developed as a feeder system to the railway, have become the principal transport carrier. The road network is dominated by a series of highways radiating from Freetown to inland urban centres. About 5,000 miles of roads exist, and are maintained by the government, local authorities, and private companies; about 500 miles of road within Sierra Leone are paved. The road system is being nationalized and modernized to meet the needs of rapidly expanding traffic. In addition, road links with Conakry, Guinea, and Monrovia, Liberia, are being modernized at the present time.

Inland waterways carry a considerable volume of mineral ores, piassava, and food products. Launches and sailing boats are important, especially on the southern route to Bonthe and the northern route to the Great and Little Scarcies. Freetown, with the finest natural harbour in West Africa, is the country's principal port. Its eight berthing facilities handle all imports and agricultural exports. The general ports of Bonthe and Sulima are silting

Port
facilities

up and commercially moribund. Specialized ports include Point Sam, which handles all bauxite and rutile exports, and **Pepel** on the Sierra Leone River, which handles iron-ore exports.

The international airport of Lungi is situated on the north bank of the Sierra Leone River opposite Freetown. It can accommodate commercial jets and a large annual volume of traffic. Domestic air transport is limited, but there are regular flights from **Hastings** near Freetown to Bo, Kenema, and Yengema. Domestic services are provided by Sierra Leone Airways, which—together with various African and European airlines—also offers international flights.

Management of the economy. Private capital dominates mining concerns, commerce, and banking. European, Lebanese, and Indian interests are predominant, and participation by Sierra Leoneans is small. The public sector features the Sierra Leone Produce Marketing Board (SLPMB), which has a monopoly on cash crops, and other public corporations, such as that of road transport, which is entirely owned by the government. Government revenue is derived from direct and indirect taxes. In addition to import and export taxes, the government can also rely on company, excise, income, and mining taxes for revenue.

Sierra Leone has a national labour congress, with about 20,000 members, comprising 20 percent of all wage and salary earners, who are grouped into 12 unions. There are also employers' associations, and there is a chamber of commerce. Arrangements exist for establishing minimum wages, but unions can negotiate with management concerning fringe benefits.

Contemporary economic policies focus essentially on internal development, economic diversification, industrialization based mainly on import substitution, the increase of exports, and the insurance of financial stability. In the early 1970s the government of Sierra Leone actively participated in partnership with private enterprises in the mining industry, in oil refining, and in Sierra Leone Airways.

The main problems facing the country are unemployment, rural emigration, and excessive reliance on a few primary products for foreign-exchange earnings. On the other hand, the diversity of natural resources, along with expanding educational facilities and trends toward political stability all seem to point toward a bright economic future.

ADMINISTRATION AND SOCIAL CONDITIONS

Government structure. The constitution of 1971 created Sierra Leone a republic within the Commonwealth of Nations. The former office of governor general was replaced by that of an executive president as head of state. The combined offices of vice president and prime minister are held in rotation, by decision of the cabinet for a period of five years. The House of Representatives is composed of a speaker and 78 members, 66 of whom are elected from constituencies that are established by an electoral commission. The other 12 representatives are paramount chiefs representing the 12 administrative districts of the three provinces. The chiefs are hereditary rulers whose local powers have been largely superseded by those of officials of the central and local government. Their influence remains important, however, particularly in matters of traditional culture and justice.

The country is divided into two units—the Western Area, which was the former Crown Colony of Sierra Leone, and three provinces, the former Protectorate of Sierra Leone.

The Western Area, with a population of about 250,000, contains the capital of Freetown, which has a city council consisting of a mayor, aldermen, and councillors representing the six wards of the city. It has the usual local government committees.

The provinces have a population of about 2,300,000. Northern Province is divided into five districts, Southern Province into four districts, and Eastern Province into three districts. Each of these provinces is under the central political control of a resident minister, and each dis-

Local
govern-
ment

trict is headed by a district officer who is, in turn, responsible to a provincial secretary, the chief adviser to the resident minister.

The districts are subdivided into about 146 chiefdoms, which are controlled by paramount chiefs and chiefdom councillors. The chiefdoms are further divided into sections and villages.

In addition, there are District Councils, which in some cases override the chiefdom administrations. The councils deal largely with local matters and are under the indirect control of the central government. Town Councils also have been established in the larger provincial towns of Bo, Kenema, Makeni, Koidu, and Bonthe.

Elections have been held regularly every five years since independence with one year's interruption of military rule. Most people belong to political parties although tribal influence is strong. There are two political parties—the Sierra Leone People's Party (SLPP) and the All People's Congress (APC). The parties operate in a manner similar to that of political parties in the United Kingdom; the party that receives a majority of seats forms a government, and the other party operates as the opposition.

Justice and the armed forces. The laws of Sierra Leone follow the pattern of British law. Until 1971 the framework of the courts was equally similar, and the final court of appeal was the Privy Council in London. Since the adoption of a republican constitution, however, the highest court is the Supreme Court, headed by the chief justice.

There are local courts that take account of indigenous laws and customs, Magistrate Courts administering the English-based code, a High Court, and a Court of Appeal. Nearly all of the judges, magistrates, and lawyers are Sierra Leone Africans trained in British universities and the Inns of Court in London. There are presiding officers in the local, magistrate, and juvenile courts who are not qualified lawyers but who are citizens of wide experience.

The attorney general is a cabinet minister and the political head of the State Law Office, which is administered by a solicitor general.

The president is commander in chief of the armed forces. There is an army of 1,500–2,000 men, a para-military force of 300, and a civil police force of about 3,000 including female police. The army served in Africa and Burma during the world wars and has been used internally to suppress rebellions and strikes. There were unsuccessful military coups d'état in 1967 and 1971. A defense pact with neighbouring Guinea allows for the exchange of army personnel. A similar agreement is also projected with Liberia.

Administrative services. Since the early 1960s, there has been a great increase in the number of children attending schools. More schools have been built and more teachers trained to meet the growing need. Significant contributions have been made by overseas bodies, such as church societies, and by volunteer corps from the United States, the United Kingdom, and Canada. There is no free or compulsory education at any level, but the government awards many scholarships.

There are about 1,000 primary schools, 80 secondary schools, 2 technical institutes, and several vocational schools, trade centres, and teacher-training colleges in the country. The University of Sierra Leone consists of Fourah Bay College, founded in 1827; Njala College, founded in 1964; and an Institute of Education, founded in 1968. Fourah Bay College was for a long time the only university-level institution in black Africa, and its alumni are scattered far and wide in positions of responsibility.

Most health and welfare services are provided free by the central government. There are also a few hospitals belonging to religious societies and mining companies and private doctors. The fee-paying government nursing home in a suburb of Freetown is used by wealthy Africans and some overseas visitors. Every district in the interior has at least one hospital. The major hospitals with specialist facilities are in Freetown and Bo; they

are staffed by highly qualified doctors who have been trained in Europe and the United States.

The Public Health Section controls port and airport sanitation, schemes for the control and eradication of malaria and other infectious or endemic diseases, and the sanitation of Freetown. In other areas sanitation is under the control of district health authorities and town councils supervised by doctors who are appointed by the central government.

The Endemic Diseases Control Unit concentrates on the mass treatment of such diseases as sleeping sickness, yaws, and leprosy. Smallpox, yaws, and measles have been almost completely eradicated.

There are slum areas at the edges of most of the main cities. Several low-cost housing schemes are in various stages of development. There are adequate middle-income houses in the urban areas and luxury villas on hilly sites.

There is a fascinating variety of housing in the interior districts, depending on the availability of materials. Roofs are made of grass in the savanna region and of bamboo in the forest areas. Walls may be circular or rectangular and constructed of dried mud bricks, palm fronds, or, more generally, lattice pole work filled with mud and coated with clay or chalk. There is usually a veranda or shaded porch. In most villages and towns along the roads, houses are roofed with corrugated zinc and the walls constructed of cement. In Freetown and Bonthe, some houses remain that were built of wood or laterite stone in a Brazilian or Victorian Colonial style and roofed with slate.

The Sierra Leone Police Force was constituted in 1894; the Frontier Police Force and the Court Messenger Force have been disbanded. The police force carries out traffic duties, riot control, and first aid and combats illicit diamond mining. Most of the senior officers were trained in the United Kingdom; they are not armed, except when on special duty.

Social conditions. The main employer of labour is the government, followed by the mining and commercial establishments. But most persons, especially in the rural areas, are engaged in agriculture. There is a seasonal exodus to the diamond areas, where both legal and illicit mining are carried out.

There are no hereditary ruling classes, except for the families of paramount chiefs in the provinces. As the chiefdoms are usually small and their political influence restricted, the privileged position of the chief's family is confined to a small local area.

In the cities successful politicians, high government officials, professional men and women, and university teachers constitute an elite, the members of which earn incomes far above those of average workers. This is a potential source of danger, since most of the elite are of Creole origin. It is hoped that the spread of education and the growth of regional cities will correct this imbalance by the 1990s.

The concentration of economic power in the hands of Lebanese and Afro-Lebanese diamond merchants is also inflammatory, as there are few wealthy African contractors and exporters.

Unemployment is high among the illiterate and partially educated Africans who have moved into the towns from the rural areas. Extreme poverty is not widespread because family and friends usually give support to those unemployed. Hunger, unemployment, and poor housing are increasing, however, and the 1970s will be difficult years unless there is a massive infusion of external capital to establish new industries.

CULTURAL LIFE AND INSTITUTIONS

The most outstanding feature of the country's cultural life is its dancing. The Sierra Leone Dance Troupe is internationally known and has performed in many foreign cities. The different communities of the nation have their own styles of costume and dance. In addition, certain closed societies, such as the Wunde, the Sande (Bundu), and the Gola, have characteristic ceremonial dances. A wide range of agility, gracefulness, and rhythm is dis-

Housing

Economic divisions of the population

played; in addition, there are elements of symbolism in most of the dances. Drums, wooden xylophones (called balaphones), and various stringed instruments provide the musical background.

The Poro society for men and the Sande society for girls play an educational role in village culture.

The Vai script has the distinction of being one of the few indigenous scripts in Africa. Some of the local languages are written in European script, but a few, especially the ones in the Muslim areas in the north, have been transcribed into Arabic.

Handicrafts. The carving of various wooden masks in human and animal figures for the dances is especially advanced in the southern region. The Sande mask worn on the head of the chief dancer during the ceremony attending the reappearance of the female initiates from their period of seclusion is perhaps the most well-known carved figure in Sierra Leonean art. It is a symetrically stylized black head of an African woman with an elaborate plaited pyramidal coiffure adorned with various figures and with a facial expression of grave dignity and beauty.

Ivory figures are characteristic of the Sherbro, Bullom, and Temne peoples of the coastal and northern regions. Fine examples of these figures, which were bought or commissioned by Portuguese traders during the 16th century, are still extant. There are also steatite human figures, sometimes distorted, called *nomoli*, which certainly date earlier than the 16th century and were used probably for ancestor worship or fertility rites. At present, they are used for ceremonies to ensure abundance of crops.

Containers or rattles are carved from gourds, and are decorated with intricate geometrical patterns that are burnt into them.

The weaving of blue or brown cloth of thick texture with linear designs is carried out in the southern and eastern regions by the Mende and the Kono. The cloth is made into coats for men or wrapped around as a lower garment by women and is also used as a bedspread. In the north, among the Temnes, imported cotton or satin is dyed with indigo, the red juice of the kola nut, or imported dyes into beautiful patterns by tie dyeing. In the west, baskets are made with dyed raffia, and patterned slippers are fashioned from dyed wool.

Painting and literature. There is an active school of modern artists who are trained in Europe and the United States and whose paintings have been exhibited locally and abroad. Olayinka Burney Nicol, Hassan Bangura, John Vandi, Koso Thomas, and Gladys Metzger are among the most well-known artists.

The Vernacular Literature Bureau produces school texts, information bulletins, and collections of folktales in indigenous languages, such as Mende and Temne. There has been a literary tradition in Freetown since the 19th century. One of the most prolific writers was James Africanus Beale Horton, who wrote books and pamphlets on politics, science, and medicine while he was a medical officer in the British army between 1857 and 1871.

There were also 19th-century works on exploration by such Sierra Leone Africans as Samuel Crowther, a bishop of the Anglican Protestant faith, and another clergyman John Christopher Taylor. Sierra Leone is represented in most anthologies of African- and English-language poetry and short stories. In addition, the modern novels and short stories of Sarif Easmon, William Conton, and Eldred Jones give a vivid picture of modern life in the country.

The Sierra Leone National Museum in Freetown contains historical, ethnographic, and archaeological collections. Fourah Bay College and Njala University College both have libraries; the former houses the public archives. The Sierra Leone Library Board has a central library in Freetown and branch libraries and book-van libraries in the provinces.

Press and broadcasting. The two daily newspapers—the *Daily Mail* and *The Nation*—are controlled by the government; they have the widest circulation. There are

also weekly papers published in Mende (*Seme Loko*), Temne (*Akera Kakethemne*), and English (*We Yone* and the *People*). Learned journals are published by the University of Sierra Leone, of which *Sierra Leone Studies* and the *Sierra Leone Language Review* are the best known.

The government-controlled Radio Sierra Leone broadcasts in English and local languages. Its programs, particularly of news and discussion groups, reach about 40 percent of the population. The government-controlled television service can only be received in the Freetown area.

PROSPECTS FOR THE FUTURE

The country has potential wealth in its agricultural and mining resources, and industrialization, although recent, is making rapid progress. Improvements in road communications and transport will certainly result in a greater exploitation and utilization of these assets. The spread of education, intermarriage, and the establishment of workers' unions that cut across tribal lines are all factors that will lessen intercommunal rivalry and will result in a more united and progressive country.

