CONTENTS

Birds

Birds are warm-blooded vertebrates whose covering of feathers is the one major characteristic that distinguishes them from all other animals. Birds have a four-chambered heart (shared with all mammals), forelimbs modified into wings (shared with bats), a calcareous-shelled egg, and keen vision, the major sense relied upon by birds for information about their environment. Their sense of smell is not highly developed, and auditory range is limited. Most birds are diurnal in habit.

In the scheme of biological classification, birds constitute the class Aves. There are approximately 8,700 living species, and more than 1,000 extinct species have been identified from fossil remains. For coverage of related topics in the *Macropædia* and the *Micropædia,* see the *Propædia,* section 313, and the *Index.*

This article is divided into the following sections:

BIRDS: THE CLASS AVES

GENERAL FEATURES

The smallest living bird is generally acknowledged to be the bee hummingbird of Cuba, which is 6.3 centimetres (2.5 inches) long and weighs less than 3 grams (about 0.1 ounce). The largest living bird is the ostrich, which may stand 2.5 metres (8 feet) tall and weigh 135 kilograms (300 pounds). Some extinct birds were even larger: the largest of the moas of New Zealand and the elephant birds of Madagascar may have reached over 3 metres (10 feet) in height. Among flying birds, the wandering albatross has the greatest wingspan, up to 3.5 metres (11.5 feet), and the trumpeter swan perhaps the greatest weight, 17 kilograms (38 pounds). A Pleistocene condorlike bird, *Teratornis incredibilis,* had an estimated wingspan of about 5 metres (16.5 feet) and was by far the largest known flying bird.

The ability to fly has permitted an almost unlimited radiation of birds, so that they are now found virtually everywhere on earth, from occasional stragglers over the polar ice caps to complex communities in tropical forests. In general the number of species found breeding in a given area is directly proportional to the size of the area and the diversity of habitats available. The total number of species is also related to such factors as the position of the area with respect to migration routes and wintering grounds of species that nest outside the area. In the United States, Texas and California have both the largest number of species recorded (545 and 461, respectively, including both resident and migrant species) and the largest number breeding (300 and 286). Seven hundred and seventy-five species, 650 of them breeding, have been recorded from North America north of Mexico. The figures for Europe exclusive of the Soviet Union are 577 and 420, and the figures for the Soviet Union are 704 and 622. Costa Rica, with an area of only about 51,000 square kilometres (about 20,000 square miles) and a known avifauna of at least 758 species, probably has the most diversified group for its size of any country.

BIRD AND HUMAN RELATIONSHIPS

Domestication

Wild birds and their eggs have been at least incidental sources of food for humans since their origin and still are in most societies. The eggs of some colonial seabirds, such as gulls, terns, and murres, or guillemots, and the young of some shearwaters (muttonbirds) are even now harvested in large quantities. With the development of agrarian human cultures, several species of birds became domesticated. Of these, chickens, ducks, geese, and pigeons, descended from the red jungle fowl (*Gallus gallus*), mallard duck (*Anas platyrhynchos*), greylag goose (*Anser anser*), and rock dove (*Columba livia*), respectively, were taken in early and have been selectively bred into many varieties. After the discovery of the New World, the turkey (*Meleagris gallopavo*), which had already been domesticated by the Indians, and the Muscovy duck (*Cairina moschata*) were brought to Europe and produced several varieties. Guinea fowl (*Numida meleagris*) from Africa were also widely exported and kept not only for food but because they are noisy when alarmed, thus warning of the approach of intruders. Besides being a food source, pigeons have long been bred and trained for carrying messages, and the ability of frigate birds to "home" to their nesting colonies has enabled inhabitants of the South Seas to send messages by these birds. For further information on domestication of birds, see FARMING: *Livestock farming* and *Poultry farming.*

With the development of modern culture, hunting evolved from a foraging activity to a sport, in which the food value of the game became secondary. Large sums are now spent annually on hunting waterfowl, quail, grouse, pheasants, doves, and other game birds. Sets of rules and conventions have been set up for hunting, and in one elaborate form of hunting, falconry, there is not only a large body of specialized information on keeping and training falcons but also a complex terminology, much of it centuries old.

Feathers have been used for decoration since early times. Their use in the headdresses of American Indians and various peoples of New Guinea is well known. Feather robes were made by Polynesians and Eskimos; down quilts, mattresses, and pillows are part of traditional European folk culture. Large feathers have often been used in fans, thereby providing an example of an object put to opposite uses—for cooling as well as for conserving heat. Whereas most feathers used in decorating are now saved as by-products of poultry raising or hunting, until early in the 20th century, egrets, grebes, and other birds were widely shot for their plumes alone. Ostrich farms have been established to produce plumes. Large quills were once widely used for writing, and feathers have long been used on arrows and fishing lures.

Many birds are kept as pets. Small finches and parrots are especially popular and easy to keep. Of these, the canary (*Serinus canaria*) and the budgerigar of Australia (*Melopsittacus undulatus,* sometimes called parakeet) are widely kept and have been bred for a variety of colour types. On large parks and estates, ornamental species like peafowl (*Pavo*) and various exotic waterfowl and pheasants are often kept. Zoological parks in many cities import birds from many lands and are a source of recreation for millions of people each year.

Birds as pests

With the rise of agriculture, man's relationship with birds became more complex. In regions where grain and fruit are grown, depredations by birds may be a serious problem. In North America various species of blackbirds (family Icteridae) are serious pests in grainfields; while in Africa a grain-eating finch, the red-billed quelea (*Quelea quelea*), occurs, like locusts, in plague proportions so numerous that alighting flocks may break the branches of trees. The use of city buildings for roosts by large flocks of starlings and blackbirds is also a problem, as is the nesting of albatrosses on airplane runways on Pacific islands. As a result of these problems, conferences on the control of avian pests are held with increasing frequency.

Although birds are subject to a great range of diseases and parasites, few of these are known to be capable of infecting man. Notable exceptions are ornithosis (or psittacosis), caused by one or more viruses that are transmitted directly to man from pigeons, parrots, and a variety of other birds, a serious and sometimes fatal disease resembling virus pneumonia. Encephalitis, an inflammation of the brain, is also serious and is transmitted from birds to man and to his domestic animals by biting arthropods, including mosquitos. Wild birds may also act as reservoirs for diseases that adversely affect domesticated birds. Much work has been done recently on the ecology of viruses, with more and more of them being found in birds.

The study of birds has contributed much to both the theoretical and practical aspects of biology. Darwin's studies of the Galápagos finches and other birds during the voyage of the "Beagle" were important in his formulation of the idea of the origin of species through natural selection. Study collections of birds in research museums still provide the bases for important studies of geographic variation, speciation, and zoogeography, because birds are one of the best known of animal groups. Early work on the domestic fowl added to the development of both genetics and embryology. The study of animal behaviour (ethology) has been based to a large extent on studies of birds by Konrad Lorenz, Nikolaas Tinbergen, and their successors. Birds also have been the primary group in the study of migration and orientation and the effect of hormones on behaviour and physiology.

Birds feature prominently in mythology and the literature of many countries. Some of their attributes, real or imagined, have led to their symbolic use in art as in language. The aesthetic and recreational pleasures of birdwatching are increasingly being recognized.

Man's impact on bird populations has become increasingly strong. Since 1680, approximately 80 species of birds have become extinct, and an even larger number are seriously endangered. While pollution and pesticides are important factors in the decline of certain large species, such as the peregrine falcon, osprey, and brown pelican, the destruction of natural areas and introduction of exotic animals and diseases have probably been the most devastating. Concerted efforts are required to ensure the survival of rare species and to learn as much as possible about them. (R.W.St.)

NATURAL HISTORY

Locomotion. Because of their body structure and their feathery body covering, birds are the best fliers among animals, better than the insects and the flying mammals, the bats. There are, however, considerable differences in flying ability among various birds. Penguins cannot fly but spend much of their time in the water swimming with their paddlelike wings; such birds as ostriches and kiwis have rudimentary wings and are permanently afoot. At the other extreme are the long-winged swifts and frigate birds that move from their perches only to fly, never to walk. Most birds alternate some walking or swimming with their flying.

Birds usually fly when they have any considerable distance to travel; there are exceptions, however. The mountain quail of California make their annual migrations up and down the mountains by foot. The murres, or guillemots, of the Greenland coast migrate southward by swimming; they begin their journey before the young have grown their flight feathers and before some of the adults at least have regrown their recently molted ones. The Adélie penguins may ride northward on drifting ice floes; at the approach of nesting time they swim back to the Antarctic continent and then walk over the ice to their breeding grounds many miles inland.

Flight. Birds fly by flapping their wings, steering mainly with their tails. A goshawk, pursuing its prey through the forest, uses its long tail in making quick turns, and the barn swallow uses its deeply forked tail in making the involved patterns of its graceful flight. Ducks with their short tails have a swift but direct flight. There is, however, such great diversity in birds' tails that the precise size and shape probably is not of critical importance.

Comparing a bird to an airplane, a bird's wing is both wing and propeller. The basal part of the wing supplies most of the supporting surface, the wing tip most of the propelling force. A bird's wing has many adjustable features: it can be shortened or lengthened by flexion; the feathers of the tip can be spread or closed; the angle of the whole wing or its parts, on one side or the other or on both sides, can be altered. All these adjustments make the aerodynamics of a bird's wing much more complicated than those of the airplane; consequently, the flight of a bird is much more varied and adaptable.

Flying ability varies widely among birds, and different types of wings correlate with different types of flight. Many songbirds use their short, rounded wings mostly to move with quick wing beats from perch to perch or from ground to perch. Ducks have pointed wings that, beaten at high speed, provide rapid flight for long distances. Swallows, terns, and frigate birds have long, pointed wings that enable these birds to fly and manoeuvre gracefully for hours with leisurely wing beats. Large herons with long, broad wings travel far with slow, measured wing beats, while buzzards soar high in the sky on their long, broad wings. Gulls and albatrosses with long, narrow wings sail along the beaches or over the waves with infrequent wing strokes. A hummingbird can whir its tiny wings so rapidly that it can hover as it thrusts its long bill into a blossom; it can even fly backward as it leaves the bloom.

Speed

The speed with which birds fly varies greatly from species to species, and of course individual birds can vary their speed. The data on the speed of birds' flight are difficult to evaluate. One of the complicating factors is that a bird's speed in relation to the ground may depend on the force of the wind. A bird flying at an airspeed of 40 mph with a 60-mph wind behind it would travel at 100 mph in relation to the ground (1 mile = 1.61 kilometeres). The same bird flying into a 60-mph wind would be losing ground at the rate of 20 mph. Despite the variables involved in determining a bird's speed of flight, the following generalized speeds, based on level flight in calm air, appear to be sound:

10–20 mph—many small songbirds such as sparrows and wrens

20–30 mph—many medium-sized birds such as thrushes and grackles, and larger, long-winged birds such as herons, pelicans, and gulls

20–40 mph—many small- and medium-sized birds such as starlings, chimney swifts, and mourning doves

40–60 mph—the faster-flying birds such as falcons, ducks, geese, and domestic pigeons

There are many faster records, often disputed, such as that of 200 mph for an Indian spine-tailed swift in level flight and 170 mph for a golden eagle in a dive. A homing pigeon has been timed at 94.3 mph.

Range

The record long-range flight of a bird species in a single season is undoubtedly held by the Arctic terns that migrate from a summering ground in the Arctic to a wintering ground in the Antarctic, travelling more than 11,600 kilometres (7,200 miles) one way. Some long-range flights are made very quickly: a blue-winged teal banded in Canada was recovered 6,100 kilometres (3,800 miles) away in Venezuela only 30 days later; a Manx shearwater, trapped at its nest in Wales and transported 5,200 kilometres (3,200 miles) to Massachusetts and released, returned home in 12½ days. Some very small birds regularly make long water crossings in a single flight. Ruby-throated hummingbirds fly across the more than 500-mile-wide Gulf of Mexico, and many warblers fly from the American coast to Bermuda, a journey of about the same distance. For further information on bird migration, see BEHAVIOUR, ANIMAL: *Animal migration.*

Flightlessness. Flight, so characteristic of birds, is maintained during the molt in most species by a gradual replacement of the flight feathers. However, ducks and geese, some rails and loons (divers), and auks shed all of their flight feathers at one time, immediately after the nesting season. Not until these feathers are replaced are the birds able to fly again. Most of these are birds that find their food by walking or swimming, as would be expected. Some ducks living in the marshes become very shy and retiring at this season, skulking in the reeds, but geese nesting in the Arctic barrens continue to walk about over the tundra, feeding. In another group of birds, however, the hornbills of Africa and Asia, only the females lose both flight and tail feathers at once; they stay in the nest until the feathers grow out again, being fed during this period by the males.

Evolutionary flightlessness

Some birds have completely lost the power of flight during the course of evolution. The close similarity in basic structure of both flightless and flying birds indicates, however, that they all had a common flying ancestor. The rudimentary wings and the flightless condition of the ostrich-like birds and the penguins is a secondary, specialized condition. That flightlessness is a secondary condition is made still more apparent in other flightless birds that belong to families most of whose members are capable of flight. The extinct great auk of the North Atlantic is one of the best known examples of such a flightless bird; the rail family also is noted for having many flightless species living on islands in the Pacific and the South Atlantic. Loss of flight seems to occur most often on isolated islands where there are no mammal predators. In New Zealand, where there are no native land mammals, not only are there many species of extinct flightless moas but also flightless kiwis, penguins, and rails and a duck, an owl, and several songbirds that are nearly flightless. The ostrich-like birds of continental distribution present an apparent contradiction to this correlation of mammal-free island habitats with bird flightlessness. Another adaptation, however, their great size, has enabled these forms to escape the predation of mammals.

Walking, hopping, and swimming. Terrestrial birds such as pheasants tend to walk; arboreal songbirds tend to hop as they travel from branch to branch. Parrots often walk along branches, and house sparrows hop when they come to the ground, while palm warblers walk on the ground and some songbirds, such as American robins and European blackbirds, may both walk and hop. Some birds with small feet, such as swifts, hummingbirds, bee eaters, and many hornbills, use their feet only for perching and rarely walk at all. Other birds with robust feet, such as guinea fowl and rails, do most of their moving about on foot. Jacanas with their greatly elongated toes and nails walk over floating water weeds, and herons with long legs wade in shallow water. The ostrich is probably the fastest running bird; some investigators have credited it with a speed of 50 mph (80.5 kph), at which time the length of its stride was about 25 feet (7.6 metres).

The usual position of a bird's body in walking is more or less parallel to the ground. But the penguins, with their feet far to the rear of their bodies, stand upright as they waddle along. When the Adélie penguin, however, makes its trek of many miles over the snow-covered ice to its breeding grounds, it may vary its awkward waddle with periods of tobogganing; *i.e.,* sliding along on its breast and propelling itself with thrusts of its feet.

Some water birds have become so adapted to swimming that they are practically helpless on land. In this class are loons, which shuffle awkwardly the few feet from the water to their nests. Swimming in birds is usually correlated with webbed feet, but coots and grebes, with only lobes on their toes, also swim and dive, and gallinules, without either webs or lobes on their toes, commonly swim. On the other hand, frigate birds, with partly webbed feet, never swim. Penguins swim through the water with their wings and use their webbed feet only for steering. Auks use their wings and webbed feet in swimming underwater.

Some birds such as the mallard usually swim at the surface, feeding only as far underwater as they can reach by dipping their heads. Other ducks, such as scoters and pochards, commonly dive to the bottom for their food, and cormorants, auks, and loons pursue fish underwater. Sometimes loons are taken at remarkable depths in fishermen's nets and on set lines, indicating that they may dive as deep as 200 feet.

Pond ducks, such as mallards and teals, spring straight up from the water's surface into the air in flight, but many swimming birds—for example, coots, grebes, cormorants, and diving ducks—take off with a long spattering run along the surface. (Au.L.R.)

Behaviour. Birds depend to a great extent on innate behaviour, responding automatically to specific visual or auditory stimuli. Even much of their feeding and reproductive behaviour is stereotyped. Feather care is vital to keep the wings and tail in condition for flying and the rest of the feathers in place where they can act as insulation. Consequently preening, oiling, shaking, and stretching movements are well developed and regularly used. Some movements, like the simultaneous stretching of one wing, one leg, and half the tail (all on the same side) are widespread if not universal among birds. Stretching both wings upward, either folded or spread, is another common movement, as is a shaking of the whole body beginning at the posterior end. Other movements have evolved in connection with bathing, either in water or in dust. Such comfort movements have frequently become ritualized as components of displays.

Many birds maintain a minimum distance between themselves and their neighbours, as can be seen in the spacing of a flock of swallows perched on a wire. In the breeding season most species maintain territories, defended areas ranging from the immediate vicinity of the nest to extensive areas in which a pair not only nests but also forages. The frequency of actual fighting is in birds greatly reduced by ritualized threat and appeasement displays. Birds range from solitary (*e.g.,* many birds of prey) to highly gregarious, like the guanay cormorants of the Peru Current off the west coast of South America, which nest in enormous colonies of hundreds of thousands and feed in large flocks with boobies and pelicans.

Vocalization

Auditory signals, like visual ones, are almost universal among birds. The most familiar vocalization of birds is that usually referred to as "song." It is a conspicuous sound (not necessarily musical) that is used, especially early in the breeding season, to attract a mate, to warn off another bird of the same sex, or both. As such it is usually associated with establishing and maintaining territories. Individual variation in songs of many species is well known, and it is believed that some birds can recognize their mates and neighbours by this variation. Many other types of vocalizations are also known. Pairs or flocks may be kept together by series of soft location notes. Alarm notes alert other individuals to the presence of danger; in fact, the American robin (and probably many other species) uses one note when it sees a hawk overhead and another when it sees a predator on the ground. Begging calls are important in stimulating parents to feed their young. Other calls are associated with aggressive situations, courtship, and mating. Nonvocal sounds are not uncommon. Some snipe and hummingbirds have narrow tail feathers that produce loud sounds when the birds are in flight, as do the narrowed outer primaries of the American woodcock. The elaborate courtship displays of grouse include vocalizations as well as stamping of the feet and noises made with the wings. Bill clapping is a common part of courtship in storks, and bill snapping is a common threat of owls.

Drawing by R. Keane based on M.H. Clench

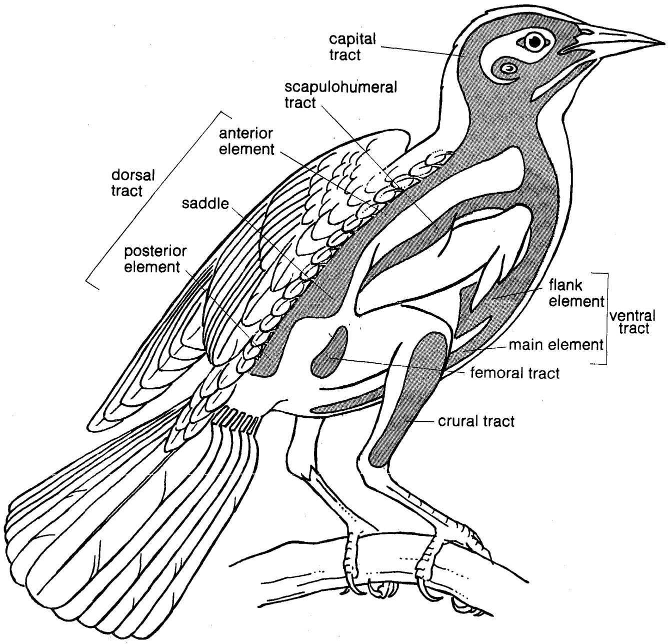

Figure 1: Basic body feather tracts on a generalized songbird. Shaded areas show the right half of each tract.

The nest

Most birds build nests in which the eggs are laid. Nests vary widely: they may be a scrape in the sand, a deep burrow, a hole in a tree or rock, an open cup, a globular or retort-shaped mass with a side entrance tube, or an elaborately woven hanging structure. The materials with which nests are made also vary widely. Some nests are lined with small stones, others are built of dirt or mud with or without plant material. Sticks, leaves, algae, rootlets, and other plant fibres are used alone or in combination. Some birds seek out animal materials such as feathers, horsehair, or snakeskin. The nest materials may be held together by weaving, sewing, or felting the materials themselves or with mud or spider webs. Swifts use saliva to glue nest materials together and to attach the nest to the supporting structure. In at least one species of swift, the entire nest is made of saliva and is the prized ingredient of birds' nest soup in the Orient. All birds incubate their eggs, except megapodes (mound builders), which depend on the heat generated by decaying vegetation or other external sources, and brood parasites, which lay their eggs in the nests of other species. Murres and the king and emperor penguins build no nest but incubate with the egg resting on top of the feet. In most birds a brood patch is developed. This bare area on the abdomen is edematous (fluid filled) and highly vascularized and is in direct contact with the eggs during incubation. Its development during the breeding season is under hormonal control. When the parent is off the nest, adjacent feathers are directed over the brood patch, and it is usually not apparent. A few birds (*e.g.,* boobies) keep their webbed feet over the eggs during incubation.

Incubation takes from 11 to 80 days, depending at least in part on the size of the bird and the degree of development at hatching. Most songbirds and members of some other groups are hatched nearly naked and helpless (altricial) and are brooded until well able to regulate their body temperature. They are fed by the parents until after they are capable of flight. The young of numerous other birds, such as chickens, ducks, and shorebirds, are hatched with a heavy coat of down and are capable of foraging for themselves almost immediately (precocial). Still others, such as the petrels and the auks are downy when hatched but remain in the nest and are fed by their parents.

The length of time parents care for young birds varies widely. Young megapodes can fly shortly after hatching and are entirely independent of their parents; young royal albatrosses may spend up to 243 days at the nest and in the area immediately around it before they can fly. The length of time needed to attain independence is related to size and condition at hatching. Ground-nesting birds tend to take less and hole-nesting birds more time than the average.

The number of eggs in a set varies from 1 to about 20. Some species invariably lay the same number per clutch (determinate laying), whereas in the majority the number is variable (indeterminate laying). In species of the latter category, clutch size tends to be smaller in tropical regions than in cold ones. There is also a tendency for birds in warm regions to make more nesting attempts in a given season. In the Arctic, where the season is very short, the cycle of breeding and the molt that follows it are telescoped into a minimum of time.

Feeding habits. The earliest birds were probably insectivorous, as are many modern ones, and the latter have evolved many specializations for catching insects: swifts, swallows, and nightjars have wide gapes for catching insects on the wing; some woodpeckers can reach wood-boring grubs while others can catch ants by probing anthills with their long, sticky tongues; thrashers dig in the ground with their bills; tree creepers and woodhewers probe bark crevices; and warblers glean insects from many kinds of vegetation. Raptorial birds have evolved talons and hooked bills for feeding on larger animals, and vultures have bare heads and tearing bills for feeding on carrion. Herons have spearlike bills and trigger mechanisms in the neck for catching fish, while kingfishers, terns, and boobies plunge into the water after similar prey. Long-billed waders probe for worms and other invertebrates. Of the many kinds of birds that feed on plant material, most use seeds, fruit, or nectar, which are high in food value; leaves and buds are eaten by fewer species. While some kinds of birds feed entirely on a single kind of food, others may take a wide range of foods, and many have seasonal changes.

FORM AND FUNCTION

Body proportions. Birds arose as warm-blooded, arboreal, flying animals with forelimbs adapted for flight and hindlimbs for perching. This basic plan has become so modified, through the course of evolution, that in some forms it is difficult to recognize. The maximum size attainable by flying birds is limited by the fact that wing area varies as the square of linear proportions, and weight or volume as the cube. On the other hand, the minimum size is probably governed by another aspect of the surface-volume ratio: the relative increase, with decreasing size, in surface through which heat can be lost. The largest flying birds have highly pneumatic skeletons (part of the bone is replaced by air cavities) and other adaptations for reducing weight; the small size of some hummingbirds may be facilitated by the decrease in heat loss resulting from their becoming torpid at night.

When birds lose the power of flight, the limit on their maximum size is lifted, as can be seen in the ostrich and other ratite birds. Some birds (auks, diving petrels, and certain ducks) use the wings for propulsion underwater as well as in the air. When birds that "fly" underwater lose the ability to fly in air, the wings become highly modified as paddles, as in the penguins.

Wing shape

The types of flight found in birds vary considerably. At least two major types of modifications for gliding or soaring are found. The albatrosses and some other seabirds have long, narrow wings and take advantage of winds over the oceans, whereas some vultures and hawks have broad wings with slotted tips and make more use of updrafts and winds deflected by hills. Short, broad wings are characteristic of chicken-like birds, which fly up with a rush of rapid wing beats. Birds like ducks, pigeons, and falcons, which fly rapidly with continuous wing beats, tend to have moderately long, pointed wings, while swifts and hummingbirds, with their narrow, curved wings fly rapidly and manoeuvre easily. The shape of a bird's tail also appears to be related to flight. Forms with deeply forked tails, such as frigate birds, terns, and some swallows, manoeuvre easily, whereas the opposite extreme, long, graduated tails, are often found in rapid, direct fliers such as some parrots and doves. Woodpeckers and some other climbing birds have strong tail feathers with stout shafts, which they use as props while on the trunks of trees.

The bipedal gait, dictated by modification of the forelimbs for flight, necessitates manipulating food by the bill and feet and poses problems in balance. The relative lengths of the segments of the legs must be such that as the bird shifts from a standing to a sitting position, its centre of gravity remains over the feet. As some birds moved out of the trees and became terrestrial or aquatic, their legs were accordingly modified. The toes became shorter and the opposable first toe was lost in rapidly running forms like rheas and ostriches, and the toes became very long in birds that walk on aquatic vegetation or soft ground. In very large, slow-moving birds such as moas, the leg bones became very heavy. Wading birds developed long legs, and climbing birds developed short legs with strongly curved, sharp claws. In swimming and diving birds, webs developed between the toes or lobes on the sides of the toes.

Feathers and molt. Feathers are unique to birds and characteristic of them. Like the scales of reptiles, and those on the feet of birds, feathers are made of keratin, a fibrous protein also found in hair. Feathers vary considerably in structure and function (Figure 2). Contour feathers form most of the surface of the bird, streamlining it for flight and often waterproofing it. The basal portion may be downy and thus act as insulation. The major contour feathers of the wing (remiges) and tail (rectrices) and their coverts function in flight. Contour feathers grow in tracts (pterylae) separated by bare areas (apteria) and develop from follicles in the skin.

Drawing by R. Keane

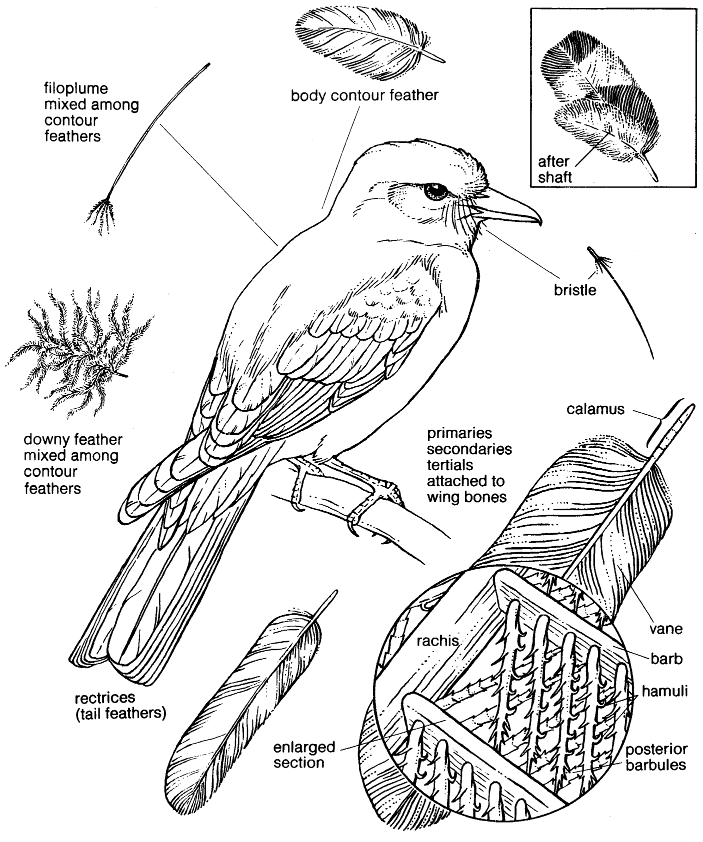

Figure 2: Feather types and their distribution on a typical perching bird.

Feather structure

The typical contour feather consists of a tapered central shaft, the rachis, with paired branches (barbs) on each side. An unbranched basal section of the rachis is called the calamus, part of which lies beneath the skin. The barbs, in turn, have branches, the barbules. The barbules on the distal side of each barb have hooks (hamuli) that engage the barbules of the next barb. The barbs at the base of the vane are often plumaceous; *i.e.,* lacking in hamuli and remaining free of each other. In many birds each contour feather on the body (but rarely on the wings) is provided with a complex branch, the aftershaft, or afterfeather, that arises at the base of the vane. The aftershaft has the appearance of a second, smaller feather, growing from the base of the first. Down feathers have loose-webbed barbs, all rising from the tip of a very short shaft. Their function is insulation, and they may be found in both pterylae and apteria in adult birds. They also constitute the first feather coat of most young birds. Filoplumes are hairlike feathers with a few soft barbs near the tip. They are associated with contour feathers and may be sensory or decorative in function. Bristle-like, vaneless feathers occur around the mouth, eyes, and nostrils of birds. They are especially conspicuous around the gape (corners of the mouth) of birds that catch insects in the air. Some bristles function as eyelashes on ground-dwelling birds, and the bristles over the nostrils may serve as filters.

The contour feathers are shed and replaced (molted) at least once a year, usually just after the breeding season. In addition, many birds have at least a partial molt before the breeding season. A typical series of molts and plumages would be juvenile plumage, postjuvenile (also called first prebasic) molt, first winter (or first basic) plumage, first prenuptial (or pre-alternate) molt, first nuptial (or alternate) plumage, first postnuptial (first annual, or second prebasic) molt, second winter (or basic) plumage, etc. Molt of the remiges and rectrices usually occurs as part of the annual molt and can be serial, from the innermost feather out (centrifugal), from the outermost in (centripetal), or simultaneous. Normally it is symmetrical between the right and left sides.

Coloration

Colour in birds is caused by pigments or structure. Buffs, red browns, dark browns, and blacks are caused by melanins, pigments synthesized by the bird and laid down in granules. Yellows, oranges, and reds come from carotenoid or lipochrome pigments; these originate at least in part from the food and are diffused in the skin and feathers. Porphyrin feather pigments occur in birds but less frequently than melanins and carotenoids. Blue colours in feathers are structural, based on a thin, porous layer of keratin overlying melanin pigment. Most greens result from the addition of yellow pigment to the structural blue colour. Iridescent colours result from thinly laminated structure of the barbules and are enhanced by underlying melanin deposits.

Birds' feet are covered with scales like those of reptiles. The scales are occasionally shed, but the timing of this molt is not known. The toes are tipped with claws, and vestigial claws are not infrequently found on the tips of the first two digits of the wing.

The bill is covered with a sheet of keratin, the rhamphotheca, which in petrels and a few other birds is divided into plates. In birds that probe for food (kiwis, woodcock, etc.), many sensory pores are found near the tip of the bill. Both melanins and carotenoids are found in the rhamphotheca and in the scales of the feet.

The skin of a bird is almost without glands. The important exception is the oil (uropygial) gland, which lies on the rump at the base of the tail. The secretion of

Drawing by R. Keane based on A. Bellairs and C.R. Jenkin, "The Skeleton of Birds," in J. Marshall (ed.), *Biology and Comparative Physiology of Birds,* vol. 1; Academic Press, Inc.

this gland contains approximately one-half lipids (fats) and is probably important in dressing and waterproofing the plumage. In a few birds, the secretion has a strong, offensive odour. Some birds, in which the oil gland is small or absent, have a specialized type of feather (powder down) that grows continuously and breaks down into a fine powder, believed to be used in dressing the plumage.

Movable upper mandible

Skeleton. The avian skeleton (Figure 4) is notable for its strength and lightness, achieved by fusion of elements and by pneumatization (*i.e.,* presence of air cavities). The skull represents an advance over that of reptiles in the relatively larger cranium with fusion of elements, made possible by the fact that birds have a fixed adult size. Birds differ from mammals in being able to move the upper mandible, relative to the cranium. When the mouth is opened, both lower and upper jaws move: the former by a simple, hingelike articulation with the quadrate bone at the base of the jaw, the latter through flexibility provided by a hinge between the frontal and nasal bones. As the lower jaw moves downward, the quadrate rocks forward on its articulation with the cranium, transferring this motion through the bones of the palate and the bony bar below the eye to the maxilla, the main bone of the upper jaw.

The number of vertebrae varies from 39 to 63, with remarkable variation (11 to 25) within the cervical (neck) series. The principal type of vertebral articulation is heterocoelous (saddle shaped). The three to 10 (usually five to eight) thoracic (chest) vertebrae each normally bear a pair of complete ribs consisting of a dorsal vertebral rib articulating with the vertebra and with the ventral sternal rib, which in turn articulates with the sternum (breastbone). Each vertebral rib bears a flat, backward-pointing spur, the uncinate process, characteristic of birds. The sternum, ribs, and their articulations form the structural basis for a bellows action, by which air is moved through the lungs. Posterior to the thoracic vertebrae is a series of 10 to 23 fused vertebrae, the synsacrum, to which the pelvic girdle is fused. Posterior to the synsacrum is a series of free caudal (tail) vertebrae and finally the pygostyle, which consists of several fused caudal vertebrae and supports the tail feathers. The sternum consists of a plate lying ventral to the thoracic cavity and a median keel extending ventrally from it. The plate and keel form the major area of attachment for the flight muscles. The bones of the pectoral girdle consist of the furcula (wishbone) and the paired coracoids and scapulas (shoulder blades). The sword-shaped scapula articulates with the coracoid and humerus (the bone of the upper "arm") and lies just dorsal to the rib basket. The coracoid articulates with the anterior (forward) edge of the sternum and with the scapula, humerus, and furcula. The furcula connects the shoulder joints with the anterior edge of the keel of the sternum. It consists of paired clavicles (collarbones) and, probably, the median, unpaired interclavicle.

Wing skeleton

The bones of the forelimb are modified for flight with feathers. Major modifications include restricting the motion of the elbow and wrist joints to one plane, reduction of the number of digits, loss of functional claws, fusion of certain bones of the "hand" (the metacarpals and most of the carpals) into a carpometacarpus, and modification of the elements, especially those toward the tip of the limb (distal), for the attachment of feathers. The wing bones are hollow, and the cavity in the humerus, at least, is connected with the air-sac system. As a general rule, large flying birds have proportionally greater pneumaticity in the skeleton than small ones. The highly pneumatic bones of large flying birds are reinforced with bony struts at points of stress. The humerus, radius, and ulna are well developed. The secondary flight feathers are attached to the ulna, which thus directly transmits force from the flight muscles to these feathers and is therefore relatively heavier than the radius. Two small wrist bones are present: the radiale, or scapholunar, and the ulnare, or cuneiform. The former lies between the distal end of the radius and the proximal part (the part toward the body) of the carpometacarpus. When the elbow joint is flexed (bent), the radius slides forward on the ulna and pushes the radiale against the carpometacarpus, which in turn flexes the wrist. Thus the two joints operate simultaneously. The U-shaped ulnare articulates with the ulna and the carpometacarpus. Anatomists differ on which bones of the reptilian "hand" are represented in the bird's wing. Embryological evidence suggests that the digits are II, III,

Drawing by R. Keane based on L. Darling and L. Darling, *Bird* (1962); Houghton Mifflin Company

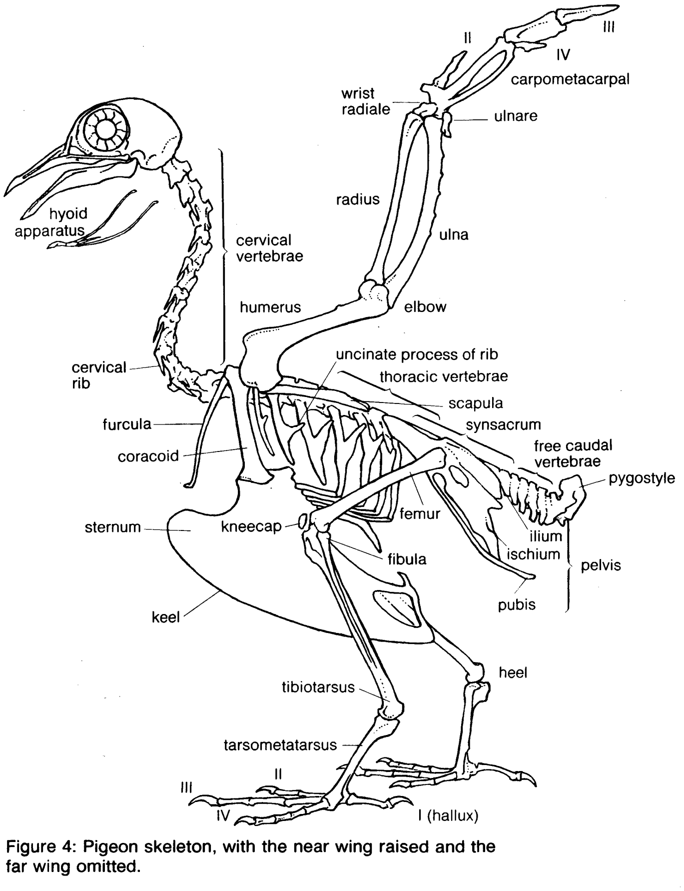

Figure 4: Pigeon skeleton, with the near wing raised and the far wing omitted.

and IV, but it is possible that they are actually I, II, and III. The carpometacarpus consists of fused carpals (bones of the wrist) and metacarpals (bones of the palm), metacarpals II and III (or III and IV) contributing the greater part of the bone. The phalanges (bones of the "fingers") are reduced to one each on the outer and inner digits and two on the middle one. The primary flight feathers are attached to the carpometacarpus and digits, the number attached to each being characteristic of the various major groups of birds.

Pelvis and leg

The pelvic girdle consists of three paired elements, the ilia, ischia, and pubes, which are fused into a single piece with the synsacrum. The ilium is the most dorsal element and the only one extending forward of the acetabulum (the socket of the leg). The ilium is fused with the synsacrum and the ischium, the latter of which is fused with the pubis. All three serve as attachments for leg muscles and contribute to the acetabulum, which forms the articulation for the femur. The leg skeleton consists of the femur (thighbone), tibiotarsus (main bone of the lower leg), fibula, tarsometatarsus (fused bones of the ankle and middle foot), and phalanges (toes). The fibula is largest at its proximal (upper) end, where it forms part of the knee joint and tapers to a point distally, never forming part of the ankle joint. The latter joint is simplified, there being but two bones involved: the tibiotarsus, consisting of the tibia (the so-called shinbone in man) fused with the three proximal tarsals (upper ankle bones), and the tarsometatarsus, resulting from the fusion of metatarsals I through IV and the distal row of tarsals. Metatarsals II through IV contribute most to the tarsometatarsus. The basic number of phalanges (sections) on the toes is two, three, four, and five, respectively; *i.e.,* one more than the number of the toe. Most birds have four toes, the fifth being always absent, but there are many variations in the number of digits, or phalanges, representing reductions of the basic arrangement.

Drawing by R. Keane based on L. Darling and L. Darling, *Bird* (1962); Houghton Mifflin Company

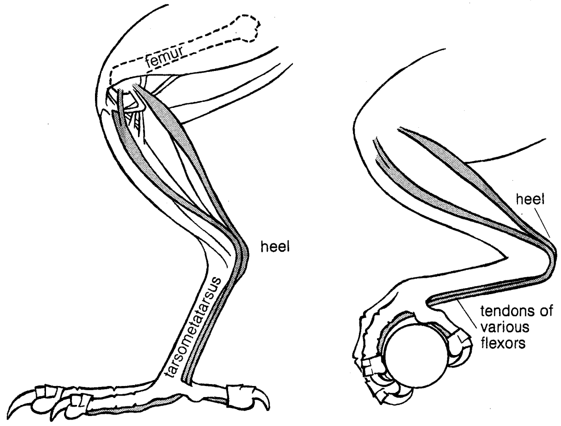

Figure 5: Perching mechanism of a pigeon with the leg extended and flexed.

The basic avian foot is adapted for perching. The first, or hind, toe (hallux) opposes the other three, and the tendons for the muscles that bend the toes pass behind the ankle joint in such a way that when the ankle is bent the toes are also. The weight of a crouched bird thus keeps the toes clasped around the perch.

Muscles

Internal organs. The cardiac (heart) muscles and smooth muscles of the viscera of birds resemble those of reptiles and mammals. The smooth muscles in the skin include a series of minute feather muscles, usually a pair running from a feather follicle to each of the four surrounding follicles. Some of these muscles act to raise the feathers, others to depress them. The striated (striped) muscles that move the limbs are concentrated on the girdles and the proximal parts of the limbs. Two pairs of large muscles move the wings in flight: the pectoralis, which lowers the wing, and the supracoracoideus, which raises it. The latter lies in the angle between the keel and the plate of the sternum and along the coracoid. It achieves a pulley-like action by means of a tendon that passes through the canal at the junction of the coracoid, furcula, and scapula and attaches to the dorsal side of the head of the humerus. The pectoralis lies over the supracoracoideus and attaches directly to the head of the humerus. In most birds the supracoracoideus is much smaller than the pectoralis, weighing as little as one-twentieth as much; in the few groups that use a powered upstroke of the wings (penguins, auks, swifts, hummingbirds, and a few others), the supracoracoideus is relatively large. Avian striated muscles contain a respiratory pigment, myoglobin. There are relatively few myoglobin-containing cells in "white meat," whereas "dark meat" derives its characteristic colour from their presence. The former type of muscle is used in short, rapid bursts of activity, whereas the latter is characteristic of muscles used continuously for long periods and especially in muscles used during diving.