BIBLIOGRAPHY. Publications by the MINISTRY OF INFORMATION AND BROADCASTING, Freetown, Sierra Leone, include well-illustrated pamphlets that appear at regular intervals and contain up-to-date information. The *Report* by the MINISTRY OF EDUCATION (annual) gives educational developments and statistics. A valuable source of information is the *Sierra Leone Yearbook*, published in Freetown. The CENTRAL BUREAU OF SIERRA LEONE also produces regular bulletins. An *Atlas of Sierra Leone* (1966), produced by the DIRECTORATE OF SURVEYS AND LANDS, gives useful information and detailed maps of the country and of street plans of some of its important urban areas.

J.I. CLARKE (ed.), *Sierra Leone in Maps* (1969), is an admirably illustrated symposium by members of the staff of the Department of Geography, University of Sierra Leone. For history, see CHRISTOPHER FYFE, *A History of Sierra Leone* (1962) the major work; and ALEXANDER P. KUP, *The Story of Sierra Leone* (1964). GEOFFREY J. WILLIAMS, *A Bibliography of Sierra Leone 1925-67* (1971), emphasizes articles on the communities of the provinces and includes a list of previous bibliographies. MARTIN L. KILSON, *Political Change in a West African State: A Study of the Modernisation Process in Sierra Leone* (1966); and JOHN CARTWRIGHT, *Politics in Sierra Leone 1947-67* (1970), give an account of modern political developments. For economic studies, see RALPH GERALD SAYLOR, *The Economic System of Sierra Leone* (1968); H.L. VAN DER LAAN, *The Sierra Leone Diamonds: An Economic Study Covering the Years 1952-1961* (1965); and SIAKA STEVENS in the *Report of the Duke of Edinburgh's Study Conference* (1956). F.W.H. MIGEOD, *A View of Sierra Leone* (1925), contains a valuable account of the culture of peoples of the provinces. K.L. LITTLE, *The Mende of Sierra Leone*, rev. ed. (1967), gives an account of the most numerous community in Sierra Leone; as does W.T. HARRIS and HARRY SAWYER, *The Springs of Mende Belief and Conduct* (1968). An account of the Limba peoples is given by RUTH H. FINNEGAN, *Survey of the Limba People of Northern Sierra Leone* (HMSO 1963). These three are the major communities in Sierra Leone. ARTHUR T. PORTER, *Creolodom* (1963); and JOHN PETERSON, *Province of Freedom* (1969), are good socio-historical accounts of the Sierra Leone Creoles.

The lives of distinguished Sierra Leoneans are well set out in M.C.F. EASMON, *Eininent Sierra Leoneans* (1961); CHRISTOPHER FYFE, *Africanus Horton, 1835-1883: West African Scientist and Patriot* (1972); DAVIDSON NICOL (ed.), *Black Nationalism in Africa, 1867* (British title, *Africanus Horton: The Dawn of Nationalism in Modern Africa*; 1969); and J.D. HARGREAVES, *A Life of Sir Samuel Lewis* (1958). *Modern African Stories*, a collection by ELLIS AYITEY KOMEY and EZEKIEL MPHALELE (1964), contains selections by Sierra Leone writers. The autobiographical *Kossoh Town Boy*, by R.B.W.A. COLE (1960), gives a vivid picture of Sierra Leone Creole childhood.

(D.S.H.W.N./S.M.S.)

Sierra Nevada Range

The Sierra Nevada is a major mountain range of western North America, running along the eastern edge of the state of California. Its great mass is the uplifted complement of the Great Valley (Central Valley) depression to the west. Extending over 250 miles (400 ki-

The weaving and dyeing of cloth

lometres) northward from the Mohave Desert to the Cascade Range of northern California and Oregon, the Sierra Nevada is about 50 miles wide. Its magnificent skyline and spectacular landscapes make it one of the most beautiful of the great physical features of the United States. As a recreation centre, its year-round facilities prove a magnet to the inhabitants of the huge urban areas of California, and it has considerable importance as a source of power and water. It was the focus of the celebrated California Gold Rush of 1849.

The Sierra Nevada is an asymmetrical range with its crest and high peaks decidedly toward the east. The peaks range from 11,000 to 14,000 feet above sea level, with Mt. Whitney, at 14,494 feet (4,418 metres), the highest peak in the conterminous United States.

Much of the rock is granite or a near relative of granite. There are dividing bands of metamorphosed (heat- and pressure-altered) sedimentary rock, all that is left of a once extensive sedimentary basin.

History of scientific study. For many readers, the naturalist John Muir's *My First Summer in the Sierra*, a diary of camping and exploration in 1869, is one of the classics of American geographical writing. Muir, the founder of the Sierra Club (1892), a conservationist group concerned with the preservation of the scenic resources of the Sierras and like areas of the United States, dedicated his book to members of the club in 1911.

Geologists have studied the Sierra Nevada from the late 19th century onward. Especially significant studies concern the Mother Lode system, Jurassic stratigraphy and its relation to intrusive granites, glacial erosion, placer gold, multiple intrusions, isotope ages, and chronology and nature of emplacement.

Geological background. It has long been recognized that the Sierra Nevada is a tilted block of the Earth's crust. A fault bounds the block on the east, and it was along this that the great mass that became the Sierra Nevada was uplifted and tilted westward. This explains the asymmetry of the range. As the block was uplifted the abrupt, east-facing escarpment was cut into by the erosive action of wind, rain, frost, and ice, and a series of steep-gradient canyons developed. Though the massive uplift started possibly 15,000,000 years ago, much of it occurred in the last 2,000,000 years. Altogether, the vertical movement along the fault amounted to at least 15,000 feet, and possibly more.

The gentle west-facing slope has been dissected by a series of streams, relatively long in comparison to those of the eastern slope. Such rivers as the Yuba, American, Mokelumne, Merced, and Kern have carved deep, V-shaped valleys into the predominant granite. These rivers drain into the Sacramento River in the Great Valley on the north, and into the San Joaquin on the south. By means of these two large rivers the range's drainage ultimately reaches the Pacific Ocean through San Francisco Bay.

During the Ice Age, which started about 2,000,000 years ago and ended in North America just 11,000 years ago, the river-eroded valleys were covered several times by great glaciers. Glacial climates came and dissipated at least five times, and each time excessive snows built snow and ice fields and long glaciers. The ice carved the V-shaped valleys into U-shaped ones, and in few ranges of the world are the forms more crisp and inspiring than in the Sierra Nevada. In the high snow fields, steep-walled basins, called cirques, were carved from the mountain sides by ice action. The resulting rock debris was transported by the glaciers down into terminal moraines, the tongue-like deposits of waste at the glaciers' end. These moraines, like the U-shaped valleys, are classical in their development. The glacial features are chiefly responsible for the scenic beauty and are the focus of the Yosemite, Kings Canyon, and Sequoia national parks. The several episodes of glacial chronology must be related to the progressive uplift of the Sierra Nevada block, and this is a remarkable story, explored in detail by geologists.

Geological and geophysical analyses have led to the conclusion that the region occupied by eastern California

and western Nevada was once a broad and long northward-trending basin, called a geosyncline, in which layers of sedimentary rock were laid down mostly in marine waters. Continued subsidence of this vast down-warp in the Earth's surface brought the lower sediments into successively higher temperature zones, where heat

The
sequence
of granites

conducted from the Earth's interior resulted in the melting of the rock layers. In consequence, the granite rocks of the range were created, for, after the sediments were melted, they became mobile and proceeded, in part, to intrude upward into overlying layers of rock. Careful mapping by geologists shows that the granite of the Sierra Nevada has been intruded as a number of separate masses, each with recognizable boundaries and its own mineralogical compositions. Further, radioactive dating techniques show that the intrusive masses are of three separate age groups. The first originated in Triassic time (about 190,000,000 to 225,000,000 years ago) and was an easterly group of intrusive bodies, mostly exposed in ranges east of the Sierra Nevada. The second occurred in Jurassic time (about 136,000,000 to 190,000,000 years ago) and was made up of a westerly lying group of intrusions now exposed along the west slopes of the Sierra Nevada. The third occurred in Late Cretaceous time (about 80,000,000 to 90,000,000 years ago) and makes up a central area of granite, now composing the high Sierras.

In Yosemite National Park a remarkable series of no fewer than nine separate intrusive masses has been mapped and ordered chronologically. Again, field surveys of the interrelationships of these masses have been confirmed by isotopic dating techniques, and this group of granite bodies is now seen as belonging to the third general age group mentioned above.

Environmental aspects. Gold nuggets were found in 1848 at Sutters Fort on the Coloma River, and the tremendous gold rush that followed was to be of fundamental significance in the historical evolution of the western United States. By the 1970s about \$1,800,000,000 worth of gold had been produced. The nuggets, found in the stream gravels of the lower western slopes of the Sierra Nevada, probably come from the quartz vein of the Mother Lode (see below). Not only did the present river bottom gravels contain the nuggets, but the older gravel layers forming terraces on either side of the streams were also gold bearing. In places where these old river gravels had been buried by solidified lava flows, mining operations proceeded under the lava beds. Large dredges were built to handle huge volumes of gold-bearing gravels and concentrate the gold. As a result, where lush meadows once existed, there are now only rows of barren gravel ridges to mark the progress of the dredges. The rivers were muddied for miles below. Fortunately, this ruinous disturbance of a scenic and ecologically important environment was long ago condemned, and this type of industry has now almost ceased to exist. Fabulously rich gold mines were also developed in the Mother Lode vein system, which was traced for about 150 miles (250 kilometres) in a northerly direction along the west side of the Sierra Nevada. Some of the mines are still operating.

Gold
mining

The moist Pacific winds drop many feet of snow each year on the Sierra Nevada, and thus the mountains become a life-sustaining watershed for many of the nearly 20,000,000 people who now reside in California. The large streams of the wide western slope drain into the Great Valley, where the most prolific truck farms, orchards, vineyards, and grain, alfalfa, and cotton fields existing in the United States are now found. Some of the drainage seeps underground and is pumped for irrigation, and the Great Valley itself provides an extensive and fine underground reservoir for water storage. Many power plants along the streams provide electric power for the Great Valley cities and smaller communities. Water that drains from the east slopes is gathered and conducted in large aqueducts to the metropolitan centres of southern California, notably to Los Angeles. Considerable lumber is harvested from the rich upper slopes of the Sierras, although the finest timber stands of the region are to be

The basic
tilted block

found in the Coast Ranges of northern California, Oregon, and Washington.

The vast growth of population in the densely settled regions of the west coast of the United States, and the attendant thirst for outdoor recreation, have placed heavy demands on the scenic Sierra Nevada area. On a national holiday, more than 40,000 people may invade the Yosemite National Park, or more than a thousand make the hike to the summit of Mt. Whitney. The whole area is ideal for summer camping, hiking, nature studies, and fishing, and great for winter skiing. Already the national forest and national park staffs are taxed to the limit in keeping the streams pure, the campgrounds clean, and nature relatively undefiled, and the situation appears to be deteriorating rather than improving. The Sierras are a great natural blessing but will require great vigilance in future environmental control if this status is to be maintained.

MATTHES, "Geological History of the Yosemite Valley," *ibid.* 160 (1930), a beautifully illustrated and scientifically accurate account of the glacial features and chronology of the Yosemite Canyon.

(A.J.E.)

Sigillography

Sigillography is the study of seals. A sealing is the impression made by the impact of a hard engraved surface on a softer material, such as clay or wax, once used to authenticate documents in the manner of a signature today; the word seal (Latin *sigillum*; old French *scel*) refers either to the matrix (or die) or to the impression. Seals are usually round or a pointed oval in shape or occasionally triangular, square, diamond, or shield-shaped.

Medieval matrices were usually made of latten—a kind of bronze—or of silver. Ivory and lead were occasionally used, gold very rarely. Steel was used from the 17th century. Matrices could include intaglio gems. The usual material for the impression was sealing wax, made of beeswax and resin, often coloured red or green. In southern Europe, notably in the papal Curia, lead and occasionally gold were used. Shellac, the wax used today, was introduced in the 16th century.

Seals were used to establish the authenticity of such documents as charters and legal agreements and for the verification of administrative warrants. In southern Europe, early medieval documents were drawn up by notaries and authenticated with their written *signa*, but this never replaced seals in northern Europe. Forgeries were manufactured as early as the 12th century, indicating how important seals had become. From that time, also, seals were used to close folded documents and thus to guarantee their secrecy. Seals were also used to affirm assent; for example, by a jury. Under the Statute of Cambridge (1388), sealed letters were used in England for the identification of people and their places of origin.

Sigillography is used to assist other historical studies. Many impressions have survived from the medieval period. Those attached to documents are most valuable, because the documents may date their use precisely and the seal may confirm the documents' authenticity. Unattached seals may still provide useful evidence from their inscription or design. Fragmentary seal impressions are

often difficult to interpret. Fewer matrices have survived and often without related impressions. Seals often reflect the taste of the owner. They provide evidence for changes in fashion in both secular and ecclesiastical costume and for the development of armour. Seals indicate heraldry before the earliest rolls of arms and are an original source for armorial bearings, which thereby enables the historian to trace the distinctions or alliances between various families and so contributes to genealogy. Craftsmen's seals often display tools connected with trade. Depictions of towns, churches, castles, and monasteries, although conventional, can often aid the architectural historian. Seals can also be used profitably for studying ancient ships, particularly their shape and details of masts and rigging. The main difficulty in studying seal designs is that they were often conservative, especially since seals were often replaced with an exactly similar design. (J.Ch.)

Seals in antiquity. Seals with designs carved in intaglio were used throughout antiquity. They were of two main types—the cylinder and the stamp. The cylinder first appeared in Mesopotamia in the late 4th millennium BC and continued to be used there until the 4th century BC. It was also widespread in Elam, Syria, and Egypt (3rd millennium BC) and in Cyprus and the Aegean (2nd millennium BC). Stamp seals preceded cylinders, first appearing in Mesopotamia in the 5th millennium BC and developing over a period of about 1,500 years until largely replaced by the cylinder in the 3rd millennium. Early stamp seals were also used in Iran, northern Syria, and southeastern Anatolia during the 4th and 3rd millennia; in Anatolia their use was continued in the 2nd millennium by the Hittites. In Mesopotamia the stamp seal gradually came into use again in the 8th–6th centuries, effectively replacing the cylinder by the 3rd century BC. In Egypt the scarab largely replaced the cylinder seal early in the 2nd millennium BC and continued as the main type until replaced by the signet ring in Roman times. In the Aegean, various types of stamp seals were used throughout the 2nd and much of the 1st millennium BC, until in Hellenistic and Roman times the signet ring became dominant.

The uses of ancient seals are known from textual references and ancient sealings, both on lumps of clay and on documents found in excavations. In historical times most prominent citizens, including women, carried their own seals. That the rank or office of the owner was often included in the inscription indicates that many of these may have been official seals. Kings had their own seals, and high officials could hold the king's seal as a mark of delegated authority.

Seals came into use before the invention of writing for the securing of jars, bales, bags, baskets, boxes, doors, etc., and this use continued throughout ancient times. The method was either to shape clay over the stopper or lid or to make a fastening with cord and place clay around the knot and then impress it with the seal.

The sealing of written documents, of which the two major ancient classes were clay tablets and papyrus scrolls, became regularly established in the latter part of the 3rd millennium BC. The clay tablet was the main vehicle of writing in Mesopotamia, where cuneiform was used into the Christian Era, and this method spread to Elam, Anatolia, Syria, and Egypt; clay tablets were also used in the Aegean Bronze Age. The tablet was inscribed while the clay was soft, and seal impressions were applied at the same time.

The main kinds of sealed cuneiform documents were contracts, accounts, and letters. Contracts were sealed by the contracting parties and by witnesses and commonly encased in clay "envelopes," on which the text was either repeated or summarized and the seals again impressed. Two special kinds of contract were the royal grant to a subject, impressed with the royal seal of the grantor, and the treaty between nations, a number of examples of which have been recovered, some of them bearing impressions of the seals of the royal contracting parties. Account tablets were sealed to authenticate the transfer of goods. A letter was often encased in an "envelope" and the sender's seal impressed on the outside to identify him

Uses of
ancient
seals

Recreation

Purposes
of seals

to the recipient and, in the case of official letters, to authenticate any commands contained in the letter.

In Egypt, papyrus documents may be assumed from soon after 3000 BC, but surviving evidence dates mostly from the latter part of the 3rd millennium onward. The method of sealing a papyrus document was to roll it into a tube, tie a strand or cord around the centre, and seal a clay lump over the knot. This method continued into the Christian Era, from which time a great number of Greek papyri have survived in Egypt. It was not until the 1st millennium BC that this kind of document, including by then leather and parchment, came into wide use outside Egypt. The spread of this kind of document, on which the space for a seal was small, probably played some part in the gradual replacement of the cylinder by the stamp seal.

No documents or sealings have been discovered from ancient India, but the still undeciphered inscriptions on the seals may include personal names, perhaps of merchants, who could have used the seals in much the same ways as their Near Eastern contemporaries, with whom they are known to have had commercial contacts.

Since seals were used throughout ancient times and are sufficiently durable to have survived in very large numbers, they form one of the few classes of ancient objects in which a continuous development can be traced. The great majority bear artistic representations, so their chief value is for art history, but, since these include details of environment (plants, animals), equipment (plows, chariots, musical instruments), or dress, they also contribute to cultural history.

Further information is provided by the inscriptions on seals. The existence of rulers known only from king lists may sometimes be confirmed by the discovery of their seals, and in some cases rulers are known only from their seals, which, because they often mention the names of their fathers, the cities that they ruled, and the chief gods that they served, form a valuable historical source. The assembling of tablets and sealings bearing the impressions of private seals can contribute to the reconstruction of business archives and the destinations of traded goods, thus providing valuable material for economic analysis, and far-flung trade contacts can be deduced from foreign seals in excavations (e.g., Indus Valley seals in Babylonia). Personal names are an important source for ethnic analysis, and inscribed seals, because they often name the owner's father and even grandfather, provide material for this as well as for genealogical reconstruction.

(T.C.M.)

Medieval European seals. The connection between Roman and medieval seals lies in the use of seals in the chanceries of the Merovingian and Carolingian kings. Many Ottonian seals had busts of the emperors. Royal seals of medieval type, with the ruler enthroned and bearing his insignia, appear from the 11th century. The use of seals by bishops and nobles became usual at this time and was widespread by the 12th century. By the 13th century, seals were used by all classes, including small landowners; and, by the 14th century, simple seal matrices could be bought ready-made.

The quality of engraving varied greatly. Some delicately designed seals date from the 12th century, such as the silver seal of Isabella of Hainaut, queen of France in 1180–90. The silver equestrian seal of Robert Fitzwalter is a notable example of the 13th century, the period of the finest seal engraving.

The names of several engravers of medieval seals are known: for example, Luke, who engraved the seal of Exeter, and Walter de Ripa, who engraved the first great seal of Henry III of England.

Forms of medieval seals. Seal matrices may be single or double, thus producing an impression on either one or both sides of the wax. Single matrices, the older type, often have a ridge along the back and end in a loop. Double matrices, known from the 11th century onward, are flat, with two to four projecting lugs pierced with holes in which vertical pins keep the halves aligned.

Sealing both sides of the wax makes detaching the seal more difficult, and so in medieval times the reverse was often sealed by a counterseal for greater security. The

official seal of an institution was often countersealed by the seal of an official, such as a town by its mayor. Single seals were often fitted with a handle; the most common type was a six-sided cone ending in a trefoil. In some matrices the centre screwed outward, enabling the device to be used without a legend. On many seals the back was marked with a cross to indicate the top.

Seals could be either applied to the surface of a document or appended from it by a strip of material. Application was the earlier system, although papal bulls were always appended. Appended seals appeared in England in the 11th century and in France in the 12th; seals were appended either on a tongue of parchment cut across from the bottom of the document or on a tag of parchment, leather, or silk inserted through a cut in the document. Some documents had many seals. Seals were often protected by woven bags or by boxes of wood, metal, or ivory known as skippets.

The legend, often abbreviated, usually declared the name of the owner or institution; it often began with a cross and the word *sigillum*, followed by the name in the genitive case. Latin remained in fashion for inscriptions, though English and French are occasionally found from the 13th century, more frequently on personal seals. On English seals roman capitals were used in the 11th and 12th centuries and Lombardic ones in the 13th and early 14th centuries. Black letter (Gothic script) was first used in England in the 14th century and was quite popular in the 15th century, although Lombardic often continued for capitals. Roman capitals reappeared in the 16th century.

Royal and official seals. The great seal, or seal of majesty (a round seal showing the seated ruler with the royal insignia), first appeared in Europe on the seal of the emperor Henry II of Germany (ruled 1002–24), in France on the seal of Henry I (ruled 1031–60), and in England on the double seal of Edward the Confessor (ruled 1042–66). The seal of William I of England (ruled 1066–87) had the King on one side and an equestrian figure on the other. The kings of France adopted double seals under Louis VII (ruled 1137–80).

The development of lesser royal seals can be illustrated by the growth of English government. Deputed great seals were used for the major legal courts and for France, Ireland, and Wales. The expansion of the kings' affairs caused the addition of smaller, more personal seals, such as the signet. The Chancery did not control these seals, and this freedom led to the evolution of autonomous offices. The privy seal appeared early in the 13th century in the custody of the clerks of the king's chamber. It was soon transferred to the wardrobe clerks, and gradually its importance increased until by the early 14th century the keeper of the privy seal was the third minister of state. The keepership gained further prestige in midcentury, when the great seal was entrusted to the keepers who went abroad with Edward III. As the privy seal grew in importance, the king preferred another small seal for authenticating correspondence and warrants. Under Edward II (ruled 1307–27) there was a secret seal distinct from the privy seal. By 1400 the signet, as the secret seal was then called, was in the charge of the king's secretary. The signet rather than the privy seal became the originating force in administration, and from 1540 there were two secretaries, each with two signets. The privy seal and signet seal were both single armorial seals.

Royal officials had their own seals. Circular admirals' seals, dating from the late 14th century to the 17th century, include a fine group of 15th-century bronze matrices. The seals show ships in great detail, with the sails displaying the arms of the admiral.

Religious seals. The principal episcopal seal was the seal of dignity, always a pointed oval. From the 11th to the 14th century it usually depicted the standing figure of the bishop, from the 13th century with a canopy above him. In the mid-14th century the standing figure was often replaced by a saint or a religious scene, with the bishop praying beneath—a form that had been used earlier on episcopal counterseals. The seal of Thomas Arundel, archbishop of Canterbury (1396), depicts the mar-

The legend

times

Bishops' and
monastic
seals

tyrdom of Becket in the centre of an elaborate series of niches, with the archbishop below.

Monastic seals, usually double-sided and of high quality, normally show the buildings of the monastery, religious scenes, or the patron saint. They were distinct from abbots' and priors' seals, which were similar to those of bishops. Notable was the elaborate four-part matrix of Boxgrove Priory (mid-13th century). The seal of Merton Priory (1241), considered the finest English medieval seal, had the Virgin and child on one side with St. Augustine of Hippo on the other.

Papal bulls were double-sided lead seals appended to the document on strings. The earliest known is that of Deusedit (reigned 615–618). The usual design, with the head of the Apostles Peter and Paul on one side and the pope's name on the other, first appeared under Paschal II (reigned 1099–1118). Although this style of portrayal of the heads was changed in the Renaissance, the design has not been altered.

Town seals. The possession of a common seal was an important part of a town's independence. Town seals were almost always round and often double. Many towns still possess their original matrices. The earliest in England date from around 1200, when many towns received their charters. The seal of Exeter has been dated to c. 1180. Maritime towns often depicted a ship with a furled sail; inland towns often showed the guildhall or the town itself. The seal of Rochester depicted the Norman castle within a wall. Counterseals often bore the figures of saints. Later medieval town seals were less common and beginning with the 14th century were often single seals.

Commercial seals. Commercial seals in England were considerably increased during the reign of Edward I, when double-sided bronze dies occurred for various customs, subsidies, and the delivery of wool and hides. Their obverse displayed the arms of England, and the reverse had the same device without the shield. The seals of merchants and craftsmen often displayed either merchants' marks or tools connected with their trade.

Personal seals. The earliest class of personal seals was that of greater barons of the 12th century, who used the device of a fully armed equestrian knight. Their shields often provide the earliest evidence for the use of heraldic charges. Some greater barons used a double seal with an equestrian obverse and an armorial reverse. The most usual type of personal seal was a single seal with the arms of the owner. Women's seals were usually pointed ovals and showed the lady standing, sometimes between shields. Nonheraldic personal seals displayed a variety of devices, such as stars, fleurs-de-lis, armorials, and religious subjects. The inscription sometimes indicated the owner, although it may simply have related to the device, as on those that bore the device of a squirrel and the inscription "I krack nuts." (J.Ch.)

Modern use of seals. The use of seals declined as the use of signatures grew. Personal fob seals were in fashion from the 17th to the early 19th century; often they were gems in gold settings that were carried in the fob or breeches pocket and were used to seal folded private correspondence before the envelope was introduced. States and institutions continued to use seals for the formal ratification of their acts, but few of these seals maintained the medieval vigour of design.

Chinese and Japanese seals. The private seals used in China (*t'u-chang*) and Japan (*ingyō*), commonly square and reading merely "seal of so and so" (XX *chik yin*), served as a confirmation of signature or a sign to be verified but have not the legal status of a signature. They are made of ivory, wood, or jade. Used by artists and collectors to mark their paintings and books, there is hardly a limit to their fanciful designs and phraseology. A man might own scores of seals, using his many sobriquets, especially those suggesting unworldly and rustic tastes. A seal is impressed in red ink—made of cinnabar in water and honey or suspended in sesame oil, hempseed oil, etc.—held ready on a pad of cotton or moss. The characters most often appear in line, but they are sometimes reserved against the inked ground.

The first record of a seal in China is from 544 BC. Actual

bronze seals survive from the 5th century BC, and the practice of sealing must be some centuries older. The emblematic characters cast on Shang dynasty bronze vessels (13th–11th century BC) imply the use of something like a seal for impressing on the mold. The royal seal and other seals of high office were termed *hsi*; other seals of rank and appointment were *chang*. The imperial *hsi* (called *pao* beginning in the Tang period, AD 618–907) was traditionally large and square, made of jade or ivory. The most famous one belonged to Shih Huang Ti (ruled 221–210 BC); it had as its knob a one-horned dragon and is fabled to have been handed down to the present day.