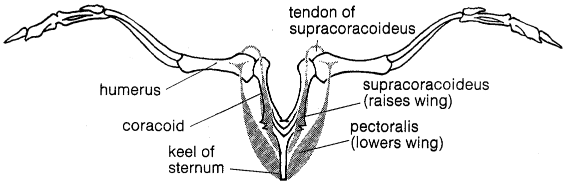

Figure 6: Pectoral girdle of a generalized bird.

Drawing by R. Keane based on L. Darling and L. Darling, *Bird* (1962); Houghton Mifflin Company

Circulatory features

The circulatory system of birds is advanced over that of reptiles in several ways: (1) there is a complete separation between the pulmonary (lung) and systemic (body) circulations, as in the mammals; (2) the left systemic arch (aortic artery) is lost, blood passing from the heart to the dorsal aorta via the right arch; (3) the postcaval vein is directly connected with the renal portal that connects the kidneys with the liver; and (4) the portal circulation through the kidneys is greatly reduced. Birds' hearts are large—0.2 to over 2.4 percent of body weight, as opposed to 0.24 to 0.79 percent in most mammals.

The avian lung differs from the type found in other land vertebrates, in containing fine tubes (capillaries) through which air passes and through the walls of which gas ex-

Drawing by R. Keane based on A.L. Thomson (ed.), *A New Dictionary of Birds;* British Ornithologists' Union and J. Marshall (ed.), *Biology and Comparative Physiology of Birds* (1961); Academic Press

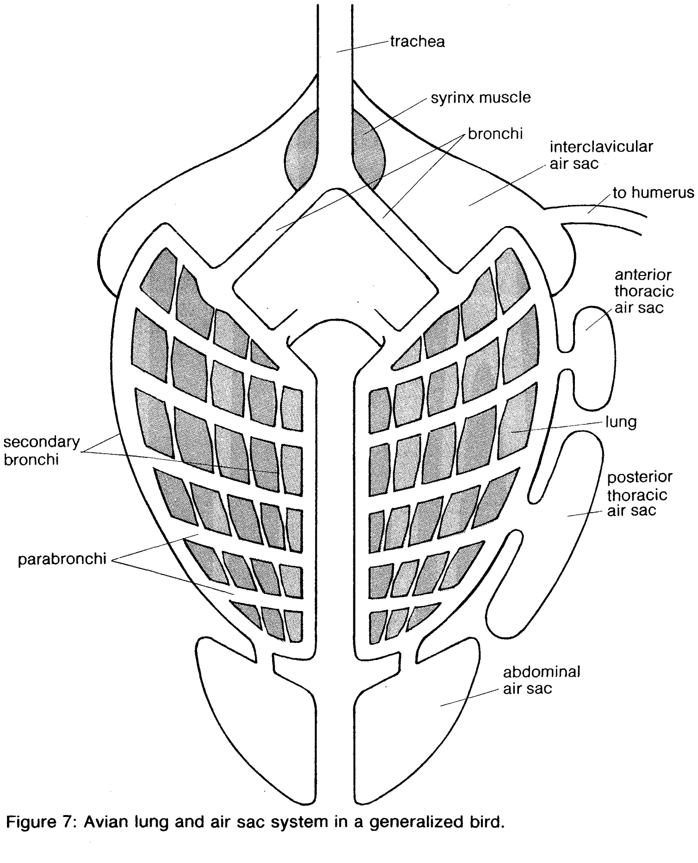

Figure 7: Avian lung and air sac system in a generalized bird.

change takes place. Several pairs of nonvascular air sacs are connected with the lungs and extend into the pneumatic parts of the skeleton. The sound-producing organ in birds is the syrinx, located where the trachea (windpipe) divides into the bronchial tubes. The sounds are made by the flow of air setting up vibrations in membranes formed from part of the trachea, bronchi, or both. Muscles between the sternum and trachea or along the trachea and bronchi vary tension on the membranes.

The avian digestive system shows adaptations for a high metabolic rate and flight. Enlargements (collectively called the crop) of parts of the esophagus permit the temporary storage of food prior to digestion. The stomach is typically divided into a glandular proventriculus and a muscular gizzard, the latter lying near the centre of gravity of the bird and compensating for the lack of teeth and the generally weak jaw musculature. Otherwise, the digestive system does not vary markedly from the general vertebrate type.

Like reptiles, birds possess a cloaca, a chamber that receives digestive and metabolic wastes and reproductive products. A dorsal outpocketing of the cloaca, the bursa of Fabricius, controls antibody-mediated immunity in young birds. The bursa regresses with age, and thus its presence or absence may be used to determine age.

The testes of the male bird are internal, like those of reptiles. Intromittent organs are found in only a few groups (waterfowl, cracids, tinamous, ratites). The distal part of the vas deferens (the seminal sac) becomes enlarged and convoluted in the breeding season and takes on both secretory and storage functions. In passerine birds, at least, this enlargement and the adjacent part of the cloaca form a cloacal protuberance, a swelling visible on the outside of the bird. Usually only the left ovary and oviduct are functional. The albumen, membranes, and shell are laid down in the oviduct as the egg moves down it. The gonads and accessory sexual organs of both sexes enlarge and regress seasonally. In the breeding season, the testes of finches may increase over 300-fold in volume over their winter size.

Temperature control

Birds are homeothermic (warm-blooded) and maintain a body temperature of approximately 41° C (106° F). This temperature may be 1–1.7° C less during periods of sleep and up to 2° C higher at times of great activity. Feathers, including down, provide effective insulation. In addition, layers of subcutaneous fat add further insulation in penguins and in some other water birds. Reduction of heat loss from the feet in cold weather is accomplished by reducing blood flow to the feet and by a heat-exchange network in the blood vessels of the upper leg, so that the temperature of blood flowing into the unfeathered part of the leg is very low.

Birds differ from mammals in lacking sweat glands, hence heat loss is accomplished by rapid panting, which reaches 300 respirations per minute in domestic hens. Some heat dissipation can be accomplished by regulation of blood flow to the feet. In hot climates, overheating is often prevented or reduced by behavioural means—by concentrating activities in the cooler parts of the day and seeking shade during the hot periods. Temporary hypothermia (lowered body temperature) and torpor are known for several species of nightjars, swifts, and hummingbirds. Torpor at night is believed to be widespread among hummingbirds. The heart rate of birds varies widely—from 60 to 70 beats per minute in the ostrich to more than 1,000 in some hummingbirds.

The kidneys lie in depressions that are located on the underside of the pelvis. The malpighian bodies, which are the active tubules of the kidney, are very small in comparison to those of mammals, ranging from 90 to 400 per cubic millimetre. More than 60 percent of the nitrogen is excreted as uric acid or its salts. There is some resorption of water from the urine in the cloaca, with uric acid remaining. There is no urinary bladder, the urine being voided with the feces. In marine birds, salt is excreted in a solution from glands lying above the eyes through ducts leading to the nasal cavity.

EVOLUTION AND PALEONTOLOGY

Archaeopteryx

The earliest known fossil bird is *Archaeopteryx lithographica*, which was discovered in Upper Jurassic deposits in Bavaria. This bird was about the size of a magpie. It resembled some reptiles, however, and differed from Recent birds in many ways: (1) the jaws contained teeth set in sockets; (2) the articulations between the vertebrae were amphicoelous (concave at both ends); (3) there were only six sacral vertebrae; (4) the long tail was made up of a series of free vertebrae each bearing a pair of rectrices; (5) the slender ribs lacked articulations with the sternum and uncinate processes (flat upward projections); (6) ventral ribs (gastralia) were present behind (posterior to) the sternum; (7) the sternum was short and not keeled; (8) the bones were not pneumatic; (9) the third metacarpal bone in the wing was fused to the carpals, but the first two metacarpals were free, resulting in three movable digits of the "hand," all with functional claws; (10) the fibula was as long as the tibia; (11) the metatarsal bones were free; (12) the cerebral hemispheres were elongated and slender, and the cerebellum lay behind the midbrain, not overlapping it from behind or crowding it downward. The avian characteristics of *Archaeopteryx* included the possession of feathers, the elongated, backward-directed pubis, the furcula, and the opposable hallux. In the structure of the beak, eye, and jaw articulation, in the fusion of the third metacarpal with the carpals, and in the fusion of each of the distal tarsals with the corresponding metatarsal, *Archaeopteryx* represented an intermediate stage between reptiles and modern birds.

The absence of a keel on the short sternum indicates that *Archaeopteryx* did not fly but glided. The opposable hallux, indicative of the perching type of foot, and the clawed digits of the hand point to an arboreal existence. From the arrangement of feathers on the wing and the number and arrangement of bones in the limbs, it appears that *Archaeopteryx* was near the main line of avian evolution. From the fact that the skull was diapsid (*i.e.,* had two "windows") and from certain features of the limb bones,

Drawing by R. Keane

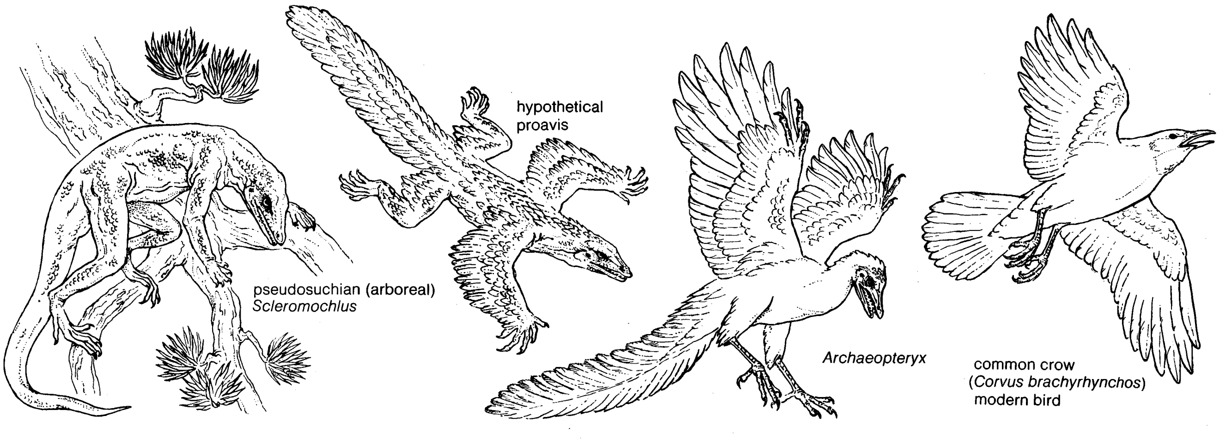

Figure 8: Four stages in the evolution of modern birds.

it appears that *Archaeopteryx* was descended from reptiles of the Triassic order Thecodontia.

The origins of flight

By the Triassic Period (225,000,000 years ago) a group of small bipedal reptiles, the pseudosuchians, were well established. Their skulls had much in common with that of *Archaeopteryx,* although they had heavier jaws and smaller eyes. It is likely that one group of pseudosuchians became arboreal. The advantages of such a life would be safety from large terrestrial predators and an abundance of insect food. Once these reptiles were in the trees, selective pressures would favour mutations leading to many avian features. The swaying of branches would favour the evolution of the grasping foot. Use of the forelimbs in climbing from branch to branch would favour enlargement of the claws and elongation of the forelimb, which was short in the bipedal ancestors. Greater visual acuity and more effective coordination are of special advantage in arboreal animals. Natural selection thus favoured larger eyes, narrower snouts (permitting better forward vision), and greater development of the cerebral lobes and cerebellum of the brain. The smaller jaws may also indicate the advantages of lightness, balance, and a specialization for feeding on insects as opposed to the apparently more general carnivorous diet of the terrestrial ancestors. Perhaps most important was the development of homeothermy (internal temperature control). A warm-blooded insect eater has an enormous advantage in being able to capture insects when they are cold and slow to react. It is also advantageous in the wind-moved environment of the treetops. In addition to increased food intake and advanced respiratory and circulatory systems, however, homeothermy requires effective insulation. It is likely that feathers evolved to fill this requirement, although many authorities believe the origin of feathers was directly connected with flight. Just how feathers evolved from reptilian scales is unknown, but it is known that the two are similar in chemical composition and that some pseudosuchians had scales bearing an imprint of a feather-like pattern on their surface. Elongated feathers on the forelimb and tail may have evolved for balancing and for gliding to produce the *Archaeopteryx* stage.

In the evolution of modern birds from an *Archaeopteryx*-like form, the development of active flight must have occurred early. This meant an increase in size of the muscles moving the wing and the development of a keel on the sternum as an added area of attachment for these muscles. As the tail took on more of a steering function and less of a supportive one, it became shorter and more readily moved as a unit. Feathers became increasingly specialized for different functions, and at the same time, the trends in the development of the eyes, brain, and respiratory and circulatory systems associated with the evolution of the homeothermic, arboreal, gliding types continued. By the time birds became strong fliers, they were ready to radiate out into many new environments; and by the Cretaceous Period (136,000,000 to 65,000,000 years ago), they had begun to do so. This radiation has produced the large array of adaptive types known today.

The lightness and pneumaticity of bird bones makes them poor candidates for fossilization. As might be expected, heavyboned diving birds and large flightless birds are disproportionally represented in the record.

Cretaceous birds

One of the best known groups of fossil birds consists of *Hesperornis* and its relatives. These birds were highly specialized foot-propelled divers of the Upper Cretaceous. The known species of *Hesperornis* were up to six feet (1.8 metres) long and had completely lost the power of flight. The sternum lacked a keel; the humerus was small and weak; and the other, more distal, elements of the wing were missing. The pelvis and hindlimb had a strong but superficial resemblance to those of modern loons and grebes—the pelvis was narrow; the femur short and stout with a hingelike articulation with the pelvis; the tibiotarsus long, with a long cnemial crest (a projection at its upper end); and the tarsometatarsus laterally compressed. Two major features (and several less obvious ones) indicate, however, that the resemblance was the result of convergent evolution: the ischia and pubes were free for most of their length, and the cnemial process was made up entirely of the patella; in the loon, this process is derived from the tibiotarsus. *Hesperornis* was remarkable for three features: it had teeth set in grooves, not sockets, in the maxilla and mandible; the phalanges of the stout fourth toe had a unique rotary ball-and-flange type of articulation; and the free tail vertebrae had broad lateral projections and limited vertical motion, indicating that the tail was somewhat beaver-like in its action. *Baptornis,* a contemporary relative of *Hesperornis,* was smaller and less strongly modified. While flightless, it had less reduced wings than *Hesperornis,* and it lacked the peculiar modifications of the fourth toe and caudal vertebrae.

Living on the same seas as *Hesperornis* and *Baptornis* was a group of flying birds known as *Ichthyornis* and *Apatornis.* Although not related to gulls, these birds resembled them superficially and may well have been their ecological counterparts. It was long believed that *Ichthyornis* had teeth, like *Hesperornis;* but it is now thought that the toothed jaws formerly thought to belong to *Ichthyornis* were really those of a small mosasaur, a marine reptile.

Large flightless predators

After the extinction of the dinosaurs and before large carnivorous mammals evolved, two groups of large flightless birds evolved to fill a similar niche. From the upper Paleocene to the middle Eocene, *Diatryma* and its relatives were major predators in the Northern Hemisphere. The largest species stood over two metres (seven feet) tall and had stout hooked beaks. They are of uncertain relationships but may have been distantly related to cranes and rails. The second group, that of *Phororhacos* and related genera, had a long history (from the lower Oligocene to the middle Pliocene) in South America, which was without large carnivores until relatively late. Fragmentary Pleistocene material from Florida has also been assigned to this group. The *Phororhacos* line evidently evolved from cariama-like stock and radiated into numerous genera and species, the largest of them (*Onactornis*) standing 2.5 metres (eight feet) tall and having a skull 80 centimetres (31 inches) long and 40 centimetres (16 inches) high.

Large grazing or browsing birds appear to have evolved several times. On continents where there are large predators, these birds have always been rapid runners (ostriches, rheas, emus), but on islands lacking such predators, they were slow-moving, heavy-bodied birds. Two such groups were the elephant birds of Madagascar and the moas of New Zealand, the largest in each group approaching 10 feet in height. Fragmentary fossil material from Eocene and Oligocene deposits in Egypt indicates that similarly adapted birds occurred there before the advent of large carnivores.

Except for the *Hesperornis* line, teeth appear to have been lost very early in the history of birds, but fish-eating birds have evolved several toothlike structures for grasping their prey. Perhaps the most remarkable adaptation was that of *Osteodontornis* and its relatives, large, flying marine birds that flourished from the lower Eocene to the Miocene. In these birds, there were bony projections of the upper and lower jaws, which were covered by the ramphotheca, forming sharp, toothlike structures.

The fact that fewer bird fossils are found in earlier deposits is well illustrated by expressing the number of known species in a given geological period in terms of the duration of the period. About 35 species of birds are known from Cretaceous deposits, which were laid down over an estimated 71,000,000 years, giving a figure of 0.5 species per 1,000,000 years. The corresponding figure for the Paleocene is 1.2 (12 species in 10,000,000 years) and that for the Eocene, 5.4 (87 species in 16,000,000 years). Up-to-date figures for the later periods are not available, but estimates based on several recent sources are 7.9 per 1,000,000 years in the Oligocene, 12.3 in the Miocene, and 21.8 in the Pliocene. The Pleistocene, which lasted approximately 2,500,000 years, has yielded nearly a thousand species of fossil birds. From this it is evident that very little is known about the early avifaunas. It is known, however, that, as might be expected, the birds in the earlier periods differ more from Recent species than do those of the later periods. Of the 12 families of birds recorded from Cretaceous deposits, only two are still extant, whereas the majority of species recorded from the Pleistocene were structurally little, if at all, different from living forms. Thus the absence of a group in the fossil record, especially in the earlier periods, is rarely significant.

The major diversification of birds probably took place in the Cretaceous, which lasted longer than the sum of all subsequent periods, and it must have started early in that period because fragmentary material of foot-propelled divers (*Enaliornis*) and of an early relative of the flamingos (*Gallornis*) are known from Lower Cretaceous deposits of Europe. Upper Cretaceous deposits have yielded, besides *Hesperornis* and *Ichthyornis* and their relatives, diving birds similar to *Enaliornis* (*Lonchodytes*), other early flamingo-like birds, and species in the same suborders as gannets, ibises, rails, and shorebirds.

Paleocene deposits have yielded the earliest known loons, cormorants, New World vultures, and gulls. In addition, the large, flightless predatory birds culminating in *Diatryma* first made their appearance during this period. From the far richer Eocene deposits have come the earliest known rheas, penguins, albatrosses, tropic birds, anhingas, true flamingos, herons, storks, secretary birds, hawks, curassows, cranes, bustards, avocets, auks, sand grouse, cuckoos, owls, swifts, trogons, rollers, hornbills, and songbirds. Almost certainly all living orders and most living families of birds were in existence by the end of the Eocene period. One of the most interesting finds from this period was fossils of *Neocathartes,* a long-legged bird allied to the New World vultures. There are several anatomical similarities between this group of vultures and the storks, and the existence of this fossil lends support to the idea that the storks and New World vultures are more closely related to each other than each family is to the birds with which it is usually grouped.

Important Oligocene fossils include the earliest phororhacoids, one of the few groups of fossil birds that is known from enough material from over a long enough time span to show evolutionary trends, in this case, both in size and in bill form.

Fossils of Miocene birds are numerous. Several early groups of pelecaniform, cranelike, and flamingo-like birds are known last from this period, and the first of the Mancallidae, superficially penguin-like auks, appeared. Otherwise, the avifauna was essentially modern.

By Pliocene times, most modern genera were probably in existence. The Mancallidae continued on the California coast at least until the middle of the period.

The appearance and extinction of large birds as well as mammals was a feature of the Pleistocene. Perhaps most notable were the teratorns, "super condors," which were found in North America. These included *Teratornis incredibilis,* the largest known flying bird.

CLASSIFICATION

Distinguishing taxonomic features. In classifying birds, most systematists rely primarily on structural characters. Plumage characters include the number of remiges and rectrices; the presence or absence of down on the feather tracts, on apteria, and on the oil gland; and the presence or absence of an aftershaft. Characteristics of the bill and feet are useful, as is the arrangement of bones in the palate and around the nostrils. The presence or absence of certain thigh muscles and the arrangement of the carotid arteries, the syrinx, and the deep flexor tendons of the toes are employed, as is the condition of the young when hatched. Advances in the study of protein structure and of chromosomes have provided new means of determining taxonomic relationships.

Annotated classification. This classification is based primarily on that of the American ornithologist Alexander Wetmore but includes the ideas of a number of other authorities. It is unlikely that most avian systematists would agree on all aspects of one arrangement, but the one presented below will satisfy many. The dagger (†) indicates extinct groups, known only from fossils.

CLASS AVES

Vertebrate (backboned) animals primarily adapted for flight with feathers. Warm-blooded, 4-chambered heart, left systemic arch lost. Lower jaw articulates with cranium via the quadrate; teeth absent in living forms. Reproduction by hard-shelled eggs, nearly always incubated by one or both parents. About 8,600 living species.

†Subclass Archaeornithes

†Order Archaeopterygiformes (Archaeopteryx). Upper Jurassic; Europe. Teeth set in sockets; long, unfused caudal vertebrae, each bearing a pair of rectrices; keelless sternum; functional claws on digits of hand. Gliding birds, about 50 cm long.

Subclass Neornithes

†Superorder Odontognathae

†Order Hesperornithiformes (Hesperornis, Baptornis). Upper Cretaceous; North and South America. Teeth set in groove in jaws. Flightless, foot-propelled diving birds, 1 to 2 m long.

Superorder Neognathae

Order Tinamiformes (tinamous). Upper Pliocene to present; Central and South America. Superficially quaillike or grouselike ground-dwelling birds with flat, elongated, and rather weak bills and very small tails. Size 15–50 cm.

Order Rheiformes (rheas). Lower Eocene to present; South America. Ostrich-like cursorial birds with very small tails and no aftershaft on the feathers. Sexes alike. Length 90–130 cm.

Order Struthioniformes (ostrich). Lower Pliocene to present (the Eocene *Eleutherornis* may belong here); southwestern Asia and Africa (fossils from southern Europe and southeastern Asia). 2-toed (3rd and 4th) running birds. Males black and white, females brown. Aftershafts, down, and filoplumes absent. Largest living bird; length to 180 cm, height 260 cm, weight 136 kg, egg 1.6 kg.

Order Casuariiformes (emus, cassowaries). Pleistocene to present; Australia, New Guinea, adjacent islands. Very large, cursorial (running) birds. Sexes alike, brown (emus) or blackish with brightly coloured wattles and skin on head (cassowaries). Aftershaft very large. Length 130–190 cm.

†Order Aepyornithiformes (elephant birds). Pleistocene; Madagascar (upper Eocene and lower Oligocene fossils from Egypt have been placed here). Very large and graviportal (heavy bodied); height to 3 m; egg weight estimated at 10 kg.

Order Dinornithiformes (moas, kiwis). Upper Miocene or lower Pliocene to present; New Zealand. Very large (to 3 m tall) and graviportal birds (moas) or smaller (length 30–80 cm); almost wingless, nocturnal, probing birds (kiwis).

Order Podicipediformes (grebes). Lower Miocene to present; worldwide. Foot-propelled diving birds with lobed toes, minute tails, and silky plumage. Length 21–66 cm.

Order Procellariiformes (albatrosses, shearwaters, fulmars, prions, petrels). Middle Eocene to present; all oceans, but most numerous in Southern Hemisphere. Web-footed marine birds with tubular nostrils; rhamphotheca divided into plates; possess a musky smell. Most have narrow wings and stiff, gliding flight. Length 14–135 cm.

Order Sphenisciformes (penguins). Upper Eocene to present; oceans of Southern Hemisphere. Wings flipper-like, for propulsion underwater; webbed feet short and stout; stance upright. Feathers short and dense, molted in patches. Length 40–120 cm (fossil forms to 180 cm).

Order Pelecaniformes (pelicans, boobies, tropic birds, cormorants, frigate birds). Paleocene to present; worldwide. Water birds with all 4 toes webbed; bill hooked or straight and sharply pointed. Length 50–180 cm.

Order Anseriformes (screamers, waterfowl). Middle Eocene to present. Web-footed birds with broad bills containing fine plates or lamellae (waterfowl); or large-footed marsh birds with chicken-like bills (screamers). Length 29–160 cm.

Order Phoenicopteriformes (flamingos). Cretaceous to present; discontinuously distributed in warm regions except Australasia. More varied and widely distributed as fossils. Web-footed birds with long legs, long necks, bent bills with lamellae, and much pink or red in the plumage. Share characters with both Anseriformes and Ciconiiformes, but evidently closer to the latter, with which they are sometimes grouped. Length 91–122 cm (some fossil forms smaller).

Order Ciconiiformes (herons, storks, ibises, spoonbills). Upper Cretaceous to present; worldwide except in extreme north. Long-legged wading birds with long bills; feet not webbed. Although usually grouped together, herons and storks may prove to belong to different orders. Length 28–152 cm.

Order Falconiformes (diurnal birds of prey). Upper Paleocene to present; worldwide. Diurnal raptors with hooked beaks, long talons, and short (hawks, falcons) or very long (secretary bird) legs or carrion-eating birds with weaker claws and tearing bills (vultures, condors). Length 15–150 cm (some fossil forms larger).

Order Galliformes (grouse, pheasants, quail, turkeys). Middle Eocene to present; nearly worldwide, except southern South America. Terrestrial or arboreal chicken-like birds; strong, scratching feet; short, rounded wings; feathers with long aftershafts. Length 13–198 cm.

Order Gruiformes (cranes, rails, coots, cariamas, bustards). Upper Cretaceous to present; worldwide. Diverse group, ranging from small quail-like hemipodes to large long-legged cranes, marsh-inhabiting rails, swimming coots and fin-foots, and cursorial bustards. The Tertiary phororhacoids belong here, as may the very large *Diatryma* and its relatives. Length 11–152 cm (fossils to 200 cm tall).

†*Order Ichthyornithiformes (Ichthyornis, Apatornis).* Upper Cretaceous; North America. Superficially gull- or ternlike water birds of uncertain affinities. Length approximately 21 to 26 cm (estimated from reconstruction of fossils).

Order Charadriiformes (plovers, sandpipers, gulls, terns, auks). Upper Cretaceous to present; worldwide. 3 basic body plans: Suborder Charadrii—waders (shorebirds), usually feeding on small animals in mud or water, bill variable but often long and used for probing; Lari—web-footed, dense-plumaged water birds feeding by plunging into water for fish, robbing other birds, or scavenging; Alcae—dense-plumaged, web-footed, marine, wing-propelled divers, feeding on fish or invertebrates. Length 13–76 cm.

Order Gaviiformes (loons or divers). Upper Paleocene to present; Holarctic. Foot-propelled diving birds with webbed feet and pointed bills. Cnemial crest an extension of the tibia. Length 66–95 cm.

Order Columbiformes (sand grouse, pigeons, doves, dodoes). Upper Eocene or lower Oligocene to present; worldwide except in extreme north. Fast-flying birds with pointed wings and weak bills; feed on seeds and fruit. Length 15–84 cm.

Order Psittaciformes (parrots, lories, cockatoos). Upper Oligocene to present; throughout tropics, with some temperate-zone species. Often brightly coloured. Strong-flying, seed-, fruit-, or nectar-eating birds with very stout, hooked bills and zygodactyl feet (*i.e.,* outer toe reversed). Length 9.5–99 cm.

Order Cuculiformes (turacos, cuckoos, roadrunners). Upper Eocene or lower Oligocene to present; worldwide except in extreme north. Long-tailed birds with zygodactyl or semizygodactyl feet. Feed on both fruits and small animals. Most arboreal, a few terrestrial. Some brood parasites. Length 16–70 cm.

Order Strigiformes (owls). Eocene to present; worldwide. Nocturnal raptorial birds with hooked beaks, strong talons, and soft plumage. Length 13–69 cm.

Order Caprimulgiformes (nightjars, frogmouths, oilbird). Pliocene to present; worldwide except in extreme north. Concealingly coloured, soft-plumaged, nocturnal birds with weak feet and very large mouths. Most feed on insects caught in flight. Length 19–53 cm.

Order Apodiformes (swifts, hummingbirds). Upper Eocene or lower Oligocene to present; worldwide except in extreme north; hummingbirds limited to New World. Rapid-flying birds that feed on the wing on insects and nectar. "Hand" and primaries constitute a relatively great proportion of the wing; feet weak. Length 6.3 to 23 cm.

Order Coliiformes (colies or mousebirds). Unknown as fossils. Africa south of the Sahara. Soft-plumaged birds with long, pointed tails and all 4 toes directed forward. Food largely vegetable, some insects. Length 29 to 36 cm.

Order Trogoniformes (trogons). Pantropical, except Australasia; upper Eocene or lower Oligocene to present. Extremely soft-plumaged arboreal birds; underparts yellow to red, head and neck often iridescent, tail long, black and white. Feet weak; 1st and 2nd toes directed backward. Food insects and small fruit. Length 23 to 34 cm.

Order Coraciiformes (kingfishers and allies). Eocene to present; worldwide except in extreme north. A heterogeneous group of hole-nesting birds. Many with long, pointed bills and blue or green in plumage. All have 2nd and 3rd or 3rd and 4th toes joined at base. Food largely animal, except hornbills, which eat much fruit. Length 9 to 160 cm.

Order Piciformes (woodpeckers, barbets, honey guides, toucans). Upper Oligocene (possibly upper Eocene) to present. Zygodactyl (rarely 3-toed) hole-nesting birds. Food insects and fruit. Woodpeckers are modified for climbing. Honey guides are brood parasites. Length 9 to 61 cm.

Order Passeriformes (perching birds). Upper Eocene to present; worldwide. The large complex assemblage of perching birds, containing more than half of the known species of birds. Bill, plumage, and habits highly varied. Length 7.5 to 102 cm.

Critical appraisal. It has frequently been stated that birds are one of the best known of animal groups. This is true, in the sense that most of the living species and subspecies in the world have probably been described; but because of inadequacies in the fossil record and repeated cases of convergent evolution within the group, our knowledge of the phylogenetic relationships between orders, suborders, and families of birds is inferior to that of mammals and reptiles.

The taxonomic positions of several bird groups remain open to question. The hoatzin, included above in the Galliformes, is often given its own order, Opisthocomiformes. The turacos, here included in the Cuculiformes, are considered by many authors to warrant separation as Musophagiformes. *Diatryma* and several related genera of extinct flightless predators are often placed in a distinct order, Diatrymiformes, near Gruiformes. The flamingos, which constitute the order Phoenicopteriformes above, are placed in the Ciconiiformes in many classifications. The sand grouse, family Pteroclidae, are believed by some to be more closely related to the shorebirds (order Charadriiformes) than to the pigeons (order Columbiformes), with which they are usually grouped.

Relationships among the ratites

One area particularly in need of study is the relationships among the various groups of ratites (ostriches, rheas, emus, moas, etc.). Formerly, some authorities argued that these birds and the penguins arose independently from cursorial reptiles, but it is now generally agreed that all of them passed through a flying stage in the course of their evolution. The ratite groups differ greatly in morphology and yet show remarkable similarities in palate and bill characters. The principal unanswered questions are how many different flightless lines evolved from flying ancestors and from how many different groups were the flying ancestors evolved. On zoogeographic grounds, it is likely that the isolated kiwi-moa, elephant bird, and emu-cassowary lines arose independently from each other and from ratites on the other continents. But the ostriches and rheas could be descended from a common flightless ancestor because of the known former land connections from Asia to North and South America.

Before organic evolution was understood and accepted, animals were grouped on the basis of general similarity. It is now known that many such groupings were unnatural from a phylogenetic standpoint but were instead the result of convergent evolution from different parental stocks. Examples are *Hesperornis,* loons, and grebes, and diving petrels and auks. It is likely that many more examples are not recognized or generally accepted. At least the following groups should be studied with this in mind: herons and storks, *Diatryma* and the phororhacoids, New World vultures and other falconiforms, sand grouse and pigeons, touracos and cuckoos, and swifts and hummingbirds. These examples are all from the ordinal or subordinal level; examples at lower levels would be far more numerous. (R.W.St.)

MAJOR BIRD ORDERS

The remainder of this article consists of a review of each of the major groups of birds, identified at the order level of biological classification and arranged in accordance with the annotated classification above.

There are some omissions, however. The extinct groups (designated in the annotated classification by the dagger [†]) are treated throughout this article under the heading *Evolution and paleontology.* Additional information on extinct birds and on avian evolution may be found in GEOCHRONOLOGY: *Fossil record.* Also omitted are the following orders: Rheiformes (rheas); Struthioniformes (ostriches); Dinornithiformes (moas and kiwis); Gaviiformes (loons, also called divers); Coliiformes (colies, also called mousebirds); and Trogoniformes (trogons). These groups are represented by *Micropædia* entries under their common rather than scientific names. Finally, the flamingos (Phoenicopteriformes) are treated in the section on Ciconiiformes.

Tinamiformes (tinamous)

The Tinamiformes, or tinamous, are a group of ground-dwelling, chicken-like birds of Central and South America. They have a superficial resemblance to partridges and quail (gallinaceous birds) but are placed in a distinct order related to the much larger rheas. Tinamous long have interested scientists because of many peculiar features of their skeleton and biology that link them to the large flightless birds or ratites: the ostriches, emus, cassowaries, and rheas.

Predation by man

Tinamous, considered by hunters to be among the finest game birds in terms of sport as well as palatability, are heavily hunted in many parts of South America. Market hunting has been curtailed by law; however, it is still practiced in some countries. Frozen tinamous from Argentina were formerly sold in the United States under the name South American quail. Although by the early 1980s only one species of tinamou was listed as endangered by the International Union for the Conservation of Nature, habitat destruction and heavy hunting have reduced a large number of populations.

GENERAL FEATURES

The 46 species of tinamous range in size from that of a small quail, about 15 centimetres (six inches) long and 150 grams (five ounces) in weight, to that of a large grouse, about 50 centimetres long and two kilograms (four pounds) in weight. Tinamous are rather uniform in body proportions and stance, resembling guinea fowl (Numididae). The head is small and the bill medium sized, relatively thin, and slightly downcurved. The long, slender neck is clothed in short feathers. The body is quite heavy, with a high rump outline from the enormous development of rump feathers, which generally hide the extremely short or even rudimentary tail. The short, rounded wings are inconspicuous on the standing bird, and the primary flight feathers are hidden by the full plumage of the flanks. The bare legs are typically rather thick and of medium length. There are three short front toes, with the hind toe either elevated or absent.

Protective coloration in spotted or barred patterns

The sexes are alike, except that the female is generally slightly heavier and has brighter coloration. The plumage coloration is highly concealing, in spotted or barred patterns of brown, gray, rufous, or tan. The variation in coloration is dependent upon the environment. The crested tinamous of the genus *Eudromia* have a long and slender crest that the bird directs forward when it is excited. The colour of the legs or of the bill is vivid and diagnostic in several species, as for example in the yellow-legged tinamous (*Crypturellus noctivagus zabele*).

NATURAL HISTORY

Locomotion. Highly adapted for ground dwelling, tinamous normally walk rapidly (especially the savanna species) and can run with amazing swiftness. If forced into extended running, however, as when chased by men or dogs, they tire quickly and are likely to stumble and fall. They are best able to escape notice by standing motionless with the neck extended or by quietly slipping away, making use of all available cover. Some species of tinamous may crouch or even feign death. They rise in flight only when almost stepped upon. Small tinamous that live in open terrain sometimes hide in animal holes, such as the burrows of armadillos.

The flight of tinamous is clumsy but swift and accompanied by an easily audible rumbling or whistling noise produced by the stiff, curved primaries. The elegant crested tinamou (*Eudromia elegans*) of the open tableland of Argentina alternates periods of flapping with short glides. When flushed, forest species sometimes collide with branches and tree trunks and may injure themselves. If forced to make several flights in short succession, tinamous soon become exhausted, apparently because of a low circulation rate, related in turn to the surprisingly small size of the heart and lungs. The flight muscles are well developed, but the circulatory system seems to be insufficient for sustained activity.

Unlike the gallinaceous birds, tinamous sleep on the ground at night. Exceptions are members of the genus *Tinamus,* which roost in trees, choosing horizontal branches or tangled lianas and perching on their rasplike feet without using the toes.

Vocalizations. The voices of tinamous are among the strongest and most pleasant of any in the neotropics. They consist of loud, stereotyped, but melodious whistles, varying from the long and astonishingly songlike sequence of the brown tinamou (*Crypturellus obsoletus*)—astonishing because most relatives of the tinamous do not produce elaborate vocalizations—to the monosyllabic call of the cinereous tinamou (*C. cinereus*). The calls of the male and female are similar but discernibly different to the human ear. The female solitary tinamou (*Tinamus solitarius*) has a special call given during the time before egg laying, and another call is uttered by both sexes of this species after perching at dusk.

Habitat selection and food habits. Collectively, tinamous are adapted to a wide variety of environments, including dense woodland, thickets, open woodland, savanna, and even to the bunchgrass-covered plateaus of the high Andes, where they occupy the ecological niche generally held by the grouse in other parts of the world. In some forest regions as many as five species of tinamous have been found to coexist, inhabiting slightly different types of plant communities. The grassland tinamous do not occur north of the Amazon River; there the tinamou niche is occupied by the crested bobwhite (*Colinus cristatus*), a species of quail.

Seasonal variation in feeding

The food taken by tinamous varies with the season and habitat. In summer the red-winged tinamou (*Rhynchotus rufescens*), for example, eats mainly animal material—largely insects, but its mouth is large enough to swallow mice. In the stomach of one bird 707 termites were counted. In winter the red-winged tinamou shifts over to vegetable food. It occasionally becomes a pest in agricultural areas, using its strong bill to dig up the roots of manioc, or cassava (*Manihot esculenta*). The small tinamous of the genus *Nothura* feeds primarily on seeds, but the spotted tinamou (*Nothura maculosa*) occasionally eats ticks in pastures. The forest-inhabiting solitary tinamou generally prefers small fruits and berries, collected on the ground. It might, however, also devour a frog when it finds one. The members of the genus *Nothoprocta* are considered beneficial to agriculture because of their large consumption of insect pests. Young tinamous of all species are more dependent upon insects than are the adults. Unlike the gallinaceous birds, tinamous do not scratch for food, as is evident by their weak toes and short nails; instead, they either turn over leaves and other debris with the bill or dig with it.

Reproduction. Courtship behaviour has been described for only a few species of tinamous. Certain species have well-defined breeding periods, and others breed throughout the year. Investigators have reported that courting birds raise the thickly feathered rump and display the brightly coloured undertail coverts. A similar display has been observed in a frightened *Crypturellus:* the bird presses the breast to the ground, raises the rump, spreads the terminal feathers like a fan, and exhibits the sharply marked undercoverts. Courting birds also have been observed to chase each other around on the ground.

Multiple mating is the rule among tinamous, although a few species such as the ornate tinamou (*Nothoprocta ornata*) maintain stable pairs. All forms of polygamy exist, the conditions varying between and even within species. Many species have uneven sex ratios; preponderance of males seems to be more frequent, the ratio reaching four to one in the variegated tinamou (*Crypturellus variegatus*). The ratio in the ornate tinamou is about one to one.

Parental behaviour by the male

The nest, a shallow depression in the ground, is constructed and defended by the male. The eggs are among the most beautiful of all bird eggs, always monochromatic and highly glazed. The colours include light chocolate brown, near black, purple, dark bluish green, light yellowish green, and gray when laid, but the shell pigments fade when exposed to light. One hen, or more, places her eggs in the nest of a male; when several females provide the eggs, the clutch may become quite large, eight to 16 eggs. Incubation, which lasts 17 to 21 days, is done entirely by the male, who broods and guides the chicks for several weeks after hatching. The chicks, blotched and streaked like the young of the rheas, are able to run as soon as they are hatched. When frightened, they squat and freeze, becoming almost invisible.

PALEONTOLOGY AND CLASSIFICATION

There is no doubt that the tinamous represent one of the oldest stocks of birds on the South American continent. To date, three genera of fossil tinamous, of one species each, have been described from a single deposit from the Miocene of Argentina (about 10,000,000 years ago). The majority of other fossil tinamous, mostly representing species still extant, has been discovered at scattered sites from the upper Pleistocene (less than 1,000,000 years ago) of South America.

Many authors have noted anatomical and biological resemblances between the tinamous and rheas, or nandus (Rheidae). The structure of the bony palate, an important feature in the taxonomy of ratite birds, quite clearly links the two groups, but most authorities prefer to maintain them as separate orders, Rheiformes and Tinamiformes, each with a single family, respectively, Rheidae and Tinamidae.

(H.S.)

Casuariiformes (emus, cassowaries)

The order Casuariiformes includes two families of large flightless birds: Dromaiidae for the emu (*Dromaius novaehollandiae*), found only in Australia; and Casuariidae for three species of cassowaries (*Casuarius*), restricted to northern Australia, New Guinea, and nearby islands. Of the two groups, the emu is far better known, both biologically and popularly, being exhibited in zoos around the world.

The emu was first identified by European explorers in 1788, more than a century after the first cassowaries had been seen by Europeans; in 1697 a Dutch navigator, Willem de Vlamingh, had seen the emu's footprints in western Australia and had attributed them to a "Kasuarius." Cassowaries first became known to Europeans in the 17th century—there was a published reference to a "Casoaris" in 1658—when the Portuguese and Dutch colonized the East Indies. Both names, emu and cassowary, were originally applied to cassowaries; the emu was known as the New Holland or New South Wales cassowary until the early 19th century, when the name emu was gradually transferred to it. By the late 19th century about 11 species of cassowaries were recognized, but greater understanding of variation within species has reduced the number to three: the double-wattled, or Australian, cassowary (*Casuarius casuarius*), the single-wattled, or one-wattled, cassowary (*C. unappendiculatus*), and the dwarf, or Bennett's, cassowary (*C. bennetti*).

IMPORTANCE TO MAN

The emu and cassowaries are important foods for the indigenous peoples of both New Guinea and Australia; the flesh of the thigh muscles somewhat resembles beef. In New Guinea cassowaries are captured as chicks and held in enclosures until they are large enough to eat. The feathers are frequently used for personal adornment. In Australia cassowary feathers formerly were used for the notorious *kurdaitcha* shoes, or "shoes of silence," worn by Aboriginal executioners on nocturnal missions of tribal vengeance or punishment. During World War I members of the Australian cavalry regiments wore tufts of emu plumes on their slouch hats.

Since the time of European settlement in southeastern Australia, the emu has become much less abundant, and three island forms have been exterminated by hunting. In Western Australia, however, the bird has remained common and has become a pest in the wheat-farming areas, breaking fences and trampling and eating crops. In 1932 members of an army machine-gun unit were employed in a campaign against a concentration of emus, estimated to be about 20,000, in the vicinity of the wheat-belt centre of Campion.

The Emu War in Australia

The outcome of this bizarre Emu War, as it was called, has been summarized by the ornithologist D.L. Serventy as follows:

> . . . the machine-gunners' dreams of point blank fire into serried masses of Emus were soon dissipated. The Emu command had evidently ordered guerrilla tactics, and its unwieldy army soon split up into innumerable small units that made use of the military equipment uneconomic. A crestfallen field force therefore withdrew from the combat area after about a month.

Yearly kills of emus in Western Australia for bounty payments vary from about 5,000 to nearly 40,000 birds. The emus, however, remain plentiful, and small parties may be seen within 15 or 20 kilometres (9 or 12 miles) of Perth, the capital of the state.

NATURAL HISTORY

Reproduction. Throughout its climatically varied range the emu is a winter breeder; egg laying begins at the end of April. The nest is a flattened bed of bark, grasses, and leaves near a tree or bush and is so situated that the sitting bird (always the male) has a good view of its surroundings. Despite their size, nests are extremely difficult to find. The large green eggs, with granulated shells, average about 130 millimetres (slightly over five inches) in length and 87 millimetres (3.4 inches) in width and weigh 450 to 800 grams (16 to 28 ounces). They are laid at intervals of about four days, and the male starts incubation when the hen has laid five to nine. The normal clutch size is eight, nine, or 10 eggs, with large clutches up to 16. In exceptionally good seasons as many as 20 eggs may be laid, in poor seasons as few as four or five. Incubation varies from about 58 to 61 days, during which the male seldom leaves the nest, even to feed.

Eggs

The newly hatched chicks, which are concealingly streaked

Drawing by R. Keane

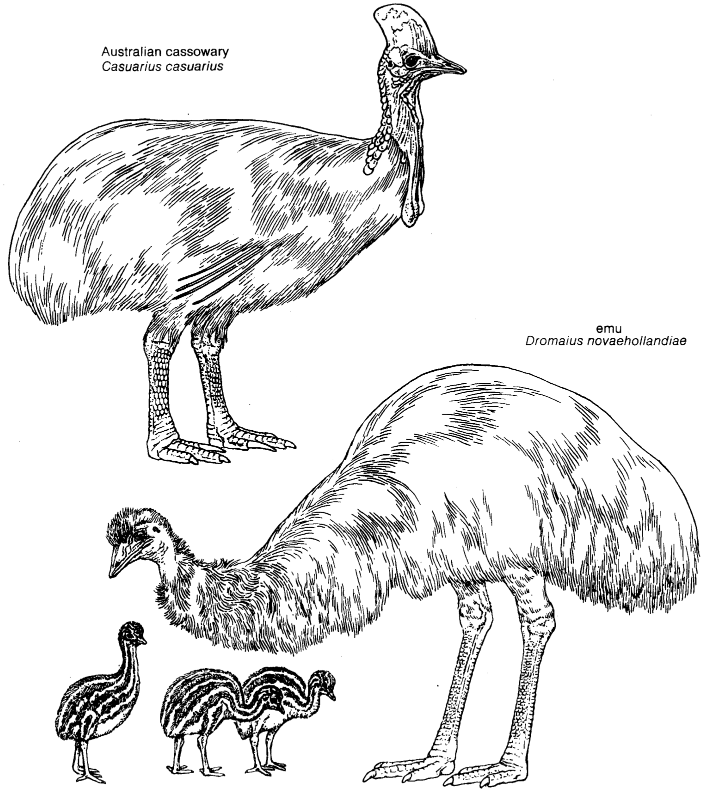

Figure 9: Emu and cassowary.

with black, are brooded by the male for two or three days before they begin to move around in his company. Normally two years are required to reach maturity. In the nonbreeding season the groups coalesce into flocks, which may undergo local movements or more extensive migrations. Marking with leg bands has proved that individual emus may travel hundreds of kilometres.

Far less precise data are available on the annual cycle of the cassowaries. According to several observers, the eggs are laid in winter and are incubated by the male for 49–52 days. The eggs are paler green than those of the emu and there are fewer in the clutch, which varies from three to eight. Maturity may not be reached until the second or third year. Cassowaries are not gregarious in the nonbreeding season but live as pairs or family parties.

Ecology. Cassowaries are more pugnacious and aggressive than the emu. They are essentially creatures of the tropical rain forests, where they are extremely difficult to observe. Their diet consists mainly of fruit. Emus, on the other hand, live under a wide variety of environmental conditions, ranging from dense temperate forest to open plains and arid scrub country. They frequently exhibit a curious inquisitiveness toward the activities of man and may be lured to close range by various devices, as for example the waving of objects in the air, a habit that was utilized by the Australian Aborigines in hunting them. Emus are basically vegetarian, subsisting on fruits, seeds, and vegetation of all kinds. They will, nevertheless, also feed on insects, including caterpillars and grasshoppers, when they occur in great numbers.

The emu and cassowaries swim well and are fast runners. The emu is capable of a stride of nearly three metres (10 feet) and can keep up with an automobile travelling as fast as 40 to 50 kilometres (approximately 25 to 30 miles) per hour for some distance.

Vocalizations. Both sexes of the emu are reported to utter resonant drumming notes and guttural grunting calls, under varying conditions. Less is known about the calls of cassowaries, but scattered accounts indicate that they are similar to those of the emu.

FORM AND FUNCTION

Size and weight of emus

Next to the ostrich (*Struthio camelus*), the emu is the largest and heaviest of living birds; large individuals stand between 1.5 and 1.8 metres (five and six feet) high and weigh up to 55 kilograms (120 pounds), although most are well below that weight. Females are slightly larger, averaging about 40 kilograms (90 pounds) while the males average about 36 kilograms (80 pounds). The sexes are alike in colour; the plumage is sombre brown, or brownish black, and the naked skin on the head and neck is blue. All three species of cassowaries are black and, except for the dwarf cassowary, have fleshy pendulous wattles of red, orange, or yellow on the head and neck. The head is crowned with a horny casque or helmet, believed by some authorities to protect the bird from injury by branches during rapid movements in the forest. The plumage of casuariiforms is loose and hairlike due to the lack of barbules, the secondary branches that interlock to form the flat vane in the feathers of most birds. There are no feathers differentiated as tail feathers, but cassowaries have five quills of the wing modified into hollow, unbranched spines.

As with many running birds, casuariiforms have only three toes, the hindtoe having been lost. The inner toe of cassowaries is armed with an elongated, dagger-like claw, making the foot a formidable weapon in kicking.

The casuariiform skeleton is similar to that of the other large flightless birds (ratites) in the reduction of the wing elements and of the keel on the sternum (breastbone) and in the enlargement of the leg elements. Vestigial clavicles (collarbones) remain in the shoulder girdle, but the humerus (upper "arm" bone) is much reduced, being shorter than the combined forewing and manus ("hand"). The manus has a single digit, now believed to be the third, which bears a long claw.

The pattern of bones in the palate, an important diagnostic feature in the taxonomy of ratites, is of the palaeognathous or dromaeognathous type (common to all ratites), in which the vomer bones of the skull extend back to separate the palatines. The casuariiforms have the simplest form of this palate type, with large vomers and short palatines.

EVOLUTION AND CLASSIFICATION

Paleontology. No fossil remains of casuariiform birds have been found outside of the Australian region, and most of those recorded are from the Pleistocene (more than 10,000 years ago), with one doubtfully from the Pliocene (about 4,000,000 years ago). The latter, although definitely a member of the emu assemblage, showed features linking it with the cassowaries. The absence of fossil material notwithstanding, the order must have had a long evolution during the Tertiary Period (from 65,000,000 to 2,500,000 years ago). The relationship of the casuariiforms with the other orders of large flightless birds—the rheas (Rheiformes), ostriches (Struthioniformes), kiwis and moas (Dinornithiformes), and elephant birds (Aepyornithiformes), formerly grouped in a distinct subclass of birds, the Ratitae—is still rather uncertain, but Casuariiformes appears to be the most primitive of the living orders. The upper Pleistocene of Australia has produced several fossil species of emus assigned to the modern genus *Dromaius* and dating from as much as 100,000 years ago. Other Pleistocene finds from Australia have been placed in a separate family, Dromornithidae. These include *Dromornis,* known only from leg bones, and the gigantic *Genyornis newtoni,* almost the entire skeleton of which is known. The only known fossil cassowary is a species from Pleistocene cave deposits in the Wellington Valley, New South Wales, Australia, which resembles closely, and is probably identical with, the dwarf cassowary (*Casuarius bennetti*), now restricted to New Guinea and nearby islands. The distribution of the Casuariidae has evidently shrunk in recent millennia; the only species occurring on the Australian mainland is the double-wattled cassowary (*C. casuarius*), which is restricted to New Guinea and the Cape York Peninsula of northern Queensland.

Relationship to other flightless birds

Classification. The following classification of the order is universally accepted.

ORDER CASUARIIFORMES

Large graviportal (ponderous) flightless birds with 3 toes. Other physical features described in *Form and Function,* above. Monogamous. Eggs green in colour.

Family Casuariidae (cassowaries)

Beak laterally compressed. Prominent horny casque on mesethmoid, nasal, and frontal bones of the skull. Coracoid bone of the shoulder much shorter than in emu. Bony union (symphysis) between various posterior elements of the pelvis may be present or absent. Femur not pneumatized by air sac system. Cervical vertebrae 18 or 19. Wing with 5 quills modified as long hollow spines. Pendulous coloured wattles on throat and neck (except in dwarf cassowary). Three species.

Family Dromaiidae (alternatively Dromiceiidae; emu)

Beak flattened dorsoventrally. Head not casqued. Pubic symphysis lacking. Femur pneumatic. Trachea with an aperture in front, leading to an inflatable neck sac. Pendulous wattles absent. Fossil record limited to the Pleistocene of Australia and nearby islands. One Recent species.

Family Dromornithidae

Fossil only; Pleistocene of Australia; 2 genera, 2 species.

(D.L.Se.)

Podicipediformes (grebes)

The order Podicipediformes includes only the grebes, foot-propelled diving birds best known for the striking courtship displays of some species and for the silky plumage of the underparts, which formerly was much used in millinery. The speed with which grebes can submerge has earned them such names as water-witch and helldiver, while the position of the feet near the tail is responsible for the early English name arsefoot, from which the family name, Podicipedidae, was derived.

Adult grebes range in weight from less than 150 grams (five ounces) to more than 1.4 kilograms (approximately three pounds) and in total length from 21 to 73 centimetres (eight to 29 inches). They vary principally in bill shape and ornamentation of the head. The group is found on all of the continents and on many island groups as well.

However, it is best represented in temperate regions. Seven species each are found in North and South America, five in Eurasia, and three each in Africa and Australia. The species range from conspicuous and gregarious to solitary and skulking.

NATURAL HISTORY

Courtship displays

Vocalization

Mating behaviour. Both parents share in nest building, incubation, and care of the young. The long pair bond that makes this possible is formed and strengthened by elaborate courtship displays, including ritualized preening, head shaking, diving, weed carrying, and rapid water treading with the body in a nearly vertical position. These displays may be combined into complex ceremonies such as the discovery ceremony of the great crested, rednecked, horned, eared, and related species or the rushing display of the western grebe. In nearly all courtship ceremonies the roles of the sexes are interchangeable. The same is true of the precopulatory displays, and reverse mounting has been reported for all species that have been thoroughly studied. Courtship feeding is known only in the western grebe (*Aechmophorus occidentalis*), the male of which feeds the female. Grebe vocalizations include advertising calls, copulation trills, "conversational" notes, and duetting trills. In the courtship of more secretive species, such as the pied-billed grebe (*Podilymbus podiceps*) and the dabchicks (a name given to several of the smaller grebes), vocalizations are relatively more important than visual displays.

Nesting. Following pair formation, grebes build one or more floating platforms of aquatic vegetation. On these mating takes place and the three to seven unmarked chalky, white eggs are laid. On leaving the nest, adults often cover the eggs with the soggy nest material, and, by the end of the incubation period (usually three to four weeks), the eggs are strongly stained. In most cases, the nest is deserted after the young hatch, and the small young spend most of their time on the swimming parents' backs, which they reach by clambering up the adult's foot. On hatching, the downy young are marked with bold longitudinal stripes, though such stripes are rarely visible on the gray young of the western grebe. Remnants of the head stripes are carried over into the juvenile plumage. In addition to the stripes, the young have either one or more patches of rufous down or a bare spot on the crown. The skin of the latter changes in colour from pink to red when the young become excited.

Feather eating

Habitat selection and food habits. Grebes breed on still or slow-moving bodies of fresh water. The dabchicks and the pied-billed grebe are most numerous on small waters with much emergent vegetation, the western grebe on large bodies of open water. Some species winter on sheltered coastal waters. Grebes' diets consist almost entirely of animal matter. The western grebe feeds largely on fish, the eared grebe (*Podiceps nigricollis*) on small invertebrates, and the pied-billed grebe takes many heavy-bodied crustaceans. Other species, such as the horned and red-necked grebes (*Podiceps auritus* and *P. grisegena*), have more varied diets. Grebes are noted for swallowing feathers, which form a plug in the pyloric pocket of the stomach and effectively filter material passing to the intestine. Adults feed feathers to the young, establishing this plug shortly after hatching. Grebes feeding on invertebrates containing much chitin regurgitate pellets rather frequently; fish eaters tend to maintain masses of feathers in the main portion of the stomach, presumably to hold fish bones until they are digested.

FORM AND FUNCTION

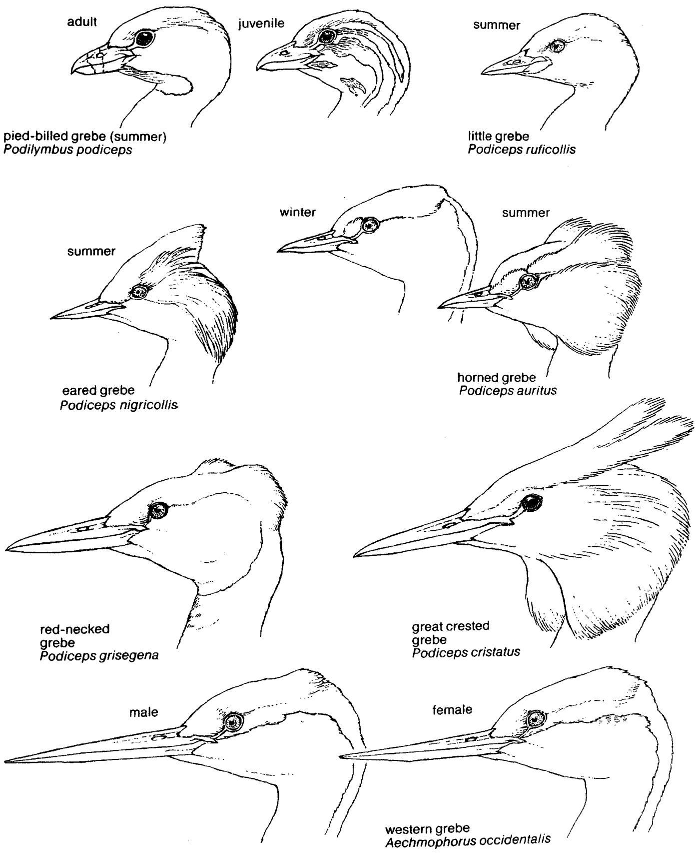
Grebes can be distinguished by their lobed toes with flat nails, greatly reduced tail feathers, and satiny breast feathers. The last is due to the relatively loose structure of the feathers on this part of the body and to spirally coiled barbules (the secondary branches of the feathers), which lie parallel to the barbs (the primary branches). As with most diving birds, the conspicuous features that distinguish species from one another are found on the head and figure prominently in courtship.

Western grebe (*Aechmophorus occidentalis*). The young are carried upon the parents' backs for protection and warmth.
Willis Peterson

Seasonal plumage

In winter plumage most grebes are brown, black, or gray above and white or light brown below. In summer plumage, rufous, buff, black, or white markings or elongated plumes are found, chiefly on the head and neck. In this plumage, the males tend to be more brightly coloured and to have somewhat longer plumes than the females. The males also tend to be larger and larger billed than the females.

Grebes' wings are short and the wing bones small in diameter. Some species nesting in cold regions are migratory. Major flights are usually made at night. One species, the short-winged grebe (*Rollandia micropterum*) of Lake Titicaca, between Peru and Bolivia, is flightless; two others, Taczanowski's grebe (*Podiceps taczanowskii*) of Lake Junín, Peru, and the giant pied-billed grebe *Podilymbus gigas*) of Lake Atitlán, Guatemala, have somewhat reduced wings and fly little, if at all.



Drawing by R. Keane

Figure 10: Heads of typical grebes.

While on the surface, grebes usually swim with alternate strokes of the feet, whereas under water, the feet move simultaneously. Between recovery and power strokes, the feet are turned 90° so that the broad side can be used for propulsion; just before the recovery stroke, the feet are rotated in the opposite direction. While resting, grebes keep one or both feet shipped under the wings, and the head is kept forward with the bill under the neck (the "pork-pie" posture).

CLASSIFICATION AND PALEONTOLOGY

Grebes comprise a single family, Podicipedidae, of the order Podicipediformes. There are approximately 18 species, usually placed in five genera: *Aechmophorus* (the western grebe), *Podiceps* (most species), *Podilymbus* (the pied-billed grebes), *Rollandia* (Rolland's and short-winged grebes), and *Tachybaptus* (dabchicks).

Distinguishing taxonomic features. The order and family are defined on the basis of structural features, especially the form of the nostrils, the absence of certain processes in the skull, and the absence of the ambiens muscle in the leg. The knee process consists of a large pyramidal patella (kneecap) and a large projection on the tibia (the main bone of the lower leg). The wing is diastataxic (*i.e.,* there is a space where the fifth secondary feather is located in many birds), with 12 primaries, seven of which are attached to the metacarpus (midhand). The oil gland is tufted and has two openings. Only the left carotid artery is present. The intestinal caeca (blind pouches) are small.

Grebes are highly specialized diving birds with no obvious relatives, living or fossil. Statements to the effect that they are "primitive" or "reptilian" are erroneously based on a superficial resemblance to the toothed Cretaceous Hesperornithiformes, themselves very specialized forms. The earliest known fossil grebe, *Podiceps oligoceanus* from lower Miocene deposits (about 25,000,000 years old) in Oregon, is essentially like modern species.

The names *Colymbus,* Colymbidae, and Colymbiformes were formerly applied to the grebes in North America and to the loons (*Gavia*) in Europe. (R.W.St.)

Procellariiformes (albatrosses, shearwaters, petrels)

The Procellariiformes are a distinct natural order of oceanic birds with approximately 87 living and 36 fossil species. Of diverse size and range, they are divided into four families: albatrosses, shearwaters, storm petrels, and diving petrels. All Procellariiformes are recognizable by their conspicuous tubular nostrils, which project upon the culmen (upper bill). This feature gives the order its alternative name, Tubinares, meaning "tube nosed." The feet of these birds are webbed, and the hind toe is either vestigial or missing. All species have a characteristic powerful musky odour, which is caused by the excretion of stomach oil. The oil can be used as a defensive discharge through the mouth when the bird becomes alarmed.

GENERAL FEATURES

Importance to man. The tube-nosed birds have been of considerable local economic importance as a source of protein food, feathers, and oil wherever humans have colonized or have been able to raid the coastal and oceanic islands where they breed. This situation has resulted in the partial or complete extermination locally of certain species. Humans, moreover, have been responsible for the introduction of various predators, including rats, pigs, and cats. In regions where bird populations have survived, people have continued to harvest the eggs, the plump young birds (at fledging time), or both. Many thousands of slender-billed, or short-tailed, shearwaters (*Puffinus tenuirostris*) are taken on the Bass Strait islands off Tasmania and sold fresh, salted, or deep-frozen as "muttonbirds." In all likelihood, the name muttonbird was derived from the use of the flesh as a supplement for mutton by the early settlers of New South Wales. The numbers of muttonbirds now harvested are regulated so as to preserve a substantial breeding stock.

"Mutton-birds"

In New Zealand the Maori people have harvested young *titi* (shearwaters of several species) from time immemorial, a right assured them in perpetuity by treaty with Queen Victoria. On the other side of the world, hundreds of Manx shearwaters (*Puffinus puffinus*) were formerly collected for food and as lobster bait on the Welsh islands of Skomer and Skokholm, which are now nature preserves estimated to contain about 200,000 Manx shearwaters and 2,000 storm petrels (*Hydrobates pelagicus*). On the Tristan da Cunha Islands in the South Atlantic, resident islanders harvest the eggs and squab (young) of a large, mixed seabird population, which includes more than 6,000,000 greater shearwaters (*Puffinus gravis*).

The harvesting of northern fulmar petrels (*Fulmarus glacialis*) is an ancient practice among peoples inhabiting the cool northern coasts where the birds choose to breed. In Iceland about 50,000 fulmars were taken annually between 1897 and 1925; however, the occurrence in 1939 of psittacosis (a virulent avian disease) among processors of the birds resulted in prohibition of the use of fulmars for food.

During the early 17th-century colonization of Bermuda, millions of cahows, or Bermuda petrels (*Pterodroma cahow*), were exterminated by the colonists. For nearly 300 years the species was believed extinct, but in 1951 a few pairs were discovered nesting on an offshore islet, where a remnant now survives under strict protection. The related black-capped petrel, or diablotin (*P. hasitata*), of the West Indies was also thought extinct (because of predation by humans, rats, and mongooses) until in 1961 a substantial population, estimated to number at least 4,000 birds, was found breeding in the inaccessible forested crags of Hispaniola.

Encounter with man

In the 18th and 19th centuries, huge numbers of albatrosses were taken for food (largely by whalers) and for the millinery trade. With the disappearance of sailing vessels, changes in fashions, and the establishment of many nesting grounds as sanctuaries, such predation has virtually disappeared, but albatrosses have not entirely escaped stress at the hands of man. On Sand Island in the Midway Atoll, Laysan albatrosses (*Diomedea immutabilis*) increased from a few pairs in 1900 to about 60,000 pairs in the early 1960s, the increase resulting from shelter provided by introduced vegetation. The use of the island by aircraft after 1935, air raids by the Japanese during World War II, and the loss of 30,000 birds humanely killed by the U.S. Navy (in a control program designed to reduce collisions between birds and aircraft) did not deter the albatrosses from this favoured nesting area. The control program was abandoned after the discovery that levelling

Drawing by R. Keane

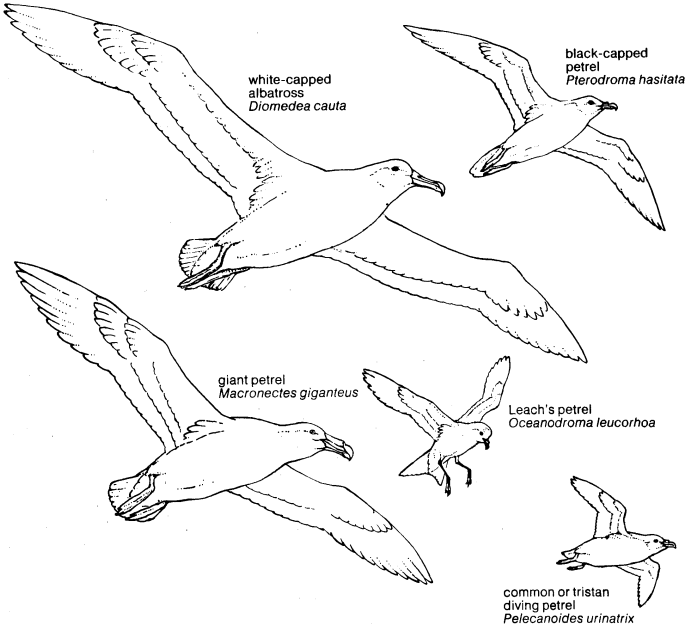


Figure 11: Representative procellariiform birds in flight.

certain sand dunes effected a 70 percent reduction in collisions by removing the updrafts near aircraft runways.

Distribution. The majority of procellariiforms breed in the Southern Hemisphere, but several species migrate thousands of miles north across the Equator to winter in the northern summer seas, where they molt, feed, and rest in preparation for the return home in the southern spring. Similarly, species that breed in the Northern Hemisphere also live in perpetual summer by migrating far south to winter in the southern summer. A number are less migratory and do not cross the Equator. Several species are almost sedentary, chiefly smaller petrels breeding in tropical and subtropical latitudes, and the subantarctic prions (*Pachyptila*) and diving petrels. All latitudes of the unfrozen oceans are thus occupied, but there are fewer living in the calm equatorial region, where there is little wind to lift their long wings and where the pelagic (open-ocean) crustacean food on which so many seabirds basically depend is scarce. The zone of upwelling water in the windy latitudes of the Antarctic convergence, between 40° and 60° south latitude, is richest in the shrimplike krill (*Euphausia* species), attracting surface-feeding tubinares and the diving penguins, prions, and diving petrels. Some feed along the edge of the ice of the Antarctic continent, and four tubinares actually breed on its shores: the Antarctic fulmar, the giant petrel, the snowy petrel, and the tiny but very numerous Wilson's petrel; the nesting burrows of the last may be blocked by snow for days during the protracted breeding season. The only tubinare nesting near the ice limits in the high Arctic is the fulmar, which reaches Franz Josef Land, Greenland, and the Arctic Circle north of the Aleutian Islands.

Of the albatrosses (family Diomedeidae), only the two Midway species and the short-tailed albatross (*Diomedea albatrus*) nest well north of the equatorial doldrums. The latter was brought close to extinction by plume hunters and by a volcanic eruption at its nesting island of Torishima. There were enough immature birds at sea at the time to allow a partial recovery, and some 60 individuals were counted there in 1969. Nine albatross species range the Southern Hemisphere, gliding on the eternal winds of the "Roaring Forties" (the region between 40° and 50° latitude) and moving north with the food-rich cold currents along the west coasts of South America, South Africa, Australia, and New Zealand. One species, the waved albatross (*Diomedea irrorata*), is unique in that it breeds only in the Galápagos Archipelago at the Equator, where probably not more than 3,000 pairs nest on Hood Island.

The family Procellariidae includes the larger petrels, such as the northern and southern fulmars (*Fulmarus glacialis* and *F. glacialoides*), the gadfly petrels (*Pterodroma*), several genera of shearwaters, and the prions or whalebirds. Several of the shearwaters and larger petrels breed in burrows far inland on mountain crags in the Andes, West Indies, Madeira, and New Zealand. The largest member of this family is the giant, or stinker, petrel (*Macronectes giganteus*), an albatross-like scavenger and circumpolar wanderer with a heavy beak and wing span of eight feet. Smallest are the prions, four species of small, stocky, little-studied birds, 22 to 30 centimetres (nine to 12 inches) long, with broad bills and a restricted cold-water range; they breed on sub-Antarctic islands, keeping much to the water, as do the diving petrels.

The storm-petrel family, Hydrobatidae, ranges both hemispheres but is strongest numerically in the Pacific, where *Halocyptena microsoma,* the least petrel of Baja California, rivals the Atlantic storm petrel as the smallest procellariiform. The word petrel ("little Peter") derives from a habit of the storm petrels of walking on the waves.

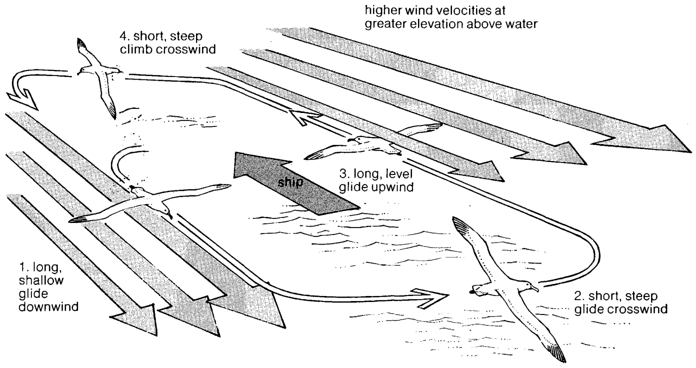
The diving petrels form a family (Pelecanoididae) and genus (*Pelecanoides*) with four species. They are small, rather sedentary, coast-dwelling birds confined to cool southern islands, including Tristan da Cunha, the Falklands, New Zealand, and southeastern Australia. The common diving petrel (*P. urinatrix*) is circumpolar; the largest species, the Peruvian (*P. garnotii*), has followed the Humboldt current along the west coast of South America and breeds from Chile to Peru; the Magellanic (*P. magellani*) is confined to the tip of South America; the Georgian (*P. georgicus*) breeds on South Georgia, Macquarie, and Auckland islands. Diving petrels are specialized birds with short, black-and-white bodies and closely resemble externally and in habits the small auks (family Alcidae, order Charadriiformes) of the Northern Hemisphere.

NATURAL HISTORY

Locomotion. All tube-nosed birds have a protracted life cycle conditioned by their evolution and oceanic environment. Because they spend most of their lives at sea, they are clumsy on land, laboriously using their wings as props to assist locomotion; their legs are too far to the rear to effect a well-balanced bipedal progress. The smaller species nest in burrows and rock crevices and are nocturnal, being helpless and unable to manoeuvre quickly on land when attacked by predators. As a rule, the incubating bird is tame and does not associate the approach of man with danger but will often allow him to stroke and fondle it. Albatrosses are especially docile, hence the name mollymawk (mallemuck), from the Dutch *mollemok* ("stupid gull").

Flight pattern of albatrosses

The long-winged tubinares require a smooth runway for takeoff on a calm day; over rough ground they will utilize the bill to hook along, and either climb a rock or tree to gain a launching height or flop over the edge of the nearest cliff. On the wing, they are perfect aviators, riding out the severest storms of their normally windy oceanic feeding grounds with ease and grace. The great albatrosses can overtake and circle a fast ship at sea, with long glides rarely interrupted by wingbeats. The ability of albatrosses to move upwind without flapping depends on the fact that wind velocity is appreciably lower near the waves than a few metres in the air. The flight pattern is a series of broad ellipses (Figure 12), characteristically including (1) a fast downwind glide beginning at the greater elevation, at which the wind velocity is higher, giving the bird considerable momentum with a small loss of altitude. As it reaches maximum speed, the bird turns crosswind (2), briefly skimming the waves, then moves upwind (3) on a long, level glide through the lower velocity air, maintaining altitude, but losing speed. As soon as its air speed reaches a critical low, the bird climbs steeply crosswind (4) to complete the ellipse, now at the same altitude as at the start of the previous downwind leg but having gained in position upwind. It then glides downwind again to gather fresh momentum. The same flight pattern may be used, of course, to travel crosswind or downwind. The normal air speed of the royal and wandering albatrosses (*Diomedea epomophora* and *D. exulans*), whose wing spans reach about 3.4 metres (11 feet), is 80 to 110 kilometres (50 to 70 miles) per hour. Although the flight appears effortless, some energy is expended in the muscular action that keeps the long, narrow wings fully extended.



Drawing by R. Keane

Figure 12: Flight pattern of the albatross.

The medium-sized tubinares (shearwaters and procellariid petrels) have a flight pattern similar to that of albatrosses, but their shorter wings are flapped regularly between the briefer gliding periods. The little storm petrels have an altogether more erratic darting, fluttering, and sometimes hovering flight, their feet hanging down to walk on the water surface.

Feeding habits. Shearwaters, storm petrels, and diving petrels feed by taking small fish and crustaceans close to the surface; they make short dives as necessary. Many of the larger procellariids consume substantial amounts of squid. Albatrosses, giant petrels, and fulmars dive little; they are surface feeders, often settling on the water. At night they devour squid that rise to the surface; during the day they take schooling fish; garbage from ships; wounded, exhausted, or dead birds; and carrion, including the flesh of dead whales and other cetaceans. The giant petrel is probably the only tubinare agile enough on land to kill other birds; at its nesting grounds it will attack young penguins inadequately guarded by their parents.

Reproduction and growth. As a general rule, the mature adults return to the established breeding site many weeks before the single white egg is laid. There is often severe competition for nesting territories in large crowded colonies on small islands. Returning each year to the same nest site, the male and female remain faithful to it and thus to each other for life. It is believed that some albatross pairs also remain together at sea in the nonbreeding season, but many of the burrowing shearwaters and petrels, meeting on land only at night, may never see their mates clearly when ashore (recognition being by voice, touch, and possibly smell) and probably do not deliberately consort in pairs at sea.

The greeting ceremony

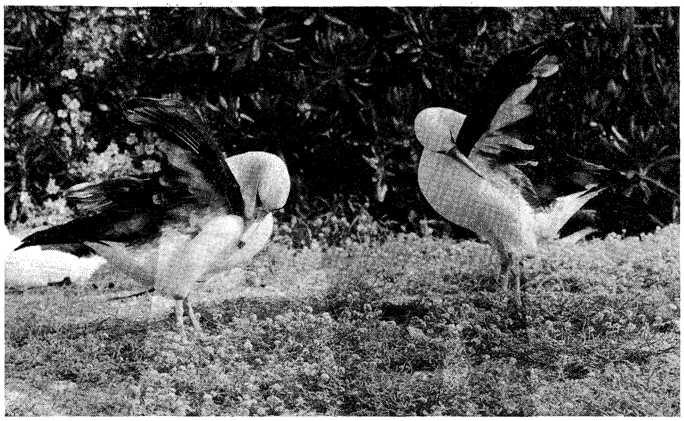
At each fresh encounter ashore between breeding birds, there is an elaborate greeting ceremony; the birds clash and fence with the bills, cackling and screaming. These antics occur in both the nocturnal procellariids and the diurnal albatrosses, and in the latter there is also a bowing and dancing display. Such behaviour provides time for mate recognition and relieves and displaces any natural aggression or fear.

The nest type varies somewhat among species. Albatrosses scrape a shallow depression or build a mound of soil and vegetation; the fulmars and other diurnal procellariid petrels nest on ledges or on level ground; most shearwaters, diving petrels, and some storm petrels dig burrows in soft soil; other storm petrels utilize natural crevices.

Once the nest site has been adopted, one member of the pair usually remains on guard against usurpation by other birds that are still in search of a suitable nest site. The male may remain on guard for several days and nights, while the female feeds at sea in order to meet the nutritional requirements of the developing egg. In some species, the female may depart on a recuperative feeding cruise within a few hours after laying if her mate is there to take over incubation. Mated birds do not feed each other; instead they incubate for periods of several days each, the bird at home fasting and losing weight while the bird at sea is feasting and fattening.

The egg is incubated for a long period, about 80 days in the wandering albatross, 52 days in the Manx shearwater, 40 days in the smallest petrels (the last about equal to the incubation period of the ostrich). For the first week or so after hatching, the helpless, downy chick requires the warmth of the parental body for survival. During this period it is brooded and fed tenderly on an oily broth of semidigested marine organisms pumped from the adult esophagus, which is muscularly constricted to control the flow to the infant's needs. Instinctively, the chick seeks the open, warm, fishy-smelling mouth of the parent, thrusting and groping blindly with its tiny bill crosswise in the open maw of the adult.

Olin S. Pettingill, Jr.—The National Audubon Society Collection/Photo Researchers



A pair of Laysan albatrosses (*Diomeda immutabilis*) in ritualized preening display, a part of the courtship that precedes nest building.

The down grows rapidly; a second down sprouts (to which the first remains attached), and the baby is soon homeothermic—*i.e.,* able to keep itself warm while its parents forage far at sea and return with increasingly large crop loads of food. Some of the fishing trips of the parents are real voyages, involving absences of several days; the Manx shearwater may travel nearly 1,000 kilometres (more than 600 miles) from Wales to the Bay of Biscay and back to load up with its favourite food, sardines. Albatrosses may leave their well-developed nestling for a week or two. If both parents happen to return at the same time, the nestling may ingest food equal to its own weight in one meal. It becomes very fat in the later stages of the long fledgling period, which is not less than two months in the small petrels and reaches nine months in the largest albatrosses. Before it leaves the nest, the chick is deserted by the parents, who retire to molt at sea. This begins a starvation period, which may last a week in the smallest petrels, 12 days in the medium-sized shearwaters, and considerably longer in the largest species, before the fledgling goes to sea. When deserted, it is well-feathered and fatter and heavier than the adult; it needs a period of thinning and exercise before it is capable of flight. After days of fasting and wing flapping, it may become airborne one windy night, especially if hatched in a burrow on a gale-swept mountain height from which it can flap and glide to the sea. Calm weather is its enemy; many island-born young tumble down to the sea, too heavy to take off again in still air. They are expert swimmers, however, and can dive deeply to avoid attacks by aerial predators.

Period of fledgling starvation

Paddling rapidly away from the dangers of land and soon gaining flight, the young procellariiform sets off along the traditional migration route, alone and unguided by the long-departed adults. Driven by an innate impulse to keep flying, it reaches winter quarters that it has never seen before, often at a surprising speed. One Manx shearwater, banded in Wales as a fledgling, travelled 9,900 kilometres (6,200 miles) to southern Brazil in 16½ days. Allowing half of each day for resting and feeding, this is equivalent to an average surface speed of 50 kilometres (30 miles) per hour over the period, a remarkable achievement for a bird just out of the nest.

The young albatross remains longest in the nest—so long in the case of the royal and wandering albatrosses that the nestling is overtaken by the Antarctic winter. It endures blizzards and savage winds that force it to grip the nesting mound tightly with its claws, yet it is warm enough under its oily plumage to survive fasting for many wintry days until a parent appears with food. Because of the protracted nesting period, these great albatrosses cannot rear more than one young every other year. To compensate for the slow rate of reproduction, albatrosses are long-lived; life expectancy, once breeding age is reached, appears to be several decades. Marking of Laysan albatrosses has shown that they do not breed successfully until seven years old. In order to maintain their numbers, the wandering and royal albatrosses, breeding for the first time even later, must have the highest average longevity among birds. The Manx and other medium-sized shearwaters lay the first egg when five years old, the least petrel in the third or fourth summer.

There is thus always a large proportion of each tubinare population that is nonbreeding. During its first year at sea, the young bird may not even approach the land. While the mature birds have completed their migration and settled to breed at home, the yearlings may lag far behind on the route, spending the summer at sea. In the next few years adolescents arrive at the breeding islands and shores too late to make more than a preliminary landing and exploration of the ground for a future partnership. At midsummer in the nesting colonies there is a considerable arrival of immature birds familiarizing themselves with prospective breeding territories. Where a colony is already overcrowded, it is always the young, eligible, but inexperienced, birds that leave to form new peripheral colonies in the region of their birthplace.

Ecology and conservation. The tubinares collectively occupy a position midway in the oceanic food chain. Their food is lower on the chain than that of animals that take subsurface fishes (*e.g.*, certain diving birds, seals, and medium-sized predatory fishes) but above that of the minute and larval fishes which feed on plankton. Insofar as man has overfished much of the oceans and removed or reduced competitors, such as the krill-feeding whales, and has taken fish species from the food chain, he might be said to have influenced the success and therefore the numbers of the tubinares, but there is no firm evidence for this. Although the numbers of some species of tubinares are recorded as increasing, it is likely that the reason is stricter protection and reduction of exploitation at the nesting sites. It is generally accepted that the considerable increase of the fulmar in the North Atlantic and its spread south from the Arctic to new breeding grounds has resulted from the great development of fishing fleets, which fulmars follow in vast numbers to devour the fish offal thrown overboard.