The official and, no doubt, the personal use of seals began in Japan with the copying of Chinese institutions in the 7th century AD. Both in China and in Japan modern seals generally employ the "small seal" character (*chuan shu*), the "great seal" character being reserved in the past for the ruler and high officers. To the historian the importance of the Far Eastern seals is greater in the earlier periods, and in China they yield more information than in Japan. Thus, seals recovered archaeologically throw light on government appointments made in the Han period, particularly in the reign of Han Wu Ti (140–87 BC), when they were tokens of rank given to internal officials and some external client rulers. Gold seals of the "King of the Han Wei-nu county," found near Fukuoka in 1784, and that of the "King of Tien" excavated near K'un-ming in 1956 have implications of this kind. But in post-Han times the seals have served little if at all as primary historical documents, and in writings on East Asia it is chiefly the art historian who appeals to their testimony in authenticating paintings and calligraphies. (W.W.)

BIBLIOGRAPHY. The best general account is SIR HILARY JENKINSON, *Guide to Seals in the Public Record Office* (1954). JOSEPH H. ROMAN, *Manuel de sigillographie française* (1912), is a longer study mainly on French seals. The basic catalog for European seals and impressions is WALTER DE GRAY BIRCH, *Catalogue of Seals in the Department of Manuscripts in the British Museum*, 6 vol. (1887–1900). Seal matrices are discussed by ALEC B. TONNOCHY in the *Catalogue of British Seal-Dies in the British Museum* (1952). ALFRED B. WYON, *The Great Seals of England from the Earliest Period to the Present Time* (1887), provides a systematic and well-illustrated account of English Great Seals. A full discussion of Classical seal use, with bibliography and occasional reference to Near Eastern sources, is given in the article "Signum," by WENGER in *Pauly-Wissowa Real-Encyclopadie*, vol. 2, col. 2361–2448 (1923); and details of use in the Aegean and Greece are conveniently given in JOHN BOARDMAN, *Greek Gems and Finger Rings* (1970). No adequate study exists of the uses of seals in ancient western Asia. See at present, however, ELENA CASSIN, "Le Sceau: un fait de civilisation dans la Mésopotamie ancienne," *Annales*, pp. 742–751 (1960); and M.I. ROSTOVTSSEFF, "Seleucid Babylonia: Bullae and Seals of Clay with Greek Inscriptions," *Yale Classical Studies* 3:1–114 (1932). A very full bibliography of ancient Eastern seal publications from which information on use may be gleaned is given by HANS H. VON DER OSTEN in *Ancient Oriental Seals in the Collection of Mr. Edward T. Newell*, pp. 168–190 (1934); and in *Altorientalische Siegelsteine der Sammlung Hans Silviu von Aulock*, pp. 156–219 (1957), but no more recent convenient bibliography exists; systematic study of use must depend mainly on the examination of sealed texts. For Egypt, P.E. NEWBERRY, *Scarab-Shaped Seals* (1907), provides a brief account, now much in need of revision. Books on Chinese and Japanese seals deal mainly with those of painters, calligraphers, and collectors. ROBERT H. VAN GULIK, *Chinese Pictorial Art As Viewed by the Connoisseur* (1958), has the most illuminating discussion of the artist's use of seals. See also VICTORIA CONTAG and WANG CHI-CH'EN, *Seals of Chinese Painters and Collectors of the Ming and Ch'ing Periods*, rev. ed. (1966); and CHEN CHIH-MAI, *Chinese Calligraphers and Their Art* (1966).

(J.Ch./T.C.M./W.W.)

Sikhism

Sikhism is the religion of an Indian group founded in the Punjab (more correctly Pañjāb) in the late 15th century AD by Gurū Nānak. Its members are known as Sikhs.

There are now about 9,000,000 Sikhs, of whom over 85 percent live in the state of Punjab. The majority of the remainder are in Haryāna state and Delhi, or are scattered in other parts of India. Some Sikhs have also settled

"Small" and "great" seals

in Malaysia, Singapore, East Africa, England, the United States, and Canada. The word Sikh is derived from the Pāli *sikkha* or Sanskrit *śiṣya*, meaning "disciple." Sikhs are disciples of their ten Gurūs (religious teachers), beginning with Nīnak (b. 1469) and ending with Gobind Singh (d. 1708).

HISTORY AND BACKGROUND

Religious and cultural origins. Sikhism was a historical development of the Hindu Vaiṣṇava Bhakti movement—a devotional movement among followers of the god Viṣṇu (Vishnu)—that began in Tamil country and was introduced to the north by Rāmānuja (c. AD 1050–1137). In the 14th and 15th centuries, and after prolonged confrontation with Islām, the movement spread across the Indo-Gangetic Plain. The Bhaktas (devotees) maintained that God, though known by many names and beyond comprehension, is the one and the only reality; that all else is illusion (*māyā*); and that the best way to approach God is through repetition of his Name (Sanskrit *nīma*), singing hymns of praise (Punjabi *kirtan*), and meditation under the guidance of a Gurī. Traditional Hindu religion and society were hierarchically structured; the Brahmin priests claimed a monopoly over religious matters and the people were divided into castes. The Bhakti movement opposed the Brahmin monopoly and the caste system.

Kabir (AD 1440–1518), a medieval mystic poet and religious synthesist, was the link between Hindu Bhakti and Islāmic Sūfism (mysticism), which had also gained a considerable following among Indian Muslims. Šūfis (mystics) also believed in singing hymns and in meditation under guidance of a leader. They welcomed non-Muslims in their hospices. Sikhism drew its inspiration from both Bhaktas and Šūfis.

The first Sikh Gurū Nānak (d. 1539) conversing with the tenth and last Guru Gobind Singh (1675–1708). The imaginary meeting is expressive of the religion's development from a pacifist to a militant brotherhood. Painting of the Guler school, c. 1820. In the collection of Mohan Singh, Punjab, India.

The Ten Gurūs: Nānak and his tradition. Nīnak was born in 1469 in the village of Rāi Bhoi dī Talvaṇḍī, 40 miles from Lahore (in present-day Pakistan). His father was a revenue collector belonging to the Bedi (conversant with the Vedas—the revealed scriptures of Hinduism) subcaste of Kṣatriyas ("Warriors"). Nānak received an education in traditional Hindu lore and the rudiments of

Islam. Early in life he began associating with holy men. For a time he worked as the accountant of the Afghān chieftain at Sultānpur. There a Muslim family servant, Mardānā, who was also a rebec player, joined him. Nānak began to compose hymns. Mardānā put them to music and the two organized community hymn singing. From the offerings made, they organized a canteen where Muslims, as well as Hindus of different castes, could eat together. At Sultānpur Nīnak had his first vision of God, in which he was ordered to preach to mankind. He disappeared while bathing in a stream. When he reappeared on the third day, he proclaimed: "There is no Hindu, there is no Mussulman."

Sikh tradition relates that Nānak also undertook four long voyages: east as far as Assam; south through the Tamil country to Ceylon; north to Ladakh and Tibet; and west as far as Mecca, Medina, and Baghdad. He spent the last years of his life in Kartārpur (in present-day Pakistan), where he raised the first Sikh temple. Before he died in 1539 he nominated one of his disciples, Aṅgad, as his successor.

Aṅgad (Gurī 1539–1552) was followed by another disciple, Amar Dās (Gurī 1552–1574), who later nominated his son-in-law, Riim Dās Soḍhī (Gurū 1574–1581) as his successor. Thereafter, the office of Gurī remained in the Soḍhī family. Riim Dās was succeeded by his youngest son, Arjun Mal (Gurī 1581–1606), who, before his execution in Lahore on May 30, 1606, nominated his son Hargobind (Gurī 1606–1644). The seventh Gurū, Har Riī (Gurī 1644–1661), was Hargobind's grandson, who, after his tenure, nominated his young son Hari Krishen (Gurī 1661–1664), who died of smallpox at the age of 13. Tegh Bahādur (Gurī 1664–1675), who succeeded him, was the son of the sixth Gurū, Hargobind. Before his execution in Delhi on November 11, 1675, Tegh Bahādur passed succession to his son, Gobind Rāi (Gurī 1675–1708).

The founding of the Khālsā. The execution of two Gurīs and persecution by the Mughals compelled the Sikhs to take to arms. This was given religious sanction when, on the Hindu New Year Day (April 13, 1699), Gobind Rāi baptized five Sikhs into a new fraternity he called the Khālsā, "the pure" (from the Persian *khāles*, also meaning "pure"), and gave them a common surname, Singh ("lion"). Kaur "lioness" is the corresponding name given all Sikh women. Gobind Rāi's military career was not very successful. He lost most of his followers including his four sons. He was hounded out of the Punjab and assassinated at Nanded (Mahārāshtra) on October 7, 1708. Before his death he declared the succession of Gurīs at an end. The military leadership of the Sikhs devolved upon Bandā Singh Bahādur (1670–1716). For eight years Bandā defied the Mughals and devastated large tracts of eastern-central Punjab, until he was captured and, along with 700 of his followers, executed in Delhi in the summer of 1716.

For a few years the Khālsā disappeared into the hills. But when Mughal power was weakened by the incursion in 1738–39 of the Persian Nāder Shāh, they re-emerged into the plains. They organized themselves under *misls* (from Persian *mēsāl*, meaning both "example" and "equal"), and began to extract protection money from towns and villages. The series of invasions by Ahmad Shāh Durrānī, 1747–1769, completely disrupted Mughal administration. In the battle of Panipat in 1761, the Afghāns destroyed rising Marāthā power in the north. In the power vacuum thus created, the Sikhs moved in as rulers of the Punjab.

The Sikh Empire of Ranjit Singh. In the years of turmoil between the Persian and Afghān invasions, Sikh *misls* had operated in loosely defined areas. Two main divisions emerged: Cis-Sutlej, the area between the Sutlej and the Jamuna rivers, and the Trans-Sutlej, between the Sutlej and the Indus rivers. In 1761 Sikhs wrested the capital city of Lahore from the Mughal governor.

Ranjit Singh's (1780–1839) *misal*, the Šukerchakīās, was based at Gujranwāla, north of Lahore. Ranjit took possession of the capital in 1799 and two years later had himself crowned maharaja of the Punjab. The English, who had advanced beyond Delhi, took the Cis-Sutlej

The
surname
Singh

Ranjit
Singh

states under their protection and compelled Ranjit Singh to accept the Sutlej River as the south-eastern limit of his kingdom. There, after Ranjit Singh systematically brought the Trans-Sutlej region under his suzerainty, he took Multan in 1818 and Kashmir in 1819. In the following winter he extended his domain beyond the Indus River into the land of the Pathans.

Ranjit Singh modernized his army by employing European officers. This army defeated the Pathans and Afghāns and extended Sikh power to the Khyber Pass. Ranjit Singh died in June 1839.

Relations between the Sikhs and the British. After taking the Cis-Sutlej states under protection, the English began to think in terms of extending their empire up to the Indus River. Even during Ranjit Singh's lifetime they had begun to interfere in the affairs of Afghanistan, and had persuaded him to join in an Anglo-Sikh expedition to Kabul. After the death of Ranjit Singh the Sikh kingdom disintegrated rapidly. Ranjit's eldest son, Kharak Singh, who succeeded him, was deposed by his own son, Naonihal Singh, and died of excessive use of opium. On the same day, Naonihal Singh was mortally injured when a gateway collapsed on his head. Kharak Singh's widow, Chand Kaur, occupied the throne for a few months until she was deposed and later murdered by Ranjit Singh's second son, Sher Singh. On September 15, 1843, Sher Singh, his son Pratap Singh, and Chief Minister Dhian Singh Dogra were murdered by Chand Kaur's kinsmen, who in their turn were slain by Dhian Singh's son, Hira Singh Dogra. Ranjit Singh's youngest son, Dalip Singh, was proclaimed maharaja with his mother, Jindan Kaur, as regent and Hira Singh Dogra as prime minister. Power passed, however, into the hands of the pañcāyat (elected council) of the Khālsā Army, which compelled the Dogra to flee Lahore and then slew him in flight.

The English began to move their troops to the Sikh frontier and commandeered boats to cross the Sutlej. On December 11, 1845, the Khālsā Army crossed the river to intercept a British force led by their commander-in-chief and the governor general. In a series of bitterly contested battles at Mudki (December 18, 1845), Ferozeshah (December 21, 1845), Aliwal (January 28, 1846), and Sabraon (February 10, 1846) the Khālsā were defeated. The British annexed the territory between the Sutlej River and the Beas, forced the Sikhs to reduce their Army, and on their failure to pay war indemnity of 1% crores of rupees, to cede Jammu and Kashmir, which were then sold to Gulab Singh Dogra. A British resident was posted at Lahore to administer the rest of the Sikh kingdom during the minority of Dalip Singh.

Administrative measures taken by the resident aroused resentment among the people. The banishment of Jindan Kaur, the queen mother, on charges of conspiracy brought matters to a head in the winter of 1848 and touched off a general Sikh uprising. A bloody but inconclusive battle was fought at Chillianwāla (January 13, 1849); however, at Gujrat (February 21, 1849) the Khālsā were totally defeated and laid down their arms. The Sikh kingdom was annexed and Maharaja Dalip Singh was exiled from the Punjab.

After many years of chaos, the Punjab was administered efficiently and fairly. Consequently when the Indian Mutiny broke out in 1857, the province stayed loyal to the British and the Sikhs took a prominent role in suppressing the Mutiny. For this loyalty and help they were rewarded by grants of land. The proportion of Sikhs in the British Army was increased. A regulation was passed requiring Sikh soldiers to observe Khālsā traditions. With the reclamation of desert lands through an extensive system of canals, unprecedented prosperity came to the Punjab. Sikhs were the most favoured settlers. By the turn of the century, though they numbered under 12 percent of the population of the province, they were paying 25 percent of the land revenue and 40 percent of the land revenue and water rates combined. Sikh loyalty was evidenced in World War I, in which Sikhs formed over 20 percent of the British Indian Army.