Man's effect on the tubinare population

Although several tubinares are considered rare and a few in danger of extinction, the majority are successful and often numerous. With their pelagic, aerial habits they are less liable to be trapped in oil slicks than are the Northern Hemisphere swimming seabirds (auks, ducks, and loons), which are killed by the thousands by oil. The diving petrels and prions, living in the cleaner Antarctic seas, are less exposed to this danger.

FORM AND FUNCTION

General features. The general body plan of procellariiform birds varies slightly from family to family. In general, they are long-winged, short-necked birds with short to moderate tails and legs. Webbing is present between the front toes, and the hindtoe (hallux) is small or lacking. In contrast to their strong-flying relatives, the diving petrels have short wings. At the other extreme, the aspect ratio (the ratio of wing span to the chord, or width) of the wing may exceed 14:1 in some albatrosses. This long, narrow wing, with a high-lift airfoil, is an extreme adaptation for fixed-wing gliding.

The bill varies from rather short and broad in diving petrels to medium in length (somewhat more than half the total length of the head) in some albatrosses. It is sheathed in horny plates and has a distinct hooked nail at the tip. In albatrosses the two nasal tubes lie separated on the right and left upper lateral surfaces of the bill; in all other procellariiforms, the nostrils are fused into a single tube lying on the dorsal midline of the bill and having a dividing wall or septum, which may end short of the end of the tube, resulting in a single opening.

Drawing by R. Keane

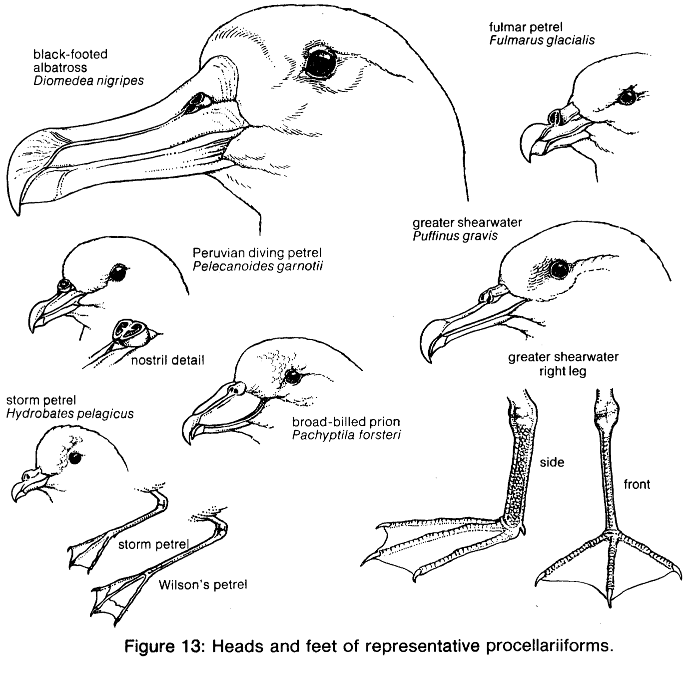


Figure 13: Heads and feet of representative procellariiforms.

Procellariiforms are totally lacking in bright plumage colours, being entirely black, white, or shades of brown or gray. Strikingly contrasting patterns of light and dark are often found, however, and the bills or feet of a few species are yellow or pink. A number of shearwaters and procellariid petrels and a few albatrosses are polymorphic; *i.e.*, they occur in light and dark phases (plumage types), some species also having intermediate forms. The polymorphism may be restricted to certain parts of the plumage, such as the underparts of the body or the upper surface of the wings.

Squirting oil as a defense mechanism

Stomach oil. Most tubinares, when handled or threatened, eject the oily contents of the stomach with some force. In some species, notably the cliff-nesting fulmars, this habit, a fear reaction that also serves to lighten the bird for flight, has been exploited as a defensive weapon. Facing an intruder, the disturbed bird ejects a spurt of evil-smelling fluid a metre or so in his direction, often with apparently planned accuracy. The habit is instinctive; a baby fulmar, on hatching, has been observed to squirt yellow oil before it is fully out of the shell. Later, the downy chick squirts oil at any visitor, even its parents. Mated fulmars may exchange little squirts of oil during the excitement of bill-fencing ceremonies.

Analysis of this unique oil shows that it is a waxy secretion of the proventriculus (the first chamber of the stomach), rich in vitamins A and D. In most birds, the walls of the proventriculus produce an acid fluid that rapidly breaks down raw food entering from the esophagus. In the tubinares, which feed their young a soup of predigested marine organisms, the proventriculus is much enlarged and internally folded, increasing the surface when dilated and enabling a larger number of glands to function. The latter are groups, or follicles, of oil-producing cells. The colour of the oil varies according to the type of food; it is often reddish from the presence of astacin, a pigment found in crustaceans.

The discharge of stomach oil is partly excretion of surplus fat, which might upset the bird's metabolism if retained in quantity. Ejected through the mouth and nose, it also disposes of excess vitamins and salt in the diet of marine food and seawater. Similar in character to the secretions of the oil glands of other birds, the crop oil may also assist in waterproofing the feathers as the tubinare preens its plumage with its oil-stained bill.

EVOLUTION AND CLASSIFICATION

Relationship to penguins

Evolution. The oldest tubinare fossil is a giant albatross (*Gigantornis*) from the Eocene of Nigeria (about 50,000,000 years ago). It may have had a wing span of six metres (20 feet) and was contemporary with the now extinct giant penguins (order Sphenisciformes). It is generally agreed that the two orders had a common ancestor from which they may have evolved. The penguins occupied the ecological niche of diving and feeding under the surface and became flightless; the tube noses specialized in flight and surface feeding. Support for a common origin (a view contested by some taxonomists) comes from the facts that the oldest fossil penguin had a bill with distinct tube-nosed apertures; the young of the blue penguin *Eudyptula*, considered to be the most primitive of penguins living today, exhibits tubelike openings to its nostrils. Mutual displays of bill fencing and wing movements in courtship, as well as the method of regurgitating digested food, are almost identical in tubinare and penguin. The short-winged diving petrels, which "fly" much underwater but little in air, seem to parallel an early stage in the evolution of penguins, especially when, during a few weeks of the annual molt, they lose their quills and must live in the water.

Classification. *Distinguishing taxonomic features.* The families of the Procellariiformes are separated mainly by the general body plan, the condition of the nostrils, and, in the case of the Procellariidae and Hydrobatidae (long considered one family), the osteology of the skull and sternum. At the genus level, characters used include the shape of the beak, wings, and tail; the degree of flattening of the tarsus (lower leg); size of the hallux; and the relative lengths of the leg bones.

Annotated classification. The following classification, proposed by American ornithologist Alexander Wetmore in 1930, is in nearly universal usage.

ORDER PROCELLARIIFORMES (tubinares)
Oceanic birds with tubular nostrils; bill covered with horny plates and hooked at the tip. Anterior toes webbed; hallux short or lacking. Wing with 11 primary feathers (the outer minute); secondaries short; diastataxic (*i.e.,* with the 5th secondary absent). Two coats of nestling down. Oil gland feathered. Strong musky smell. Single white egg; long incubation and nestling periods. About 87 living and 36 known fossil species; all marine; worldwide.

Family Diomedeidae (albatrosses)
Middle Eocene to present. Extremely long, narrow wings; short tail. Bill longer than remainder of head; nostrils semitubular, small, situated near the base of long groove. Two genera, 13 species; length 50–125 cm (20–50 in.); wing span to 340 cm (11 ft); North Pacific and all southern oceans.

Family Procellariidae (large petrels, fulmars, prions, shearwaters)
Middle Oligocene to present. Long-winged, short-tailed. Nostrils united on top of bill. Twelve genera, about 50 species; length 22–75 cm (9–30 in.); all oceans, but greatest diversity in Southern Hemisphere.

Family Hydrobatidae (storm petrels)
Upper Miocene to present. Small black and brown birds, usually with conspicuous white rump; wings rounded; tail square or forked. Often walk on water. Eight genera, 20 species; length 15–20 cm (6–8 in.); all oceans, but more species breeding in Southern Hemisphere.

Family Pelecanoididae (diving petrels)
Upper Pleistocene to present. Small stocky birds, with short wings and tails. Black above; white below. One genus, four species; length 16–20 cm (6½–8 in.); cool subantarctic seas.

Critical appraisal. In a system positing evolutionary relationships on the basis of structural affinities, the tube-nosed birds seem to fit conveniently between the penguins and the pelecaniform birds. But within the order, the arrangement of genera, species, and races of tubinares has been changed all too frequently by taxonomists. This disorder has resulted partly from new information on the structure, habits, and distribution of these birds, hitherto little studied because of their remote oceanic breeding grounds. The ordinal position occupied by the highly specialized prions and diving petrels is still in dispute. The fulmars are sometimes divided into three species because of their distinct differences in bill, body size and shape, and geographical range; but other taxonomists regard them as Arctic, Pacific, and Antarctic races of the species *Fulmarus glacialis.* Several authorities have recently placed several medium-sized shearwaters in one species *Puffinus puffinus,* with eight closely related forms or subspecies. Because there is no evidence of interbreeding between these populations, although they may mingle at sea on migration, and there are no intermediate forms even when they inhabit the same island (in which case, they nest at different times), other workers prefer to treat them as full species of *Puffinus.*

(R.M.L.)

Sphenisciformes (penguins)

The penguins are a group of flightless seabirds constituting a particularly distinct and homogeneous order, Sphenisciformes; the one family, Spheniscidae, is limited in distribution to the Southern Hemisphere. Although a few penguins inhabit temperate regions and one, the Gálapagos penguin (*Spheniscus mendiculus*), lives at the Equator, the majority of the 18 species breed on islands in subantarctic waters.

GENERAL FEATURES

The stocky, short-legged appearance of penguins has endeared them to the popular mind. They range from about 35 centimetres (14 inches) in height and approximately one kilogram (about two pounds) in weight, in the little blue, or fairy, penguin (*Eudyptula minor*), to 115 centimetres (45 inches) and 25 to 40 kilograms (55 to 90 pounds) in the emperor penguin (*Aptenodytes forsteri*). Most are black on the back and white below, often with lines of black across the upper breast or spots of white on the head. Colour is rare, being limited to red or yellow irises of the eye in some species; red beaks or feet in a few; yellow brow tufts in the three species of *Eudyptes;* and orange and yellow on the head, neck, and breast in the two species of *Aptenodytes.*

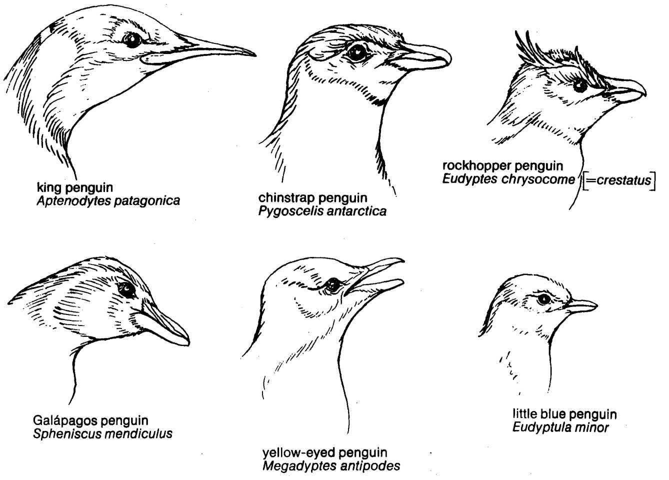

Figure 14: Heads of representative sphenisciformes.
Drawing by Christian D. Olsen

Breeding colonies

The total populations of some species, such as the emperor penguin, are estimated in hundreds of thousands, but those of most species of smaller penguins certainly run to several million. The largest breeding colonies are on the islands between 50° south latitude and Antarctica. These immense colonies, some of which contain hundreds of thousands of individuals, represent a large potential food resource, but the economic importance of penguins is negligible. Nineteenth-century whalers and seal hunters visited some colonies for meat and eggs, and a penguin oil industry once took large numbers of birds; by the early 20th century, however, this exploitation was no longer profitable, and most colonies were left alone or actively protected. Some species are now increasing in numbers, apparently as a result of the drastic reduction of Antarctic whales, which compete with penguins for the krill (minute crustaceans) on which both feed.

NATURAL HISTORY

Reproduction. Many features of the life cycle vary with the body size of the species and its geographical distribution; the chronology of breeding may also vary within a species in relation to latitude. Certain species, such as the Cape or jackass penguin (*Spheniscus demersus*), probably other members of this genus, and the little penguin, breed twice a year, but the majority of species breed only once each year and the king penguin (*Aptenodytes patagonica*) twice in three years. One egg is laid by the emperor and king penguins, and two, or occasionally three, by all others. Most penguins begin breeding in the austral spring or summer; king penguins are on a 14- to 18-month cycle, and the timing of an individual pair depends on the success or failure of the previous breeding attempt. Some populations of the gentoo penguin (*Pygoscelis papua*) also breed in winter. The breeding of the emperor penguin begins in autumn, apparently timed so that the long developmental period will produce the young in midsummer, when their chances of survival are greatest.

The gentoo, which has a circumpolar distribution, is notable for the lack of synchrony among populations, but otherwise its breeding schedule is essentially comparable to that of most penguins. In the Crozet Islands, off southern Africa, for example, egg laying takes place in July. The two eggs are incubated for 35 or 36 days, and the rearing of the chick takes two months. The last immature birds go to sea in January, leaving the adults to molt in February.

Many types of visual and vocal displays are employed between the arrival of the birds at the colony and their departure. Courtship calls are used during pairing and to a lesser degree during the succeeding phases of breeding. There is marked vocal dimorphism between sexes in the emperor penguin and the king penguin, and less marked dimorphism in some other species. Upon arrival at the colony each bird returns to the nest that it left the previous year and generally rejoins its mate of the previous year, unless the death of the latter forces it to choose another partner. This applies even to the emperor penguin, which is capable of finding its mate despite the absence of a nest and the large size of the colony.

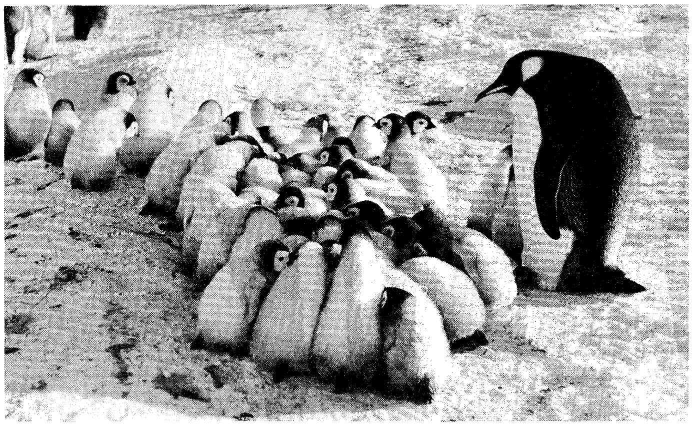
Types of display

The displays that occur with the reassembly of the colony and the finding of mates, as well as those preceding copulation, are quite similar among the majority of species, but the accompanying vocalizations are more diverse. Various species have been described as braying, trumpeting, croaking, cackling, and cooing. The behaviour of experienced older birds is more elaborate and more effective than that of younger individuals. Adélie penguins (*Pygoscelis adeliae*) may return to the reproductive colony from their third year onward but do not breed successfully until their fifth or sixth year.

Incubation of eggs is performed by both sexes in all species except the emperor penguin, in which it is done by the male alone. The incubation period begins immediately following the laying of the single egg in the emperor and king penguins and after the laying of the second egg in other penguins. With the advent of incubation, the bustle and myriad cries that characterized mating give way to quiet and inactivity. Faulty incubation behaviour by inexperienced birds frequently results in the abandonment or breakage of eggs. The mortality rate (eggs and chicks) is very important at the egg stage, varying from year to year depending on climatic conditions, the percentage of young birds in the reproductive population, and the pressure of predation. In general, the mortality (eggs and chicks) is from 40 to 80 percent of the eggs laid. In coastal colonies predators include, in order of importance: skuas (*Catharacta*); sheathbills (*Chionis*); and the giant petrel (*Macronectes giganteus*). On the Australian, African, and South American continents, the nocturnal habits of certain penguins and the fact that they nest in burrows substantially limit predation, which is mostly by gulls and man.

Following egg laying, the female usually departs for the sea to feed, returning to relieve her mate after about 10 to 20 days, depending on the species; thereafter, they alternate in periods of a week or two. The female emperor penguin, however, must often walk 80 to 160 kilometres (50 to 100 miles) from colony to the sea and does not return until the end of the incubation period. During the 64-day incubation period, which extends through the height of the Antarctic winter, the male emperor penguin incubates the egg, holding it on his feet and living on stored fat reserves. During violent winter storms, members of the colony gather for mutual protection from wind and cold in tightly packed crowds called huddles.

Jean Prevost



Crèche of emperor penguins (Aptenodytes forsteri).
To guard against predators, the young are herded into groups attended by adults while the parents fish for food.

Emergence from the shell takes 24 to 48 hours, during which the brooding parent is particularly irritable. The chick shows feeding behaviour immediately on hatching, receiving a regurgitated "soup" of crustaceans or fish by inserting its bill into the open mouth of the parent. During its early days the young bird is sheltered under the body of one of its parents, who take turns foraging and brooding. Growing larger, the young bird remains at a parent's side, although able to maintain its body heat and move about alone. In surface-nesting species, following the individual rearing phase in the nest or (in the emperor and king penguins) on the feet of the parent, the chick joins 100 or more of its contemporaries in a nursery group, or crèche, sometimes guarded by a few adults, while both its parents forage at sea. Upon returning with food, the parent calls its chick from the crèche and is able to distinguish it from other chicks (which frequently also respond) by voice and appearance. During the breeding season the number of "unemployed" adults in the colony increases with the addition of those who have lost eggs or chicks. In emperor penguin colonies, these unemployed birds often interfere with parents that have young and cause increased mortality. During the crèche stage the fuzzy down that has covered the chick since hatching is replaced by a coat of short stiff feathers, like those of the adult but usually somewhat different in colour. Once this molt is complete, the juvenile leaves the colony to seek its own food at sea.

Crèche behaviour

The period of growth of the young bird from hatching to complete independence varies from two months, in the smallest species of the genus *Eudyptula,* to $5^1/_2$ months in the emperor and 12 to 14 months in the king penguin.

Molt. Adult penguins molt all of their feathers once a year, following the breeding period. While in molt the bird is unable to enter the water and instead withdraws to a communal molting site usually situated in a sheltered area away from the colony. The duration of the molt varies from about two weeks in small species to more than a month in the larger ones.

Locomotion and orientation. Penguins are adapted for rapid locomotion in water, in which the wings, or flippers, are used for propulsion; the birds "fly" under water. When moving at high speed they frequently leave the water in leaps that may carry them a metre or more through the air; during this time they breathe.

On land, penguins are much more awkward, and their rocking walk is highly amusing to watch. Despite their short legs, however, penguins can run with surprising speed. Some species, such as the rockhopper (*Eudyptes chrysocome*) and Adélie penguins, move among rocks with agility, using the flippers for balance. When moving rapidly on snow or ice, many penguins "toboggan," sliding on the belly as they propel themselves by the feet and flippers. The flippers, along with the beak, are the prime weapons in defense and attack.

"Tobogganing"

Scientists have long wondered how penguins are able to find their way back to their colonies from far out at sea, where currents may have carried them great distances, and how they are able to direct themselves correctly on land, in the absence of clear-cut landmarks. Recent studies have shown that penguins transported into the interior of Antarctica are able to find their way back to the ocean by using the sun as a directional aid. It is probable that the same means of orientation is used at sea, and that upon approaching the coast they are able to recognize features of the shoreline and the ocean bottom.

Food habits. The type of food utilized varies with the species, the geographical region, and the time of year. Most of the smaller southern penguins feed primarily upon krill (crustaceans of the family Euphausidae), which attain high densities in the rich, well oxygenated Antarctic waters. Cephalopods (squid and cuttlefish) and small fishes may form substantial fractions of the food and, in a few, such as the Cape penguin, comprise the basic elements of the diet. The total weight (biomass) of food consumed by a large penguin colony is prodigious, often exceeding several tons per day.

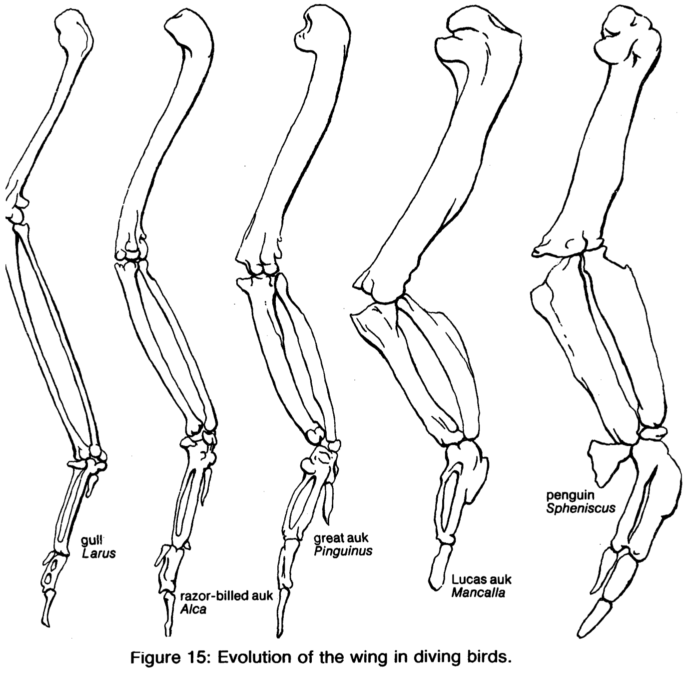
Natural enemies. The principal enemies of penguins at sea are the leopard seal, or sea leopard (*Hydrurga leptonyx*), and the killer whale or grampus (*Orcinus orca*). The eared seals (*Otariidae*) of the genera *Arctocephalus* and *Neophoca* also take penguins in the Australian–New Zealand and subantarctic regions.

FORM AND FUNCTION

The penguins are highly specialized for their flightless aquatic existence. The feet are located much farther back than those of other birds, with the result that the bird carries itself mostly upright; its walk can thus be described as plantigrade (*i.e.,* on the soles). It rests on the ground on a sole, comprising the whole foot, instead of one formed of the toes, as in other birds. The most notable character of the group is the transformation of the forelimb into a swimming member, accompanied by a body morphology particularly adapted to movement in a liquid medium. The thoracic (rib) cage is well developed, and the sternum bears a pronounced keel for the attachment of the pectoral muscles, which move the flippers. The flipper has the same skeletal base as the wing of flying birds but with its elements shortened and flattened, producing a relatively rigid paddle-like limb covered with very short feathers, which makes an ideal organ for rapid propulsion. The body plumage likewise consists of very short feathers, which minimize friction and turbulence; by their density and the layer of air which they retain, the feathers provide almost ideal insulation of the body.

Structure of the forelimb, or flipper

The insulation of the bird's body is particularly important for Antarctic species that move in water that is always below 0° C (32° F). The cooling power of seawater at −1.9° C (28.6° F) is equal to that of a temperature of −20° C (−4° F) with a wind of 110 kilometres (70 miles) per hour. The velocity of movement of the birds in the water serves to increase this heat loss. In fact, the skin is insulated by a layer of air trapped under the plumage, and the only bare skin in direct contact with the water is that of the feet. In the case of the emperor penguin on land in winter, the feet may also be in close and permanent contact with ice. The skin temperature is then in the neighbourhood of 0° C, and snow does not melt upon contact. This low temperature is made possible by remarkable anatomical arrangements in the lower limb, in which closely adjacent arteries and veins form a system of heat exchange between opposing flows; in the upper member a remarkable heat-exchange network permits the cooled returning blood to absorb heat from the outflowing blood, providing maximum economy of heat consistent with the functioning and survival of the foot.



From R.W. Storer, "Diving Birds," International Ornithological Congress (1958)

Figure 15: Evolution of the wing in diving birds.

Like the petrels, the penguins have supraorbital glands or salt glands, which enable them to ingest hyperosmotic substances (*i.e.,* those containing more salt than the body tissues); excess chloride is excreted in the form of a solution the concentration of which is greater than that of seawater. These glands are already functional in the young penguin chick, which begins to consume food of marine origin from its first day of life.

Recent research has shown that the species most isolated geographically, such as the emperor penguin, can be subject to viral diseases of the psittacosis–*Lymphogranuloma* type. Some, such as the Adélie penguin, carry in their bodies trace amounts of pesticides such as DDT, albeit in lower quantities than are found in many birds that live closer to man.

EVOLUTION AND CLASSIFICATION

Fossil record. Evidence from paleontology indicates that the penguins and tubinares (Procellariiformes: albatrosses, shearwaters, and petrels) had a common origin. Both groups are represented by well-defined fossils from the Eocene (about 50,000,000 years ago). During the Tertiary Period (from about 65,000,000 to 2,500,000 years ago) the sphenisciform line produced a number of distinctive side branches, all recognizably penguins. From the taxonomic point of view the radiation (evolutionary differentiation) had reached the level of the subfamily in the Miocene (from 26,000,000 to 7,000,000 years ago), and the diverse subfamilies of that epoch have been replaced in the present-day group by one in which the radiation has reached the level of genera. All of the fossil remains of penguins have been collected within the zone of the present-day distribution of the Sphenisciformes. Some apparently lived in warmer regions than do most of today's penguins. Certain species, such as *Palaeospheniscus patagonicus,* appear to have had a height intermediate between the large and the medium-sized modern species; others, such as *Pachydypees, Anthropornis,* and *Palaeeudyptes,* reached heights of between 120 to 160 centimetres (approximately 50 to 60 inches).

Classification. One authority has divided the *Spheniscidae,* fossil and modern, into five subfamilies: *Palaeospheniscinae* and *Paraptenodytinae* of the Patagonian Miocene; *Anthropornithinae* of New Zealand, Patagonia, and Antarctica; *Palaeeudyptinae* of New Zealand and Australia; and finally *Spheniscinae,* which includes all the present-day genera. (J.Pr.)

Pelecaniformes (pelicans, boobies, tropic birds, cormorants, frigate birds)

The order Pelecaniformes comprises a number of diverse groups of aquatic birds that share the common characteristic of webbing between all four toes. There are three main groups (suborders): Phaethontes, the tropic birds; Fregatae, the frigate birds; and Pelecani, the pelicans, boobies (including the gannet), cormorants, and anhingas (or darters). All are relatively large birds: they range in length from about 40 centimetres or 16 inches (excluding the elongated central tail feathers) in the white-tailed tropic bird (*Phaethon lepturus*) to 1.8 metres (six feet) in the Dalmatian pelican (*Pelecanus crispus*).

GENERAL FEATURES

In terms of their way of life, the pelecaniform birds fall into four adaptive groups: frigate birds—long-winged masters of piracy and aerial pursuit of surface-living marine prey; tropic birds and boobies—wide-ranging flyers that capture prey underwater by plunging from a height; pelicans—large, large-billed, long-necked, buoyant birds that fish mostly by reaching down while swimming at the surface; cormorants and anhingas—heavy-bodied, long-necked, underwater swimmers, respectively pursuing and lying in wait for their prey below the surface. The anhingas are largely confined to freshwater; pelicans and cormorants occur in both freshwater and marine habitats; and the other groups are entirely marine.

Production of guano as fertilizer

Importance to man. Most pelecaniform birds are of rather little significance to man, but the guano (excrement) of cormorants, boobies, and pelicans is an important fertilizer. Exploitation of old accumulations of guano reached its peak in the mid-19th century, and since then only the current production of guano has been available in most areas, but even this provides a substantial resource where the bird populations are large. There were an estimated 18,000,000 guano birds on the coast of Peru early in the 1960s. Of these, about 15,000,000 were guanay cormorants (*Phalacrocorax bougainvillii*), and the remainder were Peruvian boobies (*Sula variegata*) and brown pelicans (*Pelecanus occidentalis*). The harvest of guano at that time amounted to about 180,000 tons per year. The guano birds in the area feed largely on the Peruvian anchovy, and now that this fish is directly exploited on a large scale for fish meal and fish oil, there is some competition between the birds and the fishing industry. In Southwest Africa artificial platforms have been constructed in coastal lagoons and on an offshore reef, greatly facilitating the collection of guano.

Effects of insecticides

Pelicans, feeding on fish from inland and coastal waters, are among the animals whose diet tends to ensure that they will accumulate residues of insecticides (especially DDT) in their bodies. It recently has been found that among the physiological effects of these substances on birds are changes in calcium metabolism that result in their laying eggs with abnormally thin shells, or no shells at all, with the result that these eggs usually break before hatching. Effects of this kind have entirely prevented the successful reproduction of brown pelicans on the California coast during recent years, and some populations elsewhere are also showing adverse effects.

Drawing by R. Keane

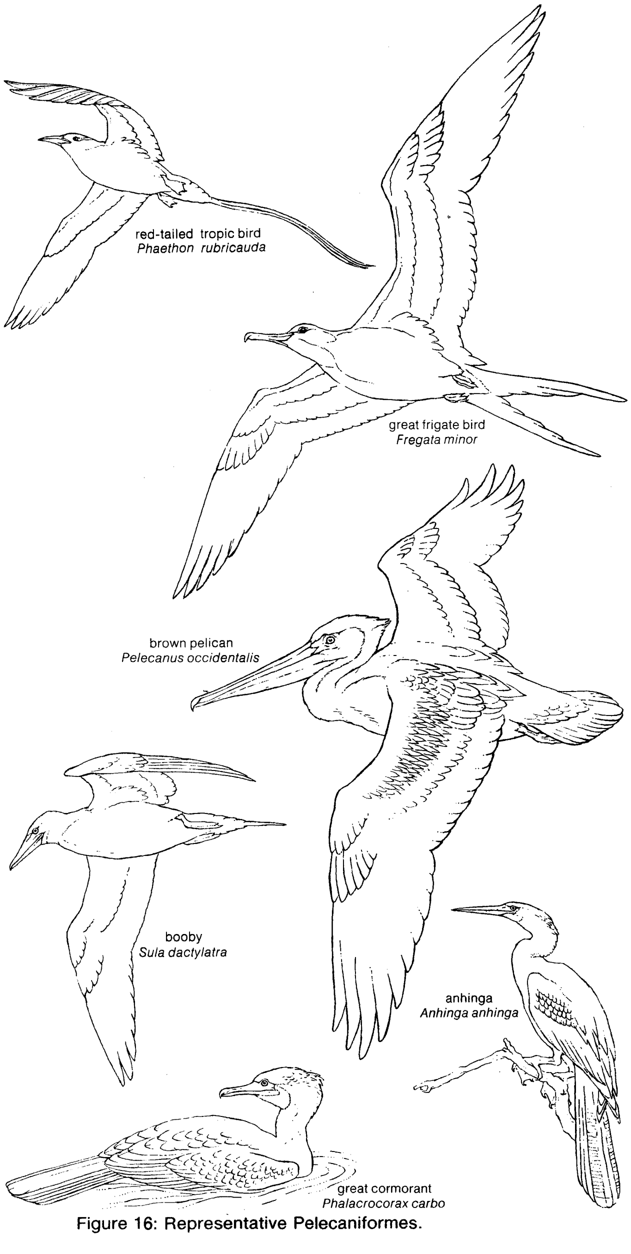


Figure 16: Representative Pelecaniformes.

Distribution and abundance. Pelecaniform birds occur all over the world except in parts of the interior of North America, Africa, Asia, and Australia, in the high Arctic, and in most of Antarctica. Two groups, the tropic birds and frigate birds, are essentially confined to the tropics; the boobies, pelicans, and anhingas are widespread in the tropics but also penetrate far into the temperate zones; and cormorants breed from the Equator to the Arctic Circle and the Antarctic Peninsula.

The tropic birds are the most pelagic (free-flying over open ocean) of the pelecaniforms and can be seen even in the most unproductive central parts of tropical seas. Some boobies and frigate birds are found far out at sea, but most of them return to land to roost at night. Pelicans, cormorants, and anhingas do not venture far from land but may commute some distance between roosting or breeding places and their feeding grounds.

NATURAL HISTORY

Breeding grounds

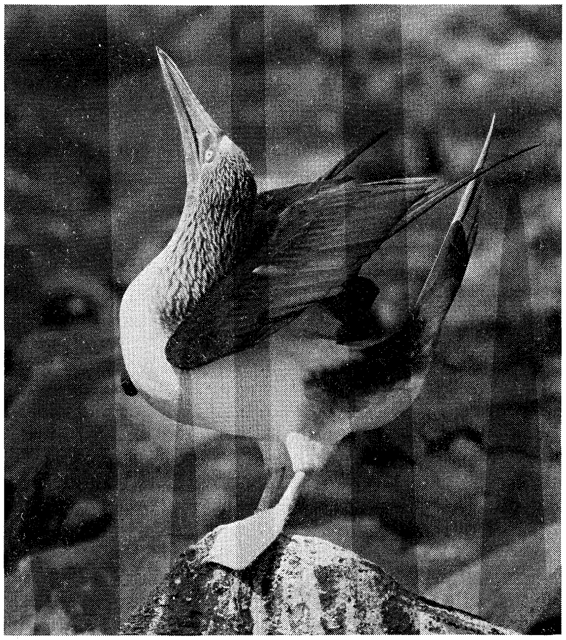
Reproduction. The breeding of pelecaniform birds is essentially restricted to places free of mammalian predators. Tropic birds, boobies, and frigate birds typically breed on oceanic islands or on small islets and stacks off continental coasts. When man has introduced predators (such as cats) to isolated islands, pelecaniforms and other marine birds have often been eliminated from their traditional breeding grounds. On Ascension Island and St. Helena in the South Atlantic, for example, tropic birds, frigate birds, and boobies, which used to breed in large numbers on the main islands, have either been exterminated or have been forced to confine their nesting to sites on small offshore islets. Pelicans and cormorants are not normally found on islands far from continental land but breed on islands in lakes or offshore, or in other protected sites such as trees standing in water or on cliffs. Anhingas breed in trees or bushes close to the sheltered waters where they prefer to feed.

Pelecaniform breeding, whether on the ground or in trees, is typically colonial, apparently because of the scarcity of safe places. If they are to breed at all, all the birds of an area must crowd into the available space. In practice, most colonies have a fairly definite upper limit of density determined by the distance that an incubating bird can reach out to repel intruders. Nests of the gannet (*Morus bassanus*) have an average density of about one per square metre; those of the guanay cormorant average about 3.5 per square metre.

In some species, colonial breeding has become obligatory, and single pairs or small groups do not breed successfully. Other species breed colonially only where there is a shortage of space for nesting. The masked booby (*Sula dactylatra*), for example, breeds in dense colonies on islets off Ascension Island but in dispersed patterns on Christmas Island (Pacific). Breeding in a number of species is normally dispersed; the red-footed cormorant (*Phalacrocorax gaimardi*) of South America, for instance, often nests on cliffs where only scattered sites are available. Similarly, tropic birds nest in holes or crevices in cliffs or under the shelter of rocks or bushes. The sites are thus normally well dispersed, and in some places there is intense competition for them.

Pair formation displays

Courtship behaviour. During courtship (except in tropic birds) the male typically selects a nest site and then displays from this site to passing females. In the male advertising display of boobies ("Sky-pointing") and of cormorants and anhingas ("Wing-waving"), the head and tail are raised and the wings partially raised. The boobies have species-specific positions of the wings and tail; the cormorants and anhingas wave either their wing tips or their whole wings, to a varying degree. In many species a particular call is associated with the display. In the "Rattling" display of frigate birds, the male leans back on his tail, extends his wings along the ground, and with his bill pointing verti-



Male blue-footed booby (*Sula nebouxii*) "Sky-pointing," a pair formation display.
Eric Hosking

cally throbs his inflated scarlet throat (gular) sac, vibrates his wings, and claps his bill.

In most pelecaniforms, when a female has finally joined a male at the nest site, he may go and fetch nest material, which is then added to the nest structure by the female, alone or with the assistance of the male. There is no courtship feeding in the pelecaniforms, but in tropic birds there are a few records of one adult feeding the other during incubation. Copulation normally occurs on the nest site, without any special precopulatory or postcopulatory displays. The pair-bond, once established, is reinforced by such activities as joint nest building and defense, and preening of one bird by the other. Certain displays functioning in individual recognition are performed in the air or on the ground when one of a pair returns to the nest and also occur during the "handling" of nest material, which continues during incubation. The boobies have a "Head-wagging" recognition display; the cormorants and anhingas have a comparable "Kink-throat" display; similarly, the frigate birds use a "Rattling" display.

In tropic birds, which do not normally have nest sites in the open, courtship display is aerial. Birds fly around in a group, calling, then two individuals may leave the group and fly together, the upper bird depressing his tail (especially the long central feathers) during gliding or hovering; the flights often end with one or both birds flying into a nest cavity. Tropic birds do not collect nest material but probably sometimes enlarge nest cavities with their bills or feet.

In all or nearly all pelecaniform families, mating frequently occurs with the same partner in successive years, and in many populations the same nest site may be occupied repeatedly. Since most species nest colonially, fighting over nest sites is common. It is particularly intense in the gannet and in populations of tropic birds when nest sites are in short supply.

Breeding seasons. Outside the tropics, egg laying by pelicans, boobies, and cormorants occurs typically in the spring, and the laying period extends over one to three months. In the tropics there is greater diversity in both the timing and extent of the laying period. Although many tropical populations have distinct laying periods at the same season in each year, a number of those in relatively seasonless environments have been known to lay in every month of the year. The blue-footed booby (*Sula nebouxii*) in the Galápagos, for example, is known to breed at intervals of less than a year. In other populations, laying is synchronized but occurs at nonannual intervals; *e.g.,* the brown booby (*S. leucogaster*) on Ascension Island has laying periods roughly every eight months. For the cormorants (*Phalacrocorax carbo* and *P. africanus*) of Lake Victoria, conditions are favourable for breeding during about eight months in each year, but the scarcity of islands free of predators forces the birds to occupy the few safe colonies in relays.

Nests, eggs, and young. Most pelecaniforms build substantial but untidy nests of twigs, grass, algae, or feathers; in many species guano accumulates on and around the nest as breeding progresses. Many cormorants and pelicans habitually build their nests on the ground, but most species that normally breed where trees or bushes are available build their nests in them. Certain cormorants and boobies sometimes nest on cliff ledges, and tropic birds and most boobies lay their eggs on the open ground in insignificant depressions.

Clutch size

There is much variation in clutch size. In general, species living in the unproductive tropical seas lay only a single egg. Those living in seasonally productive areas at higher latitudes, or in areas where surface waters are enriched by the upwelling of nutrient laden water from deeper layers, lay larger clutches and raise several young at a time. Tropic birds and frigate birds all have clutches of one egg, but pelicans generally lay one to three eggs, cormorants two to five, and anhingas three to five. The boobies show a more complex picture. The gannet of the temperate zones and the tropical red-footed booby (*Sula sula*) have clutches of one egg, but the other typical boobies of the tropics—the masked and brown boobies—normally lay two eggs. These two-egg species, however, normally raise only one chick, the older nestling apparently pushing the younger out of the nest soon after hatching. The second egg in these ground-nesting species seems to function as an insurance against infertility, loss, or breakage of the first, risks that may be lower in the tree-nesting, red-footed booby. The single-egg clutch of the gannet has not been satisfactorily explained, since pairs have been able to raise two chicks when an extra has been provided experimentally.

Except in the tropic birds, the eggs of pelecaniforms are small in relation to body size. In the tropic birds they are 9–13 percent of the adult weight, in the frigate birds, 6 percent, in the boobies, 3–5 percent, and in the pelicans and cormorants, 2–3 percent. In species with clutches of more than one, eggs are laid at intervals as short as 24 hours, or as long as five to six days in the case of the masked booby. In all of the groups, both parents participate roughly equally in incubation and feeding of the young. The lengths of the incubation shifts vary extensively, both within and between species. In some species (*e.g.,* many cormorants) shifts last only a few hours, but in tropic birds and some boobies shifts of three or more days are not uncommon; in the great frigate bird (*Fregata minor*), on the Galápagos, shifts last 10–15 days.

Incubation generally starts with the laying of the first egg (though not in some cormorants). First and last young may hatch several days apart and often differ substantially in size during the nestling period. The incubation period is just under four weeks in anhingas, four to four and a half weeks in cormorants, about four and a half weeks in pelicans, six weeks in tropic birds, and six to eight weeks in frigate birds.

Growth of young birds

The young, which are helpless and essentially naked at hatching, are brooded continuously for several days, until their down grows. The tropic birds are exceptional in that they have thick down at hatching and are sometimes left alone by their parents even on the day of hatching. The rate of development of the young varies dramatically and is correlated with the characteristics of the environments in which the birds live. The fledging period in the pelagic tropical masked booby is double that of cormorants of comparable body size living in the cool, productive waters off the coast of North America (17 weeks versus less than eight weeks). Brown pelicans in North America fledge in less time (nine weeks) than white-tailed tropic birds weighing only one-tenth as much (10 weeks) and in less than half the time needed by tropical frigate birds weighing about one-third as much (more than 20 weeks).

The young of all pelecaniforms are fed on regurgitated food that they obtain by inserting their heads into the mouths of their parents. In frigate birds and tropical boobies, the parents continue to feed their young for a long period after they can fly, apparently because the young take a long time to become sufficiently skillful in hunting to survive in tropical areas where food is generally scarce. The most extreme case is that of the great frigate bird, in which the young can fly at about five months of age but sometimes are fed for more than a year after this. In the tropic birds and the gannet, however, the young are not fed by the parents after fledging; they leave their birthplace either by flying straight out to sea or by fluttering down to the water and swimming out to sea.

Molt. In the pelecaniforms, as in most birds, replacement of the feathers (molt) occurs mainly in the intervals between breeding. In a few species molt progresses concurrently with breeding activities, but normally, a complete molt commences when breeding is over. In the anhingas the primary flight feathers of the wing are shed simultaneously, but in the other groups molt is gradual. The primary and secondary feathers typically are replaced by means of two or three molt waves that start several feathers apart and move outward in parallel until all feathers have been shed. In most, if not all, pelecaniforms, feathers of the head and neck, and some on the body, are replaced a second time shortly before the next breeding season. Special feathers (crests, neck plumes, white patches) acquired at this time are shed around the time of egg laying in some species; in pelicans some head feathers are replaced yet again during incubation.

In many of the pelecaniforms the colours of the soft parts (especially the bare skin on the face) change as the birds become sexually active. In some pelicans a horny triangular plate grows on the upper mandible towards the tip before the breeding season and is shed after laying.

Causes of death

Ecology. *Survival and mortality.* Full-grown pelecaniform birds have few natural enemies, and although some are taken by marine predators they are generally long-lived. Nestlings, recently fledged young, and sometimes even adult birds suffer heavy mortality when food shortages occur. In many tropical areas where food is generally scarce, irregular fluctuations in the supply lead to drastic variations in breeding success. Mortality from starvation also occurs among birds of richer seas, most dramatically along the west coast of South America in years when oceanographic changes cut off the normally abundant food supply of the huge bird populations. Even under average conditions, young pelecaniforms in their first year after fledging experience much higher mortality than adults. In the European shag (*Phalacrocorax aristotelis*) more than half the young die during this period, although among adults annual mortality is only about 15 percent in males and 20 percent in females. In the British population of the gannet, about 80 percent of the fledglings die before reaching breeding age (about five years), most during their first year. Adults die at an average rate of less than 6 percent per year and have a mean expectation of life exceeding 16 years. Age records for individual banded birds include a great frigate bird that was recently found breeding at an age of more than 30 years and a masked booby breeding at about 23 years. Negative evidence suggests, however, that few individuals of these species survive much longer than the two examples.

Population movements. Members of the pelecaniform populations breeding at high latitudes generally move to lower latitudes in winter but do not perform transequatorial migrations. Adequate analyses of banding results have been carried out on only a few species. Great cormorants (*Phalacrocorax carbo*) from Britain do not show a well-defined migration but disperse random distances from the colonies. In all populations of gannets, juveniles move further than adults. A number of juvenile gannets from New Zealand have been found in eastern Australia only a week after leaving their natal colonies on their first flight, having made journeys exceeding 2,600 kilometres (1,600 miles), at average speeds of more than 370 kilometres (230 miles) per day. Gannets that survive to breeding age usually return to the same cluster of nests where they were hatched. In a similar way, juvenile lesser frigate birds (*Fregata ariel*) from colonies in the central equatorial Pacific disperse on a broad front, many moving over 6,500 kilometres (4,000 miles) from their natal island. Their pattern of dispersal may be related to that of the prevailing winds in the area.

Feeding ecology. The various groups of pelecaniform birds are specialized for different ways of life and in particular for different feeding methods. Tropic birds and boobies, though they differ in many ways, are both adapted for catching prey underwater by plunging from the air. They are powerful flyers and buoyant swimmers, but, although their feet have large webs, their legs are not streamlined and they are not specialized for fast swimming. The feet are probably used underwater more for steering than for propulsion, and the birds depend mainly on the impetus of the dive to enable them to approach their prey at high speed.

Tropic birds are adept at hovering while locating prey, and probably obtain most of their food near the surface. Many boobies often dive from greater heights and probably go deeper than tropic birds; the gannet sometimes dives from more than 30 metres. Blue-footed boobies, when hunting in groups, tend to dive almost simultaneously. A disyllabic whistle is often heard from such groups as they start to dive and may be a signal given by the initiator. It has been suggested that the simultaneous plunging of several birds may confuse the fish in a school and so increase each bird's chance of catching one. Red-footed boobies, and perhaps also other boobies, catch flying fish (family Exocoetidae) in the air as well as in the water. These fish, with squid of the family Ommastrephidae, are staple foods of the tropical boobies and the tropic birds. Boobies of upwelling zones and the gannet feed almost entirely on fish.

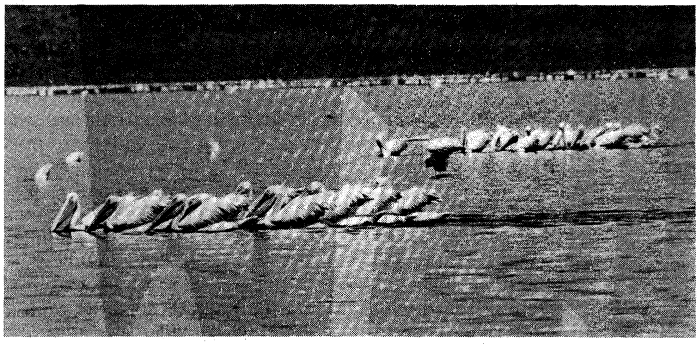
Frigate birds are among the most aerial of all sea birds. Their best known feeding habit involves piracy, in which they harry other sea birds until they disgorge their prey, after which the frigate birds catch the food in the air or pick it from the surface. They also catch prey for themselves, however, pursuing flying fish when they leap through the air and snatching fish (and probably squid) from the surface without alighting.

Feeding by pelicans

Pelicans generally catch their prey while swimming, thrusting their long bills and long necks below the surface to scoop up fish in their distensible throat pouches. When fishing in shallow water, pelicans often cooperate to form a kind of living net. They form a crescent facing the shore, or even a circle, and then close in, splashing, paddling hard. Each bird keeps station until the fish panic and can be captured as they try to escape between the birds. Pelicans have also been observed herding and capturing ducklings in a similar way. The brown pelican, unlike the other species, often forages some distance offshore and habitually fishes by plunging from the air.

Cormorants and anhingas are adapted for underwater swimming. The cormorants pursue free-swimming or bottom-living fish, and some species also eat mollusks and other invertebrate animals. When feeding on schooling fish, cormorants often engage in mass fishing activities in which a flock advances in a long line stretching at right angles to the direction of movement, apparently with the

Leonard Lee Rue III—Bruce Coleman, Inc.



Flocks of white pelicans (*Pelecanus onocrotalus*) fishing cooperatively on Lake Nakuru, Kenya.

fish fleeing ahead of them. The birds swim forward while above the surface and also while pursuing prey underwater, and laggards fly forward and land just ahead of the line. Anhingas do not pursue their prey but lie in wait underwater and then stab passing fish. Most of the fish that they eat are slow swimming and laterally flattened.

The physiological adaptations for diving have been little studied in cormorants and anhingas. It is known, however, that for cormorants feeding on the bottom the mean length of the dives is directly related to water depth. Dives of most species usually last less than half a minute, although dives as long as one minute are not uncommon. The time spent resting after a dive averages between one-half and one-third of the duration of the dive, but if dives are very long the length of the rest periods approaches that of the dives. Anhingas often stay under water for as long as two minutes, and a dive of nearly seven minutes has been recorded in a captive bird.

FORM AND FUNCTION

Distinguishing characteristics. Few generalizations can be made about the gross morphology of the pelecaniforms, since their external form reflects the diversity of their adaptations. In the larger and more aerial species, the skeleton is extensively pneumatized: nearly all the bones contain air sacs that are connected with the respiratory system. In the frigate birds, pelicans, and boobies, the major limb bones are no more than thin-walled hollow tubes with some internal struts. Pneumatization is least developed in anhingas, which need to have a high specific gravity to remain underwater while motionless.

Cushioning by air sacs

Those pelecaniforms that plunge into the water from a height (boobies, tropic birds, and the brown pelican) have a system of air sacs under the skin, connected with the lungs, that form a spongy mattress that presumably protects the bird as it strikes the water, although its presence also in species of pelicans that do not plunge suggests that the buoyancy it confers may be advantageous in itself.

The reduction of the external nostrils in most pelecaniforms is probably also connected with diving and swimming underwater. The closure, complete in boobies and in adult cormorants and anhingas, is only partial in frigate birds and pelicans; the nostrils are developed normally in tropic birds. The reduction of the nostrils in the aerial Fregatae as well as in the highly aquatic Pelecani suggests (as does the structure of the foot) that the Fregatae originated from a more aquatic stock. In the birds with nonfunctional nostrils, air enters the mouth cavity directly from the outside and then reaches the lungs in the normal way via the glottis—*i.e.,* the muscular opening to the windpipe—at the base of the tongue. In boobies and cormorants entry of air to the mouth when the bill is closed is by means of secondary external nostrils. These are slitlike openings at the angle of the mouth on each side where a horny flap (jugal operculum) at the base of the upper mandible overlaps the lower mandible.

Tropic birds, pelicans, and boobies have water-repellent plumage and are very buoyant. They swim high in the water and can reach significant depths only by acquiring momentum during aerial dives; their return to the surface is rapid. Frigate birds have wettable plumage, cannot swim or dive, and quickly become waterlogged if they alight on the water. In cormorants and anhingas the large contour feathers are wettable and trap little air when the birds are swimming underwater; this keeps buoyancy low in these birds and enables them to submerge from the surface without benefit of an aerial dive. The compressible but dense body plumage remains dry near the skin, at least in many species. The hind limbs of anhingas, which are not specialized for fast swimming, are relatively efficient for climbing and perching. Anhingas do not normally take flight from the water but climb out and dry their wings in a characteristic spread-wing posture that is also commonly used by cormorants. Once dry, anhingas show highly manoeuvrable flight and can also soar well, in contrast to the cormorants, which have a higher wing loading. Many species of pelecaniforms habitually spread their wings in "sun-bathing" postures, even when dry. The function of this behaviour is not well understood.

Physiological adaptations. Most pelecaniform birds nest in exposed situations, and special adaptations are necessary to prevent overheating of adults and young, particularly in tropical areas. The masked booby on the Galápagos, for example, stands with its back to the sun, thus shading its feet and naked throat pouch and permitting loss of heat by convection and conduction; it elevates its scapular (shoulder) feathers and droops its wings allowing maximum exposure of shaded feather areas, and it exhibits sustained fluttering of the throat pouch. Throat fluttering, which permits evaporative cooling with minimum expenditure of energy, is used under heat stress by all the pelecaniforms except the tropic birds, which do not have a naked throat pouch. The rate of throat fluttering remains roughly constant under increasing heat stress but becomes continuous instead of intermittent, and there are increases in its amplitude and in the throat area involved. All species make use of panting to increase evaporative cooling. Under heat stress the rate of breathing increases with increasing body temperature, and when it reaches a maximum the amplitude of breathing increases.

Although even the newly hatched young of certain species are capable of throat fluttering, they cannot regulate their temperature when left in the sun, until they have acquired down, and in some species not until they are several weeks old. Young tropic birds provide an exception: they have dense down at hatching and are sometimes left alone for long periods within a few days of hatching; small chicks are capable of regulating their body temperature by panting, even in the sun, but most nests are in the shade.

Salt excretion

Evaporative cooling requires much water, which is obtained from the food and probably also by drinking seawater. The resulting high intake of salt necessitates special adaptations for elimination of the excess. Marine birds have highly developed salt excretory glands, the lateral nasal glands, which function when the amount of salt taken into the body is more than the kidneys can deal with. The glands secrete a concentrated solution of sodium chloride, which flows through ducts to the nasal cavity. In most sea birds, including the tropic birds, it then flows out through the nostrils and may drip or be shaken off the tip of the bill. In boobies and cormorants, in which the nostrils are closed, the solution trickles from the internal nares in the roof of the mouth and out at the end of the bill. In some species of cormorants that occur in both marine and freshwater habitats, the salt gland is relatively larger in individuals from marine habitats, presumably reflecting higher salt intake.

CLASSIFICATION

Distinguishing taxonomic features. The classification of the order Pelecaniformes is based mainly on morphological features. Recent attempts have been made to clarify relationships by analysis of egg-white proteins and by comparative analysis of social behaviour. The parasitic feather lice (Mallophaga) found on members of the different groups also provide clues to relationships.

The six modern families of pelecaniform birds are readily distinguished, although the relationships among them are not firmly established. The families are internaly homogeneous, and in each of them the modern species are often placed in single genera; the Phaethontidae, Fregatidae, Pelecanidae, and Anhingidae are usually treated in this way. The relationships of many fossil groups—indicated below by a dagger (†)—are quite uncertain.

Annotated classification.

ORDER PELECANIFORMES

Aquatic birds with totipalmate feet (webs connecting all 4 toes); 1st toe (hallux) not pointing backward as in most birds but turned inward and joined by a web to 2nd toe.

Suborder Phaethontes

Family Phaethontidae (tropic birds)

Medium sized (16–19 in. or 40–48 cm long). Plumage satiny white with black markings; central 2 tail feathers much elongated in adult. Sexes similar. Bill laterally compressed, slightly decurved, and with undivided horny sheath (rhamphotheca). Nostrils open in slits; nasal glands each with 2 ducts. No naked gular (throat) pouch. Neck short, 14–15 cervical vertebrae. Pelvic girdle reduced, legs short, set far back. No nest-building behaviour. Single egg heavily marked with brown and black. Chick hatched covered with grey down. 1 fossil genus, *Prophaeton* (lower Eocene of England); 1 extant genus, *Phaethon;* 3 living species, worldwide in tropical oceans.

Suborder Fregatae

Family Fregatidae (frigate birds)

Large (31–34 in. or 79–86 cm long), light bodied. Plumage blackish, juveniles and some adults with white underparts; juveniles with white heads, sometimes tinged orange. Wings very long, pointed; tail deeply forked. Sexes differ in size (female larger) and in coloration of plumage and soft parts. Bill long, slender, strongly hooked at tip; horny sheath divided by deep grooves. Nostrils almost closed; nasal glands each with single duct. Small gular pouch, highly distensible and brilliant red in courting male. Neck short, 14–15 cervical vertebrae. Furculum (wishbone) fused with coracoids and with sternum (breastbone). Pelvic girdle and leg muscles reduced; legs very short. Feet small, webbing only between bases of toes. One white, thin-shelled egg. Young naked at birth, soon acquire thick white down. No fossil record. One extant genus, *Fregata;* 5 living species, worldwide in tropical oceans.

Suborder Pelecani (pelicans, boobies, cormorants, anhingas)

Horny sheath of bill divided by deep grooves (largely suppressed in anhingas). Naked gular pouch; facial skin and pouch colourful, especially in breeding season. Nasal glands each with a single duct. Neck long, with 17–20 cervical (neck) vertebrae; 8th and 9th have articulations permitting sharp S-bend, especially in anhingas. Pelvic girdle not reduced, legs strong. Feet large, fully webbed. Eggs thick shelled, with chalky white outer layer. Young naked at hatching.

Family Pelecanidae (pelicans)

Very large (50–72 in. or 127–180 cm long). Plumage white, brown, or grey; some species crested. Wings long, broad; tail short. Sexes similar. Bill long, hooked at tip, with enormous gular pouch suspended from highly distensible rami (lateral elements) of lower mandible. Nostrils almost closed. Furculum fused with sternum. Down of nestlings white. 10 fossil species in the genera *Pelecanus* (the earliest from lower Miocene of France) and *Liptornis* (middle Miocene). One extant genus, *Pelecanus;* 7 living species, seacoasts and freshwater lakes of southern Africa, central and eastern Eurasia, Australia, and North America; north and west coasts of South America.

Family Sulidae (boobies)

Large (26–40 in. or 66–102 cm long). Plumage of most species white with black on wings; some brown and white; juveniles largely grey or grey-brown. Wings long and narrow, tail rather long, wedge shaped. Sexes generally differ in voice, sometimes in colour of bare skin. Bill stout, conical, slightly decurved near the tip and finely serrated on cutting edges. Nostrils closed. Down of nestlings white. 18 fossil species, in the genera *Sula* (the earliest *S. ronzoni,* lower Oligocene of France), *Microsula, Morus, Palaeosula* and *Miosula.* Two extant genera, *Sula* with 6 living species, *Morus* with 1 species (sometimes considered 3 species, forming a superspecies); widespread but irregular distribution, on seacoasts and oceanic islands.

Family Phalacrocoracidae (cormorants)

Medium to large (19–40 in. or 48–102 cm long). Plumage usually blackish; some with white underparts, and a few largely grey; some species have ornamental crests or patches of white when breeding. Wings broad, tail long and stiff. Sexes similar, but females up to 30 percent lighter in weight. Bill slender, sharply hooked at tip. Nostrils closed in adults. Bony occipital style projecting upward from back of skull. Down of nestlings dark. 24 fossil species in the genera *Graculavus* (the earliest, upper Paleocene of North America), *Actiornis, Pliocarbo,* and *Phalacrocorax.* About 28 living species (and one recently extinct), all currently included in the genus *Phalacrocorax;* certain Old World species have sometimes been placed in a separate genus *Halietor,* and the Galápagos flightless cormorant (*Phalacrocorax harrisi*) in the genus *Nannopterum.*

Family Anhingidae (anhingas or darters)

Large (34–36 in. or 86–91 cm long). Plumage mainly black and brown with pale markings on back and wings; breeding male has light-coloured plumes on head and neck. Tail very long and stiff. In some forms the sexes differ in colour. Bill long, straight, slender, sharply pointed; cutting edges serrated towards tip. Nostrils closed in adults. Occipital style smaller than in cormorants. Head small, neck long and slender. Legs short but strong. Pyloric lobe of stomach with mat of hairlike processes. Down of nestlings brown. Five fossil species, in the genera *Protoplotus* (the earliest from the Eocene of Sumatra), and *Anhinga.* One extant genus, *Anhinga;* living forms have been treated as 1, 2, or 4 species and are here considered as 4 species comprising a single superspecies.

†*Family Elopterygidae*

Fossil. Marine birds probably related to the Pelecani, perhaps especially to the cormorants. Genera *Elopteryx* (Upper Cretaceous, Maestrichtian, of Romania); *Argillornis* and *Eostega* (Eocene of Europe).

†*Family Pelagornithidae*

Fossil. Marine birds probably related to the Pelecani, perhaps especially to boobies, but not adequately known. Genus *Pelagornis* (middle Miocene of France).

†Suborder Odontopteryges

Fossil. Very large marine birds, with long wings and short legs. Bill long and high, with sharply pointed, toothlike projections on margins of upper and lower mandibles, continuous with bony structure of jaws (and thus not true teeth). Upper and lower mandibles with longitudinal grooves, suggesting that their horny sheaths were divided.

†*Family Odontopterygidae*

Fossil. "Teeth" slant forward. Nostrils closed or nearly so. About half the size of the pseudodontorns (see below). Genus *Odontopteryx* (lower Eocene of England).

†*Family Pseudodontornithidae*

Fossil. "Teeth" vertical—not slanted forward. Wingspread about 4.5 metres. Genera *Pseudodontornis* (Miocene); and *Osteodontornis* (upper Miocene of California), one of the best preserved of early marine birds.

†*Family Cyphornithidae*

Fossil. Based on fragmentary material and with uncertain relationships but may be members of this suborder. Lower Miocene, North America. Genera *Cyphornis,* larger than pseudodontorns; *Palaeochenoides,* larger than pelicans, may be synonymous with (and take priority over) *Pseudodontornis;* *Tympanonesiotes,* smaller than the preceding form but may be related.

†Suborder Cladornithes

Fossil. Relationship to pelecaniforms doubtful. One family, with 1 genus, *Cladornis* (lower Oligocene of Patagonia); known only from a poorly preserved tarsometatarsus.

Critical appraisal. The tropic birds (Phaethontes) differ in many ways from the other members of the order Pelecaniformes and may well be wrongly placed in this order. They are united to the others primarily by the totipalmate condition, but the first toe in Phaethontes is distinctly more elevated on the tarsometatarsus than in the other groups. Some of the resemblances of the Phaethontes to the Laridae (gulls and terns) in the order Charadriiformes may not result from evolutionary convergence but may indicate that the Phaethontes arose from forms more closely related to the basal stock of the Laridae than to that of the Pelecaniformes.

The frigate birds (Fregatae) are generally treated as a distinct suborder, on the basis of a number of morphological characters that they share with members of the order Procellariiformes but not with the Pelecani. Pending further evidence from protein structure, this distinction seems worth maintaining.

There is little doubt that the suborder Pelecani is made up of closely related groups. The pelicans are sometimes placed in a separate superfamily, but it is more useful to emphasize the similarities among the modern groups by keeping them together. The anhingas have sometimes been treated as a subfamily of the Phalacrocoracidae, but their morphological and ecological differences from cormorants perhaps justify separation at the family level.

Odontopteryges show a number of similarities to Procellariiformes as well as to Pelecaniformes and also show differences from both. The suggestion that they deserve to rank as a separate order Odontopterygiformes will be strengthened if it can be proved that *Osteodontornis* lacked or had a much reduced first toe, since this is an essential element of the totipalmate foot of pelecaniforms.

Available evidence suggests that the stocks leading to the Procellariiformes, Odontopteryges, typical pelecaniform birds (Fregatae plus Pelecani), Phaethontes, and Laridae, diverged during the Cretaceous Period, probably at least 70,000,000 years ago. (N.P.As.)

Anseriformes (screamers, waterfowl)

The order Anseriformes includes the well-known ducks, geese, and swans (family Anatidae) and the little-known screamers (family Anhimidae). The Anatidae comprise about 142 species of medium to large birds, usually associated with aquatic or marine habitats and known collectively as waterfowl (in the United States) or wildfowl (in Europe). These birds are of interest to many people for varied reasons: to the romantic and the artist for their swift, massed flights and association with wild places; to the sport hunter as a difficult and worthwhile quarry; to the economist for exploitation as producers of meat and feathers; to the farmer as possible competitors for grass or as damagers of crops; to the medical worker as a possible reservoir of arthropod-borne viruses. The conservationist views them as biological indicators of the richness of wetland habitats and, like those habitats, as objects for his urgent attention. To the zoologist they are a close-knit group in evolution, but one that has adapted into a wide variety of ecological niches.

Drawing by D. Malick

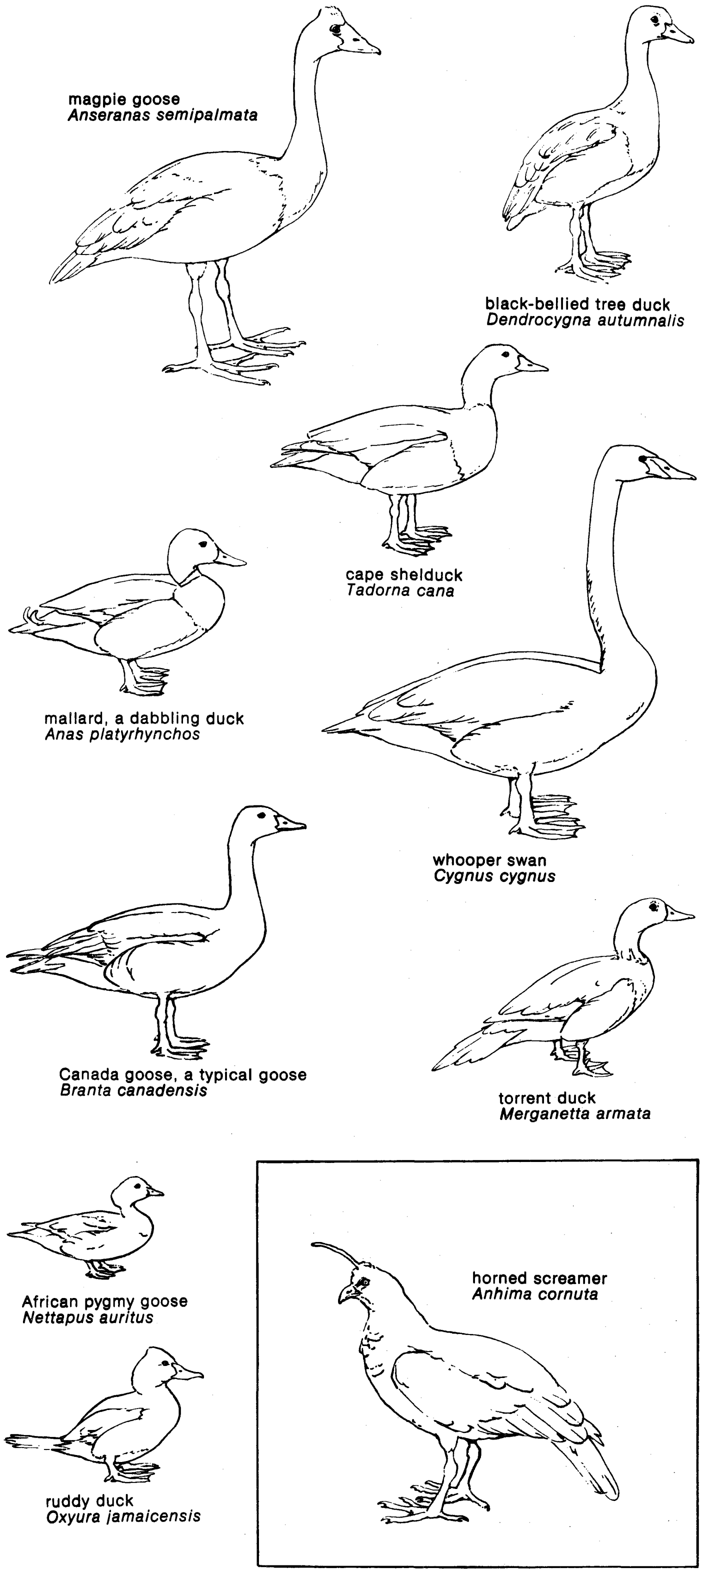


Figure 17: Comparative body plans of anseriform birds.

GENERAL FEATURES

Members of the Anatidae vary greatly in size, the largest being some 60 times as heavy as the smallest. Most are rather chunky birds (see Figure 17), with lengths from just under 30 centimetres to slightly over 150 centimetres and weights from about 300 grams to more than 18 kilograms. The neck is medium to long. The bill also varies widely, as befits birds with diets as different as grass, fish, and minute plankton, but is of medium length, typically broad and somewhat flattened, with a rounded tip, often with a pronounced nail, giving a slight hook to the tip. The bill is often provided with fine lamellae, short parallel plates at the edges of the mandibles that aid in food handling and, in some species, in straining tiny food organisms from water or mud. Anseriform behaviour patterns are an intriguing mixture of the innate and the learned; some so fixed that they can be used as taxonomic characters, others so pliable that completely new traditions can evolve within a few generations.

The three species of screamers are quite different from waterfowl in general appearance. They are moderately long-legged birds about the size of a turkey, with lengths from about 70 to 95 centimetres and weights of 2–5 kilograms. The beak is rather chicken-like, with a pronounced downward hook. The feet are exceptionally large, the toes webbed only at their bases.

Distribution

Anseriform birds breed on every major continent and island except the Antarctic, and many undertake vast migrations over thousands of kilometres. Some species are widespread and number in the millions; other are represented by a few hundred confined to a single island. In the former category come the pintail (*Anas acuta*) and the mallard (*Anas platyrhynchos*), both found throughout the Northern Hemisphere; in the latter, the Hawaiian goose (*Branta sandvicensis*) and the Madagascar white-eye (*Aythya innotata*). Extinction has overcome four species within the last century, and island forms, such as the endangered Marianas mallard, are very vulnerable. The Hawaiian goose was once down to fewer than 50 birds, the Laysan race of the mallard to seven individuals. The creation of wetland refuges has helped to restore these and other declining populations. Nonetheless, even the more common waterfowl, which teem in thousands at certain times and places, are not secure from drastic declines in numbers.

IMPORTANCE TO MAN

The large size of waterfowl has made them an inevitable quarry for man from prehistoric times. Not only do they provide protein but also large amounts of fat and feathers, especially down, much prized in the colder regions. Among the unusual uses of waterfowl parts may be mentioned the conversion of swan tracheae into children's whistles in Lapland, and the eating of the billknob of the king eider (*Somateria spectabilis*) as an aphrodisiac in Greenland. Wary and difficult to approach in their watery haunts, waterfowl exercised man's ingenuity to kill them before the advent of efficient weapons. The period of flightlessness was early discovered and exploited, the birds being driven into corrals of stone or netting. From the latter evolved the Dutch method of catching full-winged ducks by enticing them up large net-covered pipes leading from the secluded pond of a duck-decoy. The birds were seduced into the pipes by food or by their predator-following reaction to a trained dog. Many other ingenious traps were devised, from the clapnets of the ancient Egyptians to the rocket-propelled nets of today's research workers.

Threatened species

Anseriform populations are now so threatened by the loss of their essential wetland habitats to drainage and technological developments that they are no longer able to withstand commercial exploitation. This is generally recognized in civilized countries, where market hunting is banned and efforts are made to control sport hunting so that annual kill does not exceed annual production. As waterfowl migrations pay no heed to national boundaries, the need for international agreement on their conservation is paramount.

As the amount of human leisure increases, so does the importance of nondestructive recreational use of waterfowl. A great flock of waterfowl is one of the remaining spectacles of nature and one that can be made accessible to crowds of people led through covered approaches to concealing blinds. The refuges created to hold reserves of stocks for shooting will, more and more, be developed with the spectator in mind. Such refuges must be numerous and large enough to give adequate feeding grounds. Extra food, however, can be provided as standing crops or distributed from stores. In these ways the occurrence of damage to agricultural interests in the neighbourhood can be avoided. Complaints of such damage are frequently exaggerated, for in many countries migratory waterfowl arrive after the harvests have been gathered and take only spilled or rejected grain and tubers, performing a useful cleaning operation. Even when geese graze on growing cereals in winter, the subsequent crop yield is not reduced. Conflicts can arise, but these can be resolved by changes in husbandry and by techniques of scaring the birds from the fields without injuring them.

Another aesthetic exploitation of waterfowl has been possible because they readily adapt to captivity. Spending much time walking, swimming, or diving, they are less inconvenienced than most other birds by being pinioned (the tip of one wing removed) to prevent flight. They can then be kept in open paddocks instead of being confined in cages. Zoos and private aviculturists maintain waterfowl collections of varying size, the largest being that of the Wildfowl Trust, Slimbridge, England. Here no fewer than 131 of the 142 existing species have been maintained, and more than 100 have bred. Such a remarkably complete comparative collection has, of course, been useful for educational and research purposes. Breeding in captivity also enhances the possibility of restoring wild populations that have been reduced by overshooting or other excesses. The most notable case has been that of the Hawaiian goose. In 1950 fewer than 50 of these birds existed. Twenty years later, thanks to avicultural efforts at Slimbridge and on Hawaii itself, there were more than a thousand, several hundred of which had been liberated on the original habitat. For a different goal, but also effective, have been the efforts of hunting organizations to breed replacements for birds shot. Several species of geese and ducks have responded well to manipulation of habitat and the provision of nest sites. Artificially encouraged breeding may well become vital as the hitherto untouched vastnesses of northern marshes and tundras, where so many waterfowl breed, are opened up, destroyed, and polluted.

Domestication of waterfowl

In view of their ready adaptation to captivity, it is surprising that few waterfowl have been domesticated. The mallard was exploited 2,000 years ago in China, and 17 varieties have been developed, according to whether meat or egg production was important. The muscovy duck (*Cairina moschata*) was domesticated in Colombia and Peru before the arrival of the conquistadores. The greylag goose (*Anser anser*) has been domesticated for at least 4,000 years. Egyptian frescoes of that age already show changes in shape from the natural form, and eight main varieties are now known. The swan goose (*Anser cygnoides*) of eastern Asia has also been domesticated, with three varieties. Other species, such as the Canada goose, mute swan, and Egyptian goose (*Alopochen aegyptiacus*), have been kept in semidomestication for ease of exploitation but without intensive breeding to change their forms. A remarkable form of exploitation has been that of the common eider. Its breeding colonies in the Arctic and subarctic are protected and concentrated by the provision of nest sites and other techniques. The down with which the female lines her nest and covers the eggs is systematically collected during and after incubation without disturbance or loss of productivity, for these birds are very tame.

NATURAL HISTORY

Life history. Young waterfowl are hatched with a complete covering of down and can take to the water as soon as they leave the nest, within 24 to 48 hours. From the first they forage for themselves, but at least one parent remains with them, guarding, guiding, and, initially, brooding them at night and during inclement weather.

Growth and molt

The downy plumage is retained for from two weeks (small ducks) to six weeks (large swans) and is then replaced gradually by the feathers of the juvenile plumage. The flight feathers, the last to develop, likewise vary in rapidity of growth, taking from five weeks to as many months. At fledging, young ducks are freed from parental care and must make their own way on migration. In species breeding in the far north, this begins soon after fledging, in early autumn. Young geese and swans remain with their parents during their first winter, migrating to and from the wintering grounds in their company. In most large species the juvenile plumage is retained through much of the first year of life. Ducks, however, begin to lose the juvenile body feathers almost at once. Some replace the juvenile plumage with an immature nonbreeding (or "basic") plumage, acquiring the first nuptial (or "alternate") plumage in the second autumn. Other species molt directly from juvenile to nuptial and are practically indistinguishable from adults in plumage and size at the age of six months. Swans and geese do not reach full size until the end of their second year, and even at that age swans still retain some immature feathers. In migratory species social flocking and pair formation occur on the wintering grounds, followed by the return migration to the breeding grounds. In the high-Arctic regions the birds arrive ready to nest as soon as the snow cover goes and the water opens; further south the process is more leisurely. When the female duck begins to incubate, the male generally deserts her and joins forces with other males, often after making a quite extensive molt-migration, a movement to another area some distance from the breeding site. The nuptial plumage is lost, and a dull "eclipse" plumage, rather femalelike, is assumed before the simultaneous molt of the flight feathers. The resulting flightless condition lasts three or four weeks, during which the birds skulk in thick cover or remain on large bodies of water. In female ducks this wing molt is delayed until after the young have fledged. The eclipse plumage is succeeded, in three to six months, by the next nuptial plumage. In the case of swans and geese the male remains and molts with the female and family; immature birds and unsuccessful breeders may, however, make a molt-migration to a separate area.

The foregoing life cycles are typical of waterfowl breeding in north temperate or Arctic regions. In the tropics and south temperate regions, migration of waterfowl may not be necessary. When it does occur, migration may be in response to less regular ecological factors such as the onset of the rainy season. Males and females tend to be similar in plumage and to lack eclipse plumages. The birds are ready to breed at any time that conditions are favourable. Undoubtedly there is a relationship between hormonal balance and the appearance or absence of eclipse or brightly coloured plumages, but the exact mechanism is not yet known.

Life spans

The mature bird has a potentially long life, but this is seldom achieved in the wild. In captivity ducks have lived for 20 years, geese and swans for more than 30; there are reports of geese exceeding 40 years of age. Wild populations suffer heavy losses (up to 70 percent) among first-year birds. The adults then experience annual mortalities of from 10 percent to 50 percent, depending on the extent to which the population is shot and on natural factors. At the higher end of this scale the population is almost completely replaced within three years. With luck and cunning an occasional bird may survive for 15 to 20 years or more.

Behaviour. Maintenance of the plumage in an effective waterproof condition occupies much of the time not spent feeding or sleeping. The bill is used both to stimulate the oil gland (situated above the tail) and to spread the oil. Rubbing the chin and throat on oiled areas also helps the process. Preening occurs at the same time, the fine structure of the feathers being nibbled into the interlocking position necessary to prevent the entry of water. Rearrangement of the feathers involves preening, scratching with the feet, and a general body shake, produced by a muscular contraction sweeping from tail to neck. Various wing stretching movements settle the flight feathers. Bathing movements include dipping the head, beating the wings on the surface and, at high intensity, actual diving or somersaulting through the water. Sleep often follows such maintenance activities, the bill being turned and placed under the scapular (shoulder) feathers. Bathing is often a communal activity, and mutual preening is seen in several species.

Display behaviour

Social displays are one of the most interesting aspects of waterfowl behaviour, and many of the signal movements involved in the displays are clearly derived from maintenance activities. Thus preening dorsally, on the breast, and, especially, behind the wing can be seen in ritualized form in social situations. Likewise, the wing stretch and the general body shake occur in threat or sexual displays.

Most waterfowl are gregarious and have well-developed social integration signals. Many indicate the intention to fly by head-shaking or chin-lifting, so that the group takes off together. In swans and geese vocalization plays a part in this situation and also in group flight. Formal aggressive displays are important in gregarious species to prevent actual fighting and injury and to establish instead a stable dominance order. In threat, the behaviour often tends to increase the apparent body size, as when swans raise their wings and ruffle the scapular feathers. Wing flaps and flicking of the folded wings are common in geese. The chin may be lifted during aggressive display, but more frequently the head is thrust forward, often with the bill open. The striking nature of these gestures is often emphasized by patches of colour, which may be concealed before the movement is made. Since these gestures may occur without associated feather patterns, this suggests that the behaviour patterns evolved first.

Pair-forming displays

The pair-forming displays are well developed and characteristic of the species, which is necessary if mating with closely related and sympatric (coexistent) species is to be avoided. Swans and geese (tribe Anserini) cement the pair bond by the "triumph ceremony," with mutual head waving and calling, typically when the male has driven off an intruder. Male sheldgeese (tribe Tadornini) have a puffing, strutting display. Their females incite them to attack other birds by sideways jabbing movements of the bill. Female incitement behaviour is found throughout the rest of the family, but the male pairing behaviour is more varied. It is particularly striking in the dabbling ducks (Anatini), where it is often social, a group of males displaying around a solitary female, who appears to do the mate selection. Ethologists have endeavoured to give objective names to the various postures and sequences (Figure 18). Thus "head-up-tail-up" involves a simultaneous upward jerk of head and tail and a lifting of the folded wings to display the speculum, a set of metallic coloured secondary flight feathers of the upper wing. The "grunt-whistle" involves throwing an arc of water at the female by a sideways flick of the bill, followed by a rearing up of the body, shaking of the head and tail, and, during the whole sequence, giving the call indicated by the behavioural term. The sea ducks (Mergini) also have elaborate male displays, bowing while producing dovelike coos; flagging the head from side to side; jerking the head back on the tail and kicking up a spurt of water (the "head-throw-kick" of the goldeneye, (*Bucephala clangula*). Perhaps the most bizarre display is found in the stifftails (Oxyurini), such as the ruddy duck (*Oxyura jamaicensis*) of North America. The males cock their tails over their backs, inflate their lower necks, and beat on them with their bright blue bills, producing a chittering sound that terminates in a burp.

Displays that maintain the pair bond are less varied and tend to be more marked in the long-lived geese and swans, which pair for life, than in the short-lived ducks. Mutual preening and drinking displays are of this category, as are precopulatory displays, often ritualized feeding movements such as mutual head dipping, bill dipping, or

head pumping. Following copulation, other mutual displays occur. The geese and swans indulge in calling with upstretched necks and lifted wings. More extraordinary is the "step-dance" of the whistling ducks (Dendrocygnini), in which the partners rear up side by side, treading water and each raising the outside wing.

Imprinting

The display patterns, whatever their origin, have been incorporated in the genetic code, and they appear to be ready-formed and complete. Although much waterfowl behaviour can thus be said to be innate, other activities are learned during the life of the individual. One special type of learning, which is called imprinting, has been much studied in this group. The newly hatched, downy young exhibit a strong but unspecific following response to a large moving object, especially if it emits rhythmical sounds. While following such an object they become "imprinted" with the knowledge of its characteristics and thereafter treat it as the parent, even though it may be wildly unsuitable, a balloon for instance. The class of object is not necessarily treated as the sexual partner when the duck matures, but it does appear that male dabbling ducks learn the plumage patterns of the female from the ducks with which they are reared. The females, however, apparently have the ability to ignore such early experience, and to select the appropriate male when they mature; the male plumage patterns are probably sufficiently simple that their recognition is coded into the female's genetic inheritance.

Many other aspects of waterfowl behaviour show a similar interweaving of innate and learned responses. Thus the young bird hatches with distinct preferences as regards the colour, size, and shape of objects at which it will peck. Within these limits, and those imposed by its bill structure and the habitat to which it is taken by its parent, the young bird can be quite adventurous in its feeding, gradually excluding unpalatable or unsuitable objects.

Feeding behaviour

Three main lines of feeding behaviour have evolved in the waterfowl—diving, dabbling, and grazing. Those that dive for food fall into two groups: inland species (Aythyini) favouring relatively shallow lakes up to six metres deep and predominantly feeding on plants such as pondweeds; and sea ducks (Mergini), using deeper marine waters and feeding on invertebrates and fish. Dabbling ducks feed on the surface or by upending to reach the food on the bottom, largely plant material. The grazing geese and swans take grasses and sedges on dry land or in marshes and grub for roots both on land and under the surface. Many of the geese have adapted to the various farm crops, new feeding traditions spreading rapidly as the birds of a group learn from one another.