The depression that followed the war led to widespread disturbances, climaxed in the shooting, on April 13, 1919,

at Amritsar of over 400 men. Sikhs also clashed with the authorities over the possession of their *gurdwārās* ("temples"), which were under the control of hereditary priests. The Sikh masses turned from their British connection to join Gandhi's freedom movement. The progressive introduction of democratic reforms further reduced their earlier privileged status under British rule. Their participation on the British side in World War II was considerably less enthusiastic than it had been in 1914–18.

The division of the subcontinent into India and Pakistan in 1947 found the Sikh population divided equally on both sides of the boundary line. Since the partition had been preceded by savage Sikh–Muslim riots, 2,500,000 Sikhs were compelled to leave Pakistan.

Sikhism since 1947. The government of free India abolished privileges previously extended by the British to religious minorities, including the Sikhs. Thus, the proportion of Sikhs in defense and civil services declined. The partition also adversely affected the Sikh agricultural classes, who had abandoned rich farmlands in Pakistan and changed places with Muslims of east Punjab whose holdings were much smaller. The decline in their fortunes nurtured a sense of grievance and gave birth to agitation for a Punjabi-speaking province in the Republic of India in which the Sikhs would form a majority of the population. This demand was conceded after the Indo-Pakistan War in 1965. In the present-day Indian Punjab, Sikhs form 51 percent of the population.

SIKH LITERATURE, MYTH, AND LORE

Canonical and **noncanonical**. The earliest source materials on Nānak are the *janam-sākhīs* ("life stories"), written 50 to 80 years after the death of the Gurii. Most Sikh scholars reject them and rely instead on the Gurū's compositions incorporated in the *Adi Granth* and the *Vārs* (heroic ballads) composed by Bhāi Gurdās (d. AD 1629). Neither Nānak's hymns nor Gurdās' *Vārs*, however, are specific regarding the events of Nānak's life. Other historical writing was done during the 18th and the 19th centuries, notably by Mani Singh (died 1734), Kirpāl Singh Bhallā (died 1741), Sariip Dās Bhallā (1776), and Santokh Singh (1823). For the rest, Sikh historians rely heavily on records of Mughal court historians.

There is only one canonical work: the *Adi Granth* (first volume) compiled by the fifth Gurii, Arjun, in AD 1604. There are at least three recensions (versions) of the *Adi Granth* that differ from each other in minor detail. The version accepted by Sikhs as authentic is said to have been revised by Gobind Singh in AD 1704. The *Adi Granth* contains nearly 6,000 hymns composed by the first five Gurūs: Nānak (974), Aṅgad (62), Amar Dās (907), Rām Dās (679), and Arjun (2,218). Gobind incorporated 115 hymns of his father Tegh Bahādūr in it. Besides the compositions of the Gurii, the *Adi Granth* contains hymns of the Bhakta saints and Muslim Šūfis, notably Farīd, and of a few of the bards attached to the courts of the Gurii. The hymns are divided into 31 *rāgas* (musical modes), meant to be sung except for Nānak's *Jappī* (a morning prayer) that is spoken.

The *Dasam Granth* (tenth volume) is a compilation of writings ascribed to Gurii Gobind. Scholars are not agreed on the authenticity of the contents of this *Granth*, and it is not accorded the same sanctity as the *Adi Granth*.

Traditions of the Khālsā are contained in the *Rahatnāmās* (codes of conduct) by several contemporaries of Gurii Gobind Singh.

Myths and lore. Although the Gurūs themselves disclaimed miraculous powers, a vast body of *sākhīs* ("stories") recounting such miracles grew up, and with them *gurdwārās* ("temples") commemorating the sites where they were performed. It also became an article of belief that the spirit of one Gurii passed to his successor "as one lamp lights another." This notion gained confirmation through the fact that the Gurūs used the same poetic pseudonym, "Nānak", in their compositions.

A composition about which little is known, but which has played an important role in Sikh affairs, is a collection of prophecies, *Sau Sākhī* (hundred tales), ascribed to Gurū Gobind Singh. Various versions are known to have

The canonical work

Sikh role in the Indian Mutiny

been published prophesying changes of regimes and the advent of a redeemer who will spread Sikhism over the globe.

DOCTRINES OF SIKHISM

Use of
Hindu
cosmogony

Views on the nature of man and the universe. Speculation on the origin of the cosmos is largely derived from Hindu texts. Sikhs accept the cyclic Hindu theory of *samsāra*—birth, death, and rebirth—and *karman*, whereby the nature of a man's life is determined by his actions in a previous life. Man is, therefore, equal to all other creatures, except insofar as he is sentient. Human birth is his one opportunity to escape *samsāra* and attain salvation.

Concept of the *Khālsā*. *Khālsā* is a concept of a "chosen" race of soldier-saints committed to five principles: a Spartan code of conduct (consisting of abstinence from liquor, tobacco, and narcotics; and devotion to a life of prayer) and a crusade for *dharmayudha*—the battle for righteousness. The number five has always had mystic significance in the Punjab—"land of the five rivers." "Where there are five, there am I," wrote Gobind Singh. The first *Khālsā* were *pañj* piydras—the five beloved ones. The aim of all young Sikhs should be to take *pahul* ("baptism") and thus become *Khālsā*. The *sahajdhārī* ("slow-adopter") is assumed to be preparing himself gradually for the initiation.

The notion of the five K's. The five emblems of the *Khālsā*, all beginning with the letter k, have no scriptural basis, but are mentioned in the *Rahatnāms*, written by Gobind Singh's contemporaries. The most important of the K's is *kesa* ("hair"), which the *Khālsā* must retain unshorn. A *Khālsā* who cuts off his hair is a *patit* ("renegade"). The sanctity of unshorn hair is older than Gurii Gobind Singh—the founder of the *Khālsā*—for many of the earlier Gurūs also followed the tradition (common among certain sects of Hindu ascetics as well) of letting their hair and beards grow.

The other four K's are *kanghd* ("comb"); *kacch* ("drawers"), worn by soldiers; *kirpdn* ("sabre"); and *kard* ("bracelet") of steel, commonly worn on the right arm. The usually accepted explanation of the *kard* is that it is the Gurū's charm against evil—a variation of the Hindu *rakhi* tied by sisters on the wrist of their brothers to keep them from harm.

Monotheism. Unity of the godhead is emphasized in Sikhism. *Nānak* used the Hindu *Vedāntic* concept of Om, the mystic syllable, as a symbol of God. To this he added the qualifications of singleness and creativity and thus constructed the symbol *ik* ("one") Om *Kār* ("creator"), which was later given figurative representation as . The opening lines of his celebrated morning prayer, *Japī*, which are known as the *Mul* Mantra ("root belief") of Sikhism define God as the One, the Truth, Creator, immortal, and omnipresent. God is also *nirankār*—formless—and beyond human comprehension. Sikh scriptures use many names, both Hindu and Muslim, for God. *Nānak*'s favourite names were *Sat-Kartār* (True Creator) and *Sat-Nām* (the True Name). Later the word *Wāh-Gurū* (Hail Gurū) was added and is now the Sikh synonym for God.

Concepts of spiritual authority. The sole repository of spiritual authority is the *Adi Granth*. In the event of disputes, spiritual or temporal, a conclave is summoned to meet at the *Akāl Takht* ("Throne of the Timeless"), a building erected by the sixth Gurū, Hargobind, facing the *Harimandir* temple in Amritsar. Resolutions passed at the *Akāl Takht* have spiritual sanction.

Aniconic
orientation
and
anti-
ritualism

Views on idolatry and rituals. Sikhism forbids representation of God in pictures and the worship of idols. Nevertheless the *Adi Granth* itself has become an object of worship and as such is known as *Granth Sahib* (the *Granth* personified). It is "roused" in the morning and placed under an awning draped in fineries. Devotees do obeisance and place offerings before it. In the evening it is put to rest for the night. On festival days it is taken in procession through the streets. Most rituals centre on the *Adi Granth*. The nonstop recitation from cover to cover by a relay of readers (*akhand-path*), which takes two days and nights, has become very popular.

Social consequences of beliefs. The main consequence of Sikh belief has been a gradual breaking away from the Hindu social system and the development of Sikh separatism. The singular worship of the *Adi Granth* excludes worship of all other objects common among Hindus (*i.e.*, the sun, rivers, trees, etc.) and also puts a stop to the practice of ritual purifications and pilgrimages to the Ganges. Since every Sikh is entitled to read the scripture, Sikhs do not have a priestly caste similar to the Brahmins in Hinduism. Sikh insistence on *commensality* (eating together) at the Gurii ka *laṅgar* ("kitchen of the Gurii") destroyed the traditional Hindu pattern of caste among them and substituted a far less rigid social structure. Sikhs are grouped into three broad categories based largely on ethnic differences: *Jāts* (agricultural tribes), *non-Jāts* (erstwhile Brahmins, *Kṣatriyas* and *Vaiśyas*—the three highest groups of the traditional Hindu social system), and *Mazahabis* (untouchables). The *Jāts*, though *Sūdras* (lowest group inside caste system), are pre-eminent; the *Mazahabis*, though converts from Hindu outcastes (untouchables outside the caste system), and still discriminated against, have a much higher status than untouchables in Hindu society (see also *CASIE SYSTEMS*).

PRACTICES AND INSTITUTIONS

The Gurii and the disciple. The guidance of the Gurū toward the attainment of *mokṣa*—release—is absolutely essential. The Gurū or the *Satgum*—true Gurii—is accorded a status only a shade below that of God. His function is to point the way to the realization of the truth, to explain the nature of reality, and to give the disciple the gift of the divine word (*nām-dān*). Although the line of Gurūs ended with Gobind Singh and Sikhs regard the *Adi Granth* as their "living" Gurii, the practice of attaching oneself to a sant ("saint") and elevating him to a status of a Gurii has persisted and is widely practiced.

Recitation of *Nāma*. Sikhism is often described as *Nāmmārga* ("the way of *Nāma*") because it emphasizes the constant repetition (*Jap*) of the name of God and the *gurbānī* (the divine hymns of the Gurūs). *Ndma* cleanses the soul of sin and conquers the source of evil, *haumain* ("I am")—the ego. Thus tamed, the ego becomes a weapon to overcome lust, anger, greed, attachment, and pride. *Ndma* stills the wandering mind and induces a super-conscious stillness (*divya dṛṣṭi*), opens the *dasam duār* (tenth gate—the body has only nine natural orifices) through which enters divine light; and thus a person attains the state of absolute bliss.

Rites of passage and other ceremonies. No specific rites are prescribed for birth, but the practice of chanting the first five verses of *Nānak*'s *Japī* is practiced among some Sikhs. A few days later the child is brought to the *gurdwārā*. The *Adi Granth* is opened and the child given a name beginning with the first letter of the first word on the left page. When a child has learned some *Gurmukhi* script he is initiated into reading the *Adi Granth*. The most important ceremony is that of *pahul* ("baptism"), usually administered on attaining puberty. The initiate takes *amrit* ("nectar") and is admitted to the *Khālsā* fraternity. A Sikh marriage (*karaj*) requires the groom and bride to go round the *Adi Granth* four times to the chanting of wedding hymns. On death, there is continual chanting of hymns till the body is prepared for cremation. A final *ardāsā* ("supplicatory") prayer is said before the funeral pyre is lit. Ashes of the dead are usually immersed in the *Beas* at *Kiratpur*—or in one of the Hindu sacred rivers, preferably the Ganges.

Sacred times and places. Early hours of the dawn are ambrosial hours (*amritvelā*) most appropriate for prayer and meditation. Though not specifically prescribed as such, *gurdwārās* with historical associations are, in fact, places of pilgrimage. Pre-eminent amongst them is the *Harimandir* at Amritsar. *Nankāna*, the birthplace of *Nānak* (now in Pakistan) comes second. There are also four thrones (*Akāl Takhts*) that are accorded special sanctity; these are at Amritsar, Anandpur, Patna and Nanded. The last two are the places where Gurii Gobind Singh was born and died. From all of them, proclamations can be made to all the *Khālsā*.

Pilgrimage
places

The first Sikh place of worship was built by Nānak at Kartārpur and was, like Hindu temples, known as *dharma-salcī* ("place of faith"). At a later stage, a Sikh temple was called a *gurdwārā*, meaning "gateway to the Gurū." There are more than 200 historical *gurdwārās* associated with the Gurūs, which are controlled by the Shiromani Gurdwārā Prabandhak Committee (S.G.P.C.) set up by the Sikh Gurdwaras Act of 1925. Offerings made at *gurdwārās* are used for their upkeep as well as for the operation of Khālsā schools and colleges.

In addition to historical *gurdwārās*, every place with a sizable Sikh population is likely to have a *gurdwārā* of its own. In well-to-do homes, a room is often set apart for this purpose. The only object of worship is the *Ādi Granth*. Worshippers make their offerings of money and flowers and receive *karāh-prasad*, a batter made of flour, ghee (clarified butter), and sugar.

Sikhs observe all festivals celebrated by the Hindus of northern India. In addition, they celebrate the birthdays of the first and the last Gurūs and the martyrdom of the fifth (Arjun) and the ninth (Tegh Bahādūr). The biggest fair is on the first of Baisakh (mid-April), which is also the birthday of the Khālsā itself.