Migratory behaviour is likewise partly innate, partly learned. Young ducks of migratory populations set off in the autumn in approximately the right direction, even if there are no old birds to guide them. Others show a fixed orientation, after capture and release, that has no apparent function and so has been termed "nonsense" orientation. In both cases the direction is innate, and so is the ability to determine it with reference to the sun's position (making allowance for its diurnal movement) or to the patterns of the stars. It appears, however, that the details of the sun movement and star patterns have to be learned, as do the characteristics of the home from which the bird starts and the winter quarters in which it ends. Like other migratory birds, waterfowl have the ability to return to the nesting area when they are displaced from it, but it is not clear how far they can be truly said to navigate; *i.e.,* to pinpoint their position in two coordinates, again perhaps with reference to sun or stars. In geese and swans, where the young travel with their parents, the possibility exists of their learning the chains of lakes, rivers, and other landmarks down which they fly and so of "map reading" on subsequent migrations. Certainly the migratory behaviour is highly modifiable in these longer-lived birds. New wintering resorts are adopted if they become favourable because of food supply or lack of disturbance. The migratory urge can be overcome completely in geese that are reared artificially. If the climate is not too severe and food and mates are available, such birds will remain where they grow up, even though they are left full-winged and free to come and go.

One form of waterfowl behaviour that seems to be largely innate is sound production. Vocalizations are rather simple and do not apparently offer the opportunity for individual elaboration found in songbirds. A range of honks, whistles, grunts, coos, and quacks are produced, mainly in the context of social contact and flock cohesion or in courtship display. The voices of the sexes are generally quite dissimilar. Some nonvocal sounds are also produced by the wings of some species, by inflatable air sacs of others.

Locomotion. Only the screamers (Anhimidae), with their broad wings and light bodies, are able freely to indulge in soaring flight. The magpie goose (*Anseranas semipalmata*) has somewhat similar wings, but typically the waterfowl have strong, rapid flight, the heavy body and relatively small wings giving a very high wing loading. The trumpeter swan (Cygnus cygnus buccinator) is probably the heaviest flying bird there is, weights up to 18 kilograms (38 pounds) having been claimed. Trumpeter swans beat their wings about three times a second, the smaller ducks twice as fast. Geese tend to fly in long extended lines, often adopting a V formation. Cruising air speeds of most waterfowl appear to be around 65 kilometres (40 miles) per hour; when pressed they can certainly reach 100 kph. On migration most flocks fly at altitudes of between 300 and 600 metres. Uncommonly they may be seen around 3,000 metres, and the barheaded goose (*Anser indicus*), breeding in Tibet and wintering in India, must fly at 6,000 metres to get through the Himalayan passes.

Flight speeds and altitudes

Swans and the heavier geese require a running start into the wind when taking off from water or land. The Aythyini and the Mergini also skitter along the surface before becoming airborne. Three of the steamer ducks (*Tachyeres*) have lost the power of flight and when in a hurry can only churn along the surface like paddle steamers. Small geese and most ducks can launch themselves directly into the air, pushing with the legs and giving a tremendous thrust with the wings, which may strike the water. In landing, the wings and spread feet are used for braking and guidance. Height is often lost rapidly by alternate sideslips, a process carried to extremes in the downward "whiffling" of geese, in which the birds may actually roll over on their backs, still keeping the head straight and level. The Anatini are quite manoeuvrable near the ground, back-flapping their way vertically down for the last few feet. The Aythyini land faster and normally only on water.

Walking on land is well developed in the longer-legged geese and in gooselike species. The "goose-step," with exaggeratedly lifted feet, is well shown by the spur-winged goose (*Plectropterus gambensis*). Others walk more straightforwardly and when pressed, if flightless for instance, can outrun a pursuing man. In the ducks, whose short legs are situated laterally and posteriorly, the gait is at best a waddle. Most of the Aythyini and Mergini have legs so far back that the body is carried almost upright when out of the water. This development reaches its extreme in the Oxyurini, which rarely leave the water on foot.

The magpie goose, with long, nearly web-free anterior toes and a long posterior hallux, is able to perch on twigs at the tops of trees. But it is very much of an exception. A number of other ducks, especially the hole nesters, can perch on branches or scramble up rough surfaces.

Underwater locomotion

It is for swimming that most of the waterfowl are especially adapted, with their waterproof feathering, fat-insulated body, and powerful legs with webbed feet. The feet paddle alternately in slow swimming, the whole leg being used when the bird is moving fast. All waterfowl will dive if pressed, and about two-fifths use diving as their normal feeding procedure. These submerge by arching the body and propelling themselves forward with both feet so that entry is in a smooth arc. The whistling ducks, however, take a jumping "header," clearing the water like coots, while those consummate divers, the stifftails, simply slip under. Diving in fast-running streams requires great power and adaptations, such as the streamlined form and the long, stiff tail of the torrent ducks (*Merganetta*). Once a diving duck is under water, the legs are sculled together. In some species the wings are opened and used as steering rather than as propelling devices.

Long-tailed, or old squaw, ducks (*Clangula hyemalis*) have been caught in fishing nets as deep as 55 metres, but this is exceptional and most species do not dive much below 6 metres. They normally remain below for less than 30 seconds, occasionally up to 90 seconds, but are physiologically capable of much longer submergence.

Reproductive behaviour. Copulation in waterfowl typically occurs in the water, the pair being in isolation. Indeed, the avoidance of disturbance at this time may be a major function of territorial behaviour. Colonial nesting is not normal, but high densities may occur when certain areas are unusually safe and suitable, islands for instance. More than 200 gadwall (*Anas strepera*) nests per acre (494 per hectare) have been reported in such circumstances. More usually the nests are scattered, the distance between them being determined in part by the strength of the territorial activity. Some swans, shelducks, and sheldgeese are highly aggressive and defend a territory around the nest. In most species the situation is less clear-cut. The pairs of duck remain within a "home range," incorporating water, a loafing spot, nesting cover, and food, but do not vigorously defend its borders. Rather, the territory proper seems to be an area about the female, moving as she does. A male intruding on a pair gives rise to the "three-bird chase," which is a characteristic of prenesting behaviour. Geese likewise defend an area around the female but also the immediate vicinity of the nest.

Nest building

Nest site selection is done mainly by the female, although the male may accompany her in her search. Nests built over water among marsh vegetation are found in the primitive members of the Anatidae and the protection thus afforded from predators may have tipped evolution toward a more wholly aquatic existence. Many species nest on dry land, however, often, in the Anatini, several hundred yards from water. Some species, especially the shelducks (Tadornini), use crevices and holes for nest sites. They do not construct their own but take over what is available, such as rabbit burrows. Most hole nesters, however, utilize holes in trees, again preexisting ones, and will quite readily adopt nesting boxes where trees ancient enough to have holes are absent. Old tree nests of other species are sometimes used. A successful species like the mallard is adaptable in choice of nest site and may be found in any of the above situations.

The building of the nest is generally the work of the female, though the male assists in some species. It is a general rule that waterfowl are behaviourally incapable of carrying material in the bill, and even in the rare instance of courtship feeding shown by the red-crested pochard (*Netta rufina*), the female has to swim to the male to take his "gift." In most waterfowl, therefore, the nest is constructed of materials on the site within reach of the beak. They are pulled in and dropped sideways over the shoulder, forming a pile as the bird rotates. With the exception of species that share incubation, such as the magpie goose, the whistling ducks, and white-backed duck (*Thalassornis leuconotus*), the nest is progressively lined with down preened from the female's breast. This down is pulled over the eggs when the female leaves, keeping them warm and, in open sites, protected from the sight of predators.

Egg laying usually occurs early in the morning and occupies but a few minutes, though the female remains on the nest for up to an hour. Generally one egg per day is laid, with occasional gaps. The greatest spread recorded is in the velvet or white-winged scoter (*Melanitta fusca*), which takes 15 days to lay its usual clutch of nine eggs. Sperm has been shown to remain viable in a female mallard for a similar period, so it is probable that copulation prior to egg laying is sufficient to fertilize the whole clutch. Clutch size is variable within a species. The specific averages range from three to twelve eggs. There do not appear to be definite relations between clutch size and taxonomic, ecological, or geographical groupings, and its significance in anseriforms is still controversial. There is, however, a tendency for larger clutches to be laid by species that devote little parental care to their offspring. Egg size varies from 3 to 15 percent of the body weight in different species, the relatively largest being produced by the Oxyurini. In all cases the eggshells are immaculate white, green, or brownish. Surface finish ranges from very smooth to dull and large-pored.

The laying of eggs in nests other than their own is of widespread occurrence among waterfowl, and the very large clutches recorded, up to 22 in the mallard, are usually the work of more than one female. In the Aythyini and the Oxyurini such nest-parasitism is so common that it influences the breeding biology of a population. Only one species, the black-headed duck (*Heteronetta atricapilla*) of South America, is an obligate nest-parasite, always laying in the nests of other species.

With few exceptions, only the female incubates, the average period ranging from 22 to 39 days. Usually she leaves the nest periodically to feed, covering the eggs with down. In some species, like the common eider (*Somateria mollissima*), she apparently fasts during the four-week period. Her resulting constipation may be the cause of the extremely evil-smelling feces that she splashes over the clutch if suddenly flushed from it. This was once thought to deter predators, but experiments have not confirmed this. As incubation proceeds, aided by both the high temperature (around 101° F) and the high humidity maintained in the nest, the female becomes increasingly reluctant to leave the nest at the approach of a predator. If flushed late in incubation or with hatched young, she will indulge in injury-feigning, flapping or dragging her wings in an uncoordinated fashion that serves to distract predators.

Adaptations for short breeding seasons

The length of the incubation period shows little relation to taxonomic position or body size, but both it and the subsequent fledging period are correlated with the latitude at which breeding takes place. The continuous daylight of the Arctic summer enables the young to feed around the clock, but this does not sufficiently offset the fact that there is only a short interval between the melting of the snows and the onset of autumnal bad weather. Selection in the course of evolution has reduced the breeding sequence as far as possible. Thus the small high-Arctic races of the Canada goose (*Branta canadensis*) have so reduced the period from nest initiation to fledging that they can breed in areas having but two snow-free months. Larger races nesting in California take twice as long. Waterfowl are not double brooded in the wild, even when there is time enough. Most will renest, however, if the first clutch is destroyed. The second clutch is generally smaller but may have a higher fledging success in that hatching occurs in the less uncertain weather of late summer. Aviculturists regularly take advantage of this capacity, incubating the first clutch under bantam hens.

Since incubation does not start until the clutch is complete, hatching is generally well synchronized and may be complete within six hours. Another six hours is required for the down to dry, and young birds usually remain in the nest overnight. While in the nest they are brooded by the female and become imprinted with her visual and auditory characteristics. The downy young have sufficient internal food reserves to last two or three days if inclement weather prevents feeding as soon as they leave the nest.

The nesting behaviour of screamers is somewhat different from that of waterfowl. A substantial nest is built on marshy ground or in shallow water, sometimes reaching a height of 30 centimetres or more. The clutch varies from two to six eggs, depending on the species. Young screamers are covered with yellow down and leave the nest when a few days old, following their parents in the manner of young waterfowl.

Knowledge of waterfowl breeding, although far from complete, has come a long way from medieval times when barnacle geese (*Branta leucopsis*) were thought to hatch from barnacles on rocks because no one had then found their high-Arctic nests.

Ecology. Most waterfowl are associated with fresh water, at least during the breeding season. Relatively few inhabit the areas of early igneous rocks, which have deep lakes and fast streams of low productivity. More preferred are glaciated areas rich in shallow, productive lakes and marshes: the "pothole" country of North America, the silted deltas of rivers, the coastal marshes. An area with many small waters will support more ducks than a single large lake, because the extent of land-water margin is important. The longer shoreline produces diverse food organisms and provides isolation for breeding pairs, cover from predators, and shelter from winds. Paradoxically, periodic droughts are advantageous to duck production. The small lakes dry out and their bottoms become colonized with plants. When reflooding occurs, a rich diet of seeds and of invertebrate animals feeding on the decaying vegetation becomes available. Long-term or permanent droughts, such as occasioned by climatic changes or, increasingly, by man's drainage operations, can be disastrous. The widening acreage of artificial water reservoirs only partly offsets the loss, for they are normally large, deep waters, of little use to waterfowl except for roosting.

Migration

The ability to migrate greatly increases the ecological flexibility of waterfowl. They can exploit the summer resources of the northern tundra without having to evolve the encumbering adaptations needed to survive the winter there; they can move great distances to take advantage of local rainfalls in arid countries; they can retire to secluded areas when flightless and then seek the rich harvests of man-exposed environments when fully equipped to face the dangers. There are many patterns of migration, some regular and in fixed, reciprocal directions, others varying with changes in weather. The distances covered also vary widely. The longest waterfowl migrations are probably those of the blue-winged teal (*Anas discors*), which nests up to 60° N in North America and winters down to beyond 30° S, a distance of over 9,600 kilometres (6,000 miles). In the Old World the northern shoveler (*Anas clypeata*) has a similar migration distance of up to about 11,000 km. The northern pintail and the garganey (*Anas querquedula*), which breed in the Siberian tundra and taiga and winter in the tropical swamps of Senegal and Chad, are even more remarkable in their adaptability.

The general timing of regular long-distance migrations has been built into an internal hormonal cycle in the course of evolution. These "annual clocks" are kept in synchrony by changes in day length, but the immediate factors initiating the stages of migration are climatic. A mass southward movement occurs when air pressure systems produce a favourable wind flow; overcast conditions or a warm spell may temporarily halt the birds; bright, cold conditions move them on.

Causes of mortality

Sudden adverse weather may cause considerable mortality, especially where a long sea crossing is involved, as from Greenland to Britain. But the effects of weather on waterfowl populations can be most drastic at the time of breeding. Late frosts and spring floods are disastrous, especially when there is no time for renesting. Consequently, high-Arctic breeders may have near-complete reproductive failures. The brant geese (*Branta bernicla*) of the population wintering in western Europe only produce good crops of young in about half the seasons.

Parasites of many kinds inhabit waterfowl, generally in a state of tolerance, gaining the upper hand only when the bird is stressed in some way, as by food shortage. This is also true for fungal infections, particularly by *Aspergillus,* a common cause of death in captivity and, exceptionally, in the wild. Bacterial diseases take their toll and sometimes cause spectacular die-offs. Thousands of ducks have succumbed to botulism when shallow, brackish waters dry out in warm countries. *Clostridium botulinum* then multiplies, producing toxins that cause a fatal paralysis if ingested. Fowl cholera (*Pasteurella*) sometimes causes epidemics. More frequently nowadays mass mortality is occasioned by pollution, especially oil spills, pesticides, and other poisons. A peculiarly insidious danger is lead poisoning caused by the ingestion of lead pellets that accumulate in the mud of waters frequently shot over.

The direct kill by man undoubtedly makes him a major predator of waterfowl, and this must be increasingly controlled in the future. Adult ducks, other than nesting females, suffer relatively little natural predation, avian or mammalian, unless they are sick or weakened by hunger. The main predatory impact comes on the eggs and downy young. Crows and gulls, mink, raccoons, coyotes, foxes, ground squirrels, snakes, snapping turtles, bullfrogs, pike, and carp all take some toll. In normal circumstances such predation does not unbalance population dynamics, which are, after all, geared to a high rate of loss in the early stages. Predator-control measures have seldom produced any comparable increase in waterfowl production.

Beneficial relations exist with other birds and animals. Thus Aythyini and eiders (*Somateria* species) actually prefer to nest in association with the smaller gulls (*Larus* species). The latter tend to drive off predators and, by increasing the number of available eggs, share the pressure of egg predators. The muskrat clears water openings in reed beds and builds "houses" that are utilized by ducks for standing and nesting. Beaver dams create very attractive duck habitats. And, of course, man himself is not wholly destructive but creates some new areas for waterfowl and provides them with food, both unintentionally and on purpose.

FORM AND FUNCTION

Variety of bill modifications

Anatomy. The characteristic features of the family Anatidae are the skin-covered, lamellate bill and thick, fleshy tongue. The Anhimidae have a short non-lamellate bill, slightly hooked, like that of a domestic hen, and a horny tongue. Their bill is adapted for tearing aquatic plants. Among the Anatidae the basic bill has undergone a wide adaptive radiation. The geese have evolved strong, deep bills with hard, sharp lamellae. In some, such as the red-breasted goose (*Branta ruficollis*), the bill is short and slight, used only for grazing; in others, such as the snow goose (*Anser caerulescens*), it is long and heavy enough to deal with and dig for roots and tubers. The massive digging bill reaches maximum development in the magpie goose. The little pygmy geese (*Nettapus*) are so-called for their gooselike bills, but they actually feed on lotus seeds and water vegetation and do not graze or root for food. The European widgeon (*Anas penelope*), on the other hand, does graze extensively, but its bill differs little from the typical *Anas* bill, flattened with platelike lamellae. This is used for sifting particles out of mud or picking up food items from the lake bottom as the bird upends. The sieving bill is yet further developed in the shovelers and the pink-eared duck (*Malacorhynchus membranaceus*), the lamellae becoming extremely fine, enabling particles as small as diatoms to be taken from the surface film. The blue duck (*Hymenolaimus malacorhynchos*) has a rounded, expanded tip to the bill, which probably protects it when poking around sharp pebbles. The Aythyini have fewer lamellae and a narrower bill than the Anatini. In the mergansers (*Mergus* species) the lamellae have become toothlike projections in the long narrow bill, ideal for holding fish; additionally, the tongue has two dorsal rows of barbs. None of the Anatidae have developed pickax bills or ones for crushing hard food items, such as mollusks. When such are taken they are broken up in the gizzard.

Drawing by D. Malick

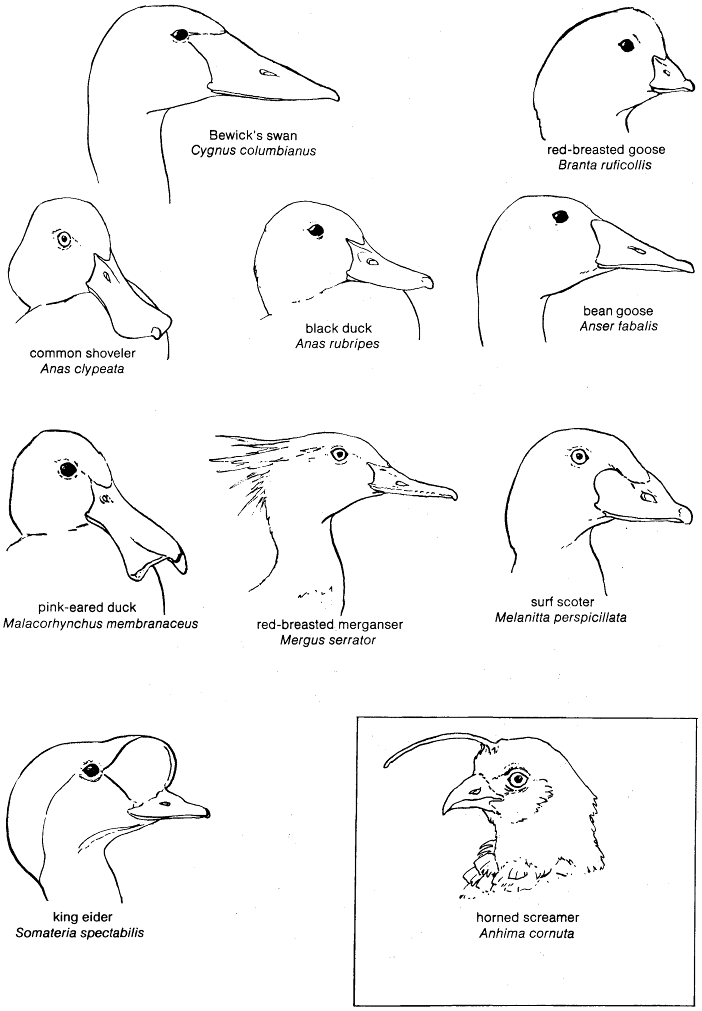

Figure 20: Heads of anseriform birds.

The legs and feet vary according to whether the main mode of progression is walking (geese) or swimming (divers). The latter have flattened tarsi to reduce water resistance on the forward stroke, the hind toe being lobed. Webs are fully developed between the front three digits, except in the magpie goose (primitively) and the Hawaiian goose, where it is believed that the greater flexibility of the toes makes for easier walking on broken lava beds. The claws on the digits are particularly sharp in forms (such as the Cairinini) that normally nest in tree holes.

The wings are not of unusual structure but vary widely in shape, from the broad expanse of the slow and manoeuvrable fliers to the narrow sweeps of the fast movers. Some of the Dendrocygnini have modified vanes on the outer primaries that produce a whirring noise in flight. The soughing creak of the wings of the mute swan (*Cygnus olor*) is well known. In a few cases the wing is so reduced in size that the bird is flightless, as is the Auckland Island race of the brown teal (*Anas aucklandica*). Many waterfowl have horny knobs on the carpal joint; in some there is a distinctly projecting spur as in the screamers, spur-winged goose, and torrent duck. In the first two, the spurs are actually used effectively in striking an adversary; in the last they may be of more use in progressing over slippery rocks in a raging stream.

Specializations of the windpipe

A structure that has received much attention, largely because of its taxonomic value, is the anatid trachea. This may be straight (geese and ducks) or looped in various ways (magpie geese and swans), the most elaborate being that of the trumpeter swan (*Cygnus cygnus buccinator*). Here it first enters the sternum, flexing twice into horizontal and vertical bony pockets, then emerging again to coil around and back into the lungs. The analogy to an orchestral wind instrument is obvious and a comparable sound is produced. Less obvious is the relation of shape to noise in the asymmetrical chamber (bulla) found at the base of the male trachea in most ducks. The male's whistle certainly differs from the female's quack, but it is difficult to account for the variation in bulla shapes—round and solidly ossified (Anatini), angular with membranous "windows" (Aythyini), or complexly membranous (Mergini).

The anseriform birds share with the curassows, tinamous, and ratites the possession of an intromittent male organ. This is not homologous with the mammalian penis but is a vascularized sac everted from the wall of the cloaca. It is protruded by muscular action and retracted by an elastic ligament. This gives it a spiral form, and sperm pass from cloacal papillae along a groove to the tip. This organ doubtless facilitates copulation on the water. Its presence is an aid to research and aviculture, since it permits the investigator readily to sex live birds that lack plumage dimorphism. The size of the organ also allows an estimate of the bird's age. That is, however, more safely done by determining the depth of the bursa of Fabricius, a glandular organ opening into the cloaca and diminishing with maturity.

Respiratory adaptations for diving

Physiology. There are interesting adaptations in the respiratory physiology of diving ducks. The accumulation of carbon dioxide does not stimulate breathing as it does in land mammals. When the bird is under water, oxygen is drawn from stored oxyhemoglobin and oxymyoglobin in blood and muscles, instead of from the respiratory system. The air sacs are compressed, reducing buoyancy. Glycogen is broken down by anaerobic and aerobic means, and the blood flow is modified so that the central nervous system receives the main supply.

Rather little is known about the physiology of digestion in waterfowl. It appears that, despite being almost entirely grazers, geese lack the ability to digest cellulose, either by the secretion of cellulases or by the symbiotic activities of microorganisms in the gut or its cecae (branches). Such inefficient digestion is probably correlated with the extraordinarily rapid passage of ingested material, which begins to appear in the droppings within half an hour and can be completely eliminated in two hours.

Salt excretion is achieved by the paired supraorbital nasal glands situated on indentations on the skull over the eyes. Races living in marine or brackish environments have these glands enlarged, quite modifying the profile of the head. In a botulism infection, it is probable that the toxins of *Clostridium botulinum* cause these glands to malfunction, resulting in the characteristic salt imbalance and paralysis.

EVOLUTION AND PALEONTOLOGY

Anseriform fragments have been recognized from as far back as the Eocene, and certainly by the late Oligocene birds assignable to the present-day tribes Anserini, Anatini, and (possibly) Oxyurini existed. The Miocene added Dendrocygnini and Aythyini, the Pliocene Tadornini, Mergini, and possibly Cairinini. By the Pliocene several species osteologically indistinguishable from modern species were present. Fossils from the Pleistocene are much more extensive and amount to more than 90 anseriforms. Paleornithologists tend to be conservative in allocating new specific names to Pleistocene anseriforms, since the observed differences correspond to those between modern races, indicating temporal as well as geographical continuity. Nevertheless, 32 of the Pleistocene species are reckoned to be extinct.

Despite the number of fossil species, the fossil record is inadequate to throw light on the origin and evolution of the Anseriformes. The greatest number and variety of their fossils have been reported from the Palaearctic Region, but this does not necessarily mean that the group originated there. Indeed, a number of other considerations point to a tropical origin, possibly in the Southern Hemisphere. At present, the greatest number of endemic and monotypic genera and the more generalized species are to be found there. Be that as it may, the Anseriformes soon spread and were to be found over all their present range quite early in their history.

Main lines of anseriform evolution

Ancestral forms were probably long-legged unspecialized birds with features related to the galliform curassows (Cracidae), ciconiiform flamingos (Phoenicopteridae), and anseriform screamers and magpie goose. While the screamers have probably advanced but little, the Anatidae have diversified rapidly and extensively. Two main lines may be distinguished. One, typified by the swans and geese, became large-bodied, long-lived, slow-breeding birds, with prolonged pair and family bonds and associated parental care of the young. The other line, characterized by most of the ducks, has favoured small-bodied, short-lived birds having but brief pair bonds and minimal care of the young, necessarily correlated with prolific production of young. Superimposed on these general trends were adaptive radiations; from omnivorous to specialized food habits; from a largely terrestrial to an almost fully aquatic existence. An adaptation for the latter, the double molt, enabled the males to develop striking nuptial plumage, which prevented interspecific hybridization when many species were sympatric. Migratory habits strengthened this requirement, and gene flow within such species was rapid. Racial differences developed only in nonmigratory or otherwise isolated species, or in those migratory forms that maintained family groupings when away from the breeding grounds, and so developed learned, traditional attachments to the area where they were born.

Despite the wide variety of present-day Anatidae, the family is basically genetically homogeneous. This is shown by the readiness with which hybrids occur, at least in the forcing conditions of captivity. More than 400 kinds of hybrids are known. Many of the interspecific crosses are fertile, and some remarkable intergeneric and intertribal hybrids are known. The evidence from serological investigations and from the physico-chemical examination of egg-white proteins and egg-shell structure similarly shows the family to be close-knit, only the magpie goose deserving classificatory isolation. Likewise the eggshell structure and nitrogen content throw some light on evolutionary relationships. Feather pigments pose a number of fascinating problems, and recently the composition of feathers has been analyzed to throw light on the geographical origins of goose populations.

CLASSIFICATION

Distinguishing taxonomic features. Broad classification divisions are based on skeletal and other internal structures. Finer divisions are decided on plumage type and patterns, including those of the downy young, and on behavioural features such as the length of pair bond and on displays associated with pair formation and maintenance.

Annotated classification. The classification here follows that of Jean Delacour (1954) as modified by Paul Johnsgard (1965, 1968).

ORDER ANSERIFORMES

Birds with skull desmognathous (maxillopalatines fused) and holorhinal (posterior border of nostrils rounded); one pair of posterior sternal notches; four digits on each foot; wing diastataxic (gap between secondaries four and five); 11 primaries, the outer one reduced; oil gland tufted; eggs unmarked; young nidifugous, with thick down.

Family Anhimidae (screamers)

Pleistocene-Recent. Short, curved, nonlamellate bill; ribs without uncinate process; feet unwebbed, hallux long; plumage uniformly distributed; extensive air cells between skin and body. South America; length 70–95 centimetres, weight 2–5 kilograms; two genera, three species.

Family Anatidae (ducks, geese and swans)

Eocene-Recent. Skin-covered bill, lamellate edges, tipped with horny nail; occipital fontanelles generally present; hallux generally reduced and raised; tongue thick, bordered with spiny processes; primary wing feathers generally molted simultaneously; male copulatory organ present; body length about 30–150 centimetres, weight 300 grams–18 kilograms; worldwide; about 37 genera, 142 species.

†*Subfamily Eonessinae.* Fossil. Known only from middle Eocene of Utah, one species.

†*Subfamily Romainvilliinae.* Fossil. Known only from lower Oligocene of France. One species.

Subfamily Anseranatinae (magpie goose). Rear of head slopes upward and forward; metasternum three-lobed; circular foramen in precoracoid bone; short descending process on lachrymal; anterior toes half webbed, long hallux not raised; long trachea coiled beneath skin; gradual molt of primaries; feeds young from bill; shares features with Anhimidae and with Anserinae. Northern Australia; one genus, one species.

Subfamily Anserinae (swans, typical geese, and whistling ducks). Legs short to medium; neck medium to long. Anterior toes webbed, hallux short, elevated, tarsal scales reticulate. Sexes much alike in plumage, voice, and behaviour. Long pair bond and extended family life. Single annual molt. Vegetarian. Wings usually moderately long, pointed; tail short. All species swim capably, many primarily aquatic.

Tribe Dendrocygnini (whistling ducks). Whistling voice. Relatively long-legged, with upright stance. Enclosed bony orbit (eye socket). Strongly patterned adult plumage; downy young with light stripe below eyes and around nape. Mature at one year. Mutual postcopulatory step-dance. Widely distributed in tropics and subtropics. Two genera, nine species.

Tribe Anserini (swans and geese). Simple trachea and syrinx. Mature in second to fourth year. Behaviour includes "triumph" ceremony and precopulatory head dipping. Breeding distribution Holarctic and north temperate, except for one tropical goose and two species of south temperate swans. Five genera, 21 species.

Tribe Stictonettini (freckled duck). Ducklike with short legs but many anserine features. Australia. One monospecific genus.

Subfamily Anatinae (ducks and aberrant geese). Tarsal scales scutellate (overlapping plates). Male trachea with asymmetrical enlargement (bulla); sexes differ in voice, and also usually in plumage and behaviour; brief pair bond and family life. Double annual molt; males often alternate a cryptic "eclipse" plumage with a conspicuous nuptial one; downy young strongly patterned. Female "inciting" display present.

Tribe Tadornini (sheldgeese and shelducks). Iridescent green wing speculum and, generally, white wing coverts; sexes alike in majority; mature in second year. Pugnacious. Downy young black and white. Worldwide except North and Central America. Five genera, 15 species (one extinct).

Tribe Tachyerini (steamer ducks). Ponderous birds with short wings; plumage mottled with no metallic colours, sexes alike. Closely related to Tadornini, but differ in display behaviour. Western and southern South America. One genus, three species.

Tribe Cairinini (perching ducks). Heterogeneous group; perching habit; metallic wing plumage; small species sexually dimorphic in plumage, larger ones in size; hole nesters; downy young sharp-clawed and stiff-tailed; pair bond usually short-lived or barely developed. Primarily tropical and subtropical; some temperate. Nine genera, 13 species.

Tribe Anatini (dabbling ducks). Short-legged; lobed hallux. Tracheal bulla round and ossified; mature in first year; iridescent wing specula; female plumage with disruptive patterning; female inciting behaviour very ritualized; female has distinctive decrescendo call; mutual head pumping as precopulatory display; complicated group displays in males. Downy young with eye and cheek stripes. Most feed on water surface or by upending. Worldwide. Five genera, 40 species.

Tribe Aythyini (pochards and scaup). Freshwater divers, mainly vegetable feeders, with large feet set well back, and strongly lobed hallux. Tracheal bulla angular with membranous "windows"; sexual dimorphism in plumage, but male nuptial plumage not strikingly patterned; mature at one year. Females without decrescendo call; courtship behaviour simple; downy young lack facial stripe. Worldwide distribution. Three genera, 16 species (one extinct).

Tribe Mergini (sea ducks and mergansers or sawbills). Mostly saltwater divers, feeding on animals. Bulla structures often elaborate; sexual dimorphism in plumage, voice and behaviour; male courtship patterns very varied; maturity requires at least two years. Typically Holarctic, one species in South America. Eight genera, 20 species (two extinct).

Tribe Oxyurini (stiff-tailed ducks). Freshwater divers with legs so far to rear that walking is difficult; lack tracheal bullae, but sound production by inflatable sacs in neck; sexual dimorphism in dense, shiny plumage, male patterns not elaborate; long, stiff tail feathers; elaborate male displays; large eggs and precocial young. Mainly Southern Hemisphere. Three genera, eight species.

†*Subfamily Paranyrocinae.* Fossil. Known only from lower Miocene of South Dakota. One species.

Critical appraisal. There is general agreement on the family and subfamily divisions of the order and at the generic level, where most workers agree on the lumping of species into large genera. Some controversy exists at tribal level. Some workers would include the Tachyerini within the Tadornini; extract the eider ducks from the Mergini and erect for them the tribe of Somaterini; reorganize the admitted "ragbag" of the Cairinini; eliminate Stictonettini and return the freckled duck (*Stictonetta naevosa*) to the Anatini. Indeed it is on the positioning of certain "difficult" species that most discussion revolves. Certain species whose taxonomic positions are in dispute are best thought of as linking species, the result of evolutionary lines that diverged early from near the bases of two major phyletic lines. Examples of such species are the white-backed duck (*Thalassornis leuconotus*), which seems intermediate between the Oxyurini and Dendrocygnini; the Cape Barren goose (*Cereopsis novaehollandiae*), placed with equal justification in the Tadornini or the Anserini; the ringed teal (*Callonetta leucophrys*), sometimes placed in the genus *Anas*, in the Anatini and sometimes the Cairinini; the pink-headed duck (*Rhodonessa caryophyllacea,* extinct since about 1940), placed either in the Anatini or in the Aythyini; the coscoroba swan (*Coscoroba coscoroba*), assigned to the Dendrocygnini or the Anserini; and the marbled duck (*Marmaronetta angustirostris,* sometimes placed in *Anas*), which is evidently intermediate between the Anatini and Aythyini. The study, in recent years, of new taxonomic characters such as behaviour patterns and biochemistry has substantially improved our understanding of relationships within the Anseriformes.

(G.V.T.M.)

Ciconiiformes (herons, storks, ibis, spoonbills, flamingos)

The Ciconiiformes constitute an order of five or six families of storklike birds: herons and bitterns (Ardeidae), the shoebill (sole species of the Balaenicipitidae), the hammerhead (sole species of the Scopidae), typical storks and wood storks (Ciconiidae), ibis and spoonbills (Threskiornithidae), and, according to some authorities, flamingos (Phoenicopteridae). Most are of substantial size, long-legged and long-necked, and adapted for wading. They are widely distributed, often abundant, and apt to be conspicuous in their open habitats or in the air. Many are notably graceful in form and movement, and some have spectacular powers of flight.

GENERAL FEATURES

Size range and diversity of structure. Some storks are very large, standing over 1.2 metres (four feet) high and having wingspans of up to 2.6 metres (8.5 feet). The larger herons are about as tall when standing erect. Flamingos are also tall, with great length of neck and legs. Species of medium size usually stand 60–90 centimetres (2–3 feet) high and some of the smaller ones as little as 30 centimetres (12 inches). Exceptionally small are the little bitterns of the widespread genus *Ixobrychus,* weighing less than 100 grams (a few ounces).

With the partial exception of the flamingos, the structural characteristics of the order are well-marked, and the same is true of the families. The storks, even including the wood storks, form a recognizable group of birds of from medium to large size. The ibis form an even more homogeneous group, birds of medium size with markedly down-curved, slender bills; the spoonbills, of the same family, differ in this respect, as the name implies. The herons are more diverse, with a greater size range, the bitterns standing a little apart in behaviour more than in structure. Each of the remaining two families contains a single species with some peculiar characteristics.

Distribution, habitat, and abundance. Ciconiiforms are found throughout the world, except in the polar regions, but the largest number of species is found in the warmer parts. Some of those breeding in the North Temperate Zone perform long migrations. The herons are the most cosmopolitan family, some being found even on remote oceanic islands. The shoebill (*Balaeniceps rex*) has a limited distribution in tropical Africa, and the hammerhead (*Scopus umbretta*) is almost confined to that continent. The typical storks (subfamily Ciconiinae) are not represented in North America and have only one species in the Australasian Region; the wood storks (subfamily Mycteriinae) are represented by one species in the New World and three in the Old World. The ibis are widely distributed, but are not found in New Zealand. The flamingos are found throughout the tropics, but are not represented in the Australasian Region.

The usual habitat of ciconiiforms is near water, chiefly fresh, and only a few species, such as the white stork (*Ciconia ciconia*), live largely on dry ground. The flamingos require brackish or alkaline water, and two species inhabit Andean lakes at elevations of up to about 4,000 metres (14,000 feet).

Threatened species

Many of the species in the order are very abundant, with world populations running into millions, and some assemblages, such as those of the lesser flamingo (*Phoeniconaias minor*) in Africa, are enormous. At the other extreme, the Japanese ibis (*Nipponia nippon*) is on the verge of extinction, only one small colony being known. Several other ibis species are rare and are declining in population.

Relations with man. Although some freshwater fishing interests may regard herons as undesirable competitors, on the whole the members of this order are considered to be either beneficial or neutral in respect to the human economy. They are not sought by man, and many are protected. At one time a number of species of little egrets were persecuted at their breeding places for the sake of their nuptial plumes—aigrettes (or ospreys)—but such killing has now largely been stopped.

The association of the white stork (now an endangered species) with mankind in its preference for nesting on buildings is further mentioned below, but it is not the only species thus involved. Abdim's stork (*Sphenorhynchus abdimii*), for instance, will nest on native huts in a treeless area. And many of the arboreal colonies of heron and stork species in Africa are in or near villages. The cattle egret's dependence on domestic stock to flush insects, as an alternative to wild herbivores, brings it into a familiar relationship with human beings.

NATURAL HISTORY

Feeding habits. Most ciconiiforms subsist wholly or mainly on animal food, which is usually swallowed whole, indigestible matter being regurgitated later as pellets. Fish are the prey of many species such as the larger herons, but small mammals, birds, reptiles, and amphibians are also taken, as well as invertebrates, including mollusks, crustaceans, insects, and worms.

The flamingos, on the other hand, live chiefly on minute algae.

Specialized feeding of herons

The methods of fishing are varied. Some of the larger herons stand solitary and motionless until a fish comes within reach and the long neck suddenly shoots out. Certain herons employ a hunting method known as "canopy feeding," in which one or both wings are held forward, forming a canopy over the head and creating a patch of shaded water. It is thought that fish mistake the shaded area for a safe refuge; another interpretation is that the canopy aids the bird's vision by reducing surface reflections. Other herons go actively in pursuit, stirring up the bottom with their feet or wading rapidly about. The night herons are largely nocturnal in their fishing. Some members of the heron family are not fish eaters. The cattle egret (*Ardeola ibis*) lives on insects caught when disturbed by the large mammals with which the bird associates.

The food of storks is also varied and may be sought on dry land, in marshy ground, or in shallow water. White storks wintering in Africa take large numbers of locusts when the latter are swarming. Wood storks fish by plowing the water, with mandibles open and partly submerged, as they wade in the shallows. The marabou (*Leptoptilos crumeniferus*) and other members of the same genus are partly predatory but largely scavengers and carrion eaters, and they may often be seen with vultures at a carcass.

Ibis use their long bills for probing the ground or mud. The spoonbills catch small organisms by moving their bills, with mandibles slightly open, from side to side in shallow water. The hammerhead often hunts for frogs and will use the back of an almost submerged hippopotamus as a vantage point. The shoebill is a fish eater.

Filter feeding in flamingos

Flamingos have a highly specialized method of feeding, which has its closest parallel in certain whales. The inside of the mandibles carries a series of fine hairlike plates that act as filters when water is sucked into the mouth and then expelled. The head is held with the forehead downward. The food particles caught on these plates are ultimately worked on to the tongue and from there are swallowed. There are differences of detail between the species.

Vocalization. Many of the ciconiiforms are rather silent, making at most various croaking or grunting sounds. Some storks utter scarcely any sounds, but often noisily clatter their mandibles. Some herons have loud, harsh cries. Among the ibis, the hadada (*Hagedashia hagedash*) of Africa is exceptional in being noisy—flying about with yelping cries.

In spring, the males of the large bitterns make an extraordinary booming sound audible at up to five kilometres; for this purpose, the esophagus is modified so that it can be inflated and serve as a resonating chamber.

Migration. The relatively few species breeding in northern areas with hard winters are summer visitors there. In some herons there is a tendency to a northerly postbreeding dispersal before the time of true migration southward.

The white stork of Europe and northern Asia is a typical long-distance migrant, travelling as far as South Africa and India. The black stork (*Ciconia nigra*) performs a similar migration, but it is doubtful that visitors to Africa now penetrate beyond the Zambezi River in Mozambique. In South Africa, on the other hand, there is a sparse resident population believed to have been derived, within the twentieth century, from migrants that formerly made a longer journey. There are migrants even among species confined to the tropics; Abdim's stork breeds in the northern tropics of Africa during the rains and migrates across the Equator.

Apart from regular movements, recent years have seen a notable range expansion by the cattle egret from Africa and Asia to the Americas and to Australia.

Behaviour. An outstanding feature in ciconiiform behaviour is gregariousness. Even where the mode of obtaining food necessitates solitude and therefore dispersal, the tendency is for reassembly at the end of the day and then flight in formation to a communal roost. Breeding is mostly colonial. Species able to feed in flocks are gregarious at all times. Some of the assemblies are enormous; for example, over 1,000,000 lesser flamingos occur on a single African lake. There may be a seasonal element, as when white storks, dispersed in the breeding season, form flocks for migration.

There are some exceptions. Bitterns and tiger herons, relying on concealment for protection, are not markedly gregarious, nor is the hammerhead. The shoebill is usually seen singly or in pairs. It is rather silent, partly nocturnal, and has even been credited with a morose disposition.

Courtship behaviour of herons

Behaviour related to mating and the pair bond is well marked and has been described in detail for several species, notably of herons. Among these, the first signs of breeding may be the assembly of birds on a gathering ground adjacent to the colony and the performance there of various strutting and dancing rituals. A male may then take off on a "circle flight" ending at the site that he has chosen for the future nest. There he may adopt a series of stereotyped display postures, such as the "stretch," in which he first extends the head and neck vertically and after a moment bends them rearward until the head is almost touching the back. There may also be a "snap" display, in which the head and neck are extended forward and downward, the feathers of the neck, face, and crest are erected, and the mandibles are brought together with a loud clap. After the male heron has attracted a mate, various mutual displays during building, or at nest relief during incubation, apparently help to maintain the pair bond. Both partners will defend their territory against encroachment by others of their kind, this defense involving various types of threat display.

Analogous sexual and hostile display rituals occur in other families of the order, but in the main have been less intensively studied than in certain herons. In a well-known greeting ceremony used by various storks, when mates are reunited at the nest after one has been absent, the neck is bent back so that the head rests upside down on the body with the bill pointing toward the tail. Occasional mass aerial manoeuvres above the nesting colony are performed by wood storks and others.

Locomotion. On land or in shallow water these birds commonly walk with deliberate gait, but with rapid strides when necessary. All, except the flamingos, ordinarily perch on trees or, in a few cases, among reeds, most species roosting and nesting there. Bitterns and small herons often climb with agility among reeds or branches. Only the flamingos commonly swim when the water is too deep for wading, although some others immerse themselves to some extent while catching food.

The flight of ciconiiforms is strong, on broad wings, with the legs trailing behind. The neck is drawn back in herons, slightly so in the hammerhead; in the shoebill it is fully drawn in with the heavy bill resting on the breast, as in pelicans. In the other families, with the exception of storks of the genus *Leptoptilos*, the neck is stretched forward. In direct flight, flocks often assume V-formation. The larger storks perform impressive feats of soaring in thermal upcurrents.

Reproduction and nesting. The breeding of ciconiiforms tends to be in large, sometimes enormous, colonies, which may comprise a mixture of species. Exceptions are tiger herons, bitterns, the shoebill, and the hammerhead, birds not markedly gregarious at any season.

Considering the feeding environment essential for most

Common egrets, *Egretta alba* (top left and right), with snowy egrets, *Egretta thula* (centre), in a typical colonial nesting situation.
Allan D. Cruickshank—The National Audubon Society Collection/Photo Researchers

ciconiiforms, it is remarkable that so many of them should be arboreal nesters. The commonest site is in a tree and often at a great height. Exceptions include the bitterns, which nest among reeds; the shoebill, which nests on the ground; and the flamingos, which also nest at ground level, often in shallow water. Among the storks the choice is more varied. Most species nest in tall trees, but some use cliffs or buildings. In parts of Europe, as an alternative to buildings, the white stork often uses artificial platforms erected for its benefit, commonly a cartwheel lying horizontally on top of a high pole, or a similar structure. The site is variable in night herons, ibis, and spoonbills, whose nests may be in trees, in low bushes, among reeds, or even on the ground (ibis and spoonbills), or on cliffs (some species of night herons).

Nest structure

The nest itself is usually a loose platform constructed of sticks and stems. Rushes are frequently used in marshy situations. The nest of the hammerhead, placed in a tree and often at no great height, is an enormous structure of sticks and other vegetation, forming a closed chamber sometimes a metre or more in diameter with an entrance tunnel at one side. The cavity is lined with mud or dung. The shoebill, in contrast, does no more than flatten a patch of long grass on dry ground. Flamingos build cones of mud on the lakeshore, 15–35 centimetres (6–14 inches) high, with a shallow depression scooped out of the top of each. The incubating bird sits on top of this nest, with its long legs folded beneath its body. Sometimes, as on small rocky islands, other materials are used in the absence of mud.

As a rule, flamingos lay only a single egg and the shoebill one or two. The usual clutch is three or four in ibis and spoonbills, three to six in storks and the hammerhead, three to seven in herons, and four to six in bitterns. There is a tendency for the eggs to be ovoid (*i.e.,* with the ends equally rounded) and to have a white chalky outer layer, underneath which there may be a coloured shell. The colours range from white to pale blue, green, or buff in most groups, to olive brown in the bitterns, and to dark greenish-blue in some ibis. The ground colour of ibis eggs may be spotted or blotched with brown, but the eggs of most others are plain. There are faint or scanty markings in a few.

The chicks are downy when hatched, or quickly become so, but, except for those of flamingos, they remain in the nest, dependent on their parents for food until full-grown. In the herons there is only one down plumage, but in storks and ibis there are two in succession. The downy young of flamingos are gray, with bills and legs that are red at first, but become black within a few days. After the first two or three days, the flamingo chicks leave the nest and move freely about the adjacent part of the colony. As they grow older they are herded in groups by a few adults, but each apparently continues to be fed by its own parents. The bill acquires its specialized form only as the young flamingo grows. Among some other members of the order, there is a tendency for the bill to be shorter and of a more generalized type during the early stage of postnatal development.

So far as information is available for different species, ciconiiform birds first breed when from two to four years old. Parental care is usually shared between the sexes, both taking part in building the nest, incubating the eggs, and feeding the chicks. Bitterns of the genus *Botaurus* seem to be exceptional in that only the female incubates the eggs and tends the young. Feeding is usually by regurgitation. In herons, for example, the parent's bill is seized crosswise by the young bird, and the food is passed sideways to its mouth from between the adult's mandibles. In flamingos, the regurgitated food is of fluid consistency, and the young must continue to be fed in this way until their own filtering apparatus is adequately developed at the age of some two months.

Feeding of nestlings

FORM AND FUNCTION

General characteristics. The carriage of the body is markedly upright in many species, but more horizontal in others. Length of neck and length of legs tend to be correlated; but the chestnut-bellied heron (*Agamia agami*) of tropical America combines short legs with a long neck. In herons, particularly, the neck is curled back on itself at rest but can be instantly straightened on alert or to seize prey.

Long legs and toes are often an adaptation for wading. The toes of herons are long and flexible, with just a hint of webbing for walking or standing on soft ground, the functional hind toe aiding in perching. The hind toe of storks and ibis is reduced and elevated, an adaptation for more walking and less perching. The relatively short front toes of the flamingos are completely webbed and the hind toe small or absent; these birds walk extensively on soft bottom mud. In the herons, and also in the hammerhead, the claw on the middle toes is serrated (pectinate) on its inner border, an aid to preening.

Bill shape. The bill shows various adaptations to methods of feeding (Figure 21). In herons it is typically long, straight, and pointed; although spearlike in appearance, it is used for grasping rather than impaling. In the boat-billed heron (*Cochlearius cochlearius*) the bill is flattened into a broad scoop and is used as such in feeding. In bitterns, both mandibles are finely serrated near the tip. The bill of the hammerhead is relatively short and slightly hooked. The shoebill has a large head with a heavy, bulging, hooked bill; this may be an adaptation to digging lungfish out of the mud but is used also for catching other fish.

In storks, the bill is usually long and strong, as in herons, but not always straight; it may be decurved as in the wood storks, or slightly upturned as in the jabiru (*Jabiru mycteria*) of tropical America. In the two openbills of the genus *Anastomus,* when the mandibles are closed a wide gap remains between their outer portions, except at the tips, probably in adaptation to holding large water snails. The ibis have long, thin, and markedly decurved bills; and in the spoonbills the tip of the long straight bill is flattened and broadened, thus forming a thin spatula.

In the flamingos the bill is bent downward in the middle of its length and has the filtering mechanism already described.

Plumage and coloration. Among the herons, plumages in patterns of blues, grays, and white are common; some, such as various egrets, are all white. In storks, contrasting areas of black and white are characteristic. Some of the ibis are notable for the metallic sheen on the feathers. The hammerhead is of a sombre brown hue. The large bitterns and the tiger herons have cryptic coloration, which is associated with their habit of standing motionless among the reeds with their bills pointing toward the sky.

Ornamental coloration

Touches of bright red on the plumage or on bare parts are not infrequent. A few species have brightly coloured plumage, such as the scarlet ibis (*Eudocimus ruber*) and the roseate spoonbill (*Ajaia ajaja*), both of tropical America, and, in varying degree, the flamingos.

The sexes are usually alike in plumage, or nearly so, exceptions being the little bitterns. The immature may be like the adult or quite different; in the scarlet ibis it is dull brown. Some herons have, in both sexes, long plumes

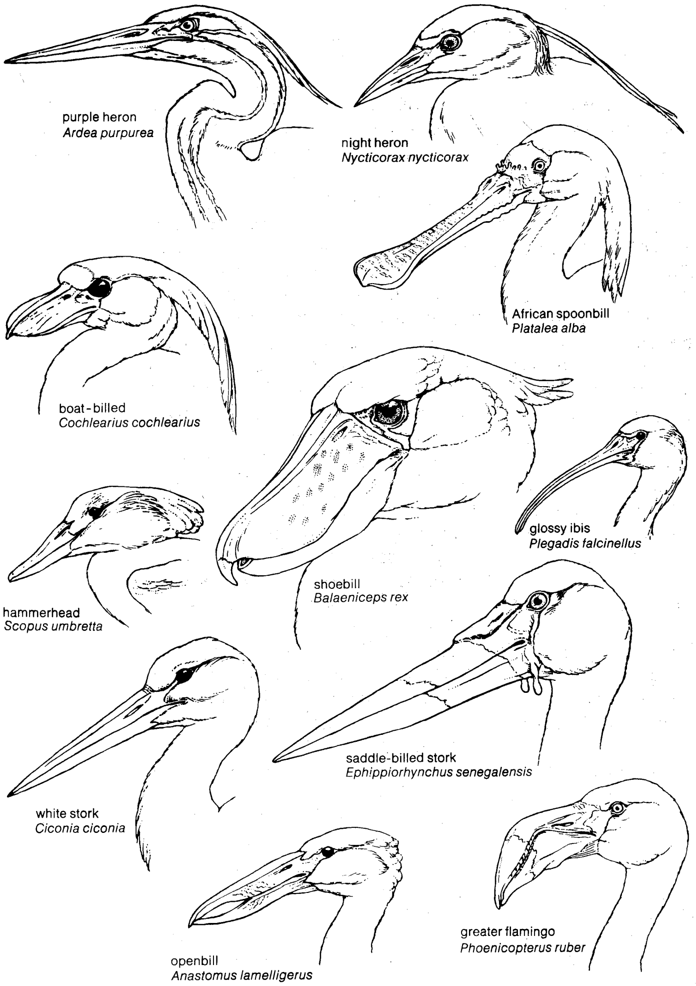

Figure 21: Variation in beak structure among ciconiiform birds.
Drawing by R. Keane

descending from the head, neck, breast, or back, in most only during the breeding season. Some species (*e.g.,* certain ibis, the boat-billed heron, and many typical herons) have crests on the crown or nape. The hammerhead gets its name because the bill appears balanced by an erectile tuft of feathers projecting backward. Patches (two or more pairs) of powder-down feathers are especially characteristic of the herons. These feathers break down to produce a fine powder, which is distributed to the plumage with the bill in preening.

The head and neck are partly or wholly bare of feathers in some species, and the exposed skin may be black, as in the sacred ibis (*Threskiornis aethiopica*), or brightly coloured red in the hermit ibis (*Geronticus eremita*) and others. In the marabou, the head and neck are almost naked and from the front of the neck extends a distensible pouch of pink skin.

Seasonal change in plumage is seen mainly in the shedding of the ornamental breeding plumes of some herons, but there are some changes in the colour of the bill, irises of the eyes, legs, and bare patches of skin during the season of sexual display. At this time the colours become brighter, with a common tendency toward red, and there may even be an intensification of the hue in moments of excitement.

Another characteristic of the herons, notably the egrets, is a tendency to dimorphism, resulting in a population containing both white and slate blue individuals.

EVOLUTION AND PALEONTOLOGY

The Ciconiiformes are generally accepted as being a primitive group. Apart from the equivocal position of the Phoenicopteri, and with possible reservations about *Balaeniceps,* there seems to be little doubt that the order evolved through a single phyletic line. The two main branches of the Ciconiiformes produced both the herons and the storks, with the remaining forms probably nearer the latter.

In the fossil record, the first heron, *Proherodius,* dates from the lower Eocene of England (about 54,000,000 years ago), and other herons from later in the Eocene of North America. The first ibis (*Ibidopsis*) is from the upper Eocene of England and the first stork from the late Eocene or very early Oligocene of France. From the Pliocene of North America (about 7,000,000 to 2,500,000 years ago) there are fossil forms of modern heron genera (*Ardea* and *Nycticorax*) and a modern ibis genus (*Eudocimus*).

The flamingos and their extinct allies have a long record, beginning with *Scaniornis* from the lower Paleocene (about 65,000,000 years ago) in Sweden. The first true flamingo (*Elornis*) is from the late Eocene of England, and another flamingo-like form, *Agnopterus,* from the same level; *Paloelodus* dates from the lower Miocene in France (about 26,000,000 years ago). Fossil families have been named for each of these three extinct genera.

CLASSIFICATION

Distinguishing taxonomic features. The members of the order possess in common, but not exclusively, a number of anatomical characters that are considered to be conservative (*i.e.,* changing only slowly in evolution), indicative of kinship in descent, rather than convergent evolution. These features include the arrangement of the palatine bones, the presence of diastataxy (*i.e.,* the wing apparently lacks a secondary feather associated with the fifth secondary covert, which is present), the presence of intestinal ceca (blind pouches), nearly always minute, the possession of 16–20 cervical (neck) vertebrae, and the presence of only a single pair of sternotracheal muscles in the syrinx (voicebox).

Annotated classification. The following taxonomic arrangement is widely accepted by students of this order. Groups marked with a dagger (†) are known only from fossils.

ORDER CICONIIFORMES

Suborder Ardeae

Family Ardeidae (herons, egrets, and bitterns)

Lower Eocene to Recent. Loose-plumaged wading birds of moderate to large size, most with slim body and long neck; bill usually long, straight, and sharp; legs medium to long, lower tibiae bare; partial web between outer and middle (sometimes also between middle and inner) toes, and hind toes at same level as front toes; claw on middle toe pectinate (*i.e.,* with comblike inner edge). Many with ornamental plumes in breeding season. Adult length 28–142 cm (11–56 in.). About 75 species (and 17 fossil species) usually divided into 2 subfamilies: Ardeinae (typical herons, egrets, tiger herons, night herons) and Botaurinae (bitterns). Worldwide, except in polar regions.

Suborder Balaenicipites

Family Balaenicipitidae (shoebill or whale-headed stork)

A large wading bird, stoutly built, with moderately long neck and short tail. Bill large, broad, and flattened, with hooked tip on upper mandible. Legs long, hind toe on same level as others, claw on middle toe slightly pectinate. Plumage sombre; short bushy crest. Length 117 cm (46 in.). One species, confined to tropical east central Africa.

Suborder Ciconiae

Family Scopidae (hammerhead, hamerkop, or hammerheaded stork)

A moderate-size bird with large head, short neck, rather long wings, and moderate length tail. Bill medium length and laterally compressed, straight, and slightly hooked at the tip. Legs long; toes slender, with partial web connecting front three; hind toe at same level. Plumage brown, substantial crest projecting horizontally from back of head. Length 50 cm (20 in.). Africa, southwestern Asia, Madagascar.

Family Ciconiidae (storks)

Upper Eocene to present. Medium to large wading or walking birds, stoutly built, with long necks. Bill long and massive, straight or curved up or down (or with gap between closed mandibles); legs long, with partial web between middle and outer toes, hind toe smaller and raised. Plumage often boldly patterned in black and white; parts or whole of head bare in some species. Length 76–152 cm (30–60 in.); 21 fossil and 17 Recent species, divided into 2 subfamilies. Ciconiinae (typical storks) and Mycteriinae (wood storks). Worldwide in warm regions, but most species in the Old World.

Family Threskiornithidae (ibis and spoonbills)

Upper Eocene to present. Medium to large wading or walking birds, with long neck and short tail; bill long, slender, curved downward (ibis), or straight and spatulate at the tip (spoonbills). Legs long; front toes slightly webbed at base, hind toe small and elevated. Many with crests; some ibis with whole or part of head and neck bare. Length 48–107 cm (19–42 in.). Seven fossil and about 28 Recent species, in 2 subfamilies. Threskiornithinae (ibis) and Plataleinae (spoonbills). Virtually worldwide in tropics and subtropics, a few species in temperate regions.

†*Family Plegadornithidae*

Fossil only; 1 species; Upper Cretaceous of Alabama.

Suborder Phoenicopteri

†*Family Torotigidae*

Fossil only; 3 monotypic genera; Cretaceous of western Europe and western North America.

†*Family Scaniornithidae*

Fossil only; 1 species; lower Paleocene of Sweden.

†*Family Telmabatidae*

Fossil only; 1 species; lower Eocene of Argentina.

†*Family Agnopteridae*

Fossil only; 3 species; upper Eocene of England and France, and upper Oligocene of Kazakhstan, U.S.S.R.

Family Phoenicopteridae (flamingos)

Upper Eocene to present. Very tall wading (and swimming) birds, with slender bodies, long thin necks, large wings, and short tails. Bill stout, bent sharply down at midpoint, and furnished with lamellar filtering apparatus. Legs very long; front toes relatively short and fully webbed, hind toe small or absent. Plumage mainly white, tinged pink, or light vermilion; face bare. Length 91–122 cm (36–48 in.). Nine fossil and 4 Recent species; shallow lakes and lagoons in tropics; worldwide, except Australasia.

†*Family Palaelodidae*

Fossil only; 8 species, lower Miocene to lower Pliocene; France, Germany, and western United States.

Critical appraisal. There is little controversy about the limits of the order Ciconiiformes apart from the question of whether the flamingos (Phoenicopteri) should be given separate ordinal rank (Phoenicopteriformes). Flamingos have affinities with Anseriformes and Ciconiiformes. There is not much dissagreement about the division into families, except that some place the boat-billed heron (*Cochlearius*) in its own family, Cochleariidae. Apart from the shape of the bill and associated skull modifications, clearly adaptive features, the characters seem to be mainly of the Ardeidae. Superfamilies have been erected from the three families of the Ciconiae; but with only one family in each, the device merely emphasizes their distinctiveness. On the other hand, some do not place the Balaenicipitidae in a separate suborder, but with the Ciconiidae as the superfamily Ciconioidea.

The precise position of the two species in monotypic families has been debated. The strongest affinities of *Scopus* appear to be with the suborder Ciconiae, in which its family is here placed, but it also shows resemblances to the Ardeae and the Balaenicipites. *Balaeniceps* was at one time placed in the order Pelecaniformes, and further osteological evidence tending in this direction has recently been adduced; others attribute the resemblances to convergence. Within the Ciconiiformes, the shoebill has affinities with both the Ciconiae and the Ardeae. (A.L.T.)

Falconiformes (falcons, hawks, vultures, and allies)

More than any other group of birds, the diurnal birds of prey, order Falconiformes, have long interested men. They are often large, conspicuous birds of swift, graceful flight, attracting attention from the smaller birds. Falconiforms compete with man for food by occasionally preying on his domestic stock (though on a small scale). But more significantly, they feed upon pests of human food supplies. Because of their predatory, or raptorial, skill, a few falcons and hawks are used for falconry, mainly for sport, much less importantly to obtain food.

GENERAL FEATURES

Habits and appearance

Falconiforms are seldom abundant but may be common or widespread, occurring in varied habitats. All are diurnal, none truly nocturnal, though several are active at dawn and dusk. With few exceptions they feed on the flesh of other animals, taken alive or found dead. Although some, especially in high latitudes, migrate, most do not. Some, especially large eagles, are of economic importance, preying upon animals maintained by man (sheep, game birds, etc.), eating otherwise noxious carrion, or feeding upon pests of human crops (hares, rodents, game birds, locusts). The low population density of most species indicates that their economic importance is usually exaggerated. They do not feed upon man himself (except when he is dead, in the case of vultures), do not eat babies (as eagles have been accused of doing), and are not important disease vectors.

Falconiforms vary from tiny falconets (*Microhierax*), weighing 35 grams (1.2 ounces) or less, to huge vultures and eagles, with weights up to 14 kilograms (31 pounds), certainly the most formidable avian predators. Structure varies according to hunting methods, type of prey, and habitat. Carrion-eating vultures have broad, soaring wings and weak feet; speedy falcons have bullet-shaped bodies and long, pointed wings; manoeuvrable forest-living species, such as accipiters, some eagles, and forest falcons, have short, rounded wings and long, rounded or graduated tails. The beak is always hooked and is used to tear flesh from prey held in the feet; it may be further modified for special types of food, such as snails or bone marrow. The feet, which are the primary means of killing prey, are exceptionally strong, equipped with long, curved talons, except in the vultures, which feed on carrion. Sight and hearing are highly developed, but the sense of smell is usually poor or absent.

Distribution

Falconiforms occur worldwide, on all continents except Antarctica, and on many oceanic islands. They are found from Arctic to equatorial latitudes, in habitats ranging from almost stark desert to tropical forest, but are commonest and most varied in warm, relatively open country; many, especially in South America, have adapted to forest life. They are never abundant, except locally, where gregarious species may roost or feed together, and are usually dispersed at the rate of a pair to 15 square kilometres (six square miles) or more. Their numbers are not always density dependent on those of food animals, but, where food is abundant, raptor numbers may be limited by territorial behaviour.

NATURAL HISTORY

Life history. Large falconiforms are among the longest lived birds, as shown both by records in captivity and by the slow breeding rates observed in the wild. Where not persecuted, populations of large falconiforms are remarkably stable; breeding rates are presumably adjusted to the mean life span of individuals, taken from hatching. A species that averages two young annually per pair has a mean life span of one year; and one that rears one young every two years, a life span of four years.

Four stages of life cycle

The falconiform life cycle includes four stages, each of which varies mainly according to size—the larger the bird, the longer the stage. Latitude also affects these periods, with longer fledging periods in equatorial than in temperate latitudes for species of similar size.

The fledging period. The fledging period, from hatching to first flight, varies from 23 days in small accipiters to 120–130 days in large eagles and vultures and up to 150 in condors. In this stage the downy nestling develops to adult size (weight increases up to 40 times), grows feathers, and finally flies. It must be fed at first, but before its first flight it learns to tear up prey brought by the parents. Fledging periods are longer, in birds of a given size, in the tropics, probably associated with shorter summer day length.

The post-fledging period. The post-fledging period, in which the young remain near the nest and food is brought by the parents, ends when the young become independent, apparently often of their own accord, not, as in some other birds, in response to increasing parental aggression. They grow no larger, but their flight quills harden. These immature birds are not strong on the wing for three to eight weeks after the first flight. This phase varies from one to 11 months or even more, again mainly according to size, but also showing specific variation. In the crowned eagle, the post-fledging period is nine to 11 months, but in the related martial eagle it is much shorter.

The period as a juvenile. The period as a juvenile, an independent, sexually immature form, is distinguished by various immature and subadult plumages, often very different from the adult. The young raptor flies about, migrates if necessary, kills its own prey, and behaves like an adult except that it cannot breed. This period varies from about nine months in small species, sexually mature in their first year (sparrow hawks, kestrels, and some kites), to four or more years in large eagles and up to seven years in condors. It is usually a period of heavy mortality, particularly in migrant species of temperate climates.

The breeding adult life. The breeding adult life is characterized by mating, nesting, and the rearing of young. Most adults pair. The duration of this phase has been rarely recorded for wild individuals, but a peregrine falcon (*Falco peregrinus*) bred on the Sun-Life Building in Montreal, Quebec, for 16 years. Two female crowned eagles bred for nine and eight years and one male for 13 years.

Life spans of wild raptors may be calculated from banding (ringing) records, from observed changes of mate, and from the percentage of immatures in the population, especially if different ages are recognizable.

Life span

Recoveries of banded birds indicate that 50–75 percent of young raptors die before sexual maturity. The smaller falcons and accipiters apparently average less than three years' total life span, but some individuals may attain 10 to 12 years. Larger species live longer. Ospreys and buteos may average eight to 10 years but have higher mortality rates (75–80 percent in the first year). Life spans of more than 20 years have been recorded from both groups, but the longest known life span among wild falconiforms is that of a red kite of 26 years.

In certain large falconiforms, differences in plumage due to age and individual variation allow an observer to recognize individual birds. Since large eagles mate for life, it may be assumed that a change of mates indicates that one of the pair is dead. L.H. Brown has found that in crowned eagles (*Stephanoaetus coronatus*) such changes occur every six to seven years, giving a mean adult life of 12–14 years or 16–18 years when the four years prior to maturity are included.

In many species immature birds are easily distinguished from adults, and the percentage of immatures in the population can be related to assumed mortality before sexual maturity and to the number of years before adulthood, allowing an estimate of the average age of adults. Immatures comprise about 30 percent of the population in the bateleur (*Terathopius ecaudatus*), 18 percent in the lammergeier (*Gypaetus barbatus*), and 16–25 percent in the African fish eagle (*Haliaetus vocifer*). With about 75 percent loss during the period of immaturity and the acquisition of adult plumage at seven, five, and four years, respectively, the mean adult life span in these species may be estimated at 23, 27, and 18–24 years.

Such methods provide, at best, an informed estimate and the potential life span is rarely, if ever, attained in the wild state. In captivity many large raptors live for over 30 years, eagles and vultures for 40–50 years. A bateleur, at 55, is the oldest acceptable record; records of 60 or more years are poorly documented.

Behaviour. Falconiforms hunt by sight in daylight and normally roost on a perch, a tree branch, a rock ledge, or occasionally (harriers) on the ground in long grass. A few, including some falcons and sparrow hawks, are active at twilight; in fact, the bat hawk (*Machaerhamphus alcinus*) catches all its food in about half an hour at dusk. The only species actually recorded feeding at night are certain Indian vultures (in moonlight on tiger kills). Most raptors sleep all night, with head buried in the feathers of the back or hunched upon the shoulders.

General activity

Activity may begin soon after dawn with short "warming-up" flights, serious hunting beginning later. Some accipiters commence hunting at daybreak, when their avian prey is most active. Large, heavy species, however, do not usually start hunting or foraging until some time after dawn. Large vultures are unable to fly until updrafts are generated by thermal activity, but smaller species are able to fly soon after dawn. Certain specialized types with flapping flight, such as harriers, can fly equally easily at any time of the day. Bateleurs get on the wing early and fly most of the day, travelling perhaps 200–300 air miles on most days; however, very large species such as eagles and vultures probably fly for no more than four to six hours a day.

Before the day's flight, a raptor usually preens, casts, and defecates. Castings are regurgitated indigestible balls of fur, feathers, insect hard parts, etc. Preening is performed mainly with the bill, but falconiforms also scratch with their formidable talons. They frequently "rouse," fluffing out and shaking all their feathers.

Hunting and feeding

Many falconiforms hunt daily, others every few days, feeding in the interim on the remains of their kills. Killing frequency depends on appetite and the size of the animal killed; a kestrel consumes many grasshoppers per day, a crowned eagle one suni antelope (about four kilograms; eight pounds) every three to four days. Appetite and crop capacity permit ingestion of several days' ration at a meal, and larger species can go without food for long periods without ill effect. With rare recorded exceptions, falconiforms will not hunt unless hungry and do not kill wantonly. Many species hunt from perches, flying from one to another. Others hunt on the wing, soaring or hovering at up to 100 metres above the ground or water. One species, the secretary bird (*Sagittarius serpentarius*), is mainly terrestrial, and several others (chanting goshawks, honey buzzards, and the spotted eagle) walk about on the ground. The honey buzzard digs out wasps' nests. One species, the Egyptian vulture (*Neophron percnopterus*), hurls stones with its beak to break ostrich eggs.

In warm climates, hunting time may be short, one to two hours in 24; in temperate winters, when prey is scarce, it occupies up to five to seven hours. When not hunting, falconiforms loaf on perches or soar, sometimes at great height. Vultures or eagles encountered soaring very high up are not hunting, especially when their crops are full.

Roosting

Toward evening a falconiform may return to a regular roosting place or may settle for the night where it is.

Drawing by R. Keane

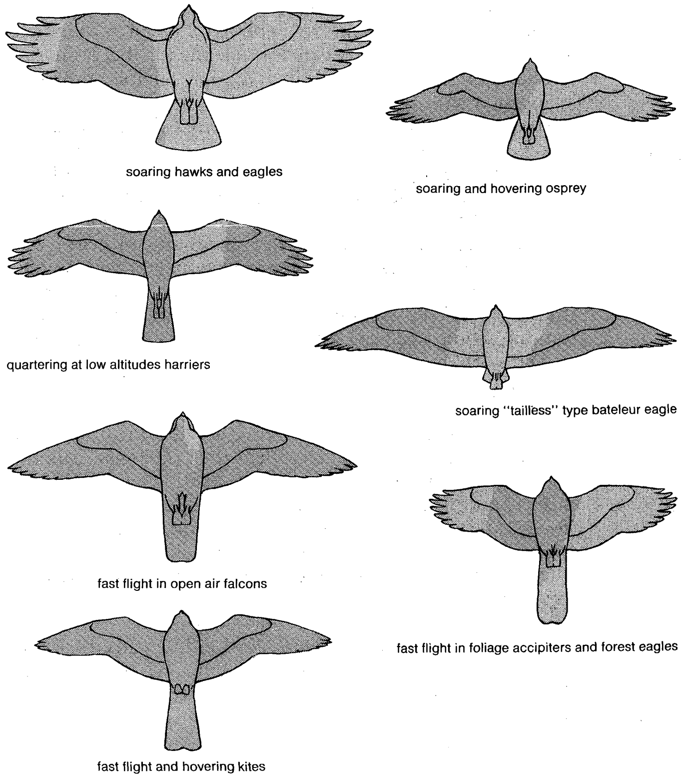

Figure 22: Modifications for specialized types of flight among falconiforms.

Vultures often return nightly up to 100 miles to regular roosting cliffs or trees. In many less active species, the roost is in the same general area as the nest. Members of a pair separated all day may rejoin at roosting time, and gregarious species (vultures, kites, and some others, such as the red-footed falcon) are most gregarious at roosts. Prior to settling to sleep, the bird usually preens again, but activity is reduced once the bird has settled on the perch for the night. Finally, when light fails, the raptor falls asleep on its perch and remains thus without moving until the following morning. If disturbed at night, however, it can fly well enough to save itself but will not travel any distance.

Locomotion. All falconiforms fly well, some excellently. Few hunt on the ground, but all can walk or hop. With one exception—the secretary bird—flight is the most important method of locomotion. Modes of flight include flapping, gliding, soaring, or diving (stooping) and are used to locate and kill prey, move from perch to perch, or migrate. Adaptations for swift or slow flight, mainly associated with habitat or type of prey, are varied.

All species can use flapping flight, but it is laboured in heavy species (vultures, condors). Most use it only to get under way or to move from perch to perch, thereafter gliding, hovering, or soaring. Harriers sustain flapping flight, interspersed with short glides, for long periods as they hunt small animals in open, grassy country. This also assists them to migrate across open water, usually avoided by soaring species because of the lack of thermal updrafts. Accipiters accelerate in pursuit by rapid flapping flight, and many other species travel short distances by flapping alternated with gliding, especially when air currents are lacking.

All of the large species are adapted for soaring flight and even accipiters, swift falcons, and the secretary bird can soar well. A typical soaring wing is rather long and moderately broad; *i.e.,* of low aspect ratio. High-aspect-ratio wings (long and extremely narrow), found in seabirds, would presumably be inconvenient to falconiforms, which often require manoeuvrability in tight spaces. The wing usually has the outer four to six primaries more or less emarginated on one or both webs, forming at the spread wing tip slots that reduce turbulence, and permitting each feather to bend as an individual airfoil under a differential load, thereby increasing lift. Such a wing is typical of eagles, buzzards, vultures, and kites. In a few species (Indian black eagle, African harrier hawk), the primaries are long, soft, slightly emarginated, and flexible, probably associated with slow flight.

Soaring on updrafts

The ability to soar and circle in thermals is controlled by wing loading (the ratio of weight to wing area). The higher the wing loading, the larger the turning circle and the larger the thermal "bubble" required for soaring to gain height. Smaller species (*e.g.,* the black kite), with low wing loadings, can utilize smaller thermals than can heavy vultures. Wing loading increases proportionately with weight (as the cube of body size) while wing area increases as the square. The general rule is varied by specific adaptations. Some species (lammergeier, harriers) have much lower wing loadings than others of similar weight and have more buoyant, easy flight. In soaring flight, forward velocity is attained by gliding, with the aid of gravity; the bird mounts on rising air. Increasing the angle of glide increases speed until, in a vertical dive (falcons), it is believed to attain 160–240 kilometres (100–150 miles) per hour. Some species (bateleur, lammergeier) are specialized for gliding, almost without wing flapping. Bateleurs glide at an airspeed of 55–85 kilometres per hour for much of the day; they have long wings and very short tails, steering by sideways tilting, or canting. Lammergeiers glide rather slowly, assisted by long, diamond-shaped tails.

Falcons, especially the large bird-killing species (peregrine, gyrfalcon, lanner, etc.), have heavy, bullet-shaped bodies and long, pointed wings; their high wing loading provides high diving speed. They often attack in the air and in a dive can overtake species that would easily evade them in straight flapping flight. Few eagles are as swift, but many combine distinguished soaring and gliding ability with swiftness and agility in attack upon prey.

Walking and hopping

On the ground falconiforms progress by walking or hopping; in especially large vultures hopping is elaborated into bounding threat displays. On a branch they move sideways by sidling or by walking "hand over hand" (vulturine fish eagle, harrier hawk). On the ground eagles walk slowly and deliberately. African harrier hawks and South American crane hawks have long, slim legs that can bend somewhat backward at the tarsal joint, permitting the attainment of peculiar situations and enabling the birds to probe cavities.

The secretary bird is the only primarily terrestrial species. It flies only to move from place to place or in display but nevertheless has been seen soaring at 4,000 metres. It walks with a rapid, steady pace, head jerking to and fro, varying this regular progress with bouts of quick stamping steps, to flush possible prey. It has short toes (like the gruiform bustards) and long, cranelike legs, suited for rapid walking over long distances. It roosts in trees but descends to the ground to hunt soon after daybreak.

Reproduction. Many falconiforms pair for life; others, notably migrant species, may pair anew each year. Occasionally, immatures pair with adults, but usually only sexually mature individuals attempt to breed. Immatures, however, often perform typical display movements and a pair bond may be formed between an adult and an immature, but the latter may be replaced by an adult if one should appear.

The breeding pattern follows the usual sequence of nuptial display, nest building, incubation, fledging period, and post-fledging period. The length of the breeding period varies from about three months in the smallest species to over 15 months in condors, crowned eagles, and probably harpy eagles. No species regularly produces two broods in a season, but second broods have been recorded, even in some large species. Some nomadic species, such as the elanine kites, may breed more often in response to, for instance, high local rodent populations.

Nuptial displays are often spectacular, sometimes inconspicuous. The common forms are: calling from a perch; calling from soaring flight; undulating flight, diving, and swooping up, often with loud calling; mutual displays, in which the male dives with lowered feet at the female, who turns over and raises her claws to his; rarely, cartwheeling, in which the pair lock feet and descend in whirling flight (*e.g.,* some eagles and kites). Most species perform several types of display, but species inhabiting woodland or forest display more often and more vociferously than related species of open country.

Nesting

Most species build nests on trees, ledges of cliffs, or, rarely, on the ground. All Accipitridae, Pandionidae, Sagittariidae, and the caracaras construct nests, usually of sticks. The Cathartidae and the remaining Falconidae (forest falcons, falconets, and true falcons) do not make nests but use a hollow tree, another bird's nest, or a scrape on a ledge. Constructed nests vary from small structures of twigs and vines (*Aviceda*) to enormous, annually augmented piles of sticks (many eagles). Small species usually build a new nest annually; large species tend to return to, and repair, an old nest. Imminent occupation is usually indicated by fresh green material, which continues to be added until late in the fledging period but does not necessarily mean that eggs will be laid. The same site, but not always the same nest or ledge, may be occupied for several years, generations, or centuries. Some large eagles use the same nest for 50 years or more, others haphazardly use several alternates.

Many species lay only one egg; few lay more than four. The largest clutches are laid by small falcons and accipiters of temperate latitudes and by ground-nesting harriers. Clutches of related species are smaller in the tropics than in high latitudes. The eggs are laid at two- to four-day intervals, incubation beginning with the first egg. Falconiform eggs are rather large for the size of the birds and are usually rounded ovals, white or greenish, more or less heavily spotted, occasionally completely covered with brown or red-brown pigment. In Carthartae the colour of the inside of the shell is yellowish white; in Accipitridae, Sagittariidae, and Pandionidae it is green or blue green; and in Falconidae, buff or reddish. Incubation, usually by the female alone (the male sometimes takes a share), occupies from 28 days in small falcons to 50 days or more in large vultures. Buzzards (*Buteo*) incubate for 30–35 days, though some are larger than small eagles with incubation periods of 45 days.

The eggs hatch in the order in which they were laid. By the time the last egg has hatched, the first-hatched chick may have tripled its weight and may kill its sibling, either directly or through competition for food. Newly hatched chicks are covered in natal down, later replaced by a thicker, woollier coat; at this stage parental brooding is reduced by day. Feathers erupt during the fledging period and almost cover the nestling at midpoint. At this stage most young learn to tear up their own prey.

Fledging

Parental attention is steadily reduced, from continuous brooding day and night to leaving the feathered young entirely alone except for brief feeding visits. The young make their first flights unaided by parental coaxing. The adult roles are usually clear-cut. In the early fledging period, the male kills for himself, his mate, and the brood doubling or trebling his previous killing rate. When partly feathered young can tear up their prey, the female no longer stays near the nest but hunts and thereafter brings more prey than the male.

After their first flight, the young remain near the nest for several weeks or months. They are provided with food by the parents but may also learn to kill. The longest known post-fledging periods are in crowned eagles and condors; in the crowned eagle the young remains dependent for nine to 11 months, and this species normally breeds only every second year.

Especially in large species, breeding does not necessarily occur annually. The number of young reared per pair per year varies from 2.5 to three in small falcons and sparrow hawks of temperate climates to 0.4 or even less in some tropical eagles and vultures. Breeding success, like clutch size, tends to be lower in related species in the tropics than in temperate zones. Low breeding success may fluctuate with adverse winters, poor food supplies, or even territorial behaviour in crowded habitats.

Ecology. Falconiforms prey on small animals or eat carrion; the vulturine fish eagle, however, feeds mainly on oil palm fruits.

Food supplies exert a general influence over populations, but it also seems that when food is superabundant the population does not rise proportionately. In the Scottish golden eagle, the home range of a pair is about 4,400 hectares (11,000 acres), irrespective of food abundance. A breeding pair of raptors apparently maintains a territory containing much more food than it can possibly utilize. In some cases such home ranges are maintained by aggressive behaviour; in others the precise method is obscure. In colonial vultures no home range is maintained, and the only defended territory is the few yards round the nest.

Food requirements

From a combination of factors a reasonably accurate estimate of the minimum daily food need for a raptor can be made. The amount of kills wasted (varying from less than 5 to 20 percent by weight, according to type of prey taken) is added to the minimum daily food demand, to determine the amount that must be killed to maintain a pair and their young for one year. For example, if a falconiform weighs 1,200 grams, has a mean food requirement of 8 percent of bodyweight, eats 96 grams a day and 36 kilograms each year, and feeds on birds, involving waste of about 15 percent of all kills, it must kill 41 kilograms of prey each year to fulfill its needs.

Individuals of one species do not usually tolerate others of the same species in their home breeding range. The same area, however, may support several other species, preferring different types of prey and so not competing with one another. In an area of varied habitat, up to 20 different species may occur (even more with migrants), exerting a much greater and more complicated, but still broadly quantifiable, pressure on populations of available prey. Closely related groups may show ecological separation. For example, some African vultures feed in groups upon the soft flesh and intestines of preys, while others tear at sinews and hide or snatch meat from other species. Smaller vultures pick up scraps or use their slender beaks to reach cavities inaccessible to birds with heavier beaks. All these birds may feed together at the same carcass, but without competing for food, though individuals of each species maintain a dominance hierarchy by aggressive movements to each other.

In the Arctic only the gyrfalcon does not regularly migrate but subsists on wintering ptarmigan. In summer several other species arrive, but so do many species of prey, and lemmings multiply, greatly increasing food supplies. In African savannas and southern Indian rice fields, resident falconiform populations are greatly augmented in winter by migrant populations of buzzards, kites, harriers, and small falcons. This sharply increases the total predator pressure on prey populations, but it does not appear that this influx of migrants has any adverse effect on the resident populations, which may be breeding while the migrants are present.

In most cases it appears that falconiforms have a slight or negligible effect on prey populations. The annual needs of resident species may vary from $^1/_{20}$ to $^1/_{1,000}$ or even less of available prey. In migrant winter populations, the effect, locally, may be much greater than in resident breeding populations. The availability or visibility of the prey also plays a part. Among the food of the European sparrow hawk (*Accipiter nisus*), conspicuous or gregarious birds of open ground are more often killed than inconspicuous skulking species. Prey risk (the likelihood of an individual's being killed) is increased by low prey numbers, reduced cover, and behaviour that exposes the animal. The total effect of falconiforms on their prey is compounded of their own behaviour and that of the animals they feed upon.