The *Khālsā Saṅgat*. The *Saṅgat* ("congregation") is usually called the *Sādh-saṅgat* (congregation of holy men), and thus is invested with sanctity. The *Saṅgat* in each *gurdwārā* elects its own governing body and decisions are taken by vote. As a rule women do not participate in the deliberations. The Shiromani Gurdwārā Prabandhak Committee (S.G.P.C.) at Amritsar is the general governing body of Sikhism.

Sectarian differences. The first dissenters from the mainstream of Sikhism—known as the Udāsīs—were followers of Nānak's elder son, Śrī Chand. The order inclined towards asceticism and later furnished priests (*mahants*) for *gurdwārās*. They were ousted from control by the S.G.P.C. in 1925. Followers of Rām Rāi, who was passed over by his father, Har Rāi (seventh Gurū), in favour of a younger son, Hari Krishen (eighth Gura), broke away to become Rām Rāiyās. They have their headquarters in Dehra Dūn, Uttar Pradesh.

Khālsā who do not believe that the line of Gurūs ended with Gobind Singh have continued the tradition of having a living Gurū. Among these, the Bandai Khālsā (followers of Bandā Bahādūr) are now extinct, but the Nāmdhāris and Nirāṅkārīs worship living Gurūs.

Sikh welfare and educational institutions. The S.G.P.C. is the chief welfare organization of the Sikhs. The Sikh Educational Conferences, meeting annually since 1908, are the chief educational organizations credited with the establishment of innumerable schools. In 1965 two religious-social organizations, the Gura Gobind Singh Foundation and the Gurū Nānak Foundation, endowed many university chairs for the study of Sikhism and the publication of material on Sikh history and religion.

POLITICAL AND SOCIAL ROLE IN INDIA SINCE INDEPENDENCE

Caste attitudes. The three-tiered caste structure among the Sikhs—Jāṭs, non-Jāṭs, and Mazahabis—is in a state of flux. Among the educated urban classes it is breaking up, but in the villages a form of apartheid persists, excluding Mazahabis from community wells. State laws provide untouchables with free schooling, preference in services, and reservation of seats in village councils.

Church-state relations. Sikh religion and politics have always been intimately connected, and belief in a Sikh state is an article of faith. *Rtiṅ karey Gā Khālsā*—"the Khālsā shall rule"—is chanted at the conclusion of every service and was one of the motivations of the demand for a Sikh-dominated state, Punjab, with Chandigarh as its capital (since February 1970).

The place of *Sikhism* in Indian religions. Close religious and social affiliation with Hinduism has always presented a danger to Sikhism as a separate socio-religious system. The tendency of the younger generation of Sikhs to abandon the Khālsā emblem of unshorn hair has increased the rate of lapse back into Hinduism. Efforts are made to combat this tendency by emphasizing features that are unique to Sikhism and elements that the faith has adopt-

ed from non-Hindu sources, chiefly Islāmic mysticism.

BIBLIOGRAPHY. J.D. CUNNINGHAM, *History of the Sikhs*, 2nd ed. (1853), was the first scholarly work on the Sikhs up to the first Anglo-Sikh war of 1845–46. His interpretation of Sikhism as an eclectic Hindu-Muslim faith remained unquestioned until McLeod's work in 1968. Cunningham was censured for suggesting that British designs on the Sikh kingdom provoked Sikh aggression. M.A. MACAULIFFE, *The Sikh Religion*, 6 vol. (1909), is a compilation of all the legends about the Sikh Guras based on *Janam-sākhis* and on saints whose writings are in the Sikh scriptures; full of literal translations of Sikh hymns. SHER SINGH, *Philosophy of Sikhism* (1944), is a scholarly work interpreting Sikhism as an offshoot of Vaiṣṇavite Hinduism. A selection of hymns from the *Ādi Granth* and Gobind Singh's *Dasam Granth* carried out by a panel of Sikh scholars may be found in *Selections from the Sacred Writings of the Sikhs*, trans. by T. SINGH et al. (1960). KHUSHWANT SINGH, *A History of the Sikhs*, 2 vol. (1963–66), interprets Sikhism as an aspect of Panjabi nationalism and ends with a note of warning about the future of Sikhs. See also KHUSHWANT SINGH, *Ranjit Singh, Maharajah of the Punjab* (1963), a biography based on Persian, Panjabi, and English sources, and (trans.), *Hymns of Guru Nanak* (1969), a selection of Nānak's hymns with a short introduction; and GOPAL SINGH, *The Religion of the Sikhs* (1971). W.H. MCLEOD, *Gurū Ndnak and the Sikh Religion* (1968), casts serious doubt on source material on the life of Nānak, reflects the theory of Sikhism as an eclectic faith, and asserts that it is a branch of Hindu Vaiṣṇavism tinged with yogism.

(K.S.)

Sikkim

Sikkim, the smallest constituent state of the Republic of India, covers an area of 2,818 square miles (7,299 square kilometres) in the eastern Himalayan mountains. It is bordered by the independent Himalayan kingdoms of Nepal, to the west, and Bhutan, to the east; by the Tibetan Autonomous Region of the People's Republic of China, to the north and northeast; and by West Bengal state, India, to the south. Sikkim was inhabited by 315,682 persons in 1981. Gangtok is the state capital.

Although Sikkim was long a sovereign state, its relations with India were governed from 1950 until 1975 by a treaty, under the terms of which India defended Sikkim's territorial integrity and accepted responsibility for its foreign relations and strategic communications. Formal union with India was established in 1975 (see below).

Sikkim has great extremes of altitude and climate within its borders; its lowest point is about 700 feet (200 metres) above sea level, and its highest is the peak of Kāngchenjunga (28,208 feet [8,598 metres]), the third highest mountain in the world.

HISTORY

Three tribes—the Naong, Chang, and Mon—are believed to have inhabited Sikkim in prehistoric times. The Lepchā entered Sikkim sometime later and completely assimilated with the earlier inhabitants, but they are generally thought of as indigenous to the land. The Lepchā were and continue to be peace-loving, deeply religious, and shy. They speak a Tibeto-Burman language, using a script that was devised by King Chagdor Namgyal at the beginning of the 18th century. Most Lepchā have accepted Buddhism, although the pre-Buddhist Lepchā religion, Bon, has influenced Sikkimese Buddhism.

Other tribes that are either indigenous to Sikkim or that may have entered the country from the trans-Himalayas in the prehistoric period are the Magar and the Tsong. The Magar are renowned warriors who formerly were an important part of the Sikkim Guards. They are mentioned as one of the groups to have celebrated the coronation in 1642 of Phuntsog (Penchoo) Namgyal, the first chogyal (temporal and spiritual king) of Sikkim and founder of the Namgyal dynasty, which ruled Sikkim under a feudal system until 1975. The name Sikkim may have been derived from the Tsong term *sukkim*, meaning "new house" or "happy house." The second chogyal, Tensung Namgyal, married a Tsong.

The Bhutia, a Tibetan-speaking group that entered Sikkim in the 13th century, previously lived a pastoral life on the plateaus of Tibet; they belonged to the Rnying-ma-pa

The Bhutia migration

Minor subgroups and orders

(The Old Order), a liberal sect of Mahāyāna Buddhism. Their migration, which was from Kham in Tibet, was led by a prince of the Namgyal dynasty. In adapting to the lush geography of Sikkim, most of them settled as farmers, although some still prefer to live in the high valleys of northern Sikkim, herding yaks and sheep. An aggressive people, they occupied lands with little resistance from the docile Lepchā. Over the years, the Bhutia came into increased contact with the Lepchā and intermarried with them.

The largest migration to Sikkim took place between the mid-18th and 19th centuries, when various tribes entered from northern and eastern Nepal. The first large Nepalese group was the Newar, a Tibeto-Burman people skilled in metalwork. The ruling *chogyal* granted them the right to mine copper and to mint Sikkimese coinage. The Newar were followed by the Gurung, Tamang, Rai, and Sherpa; these were peoples of Tibetan origin who were adept at farming at high altitudes. To accommodate this influx of settlers, new lands were opened to cultivation. As pressure on the land grew, new, intensive methods of farming were introduced, including the terracing of steep slopes. Other groups that migrated from Nepal included clans of the Chettri, the Bahun, and the Bishu Karma, all of whom were probably of Aryan origin.

The various Nepalese tribes spoke their own languages; today, most of them speak Nepali (also called Gorkhali). The newcomers were mainly Hindus of a peculiarly Himalayan type, bringing with them a pantheon of both Hindu and Buddhist deities. Today many clans worship deities of both religions; in Sikkim, as in Nepal, Buddhist and Hindu beliefs have traditionally interacted or amalgamated over the centuries.

Sikkim, being a small country, was obliged to struggle to maintain its territorial integrity. In the mid-18th century Sikkim fought a series of territorial wars with Bhutan. The expansionism of the Nepalese ruler Prithvi Narayan Shah (reigned 1742–75) and his successors obliged Sikkim to defend its western borders, which had once extended as far as Ilām, Nepal. In a series of wars that were to last for nearly a century, Nepal briefly occupied part of western Sikkim, but was obliged to relinquish part of it in 1793 and another part, the submontane Terai, in 1816.

In 1839 the British East India Company obtained Darjeeling from Sikkim as a health resort. British advocates of expansionism policy then attempted to bring independent Sikkim within their sphere of influence and succeeded in annexing the submontane regions by 1849. The annexation was resisted but, after the defeat of Sikkimese troops by the British, an Anglo-Sikkimese treaty was signed in 1861. By the terms of that treaty, the British obtained the right to build a road through Sikkim to Tibet, while Sikkim's sovereignty was recognized, thus establishing its role as a buffer state between British India and Tibet. In 1890, after a series of Tibetan incursions across the frontier of Sikkim, a convention was concluded between the British and China, which then controlled Tibet. Under this agreement, the border between Sikkim and China was defined and China acknowledged the special relationship of British India with the kingdom of Sikkim. A British political officer was subsequently appointed to assist the *chogyal* in the administration of Sikkim's domestic and foreign affairs.

India attained independence in 1947, and a treaty was signed between Sikkim and India in 1950. By the terms of the treaty, Sikkim was deemed to be an Indian protectorate, and an Indian representative, who was simultaneously accredited to Tibet and Bhutan, was sent to Sikkim. Thus India became responsible for the external relations, defense, and communications of Sikkim.

This period was a difficult one in Sikkim's history. Political parties were formed for the first time, social distinctions were sharply felt, and some factions exerted considerable pressure to persuade Sikkim to accede to India. In the political awakening that then swept Sikkim, political parties began to demand a more popular form of government, demands that the *chogyal* resisted. General elections based on adult franchise were held in 1952, 1958, 1967, 1970, and 1973. In the last of these elections,

two rival parties merged to form the Sikkim National Congress, which swept the polls. The winning party launched *Satyagraha*, a movement to obtain greater political liberties and rights that the *chogyal* attempted to suppress. Finding that a solution was out of his control, the *chogyal* asked the government of India to take over the administration. India prepared a constitution for Sikkim that was approved by the Sikkimese national assembly with eight amendments; this became the Government of Sikkim Act of 1974, under which fresh elections to the national assembly were held in 1974. Following passage of a resolution by the national assembly on April 10, 1975, and a special referendum on April 14, 1975, in which more than 97 percent of the electorate voted for the merger of Sikkim with India, the government of India approved the 38th amendment of its constitution on April 26, 1975. The President of India accorded his consent to the Sikkim bill on May 15, 1975, and Sikkim became the 22nd state of the Indian union.

THE LANDSCAPE

Physiography. Known in popular parlance as "a fabulous kingdom," Sikkim is surrounded by precipitous mountain-walls on three sides and appears like "a-pearl in a craggy oyster." The Singalila Range separates Sikkim from Nepal in the west, while the Dongkya Range forms the border with China to the north and northeast. Along the northeastern border, Sikkim is separated from Bhutan by the Chumbi Valley of Tibet. This Tibetan enclave has made the location of Sikkim strategically and politically sensitive out of all proportion to its size.

Sikkim is small, stretching about 70 miles (113 kilometres) from north to south and about 40 miles from east to west. Its horseshoe-shaped mountains offer no sizable flat area, and only in the south is the state not separated from its neighbour, the Darjeeling district of West Bengal state, by a mountainous wall.

About two-thirds of the total territory of Sikkim consists of perpetually snow-covered mountains that act as snow-fields for numerous glaciers. These lofty ranges are without permanent human habitation, although seminomadic herdsman visit these areas with their yaks and sheep during the summer phase of transhumance. The most significant and noteworthy group of mountains is that dominated by Kāngchenjunga, 28,208 feet (8,598 metres) above sea level, the highest mountain peak of India and the third loftiest summit in the world. An expedition climbed the peak successfully in 1955 but left the last few feet of snow untrampled in deference to the Sikkimese belief that the mountain is both a god and the abode of gods. Kinchinjahan (22,700 feet), Siniolchu (22,620 feet), and Chomo Yummo (22,386 feet) are other important mountain peaks of Sikkim.

Within the mountains on the east and west of Sikkim, there are deep valleys, of which the Tista Valley is the largest. On the whole, the altitude in Sikkim varies between 720 feet in the southern foothills to more than 27,800 feet along the northern and northwestern borders. A number of passes connect Sikkim with neighbouring countries.

Elevation, forest cover, gradient, and aspect affect the soils of Sikkim, which are extremely varied. The soils of the tropical forest zone are no doubt leached, but the decomposition of tree leaves, grasses, and ferns has enriched their humus content. In the temperate forest belt, alluvial soils are found along riverbeds, while in areas dominated by conifers and oaks, podzolized acidic soils and brown soils have developed, respectively. Active erosion on the steep slopes has led to the formation of immature soils. In higher reaches, fluvio-glacial soils are found on terraced patches.

Much of Sikkim forms the drainage basin of the Tista River. The river originates in the extreme northeast from the Zemu glacier above Lachen Gompha, near the Chinese frontier. From its source the river descends steeply, dropping about 15,700 feet within its 65-mile course to Rongphu (Rangpo). The Ranjit, Rongni Chu, Talung, Ragpo, Lachen, and Lachung, all snow-fed torrents, are the major tributaries of the Tista. All these southward-

influence

sloping streams have cut deep, beautiful valleys with almost precipitous walls; several hydroelectric power projects supply electricity to Gangtok, Rongphu, Singtam, and Mangan. There are also a number of lakes and hot springs; of the latter, the Phut-Sachu, Ralong Sachu, Youmthang, and Momay springs are the most important. (For associated physical features, see HIMALAYAN MOUNTAIN RANGES.)

Climate. The extremely varied climatic conditions of Sikkim result from variations in elevation. The climate ranges from the tropical heat of low valley bottoms to the alpine cold of the higher reaches. Up to an average altitude of 2,000 feet, moist tropical climate is experienced. Beyond that, a cool temperate climate prevails to an altitude of 6,600 feet. Thereafter, cold temperate climatic conditions are found to 9,800 feet. Higher up, cold increases progressively to Arctic and polar conditions. Depending upon altitude and aspect, annual rainfall varies from 50 to 200 inches (1,250 to 5,000 millimetres). Because of the proximity of the Bay of Bengal and direct exposure to the effects of moist summer monsoons, Sikkim is one of the most humid regions in the Himalayas. Most of the annual rainfall is received during the months of May through October.

The copious rainfall causes numerous landslides that interrupt traffic and sometimes result in the loss of human life and property. In winter the higher reaches are covered with snow that, in many places, attains a thickness of about 100 feet. The heavy snow mass results in avalanches that often cause huge losses of life and property.

Vegetation and animal life. Sikkim contains luxuriant, seemingly endless forests. About 4,000 species of plants are found in the tiny state, making it a botanist's paradise. The monsoonal rainfall is often accompanied by lightning, which adds nitric acid, a source of plant nutrients, to the soil and atmosphere.

The type of vegetation varies with altitude, and three broad vegetation categories are recognized in Sikkim. The subtropical type, which extends to a height of 5,200 feet, includes varieties of bamboos, ferns, tree ferns, canes, palms, sals, pandanus, and orchids. Twenty varieties of bamboos alone are found in this zone. Out of the known 5,000 species of orchids, 601 are found in Sikkim.

In the temperate forests (5,200 feet to 13,100 feet) oak, laurel, maple, chestnut, magnolia, alder, birch, rhododendron, fir, hemlock, and spruce form the predominant vegetation. The alpine forests (13,100 feet to above 16,400 feet) are characterized by such flowering plants as primulas, gentians, blue poppies, aconites, and Himalayan rhubarb. The primula flower is held in very high esteem in Sikkim and Bhutan.

Sikkim has a rich animal life, including about 81 species of mammals, 600 species of birds, 631 species of butterflies, and 2,000 varieties of other insects and creepers. Notable animals include the black bear, brown bear, and panda; the musk deer, sambar, barking deer, and Tibetan antelope; the tiger, leopard, leopard cat, and marbled cat; the goral, wild sheep, and wild goats; the wild boar; and the wild ass. In the upper reaches are tailless mountain rats, rock lizards, and the snow fox. The legendary Abominable Snowman, known as *Nee-gued* in Sikkim, is believed to roam the glaciers and ice slopes.

Birdlife includes pheasants, partridges, teal and other ducks, quail, eagles, barbets, Himalayan cuckoos, babblers, thrushes, Tibetan black crows, and miniwets. Trout and carp abound in Sikkim's streams and lakes.

THE PEOPLE

Most of Sikkim's 315,700 inhabitants live in the central, western, and southern parts of the state. In the far north, the land is rugged, snowbound, inaccessible, and uninhabitable. As there is little flat land, villages are few, each consisting of many hamlets of small homesteads scattered over the slopes of the hills.

The average crude density of population amounts to 112 persons per square mile. The sex ratio in the state is about 836 females for every 1,000 males. Only about 34 percent of the total population has been classified as literate. Almost all the people are Buddhists and Hindus,

although there are also adherents of Christianity and Islam.

Sikkim had no urban area until 1951, when the capital of Gangtok was accorded that status. In 1971, six other towns were accorded urban status; they are Singtam, Rongphu, Mangan, Gyalshing, Jorthang-Nayabazar, and Manchi. About 68 percent of the total urban population, however, resides in Gangtok,

Urban
areas

ECONOMY

Resources. Considering its size, Sikkim is rich in mineral wealth. Copper, lead, zinc, coal, iron ore, garnet, graphite, pyrites, marble, and steatite have been found in the state. Copper mining was a traditional vocation in the region, abandoned long ago for unknown reasons. The Sikkim Mining Corporation, however, was established in 1960 and has done an appreciable job. Copper deposits are found in numerous locations, and coal deposits have been located in Ranjeet Valley. Graphite has been found near Chatterry, while garnet is available in small quantities at Panchikhani. Iron ore has been found at Bhotang and lead-zinc ores in small quantities at Rongphu, Dickchu, and Jugdum. Limestone occurs at Rinchinpong and Changgu and steatite near Chakung.

Copper
mining

Forests, which cover about 36 percent of the state's territory, have immense potential economic value. There is a sawmill at Rongphu, and a paper-pulp project was planned in the early 1980s.

Agriculture. The economy of Sikkim is predominantly agricultural, although agriculture has had a checkered history in the state. The original inhabitants were not agriculturists, but were hunters, fishermen, and gatherers of wild roots and fruits. When the Bhutia migrated to Sikkim, they established both a semi-pastoral economy and slash-and-burn cultivation. It was the Nepalese immigrants who started settled cultivation in Sikkim. These sturdy, hardy, energetic, and innovative people cleared large tracts of woodlands to make the land fit for permanent cultivation and introduced terraced farming along the slopes. Maize (corn), paddy (rice), buckwheat, wheat, and barley are the principal cereals of the region. Sikkim is one of the world's main producers of cardamom, producing more than 2,000 tons annually. The region has also become an important exporter of mandarin oranges, apples, and potatoes. Beans, cabbage, ginger, cauliflower, peas, and tomatoes are also grown.

Cardamom
production

Animal husbandry also plays a major role in the economy. Though yet in a crude form, it is mixed farming that provides sustenance for a large number of people. Cattle, buffalo, yaks, sheep, goats, pigs, mules, ponies, and poultry are the important domesticated animals. Cattle and buffalo are limited mainly to the subtropical humid belt.

Handicrafts and industry. Among the handicrafts, cotton and wool weaving; the making of carpets, rugs, and blankets; and bamboo work have a name in Sikkim. The Cottage Industries Institute offers instruction in these pursuits, as well as in doll-making, ceramics, dyeing and batik, traditional scroll painting, embroidery, the preparation of handmade paper, canework, woodwork, tailoring, and toy-making. Sikkimese caps and ornaments are attractions for visitors.

As a result of economic planning, a fruit preservation and canning plant at Singtam, a distillery at Rongphu, a wine-nail plant and tannery at Rongphu, and a tea-processing factory at Temi have been planned. The Sikkim distillery, set up in 1956, has earned a reputation for its high-quality products.

Transport and communications. Road transport is the primary mode of travel. In 1954, only 50 miles (80 kilometres) of long trunk road connected Gangtok with the town of Rongphu. As a result of sustained efforts by the government, however, Sikkim had 932 miles of metalled roads connecting different parts of the state by 1980. Ropeways have also been provided at many points.

Gangtok is nearly 75 miles from the nearest airport at Bagdogra, in West Bengal state, while Siliguri, 70 miles away in West Bengal state, is the nearest railway station to the Sikkim state capital.

There is a network of government radio stations in the

Bamboo
and
orchids

interior, and telephonic communications link important towns.

GOVERNMENT AND EDUCATION

Under the formal feudal system, the chogyal was the head of state of Sikkim. Since 1975, the Sikkim government, like that of any other state of India, has been headed by the governor, who is appointed by the president of India and who holds office during his pleasure. The governor appoints as his chief minister the elected leader of the majority party represented in the state's Legislative Assembly. The chief minister is assisted by a council, the members of which are appointed by the governor.

The state Legislative Assembly consists of 32 seats, which are equally apportioned between the Lepchhi-Bhutia population and the Nepalese. One of the seats awarded to the Lepchhi-Bhutia group is reserved for the nominee of the lamas (Buddhist religious leaders), and one seat of the Nepalese group is reserved for the representative of the scheduled castes.

The state is divided into the four districts of Gangtok, Namchi, Mangan, and Gyalshing. Each district is headed by a district officer, who is also the district collector. A headman elected from each area serves as a liaison between the people and the district administration. Committees (*pañcāyats*) of elected representatives administer the villages and implement welfare schemes. The village system is particularly strong in the northern areas. Each district has a court with a judicial magistrate.

There are 260 primary schools and 55 secondary schools providing education to about 37,000 students. No student lives more than two miles from a school. The state's only university college is located in Gangtok. (S.S.Ch.)

CULTURAL LIFE

Sikkim's cultural life is related to Tibetan religious and aesthetic traditions, but it retains a unique character from the various tribes of Sikkim and their pre-Buddhist customs. The cultural climax of the year is represented by the national day, Phanglhapsol, when masked dances are performed in honour of the presiding national deity and of the mountain *Kāngchenjunga*. There are also many secular folk dances. Music is an important part of the school curriculum. The Namgyal Institute of Tibetology has the third largest collection of Tibetan books in the world, exceeded only by the libraries of Leningrad and Peking. Many monasteries are repositories of artistic treasures, including wall paintings, *tankas* (religious paintings mounted on brocade), and bronze images. (K.C.Pr.)

Sikorsky, Igor

An outstanding pioneer of aircraft design, Igor Sikorsky is known for his successful development of the helicopter in the 1930s. This contribution, and others in fixed-wing design, changed the course of flight history.

Igor Ivan Sikorsky was born in Kiev, Ukraine, on May 25, 1889. His father was a graduate physician and professor of psychology. His mother also was a physician but never practiced professionally. Her interest in art and in the life and work of Leonardo da Vinci undoubtedly stimulated her son's early interest in model flying machines; when he was 12 years old he made a small rubber-powered helicopter that could rise in the air.

By courtesy of Sikorsky Aircraft

Sikorsky.

In 1903 Sikorsky entered the Naval Academy in St. Petersburg (now Leningrad), with the intention of becoming a career officer, but his interest in engineering led to his resignation from the service in 1906. After a brief period of engineering study in Paris, he returned to Kiev and entered the Kiev Polytechnic Institute. Following a reasonably successful academic year, however, he concluded that the abstract sciences and higher mathematics as then taught had little relationship to the solution of practical problems, and he left the school, preferring to spend his time in his own shop and laboratory.

A trip through Europe in the summer of 1908 brought him into contact with the accomplishments of the Wright brothers and the group of European inventors who were trying to match their progress in flight. Returning to Kiev, Sikorsky came to the conclusion that the way to fly was "straight up," as Leonardo da Vinci had proposed, a concept that called for a horizontal rotor. Assisted financially by his sister Olga, he returned to Paris in January 1909 for further study and to purchase a light-weight engine.

Back in Kiev in May of 1909 he began construction of a helicopter. Its failure revealed some of the practical obstacles. A second machine with a larger engine was tested in 1910, but also failed to fly. He then made a major decision: "I had learned enough to recognize that with the existing state of the art, engines, materials, and—most of all—the shortage of money and lack of experience . . . I would not be able to produce a successful helicopter at that time." In fact, he had to wait 30 years before all conditions could be met.

For the time being Sikorsky decided to enter the field of fixed-wing design and began construction of his first airplane. His S-1 biplane was tested early in 1910, and, although its 15-horsepower engine proved inadequate, a redesigned airframe with a larger engine (S-2) carried him on his first short flight. The S-3, S-4, and S-5 followed in quick succession, each a refinement of its predecessor, and each adding to his piloting experience. Finally, by the summer of 1911, in an S-5 with a 50-horsepower engine, he was able to remain in the air for more than an hour, attain altitudes of 1,500 feet (450 metres), and make

First
helicopter

short cross-country flights. This success earned him International Pilot's License Number 64.

The subsequent S-6 series established Sikorsky as a serious competitor for supplying aircraft to the Russian Army. Characteristically, he soon took a giant step: the first four-engined airplane, called "Le Grand," the precursor of many modern bombers and commercial transports, which he built and flew successfully by 1913. Among its innovative features, not adopted elsewhere until the middle 1920s, was a completely enclosed cabin for pilots and passengers.

In the period of disruption following the Russian Revolution and the collapse of Germany, Sikorsky saw little opportunity for further aircraft development in Europe. He decided to start over again in the United States and in March 1919 landed in New York as an immigrant.

After several lean years as a lecturer and school teacher, while trying to find a place for himself in the contracting postwar aircraft industry, he and a few associates, some of them former Russian officers, formed their own company, the Sikorsky Aero Engineering Corporation. They set up shop in an old barn on a farm near Roosevelt Field on Long Island. Sikorsky became a U.S. citizen in 1928. By 1929 the company, having become a division of United Aircraft Corporation, occupied a large modern plant at Bridgeport, Connecticut, and was producing S-38 twin-engined amphibians in considerable numbers. In 1931 the first S-40, the "American Clipper," pioneered Pan American World Airways mail and passenger routes around the Caribbean and to South America. By the summer of 1937 Pan American began transpacific and transatlantic service with the first four-engined S-42 "Clipper III," the last of the Sikorsky series, the ancestor of which had been "Le Grand" of 1913.

By the late 1930s changing requirements for military and commercial air transport forecast the termination of the large flying boat, and Sikorsky returned to his first love, the helicopter. Once again he was involved in "advanced pioneering work . . . where extremely little reliable information and no piloting experience whatever were available." The essential aerodynamic theory and construction techniques that had been lacking in 1910, however, were now available. Early in 1939, with a well-trained engineering group at his disposal, he started the construction of the VS-300 helicopter. As he said later, "There was a great satisfaction in knowing that, within a short period of time, good engineering along a novel line produced encouraging results." On September 14, 1939, the plane lifted off the ground on its first flight. Its designer was at the controls; during his entire career Sikorsky always insisted on making the first trial flight of any new design himself. On May 6, 1941, in an improved machine, he established an international endurance record of 1 hour, 32.4 seconds.

It is doubtful that Sikorsky at that time fully envisioned the remarkable development of the vertical lift machine in the next 30 years. Certainly he did not anticipate widespread use of the helicopter as an offensive military weapon as in Vietnam. He regarded it as a useful tool for industry and air commerce but primarily as an effective device for rescue and relief of human beings caught in natural disasters, such as fire, flood, or famine. He estimated that over 50,000 lives had been saved by helicopters.

Igor Sikorsky's active professional life covered virtually the entire span of practical flight by man, from the Wright brothers to space exploration. Few in aviation can claim such a span of personal participation, or personal contribution with such a wide range of innovative ideas. He only complained that of all his past predictions, those that he lived to regret were on the "too conservative" side.

Sikorsky retired as engineering manager for his company in 1957 but remained active as a consultant until his death on October 26, 1972, at Easton, Connecticut. In addition to his wife (married in 1924), he left one daughter and four sons, all of whom have professional careers. Sikorsky received many honorary doctorates in science and engineering, honorary fellowships in leading

scientific and technical societies in the United States and Europe, and the highest medals and awards in aviation, including the Cross of St. Vladimir from Russia; the Sylvanus Albert Reed Award for 1942 from the Institute of Aeronautical Sciences in New York; the United States Presidential Certificate of Merit in 1948; the Daniel Guggenheim Medal and Certificate for 1951; the Elmer A. Sperry Award for 1964; and the National Defense Award in 1971.

(1967), an autobiography, including a detailed account of the author's life and work through 1938, with supplementary chapters on his first helicopter experiments of 1939–40 and later work; see also a definitive study by F.J. DELEAR, *Igor Sikorsky: His Three Careers in Aviation* (1969).

(S.P.J.)

Silica Minerals

Silica minerals make up approximately 12 percent of the Earth's crust and are second only to the feldspars in mineral abundance. Free silica occurs in many crystalline forms with a composition very close to that of silicon dioxide (SiO_2), 46.75 percent by weight of silicon and 53.25 percent oxygen. Quartz is by far the most commonly occurring form. Tridymite, cristobalite, and the hydrous silica mineral opal are uncommon. and vitreous (glassy) silica, melanophlogite, coesite, and stishovite have been reported from only a few localities. Several other forms have been produced in the laboratory but have not been found in nature.

Quartz is the only natural silica mineral used in significant quantities; millions of tons are consumed annually by many industries. The sand that is an essential ingredient of concrete and mortar is largely quartz, as are the sandstone and quartzite used as building stones. Crushed sandstone and quartzite are used for road and railway construction, roofing granules, and for riprap—erosion-control linings of river channels. Quartz is hard (7 on Mohs scale of mineral hardness, on which diamond is 10) and resists fracture because it lacks easy cleavage (*i.e.*, the tendency to split along crystallographic planes). These properties, combined with its ready availability, lead to its use as a sandpaper abrasive and in sandblasting; for polishing and cutting glass, stone, and metal; and for providing traction on stairs, streets, and rails. Large amounts of relatively pure quartz are used in refractory products, such as insulating and firebricks, foundry molds, and electrical insulators, because of the combination of its high melting temperatures, low coefficients of expansion, inertness of the high-temperature forms of silica, and low costs.

Relatively pure quartz is required in large tonnages as an ingredient for glass and porcelain manufacture. High purity quartz is fused to make premium grades of chemical and optical glass for which one or more of its desirable properties of low thermal expansion, high shape stability, elasticity, low solubility, and transparency to various kinds of light can justify the greatly increased costs involved. Fibres of vitreous silica are essential for precision instruments, such as balances, galvanometers, and gravimeters. Large tonnages of quartz of various qualities are used as raw materials for processes in which silica is not the final product. These include the production of water glass, or sodium silicate, various sols—very fine dispersions of solids in liquids—that are used as hydrophobic coatings, organic silicates and silicones, silicon carbide, silicon metal, smelting flux, and alloying in metallurgy.

Quartz and its innumerable varieties have been used since antiquity as semiprecious gems, ornamental stones, and collector's items and are very popular today. Precious

properties

opal, a hydrous form of silica, has been one of the most attractive gemstones since Roman times.

This article treats the properties of the silica minerals, including their physical and chemical characteristics and crystallography, and their formation and occurrence in nature. For further information on crystal structure and mineralogical properties in general, see CRYSTALLOGRAPHY AND MINERALS. See also SILICATE MINERALS; GEMSTONES; SILICEOUS ROCKS; and SANDSTONES for coverage of related minerals, gem varieties, and principal occurrences in sedimentary rocks. The occurrence of shock-related varieties, such as coesite and stishovite, is covered in the article METEORITE CRATERS.

Physical and chemical properties. The crystallographic structures of the silica minerals, with the exception of stishovite, are three-dimensional arrays of linked tetrahedra, each of which consists of a silicon atom coordinated (surrounded and bonded) by four oxygen atoms. (For a comprehensive description of the nature of several kinds of bonds, see CHEMICAL BONDING.) The tetrahedra are usually quite regular, and the silicon-oxygen bond distances are 1.61 ± 0.02 Å (one angstrom unit [Å] equals 10^{-8} centimetres). The principal differences among the silica minerals are related to the geometry of the tetrahedral linkages, which may cause small distortions within the silica tetrahedra. High pressure forces silicon atoms to coordinate with six oxygen atoms, thus producing nearly regular octahedra in the stishovite structure.

The silica minerals when pure are colourless and transparent and have a vitreous lustre. They are nonconductors of electricity and are diamagnetic (inert in a magnetic field). All are hard, strong, and fail by brittle fracture under an imposed stress.

Some of the more important physical properties of the silica minerals are compared in the Table. All except low tridymite and coesite (among the crystalline varieties) have relatively high symmetry. There is a linear relationship between the specific gravity values listed in the Table and the arithmetic mean of the indices of refraction (measures of the velocity of light that is transmitted in different crystallographic directions) for silica minerals composed of linked tetrahedra. This relationship (Figure 1) does not extend to stishovite because it is not made up of silica tetrahedra. Melanophlogite is notable because it plots below vitreous silica on the graph; one other poorly defined silica polymorph, called silica W, may also plot below vitreous silica. The specific gravities of silica minerals are less than those of most of the dark-coloured silicate minerals associated with them in nature; in general, the lighter coloured rocks have lower specific gravity for this reason.

Figure 1: The linear plot obtained for silica minerals made up of linked tetrahedra (see text).

Silica minerals are insoluble to sparingly soluble in strong acids except hydrofluoric acid. There is a fair correlation between specific gravity and the solubility in hydrofluoric acid. The less dense phases dissolve rapidly in cold acid; quartz dissolves slowly in cold acid and rapidly in hot; coesite is nearly insoluble in cold and slowly soluble in hot acid; and stishovite is nearly insoluble even in hot hydrofluoric acid. All silica minerals are dissolved by strong alkali, particularly in hot and concentrated solutions, and by some fused salts, such as ammonium bifluoride.

Descriptions and characteristics. *Quartz.* Quartz occurs in many varieties in almost all types of igneous,

Some Physical Properties of Silica Minerals

*The unit cell of a mineral is the smallest volume that contains a complete sample of the atomic composition and symmetry. It is described in terms of crystallographic axes and the angles at which they intersect. These axes are designated a, b, and c when of unequal length (monoclinic and orthorhombic symmetry); if a equals b, then only a and c cell lengths are given, and if a, b, and c are all equal (isometric symmetry) then only a is given. Hexagonal symmetry is related to three axes of equal length that are 120° apart; the c axis is perpendicular to the plane containing these a axes. In monoclinic symmetry, two axes intersect obliquely, and the angle formed is designated β .

sedimentary, and metamorphic rocks. It has also been found in meteorites and in some lunar rocks.

Quartz crystals lack a centre of symmetry or planes of symmetry and have one crystallographic axis (c) perpendicular to three polar axes (a) that are 120° apart. One end of a polar axis is different from its other end; when mechanical stress is applied on such an axis, opposite electrical charges develop on each end. This leads to important applications in electronics as a frequency control and in pressure gauges and other devices. The lack of symmetry planes parallel to the vertical axis allows quartz crystals to occur as two types: left-handed or right-handed (enantiomorphism). Left-handed quartz is less than 1 percent more abundant than right-handed quartz. The structural tetrahedra spiral upward through the crystal in the sense of the handedness parallel to the c axis. Similarly, if polarized light—which is light vibrating in a single plane—is transmitted by a quartz crystal along the c axis direction, the plane is rotated in the direction of the handedness by tens of degrees per millimetre, the amount depending on the wavelength of the light. This property is used in the manufacture of optical instruments such as monochrometers.

Twinning—the symmetrical juxtaposition of two or more crystals of the same mineral species—is ubiquitous in quartz, even if not conspicuous to the eye. One general class of twins occurs with the two sets of a axes parallel to each other, and the twinned portions may be complexly intergrown so that they penetrate each other. When the two crystals are of the same handedness and the a axes are of opposite electrical polarity, such twinning constitutes the Dauphiné law, which is also known as electrical twinning. When one of the crystals is left-handed and the other right-handed, this also causes the parallel a axes to be of opposite electrical polarity; this type is called Brazil, or optical, twinning. In another general class of quartz twins, the sets of a axes of the twinned crystals are inclined to each other, and the crystals ordinarily do not penetrate one another. This twinning is the Japan law.

twinning for electronic frequency applications have led to the development of industrial synthesis methods based on the differences in silica solubility with temperature. Nutrient crystals are placed in the hot portion of a solution-filled autoclave, and an oriented seed crystal free from twinning is placed in the cooler portion. Crystals weighing thousands of grams can be grown in a few weeks.

Quartz shows less range in chemical composition than do most other minerals, but it commonly contains tens to hundreds of parts per million of aluminum atoms substituting for silicon atoms, with charge balance maintained by the incorporation of small atoms, such as hydrogen, lithium, or sodium. Titanium, magnesium, or iron atoms substituting for silicon atoms also have been reported, but anionic substitution (*i.e.*, substitution for the negative ion, oxygen) is limited because the linkage of the tetrahedra is disrupted.

Coloured varieties of quartz are numerous and have many causes. Most colours result from mechanically incorporated admixtures within fine-crystallized or granular quartz, but some coarse-crystallized varieties, such as amethyst (violet), citrine (yellow), milky quartz, smoky quartz or morion (black), or rose quartz, may be coloured by ions other than silicon and oxygen that occur within the crystal structure (see Figure 2). Small fractions of 1 percent by weight of iron, aluminum, manganese, titanium, hydrogen, and small alkali atoms, such as lithium and sodium, have been shown to be the cause of different colours. Heat treatment or various irradiation treatments under oxidizing or reducing atmospheres are used to change one coloured variety to another. Citrine is commonly produced by heat treating amethyst at 250°–400° C (500°–750° F), for example.

Quartz may contain inclusions of other minerals, such as rutile (rutilitated quartz), asbestiform amphiboles (tiger's-eye is the yellow-brown variety from South Africa; hawk's-eye, the blue variety), or platy minerals, such as mica, iron oxides, or chlorite (aventurine).

Chalcedony. Chalcedony is white, buff, or light tan, finely crystallized or fibrous quartz that forms rounded crusts, rinds, or stalactites (mineral deposits suspended from the roofs of caverns) in volcanic and sedimentary rocks as a precipitate from moving solutions. If chalcedony is conspicuously colour banded, it may be called agate; onyx is agate with alternate bands of white and black or dark brown. Some concentrically banded "eye" agate nodules contain cores of coarsely crystalline quartz, and other agates are mottled or variegated in colour.

Arborescent or dendritic (branching) dark-coloured patterns set in a lighter field are called moss agate or Mocha stone. Translucent red chalcedony is called carnelian, and translucent brown shades are called sard; both are pigmented by admixed iron oxides.

Chrysoprase, plasma, and prase are names for green varieties of chalcedony coloured by admixed green minerals, such as chlorite, fibrous amphiboles, or hydrous nickel silicates. Bloodstone and heliotrope are green chalcedony with red spots. Much chalcedony is coloured by artificial methods.

Jasper, chert, and flint. Jasper is opaque red, brown, or yellow quartz that contains much admixed material. Touchstone, or basanite, is black or dark gray jasper that has been used to estimate the composition of precious alloys by the colour of their streak (powder). Chert and flint are finely crystallized varieties of gray to black quartz that occur as nodules or bands in sedimentary rocks.