IMPORTANCE TO MAN

Beneficial effects

Most falconiforms are directly beneficial to man—feeding on pests or carrion—or neutral—feeding on animals and birds that do not directly affect man. A few species, usually large, spectacular, and uncommon (larger eagles, falcons, and accipiters), may prey on man's domestic stock or poultry or on game birds or fish. In East African grasslands about 86 percent of falconiforms are beneficial, 11 percent neutral, and only 3 percent potentially harmful. Such figures vary from one region to another, but potentially harmful species are always in the minority. It is the more regrettable that, because of ignorance and unreasoning prejudice (especially in the more advanced areas such as North America, Europe, and Australia), beneficial, neutral, and potentially harmless species are all indiscriminately destroyed, even rendered extinct locally.

Detailed quantitative studies invariably have shown that the harm done to man's interests by any falconiform has been grossly exaggerated; even the supposedly harmful species often kill other potentially harmful species (*e.g.*, crows, rats, mustelids). The predation effect of any species is relatively small in relation to the total number of potential prey in any home range. Moreover, even in potentially harmful species, few animals of potential or actual interest to man are taken. In the African fish eagle and Scottish golden eagle, the population may take a fraction of 1 percent of the human fish catch or of the lambs available in an average home range. In North America and Australia, where large eagles have been destroyed on a greater scale than elsewhere, persecution is not based on even rudimentary assessment of the eagles' diet and appetite. Damage to human interests is worst under poor management conditions; for instance, when unfed poultry are on free range or weak lambs live on overgrazed pasture. In rare cases, such as where hatchery trout or reared pheasants are unnaturally concentrated, individual hawks or eagles may have to be controlled when damage is proved; but this is no excuse for wholesale persecution of a species.

Entirely beneficial species include vultures, elanine kites, kestrels and other small insectivorous falcons, most buzzards (*Buteo* and related species), and many small eagles. Neutral species, such as snake eagles and chanting goshawks, can safely be ignored. Objective analysis of the predation situation indicates that diurnal raptors deserve protection except where extensive damage can be proved. Extensive damage is frequently claimed without proof; for instance, in the southwestern United States, where the golden eagle has been persecuted for alleged damage to sheep, improbable in any event and impossible on the scale claimed.

A few falconiform birds have been trained to secure game animals for man, either for sport or to provide food.

Need for protection

Falconiforms need no protection except from man. Conservation problems, therefore, mean conserving raptors living in or passing through inhabited areas. Undoubtedly the main difficulty is ignorant prejudice against falconiforms by educated, civilized man, which is seldom found, much less effectively exercised, in more primitive human communities. A recent threat, since 1950, is the persistent effect of highly toxic agricultural chemicals (DDT, dieldrin, etc.)—again, the product of civilized man. Positive conservation of falconiforms must include the control of habitat destruction; of active persecution by shooting, trapping, poisoning, and collecting of eggs of threatened species; and of the widespread toxic effects of persistent agricultural chemicals.

Agricultural communities destroy some types of habitat, especially forests, but create others in the process. In Africa, for instance, some forest falconiforms may be eliminated, but much larger populations of adaptable species such as black kites, hooded vultures, and long-crested eagles may move in. The effect of agriculture is not always detrimental, especially when a mixed landscape of forest and open country results. Before the advent of chlorinated hydrocarbons, the peregrine was most numerous in Britain in habitats close to agricultural areas with high populations of avian prey. A sparse population of rural cultivators may have no appreciable effect on a mixed population of falconiforms over long periods of time.

Overcollecting for zoos and museums, and for falconry, has severely affected some species. The behaviour of the few individuals who collect the specimens or eggs of threatened species for commercial purposes must be controlled. In a few instances, chiefly of island species such as the Philippine monkey-eating eagle, this is urgent.

Effect of pesticides

Toxic agricultural chemicals are the most difficult of conservation problems because of their subtle and widespread effects (affecting even migrant populations of some hawks that breed in uninhabited areas) and the benefits they confer on human food supplies. The best hope, other than new developments of less toxic substances, is realization of the probably serious overall effect of these long-lasting poisons in contamination of the whole environment. If, as appears likely, the chemicals eventually will adversely affect man himself, control of the use of these chemicals will follow; and the falconiforms will benefit indirectly.

FORM AND FUNCTION

The main distinguishing characters of falconiforms are: the hooked beak, used for tearing flesh; taloned feet, used for piercing, grasping, and killing prey; and large eyes, with very acute vision. The hooked beak and taloned feet are shared with the unrelated owls, which show similar or parallel evolution. In the falconiforms themselves, parallel evolution for scavenging is shown by the New World vultures (Cathartidae) and the Old World vultures (Accipitridae).

Parallel evolution

Size and weight. Most falconiforms are large. Extremes are the Andean condor (10 to 14 kilograms, wingspan three to 3.35 metres) and the tiny eastern falconets (*Microhierax* species; 35 grams or less). Many species range from 400–2,000 grams in weight. Females are normally 20–100 percent larger than males, especially in bird-killing falcons and accipiters. In vultures, however, the male is normally 10–15 percent larger.

Plumage and molt. Falconiforms are bulky, heavily feathered birds, lightweight in relation to their apparent size. The first plumage is usually white or gray down, the prepennae. The preplumulae, or second down, grows through the first after days or weeks and is itself superseded by feathers erupting from the prepennae follicles. The latest feathers to develop fully are wing and tail quills, which are large, strong, and often especially adapted.

The immature plumage, presumably representing a primitive type, usually differs markedly from the adult. Adult dress is acquired by a series of molts with, in large species, several intermediate or subadult stages. Immatures usually are brown and streaked or spotted; adults may be more brightly coloured. The sexes usually are alike in plumage. In some island species—*e.g.*, the Madagascar cuckoo falcon (*Aviceda*)—the plumage type found in the immature persists in adult life.

Plumage is replaced by a molt lasting four months to several years, slower and more irregular in larger species. Wing quills are molted in definite sequence. In many Accipitridae molt begins with primary feather number 1 (innermost) and proceeds in regular sequence to number 10 (outermost). In falcons it begins at primary feather 4 and proceeds both ways, outward and inward. Large species tend to replace quills irregularly, perhaps because their greater wing loading would make the lack of several adjacent quills disadvantageous.

Vision, hearing, and smell. The eyes are globose and move little in their sockets. To see behind it, a falconiform must rotate its head. The focal length is adjustable by muscles controlling the curvature of the lens. Forward binocular vision is through 35–50° of arc. The proverbially high resolving power of hawks' eyes depends partly on a large image on the retina, partly on the concentration of rods and cones. There are two foveae (areas of high visual acuity), one laterally directed for monocular vision, the other forward, for binocular vision; in each fovea the visual cells are still more concentrated, providing resolving power up to eight times that of the human eye. There is a screenlike pecten, which may cast a lattice-like shadow on the retina, permitting good perception of shape of moving objects. The iris in many adults is yellow, red, or orange.

Hearing is good, but not especially acute. The ear apertures are large and in harriers and forest falcons are above average size and surrounded by especially modified feathers, forming partial facial ruffs. The forest falcons live in dense woodlands and are seminocturnal, and the harriers hunt small mammals in long grass, both situations where unusually acute hearing would be advantageous.

Except in the New World vultures, which occasionally use their sense of smell to locate food, the olfactory chambers are poorly developed. The sense of smell is normally rudimentary and less important than sight.

Feet and bill. These appendages comprise the main killing and feeding adaptations distinguishing birds of prey. The exact structure of the bill varies according to prey eaten (see Figure 23). Falconidae and some insectivorous kites have notches or teeth on the cutting edge of the beak. In falcons these assist in breaking the necks of prey, but their purpose in kites is obscure. In Old World vultures the bills vary, permitting ecological separation while at food.

Killing of prey

Prey is normally killed with the feet. Three toes are directed forward, one behind. The hind toe is usually heavier and longer taloned than the others. In the osprey the outer toe is reversible, for more effective handling of fish. Fish-eating falconiforms have sharp spicules on the soles of the toes to grasp slippery prey. The feet may vary from long, slim toed, needle taloned (bird killing, as in accipiters) to short, thick toed (snake grasping, *Circaetus*) or heavy toed, with thick, strong talons, capable of paralyzing medium-sized mammals. In Old and New World vultures, which seldom or never kill, the feet lack long sharp talons.

EVOLUTION AND PALEONTOLOGY

Falconiforms have no obvious evolutionary links with other birds. Currently they are placed between ducks, on the one hand, and game birds on the other; but they bear no clear resemblance to either, while fossil evidence does not indicate intermediate links. The most obvious physical specializations of falconiforms—the cutting, tearing bill and taloned feet—do not indicate close relationships with owls but are due to similar trends in evolution, though some recent anatomical work indicates that owls and the family Falconidae may be more closely related than was at one time thought.

Fossil falconiforms

Rather few fossils of falconiforms have been found, and those that have may repay re-investigation. A generalized type is known from the Eocene (50,000,000 years ago). The oldest known raptorial bird, *Lithornis,* of the upper

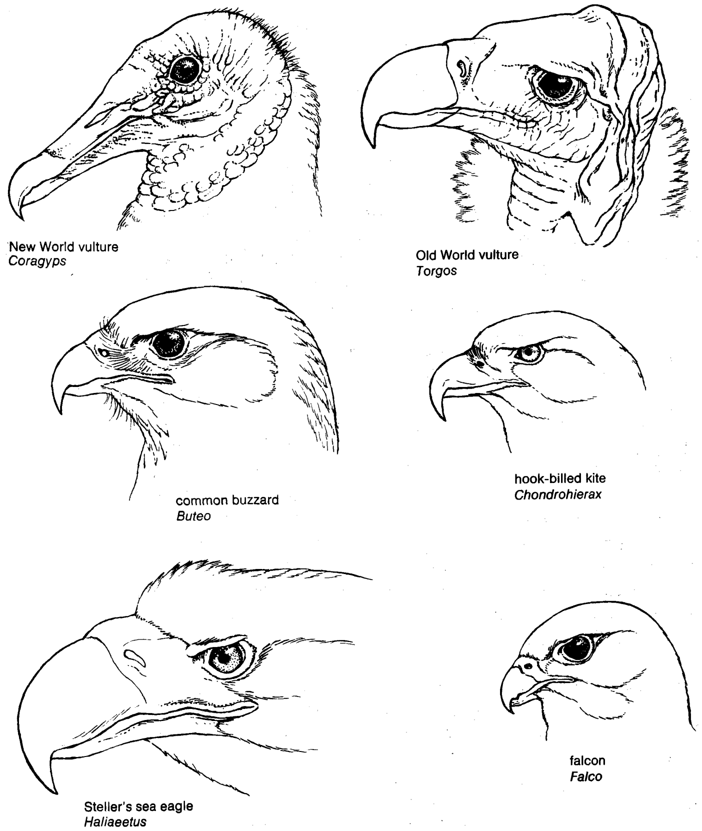

Figure 23: *Heads of some falconiforms.*
A New World vulture, *Coragyps,* with a weak beak for carrion eating; an Old World vulture, *Torgos,* with a stronger beak for tearing at larger animals; a buzzard, *Buteo,* with a simple raptorial beak for killing and eating small mammals; a hook-billed kite, *Chondrohierax,* with a strongly hooked beak for eating snails; a sea eagle, *Haliaeetus,* with a deep, narrow beak of uncertain adaptive value; a falcon, *Falco,* with a toothed beak for shearing and plucking feathers.
Drawing by R. Keane

Paleocene, may have been a cathartid vulture. The Cathartae may have evolved in the Old World, dying out there and surviving only in the New World. Fossil New World vultures include a large terrestrial species, *Neocathartes grallator,* and a huge vulture, *Teratornis merriami,* from the Rancho La Brea tar pits in California. Because of their apparently ancient origin, cathartids may be regarded as primitive survivors.

The secretary bird is thought by some to be a descendant of formidable terrestrial predators, *Brontornis, Mesembryornis,* and *Diatryma.* These also may have evolved into the South American Cariamidae, which accordingly may be more closely related to the secretary bird than are the latter to other falconiforms.

Such evidence as there is indicates that the falconiforms diverged from their ancestral types 20,000,000 or more years ago, and that relationships with other groups have since become obscured. Certain evidence suggests that the order is polyphyletic in origin; however, their Mallophaga (feather lice) are similar throughout, and this question must remain unanswered until extensive additional information is available.

Functional specialization

Among present-day falconiforms adaptive radiation has led to the development of certain climax types in apparently not very closely related birds. For instance, in Australia, buzzards (*Buteo*) are absent, but certain large kites have evolved to fit this ecological niche. In South America the buzzard-like harpy eagle represents a climax of one line of evolution, filled in the Old World by large booted eagles such as *Stephanoaetus.* There has been much adaptive specialization for particular function in unrelated species; for instance, in the bullet-like shape of falcons, in the spiculed feet of ospreys and certain eagles, and, perhaps most striking, in the auditory specialization of the harriers and the forest falcons.

CLASSIFICATION

No entirely satisfactory system of classification of the order Falconiformes has been agreed upon. Two rather different systems have been proposed, and much work is needed on several outstanding problems.

Distinguishing taxonomic features. The main features of falconiforms include the hooked "raptorial" bill; the basal cere, or bare skin, covering the nostrils; the powerful feet with hooked claws; sustained powers of flight and carnivorous habits; and difference in size between the sexes. Some suborders or families have additional characters: the Cathartae have pervious nostrils (*i.e.,* incomplete partition between nostrils) and a rudimentary hind toe; Pandionidae, a reversible outer toe; Sagittariidae, long legs with short, blunt toes; and Falconidae, toothed beak, sharply pointed wings, and a noncentrifugal wing molt.

On the basis of inside eggshell colour, the order may be divided into three rather distinct groupings or suborders: the Cathartae, the Accipitres (with the secretary bird and osprey), and the Falcones. Biochemical analysis of egg-white protein tends to support these groupings and suggest that all are rather more closely allied to one another than to other groups of birds, even though there are some similarities with apparently unrelated orders, such as Procellariiformes. Egg-white proteins also indicate that cathartids are all closely interrelated and that they are related to Accipitridae. The Accipitridae are all rather closely related, though the egg-white patterns of Old World vultures and some kites indicate divergence. The egg-white patterns of Falconidae indicate close relationship within this family, but less close affinities with other falconiforms.

Annotated classification. The classification of L.H.

Drawing by R. Keane

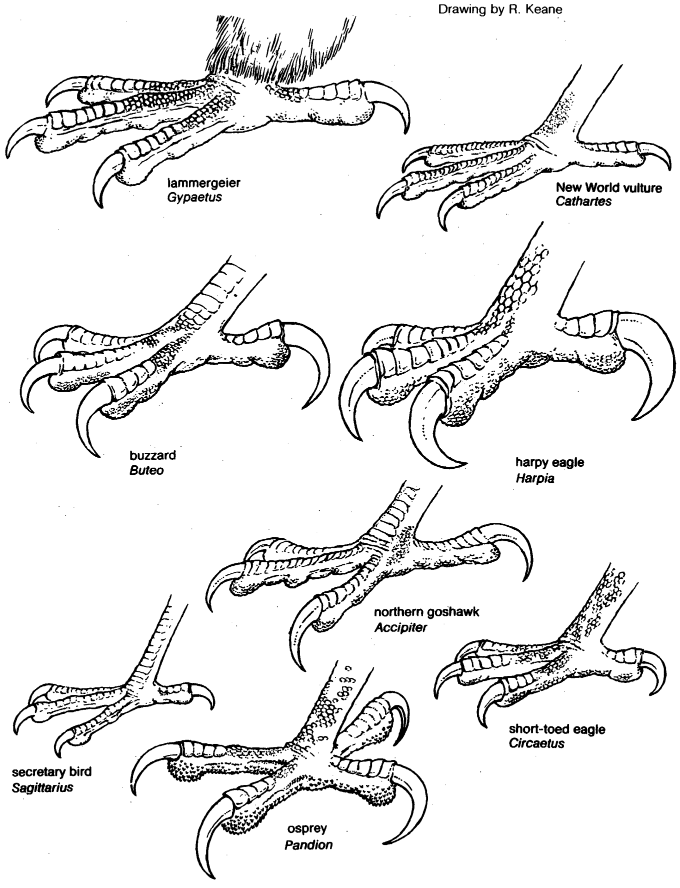

Figure 24: *Specialization of the feet of falconiforms.*
The moderately powerful foot of the lammergeier (*Gypaetus*); the weak foot of a New World vulture (*Cathartes*); the generalized raptorial foot of a buzzard (*Buteo*); the extremely powerful foot of the harpy (*Harpia*); the foot of a bird-catching accipiter (*Accipiter*), with long toes and talons; the fish-gripping foot of the osprey (*Pandion*), with reversible outer toe and rough spicules on the soles; the foot of the short-toed eagle (*Circaetus*) for gripping snake; the foot of the secretary bird (*Sagitarius*) adapted for walking.

Brown and D. Amadon, 1968, which is given below, was based upon that in J.L. Peters' *Check-List of Birds of the World,* modified as necessary in the light of modern knowledge. The main divergent view has been that of E. Stresemann, which was based largely on the sequence of wing molt and departed strongly from the order of Peters and from Brown and Amadon. Those groups indicated below by a dagger (†) are known only from fossils.

ORDER: FALCONIFORMES

Suborder Cathartae (New World vultures)

Nearctic to Neotropical. Seven existing species; fossils dating back perhaps to Eocene.

†*Superfamily Neocathartoidea*

One family, Neocathartidae. Fossil Nearctic, including *Neocathartes grallator,* differed from other Cathartae in having terrestrial habits.

Superfamily Cathartoidea

Pleistocene fossil and present-day species, Nearctic and Neotropical, perhaps formerly Palearctic.

Family Cathartidae (New World vultures). Seven present-day Nearctic and Neotropical species and Pleistocene, Nearctic, and neotropical fossils. Pervious nostrils, rudimentary hind toe, large olfactory chambers. Large or medium sized (1.5–14 kg; 1.2–3 m wingspan); do not build nests; inside egg colour yellowish.

†*Family Teratornithidae* (teratorns). Very large-sized fossil Pleistocene species, including *Teratornis merriami* (estimated about 22.5 kg; 4.3 m wingspan) and still larger species.

Suborder Accipitres

Superfamily Accipitroidea

There are 207 worldwide existing species, small to large, and many fossils.

Family Pandionidae (osprey). One species, *Pandion haliaetus,* nearly worldwide, present-day; large, weight 900–1,500 g; wingspan 135–175 cm; resembles some kites in similar sternum and absence of bony eye shield; reversible outer toe, with talons rounded, not grooved; green inside eggshell; squirt droppings; littoral; builds own nest.

Family Accipitridae (kites, hawks, buzzards, harriers, eagles, Old World vultures). There are 206 species, worldwide, but some subgroups—*e.g.,* Old World vultures—confined to Europe, Asia, and Africa. Small to very large (100 g to about 10 kg); many adaptive radiations; forest or open country. In all, inside eggshell green; strong hooked talons in all but Old World vultures; squirt droppings; build own nests.

Superfamily Sagittaroidea

Family Sagittariidae (secretary bird). One species, *Sagittarius serpentarius,* central Africa; present-day, with some doubtful fossils. Large (weight 3.4–3.8 kg; wingspan 1.5–2 m); terrestrial, long legged, short toed; in nesting and display resembles Accipitridae. Inside eggshell green but certain other characters indicate affinity with South American Cariamidae (order Gruiformes). Usually accepted as falconiform but may not be.

Suborder Falcones

There are 61 worldwide species, present-day and fossils. No superfamily designations; the order comprises only 1 family.

Family Falconidae (caracaras, milvagos, forest falcons, falconets, and true falcons). Some genera (*Polyborus, Daptrius, Herpetotheres, Milvago, Micrastur*) confined to New World, and others (*Microhierax*) only Oriental; very small to medium sized (35–1,800 g). Resemble Accipitridae in hooked beaks, talons, sexual dimorphism, etc.; differ in molt sequence, some anatomical characters, behaviour (droppings fall below perch; head bobbing in some; in all but caracaras no nest made); inside eggshell reddish.

Critical appraisal. Stresemann's classification of present-day falconiforms differed from the one given above in being based almost exclusively on the order of wing molt, classified in three ways: (1) beginning with primary number 4 and proceeding inward and outward from there; (2) "descendant," beginning with primary number 1 and working outward to the wing tip; (3) "irregular," with no clear sequence. The third category can again be subdivided into types that molt "descendant" (number 2 above) in juvenile molt and irregularly in adult plumage, and others that molt irregularly in all stages of plumage.

On this basis the order Accipitriformes of Stresemann (*cf.* Falconiformes of most authors) was divided into three suborders, Cathartae, Accipitres, and Sagittarii. The suborder Cathartae contained the New World vultures (*e.g.,* Cathartae of Brown and Amadon); the Accipitres included all those species included by Brown and Amadon in their suborders Accipitres and Falcones, with the exception of the secretary bird, Sagittariidae. Stresemann places the secretary bird alone in a separate suborder, Sagittarii. He thus included all but eight species of present-day falconiforms in the suborder Accipitres. Stresemann divided his Accipitres into two families: Accipitridae, molting "descendant" (number 2 above) or irregularly; and Falconidae, molting from primary 4 (as in number 1 above). Each of these families was divided into a number of subfamilies, and it was in the arrangement and order of these subfamilies that Stresemann's order of classification differed most strongly from the other current systems.

The relative merits of these two classifications are still open to discussion. That of Stresemann has been criticized on the ground that virtually all of the birds that molt irregularly are either large or very large. This applies to all his Cathartae; to all or most of his subfamilies Gypaetinae, Aegypiinae, Polyboroidinae, Circaetinae, Haliaeetinae, Machaerhamphinae, and Pandioninae of his family Accipitridae; to the larger and heavier members of his subfamily Accipitrinae; and to the secretary bird. No member of his Falconidae molts irregularly, but then none, except some caracaras and perhaps the gyrfalcon, can be called large and heavy. It appears at least as probable that the order of wing molt is as related to weight, size, and wing loading as to phyletic relationships. No one, however, questions the obvious differences between falcons and hawks, which are more strongly stressed by Brown and Amadon in their suborder Falcones than by Stresemann, who gives the falcons only family rank.

Controversies of evolutionary ranking

Modern birds usually are classified by the principle of placing the most primitive first and leading successively to the most highly evolved. Brown and Amadon suggested that Stresemann's ordering of subfamilies in his Accipitridae reversed that order by beginning with the rather specialized Old World vultures and ending with the sea eagles, kites, and osprey, which they regard as relatively primitive falconiforms. The position of the osprey remains controversial. Comparison of egg-white proteins indicates that the Old World vultures are closer to the typical eagles and buzzards than to the snake eagles and harriers. Stresemann concluded his large subfamily Accipitrinae with the buzzard-like harpy and monkey-eating eagles (*Harpia* and *Pithecophaga*), which Brown and Amadon considered less highly evolved than the booted eagles with feathered toes, such as *Spizaetus* and *Stephanoaetus.*

The whole subject of the classification of the Falconiformes is, in several respects, in need of thorough critical reappraisal and review. The best of the existing classifications is a compromise that still leaves many questions of precise relationships unanswered. (L.H.B.)

Galliformes (grouse, pheasants, quail, turkeys)

The bird order Galliformes, or gallinaceous (*i.e.,* fowl-like or chicken-like) birds, includes about 240 species, of which the best known are the turkeys (family Meleagrididae); chickens, quail, partridge, pheasant and peacock (Phasianidae); guinea fowl (Numididae); and grouse (Tetraonidae). Lesser known members of the order are the megapodes and the chachalacas, guans, and curassows. Although the hoatzin is here treated with the Galliformes, evidence from studies of egg-white proteins indicate that it should be assigned to the subfamily Crotaphaginae of the family Cuculidae (order Cuculiformes).

GENERAL FEATURES

Size range and diversity of structure. Most galliforms are medium-sized birds, from the size of a pigeon to that of a domestic chicken, 40 to 60 centimetres (16 to 24 inches) long and 500 to 2,500 grams (one to five pounds) in weight. The smallest members of the order are the sparrow-sized painted quail (*Excalfactoria*), about 13 centimetres (five inches) long and about 45 grams ($1\frac{1}{2}$ ounces) in weight. The heaviest galliform is the common, or wild, turkey (*Meleagris gallopavo*), wild specimens of which may weigh up to 11 kilograms (about 24 pounds);

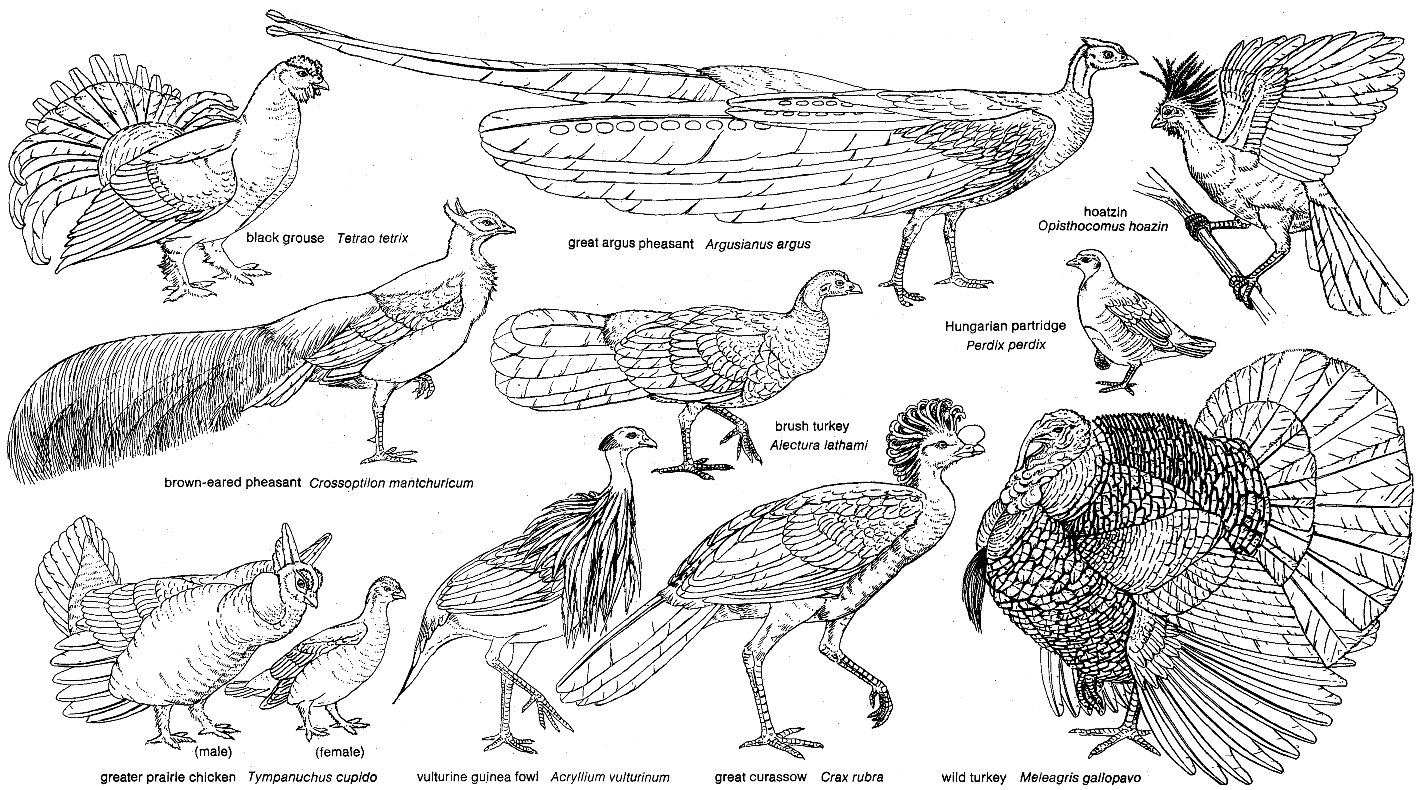

Figure 25: Body plans of galliform birds.

the longest is the argus pheasant (*Argusianus argus*), the male of which reaches two metres (79 inches) in breeding plumage, including wing and tail feathers, whose length exceeds one metre.

The majority of gallinaceous birds are heavy bodied, with short, rounded wings and strong, four-toed feet, adapted for life on the ground; a few, such as cracids and the hoatzin, live mainly in trees. The bill is short and slightly downcurved. The flight is fast but rarely sustained for long distances, most being sedentary, nonmigratory birds.

Distribution. Some members of the order are found in virtually every habitat in subarctic, temperate, and tropical regions of the larger landmasses, and a few species (ptarmigan, *Lagopus*) live within the Arctic Circle. The phasianids, the 178 species of which comprise by far the largest family, have nearly the distribution of the order. The cracids, with about 34 species, are restricted to tropical woodlands of Central and South America. The 18 species of grouse are found in northern temperate and Arctic regions of both hemispheres. The remaining groups are more restricted in distribution. The 10 species of megapodes inhabit forests from the East Indies east to the Fiji Islands and south to central Australia. Guinea fowl are restricted to Africa south of the Sahara but have been widely introduced on other continents. The two turkeys are native to North and Central America; the common, or wild, turkey in temperate woodlands of eastern United States and Mexico; and the ocellated turkey (*Agriocharis ocellata*) in Guatemala, British Honduras, and the Yucatán Peninsula of Mexico. The hoatzin (*Opisthocomus hoazin*) inhabits wooded river edges in northern and eastern South America.

IMPORTANCE TO MAN

Origin of the domestic chicken

Gallinaceous birds are unquestionably the most important avian group from the human standpoint. The chicken (*Gallus domesticus*) was domesticated in southern Asia at least 4,000 years ago from a parental stock of one or more species of jungle fowl (principally *G. gallus*). Selective breeding has produced well over 100 varieties, most of which are specialized for the production of either eggs or meat. In North America and to a lesser extent in northern Europe, the turkey is raised in numbers second only to those of the chicken. Domestic breeding of the turkey has been primarily for rapid growth and high market weight, the birds being raised solely for meat. Mature toms (males) may reach 23 kilograms (about 51 pounds). In many parts of the world, guinea fowl are an important barnyard species and are valued for the readiness with which they give alarm at the approach of a predator. (For a complete account of domestic gallinaceous birds, see FARMING: *Livestock and poultry farming.*)

Galliform birds constitute the large majority of land game birds, in number both of species and of individuals. Populations in North America and in western Europe are often carefully managed through habitat manipulation, supplemental feeding, and artificial rearing to ensure maximum hunting yields. The common pheasant (*Phasianus colchicus*, called the ring-necked pheasant in the United States) was introduced in North America late in the 19th century and has become widely established. Several species of quail (especially those of the genera *Coturnix* and *Colinus*) and partridge (*Perdix* and *Alectoris*) provide much sport hunting. A widespread tendency in game-bird management has been the introduction of species to areas where they have not been found previously.

The North American wild turkey, once nearly exterminated by overhunting, has responded to careful management and is now taken in fair numbers in the hardwood forests of the eastern United States. Grouse (including ptarmigan) are hunted throughout their range. (For further information on game birds, see *Micropædia*: HUNTING.)

NATURAL HISTORY

Habitat selection and food habits. As an order, the galliforms inhabit a wide variety of vegetational types, including dense and open forest, open grasslands, scrub and second-growth forest, and flooded riparian (river) forests. Megapodes live in dense jungle, some appearing in the open only to lay eggs on sandy beaches. The mallee fowl (*Leipoa ocellata*) is an exception, inhabiting the eucalyptus thickets that characterize the arid interior of Australia. The majority of galliforms roost on elevated perches at night, even those species that spend the daylight hours foraging on the ground. Virtually the only ones that live in treeless regions are certain of the grouse, such as the tundra-inhabiting ptarmigan, the prairie chickens (*Tympanuchus cupido* and *T. pallidicinctus*), the sage grouse

(*Centrocercus urophasianus*), and the sharp-tailed grouse (*Pedioecetes phasianellus*). The Eurasian black grouse (*Tetrao tetrix*) occurs in open country and in forested regions. Most of the true pheasant, including the peafowl, are residents of open forest with clearings. Guinea fowl of the genera *Guttera* and *Agelastes* and quail of the New World genus *Odontophorus* inhabit dense tropical forest. The hoatzin is closely associated with water and is almost never found far from it.

The food of galliforms is varied, most species being basically vegetarian, but they also take large numbers of insects, worms, and other invertebrates. Many use their feet to uncover food in leaf litter. The hoatzin feeds on leaves and fruit, especially those of arums (Araceae), rarely descending to the ground but occasionally entering the water to take small crabs or fish.

Polygamous and monogamous types

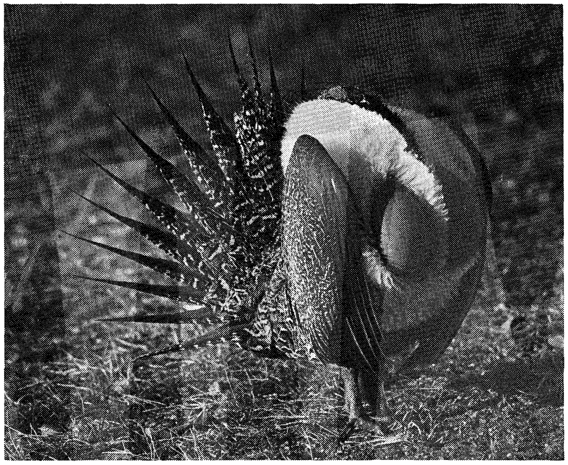
Courtship and mating. Gallinaceous birds vary considerably in reproductive behaviour, some exhibiting monogamous pair formation with a pair bond lasting through the breeding season, others showing varying types of polygamy, usually with members of both sexes being more or less promiscuous. Many, if not most, quail and partridge are monogamous, as are ptarmigan, guinea fowl, the hoatzin, some pheasant, and those megapodes and cracids that have been studied. Polygamy is known to occur in many grouse, including the North American grassland species, and in peafowl (*Pavo*) and some other phasianids. In the social displays of the grouse, a number of males assemble in a special assembly area, called a court, dancing ground, arena, or lek. The dancing ground lies outside of all nesting territories, and the same dancing ground is used year after year. Each of the males, which may number up to several dozen, has his own area within the chosen dancing ground. There he struts and postures, producing strange calls (some of which are produced in special esophageal air sacs) to attract the females, who visit the dancing ground to select a male and copulate. Dominant males occupy central positions in the arena group and may copulate with several females. Some species, such as the black grouse and the capercaillie (*Tetrao urogallus*), are variable in the degree to which males gather for display purposes, populations in more open areas tending more toward social displays. Males of the North American ruffed grouse (*Bonasa umbellus*) and those of some phasianids, the peacock pheasant (*Polyplectron*) and argus pheasant being examples, live in isolation, displaying to and copulating with any receptive female.

Nesting. The large majority of gallinaceous birds nest on the ground, the nest being only a shallow scrape, lined with soft grass or leaves. Cracids, the hoatzin, and the horned pheasant (*Tragopan*) build nests in trees, those of the cracids being relatively small for the size of the birds.

Construction of "incubators" by megapodes

The nesting of megapodes is unique among birds. The eggs of all species are placed in sand or soil, the heat for incubation coming from solar radiation, fermentation of plant matter, or even volcanic steam. Young megapodes, extremely precocious at hatching, dig their way to the surface and forage for themselves. They are fully feathered when hatched and can fly when 24 hours old. The simplest form of nesting, found in the maleo (*Macrocephalon maleo*), Wallace's megapode (*Eulipoa wallacei*), and some individuals of Freycinet's megapode (*Megapodius freycinet,* called jungle fowl in Australia), consists of placing each egg in a hole dug in sand to a depth of up to one metre (about one yard) in a site chosen for receiving the appropriate amount of solar radiation. Once laid and buried, the egg receives no further attention from the parents.

Harry Engels—The National Audubon Society Collection/Photo Researchers



Male sage grouse (*Centrocercus urophasianus*) in courtship display, revealing the bare air sacs in the sides of its neck.

Some members of the genus *Megapodius* (including jungle-dwelling members of *M. freycinet*) build mounds of decaying vegetation, up to 10 metres (35 feet) long and five metres high. Mounds built by the brush turkeys (*Alectura, Aepypodius,* and *Talegalla*) are smaller, up to about four metres in diameter and a metre high. The mallee fowl, the most studied of the megapodes, uses a combination of solar radiation and fermentation to maintain the incubation temperature.

In the mound-building species of megapodes, the male maintains the mound for much of the year. Prior to and during the incubation period, he opens the mound once or twice a day to control the generation, absorption, and radiation of heat. It is generally believed that the bird measures the temperature of the egg chamber when opening the mound. The temperature sensing organ is not known, but the most likely organ is the tongue. By instrumentation of mallee-fowl mounds, an Australian biologist, H.J. Frith, has found that the mound is maintained within a degree or two of 33° C (91° F) throughout the period of several months that there are eggs in it. Observations of one species of brush turkey, *Alectura lathami,* indicate that the frequent opening of the mound may be as important for ventilation as for temperature control.

Determinate versus indeterminate layers

The eggs of most gallinaceous birds are solidly coloured in white, buff, or olive, but those of species nesting in open areas are usually protectively coloured with blotches of brown or black. There is great variation in the number of eggs laid. Most members of the order are indeterminate layers, the female producing eggs until a certain number has accumulated in the nest. This characteristic has allowed man to exploit galliforms (especially the domestic hen, of course) for egg production. If the domestic hen were a determinate layer, as are members of many other bird orders, each individual would produce her clutch of about a dozen eggs and, regardless of whether or not the eggs were removed, would discontinue laying for at least two months.

The clutch size varies from two to about two dozen, the largest number occurring in megapodes. Partridge, quail, and the smaller pheasant lay from 12 to more than 20 eggs, but the larger pheasant, such as the crested argus (*Rheinardia ocellata*) and the great argus, normally lay only two eggs. The hoatzin and the cracids lay two or three eggs, three being the rule in the smaller cracids, such as chachalacas. Guinea fowl lay seven to 20 eggs, and turkeys eight to 18.

Incubation is usually performed by the female alone. Males of some New World quail, including the Montezuma quail (*Cyrtonyx montezumae*), the bobwhite (*Colinus virginianus*), and other members of the genus *Colinus,* incubate for short periods. The female of the southern European red partridge (*Alectoris rufa*) has been reported to lay two clutches, one incubated by the male, the other concurrently by herself. This behaviour, unique among birds, is in need of further investigation.

It is uncertain whether or not the male hoatzin incubates the eggs. Both sexes have been observed in nest building and taking care of the young, so it is possible that the male also assists in incubation.

Chick mortality

Care of the young. Young gallinaceous birds (except those of the hoatzin) are extremely precocious, walking and feeding within a few hours of hatching. Parental behaviour parallels mating behaviour: males of species in which a pair bond is formed usually assist in sheperding the young. Although clad in a protective coat of down and usually camouflaged with spots and streaks, the chicks suffer high mortality from predators and adverse weather.

Mortality rates of 50 percent or more are reported to occur in the period of a few months between hatching and independence of the young. Partridge, quail, and grouse maintain family groups (coveys) of a dozen or more birds that remain together until the next breeding season.

Hoatzin nestling wing claw

The hoatzin, unusual in many ways, also differs from other galliforms in that its nestlings are hatched practically naked and are fed by the parents in the nest. The young are fed regurgitated food from the crops of their parents. Although they have a long fledging period, young hoatzins scramble about in the branches around the nest, holding on with the clawed first and second digits of the wings and, in the manner of parrots, with their bills. The fact that the second digit of the wing (now considered to be digit III, in the evolutionary sense) is free and bears a functional claw was once thought (erroneously) to indicate affinities with the reptilian forebears of birds. Most authorities now believe that the free digits are a secondary adaptation that allows the young hoatzin great mobility during its flightless period and allows it to climb out of the water, into which it may deliberately drop when danger threatens.

Most gallinaceous birds reach sexual maturity at the age of at least one year. Some species, however, may be physiologically capable of reproduction at a much earlier age. The common quail (*Coturnix coturnix*), wild individuals of which normally breed at one year of age, matures to breeding condition in seven weeks in captivity. It is uncertain whether wild birds, hatched in the spring, actually do breed during the summer; environmental control factors, especially decreasing daylength, probably prevent the attainment of breeding condition by two-month-old birds in natural situations. Even the Congo peacock (*Afropavo congensis*), a relatively large species, is able to reproduce at one year of age when reared in captivity.

Vocalizations. Like many other birds that inhabit dense cover, forest galliformes are endowed with strong voices, ranging from musical whistles to harsh screams. The repertoire of most species includes alarm notes, food calls, "crowing" by males to advertise territories, and notes used to maintain social groups. Many species are especially vocal at daybreak; a few are reported to call at night. Megapodes give clucking and cackling calls during the day and mewing calls at night. Cracids produce loud calls that have immense carrying power. Males of some species have elongated, looped tracheae (windpipes), which are believed to add to the carrying power of the calls. Members of the social groups often cackle noisily together. Male peafowl utter a long mournful scream that sounds quite like a child in distress.

FORM AND FUNCTION

With the exception of the hoatzin, all galliforms have the same general body plan, being adapted for a primarily terrestrial existence. The feet and claws are large in all families, particularly so in the megapodes, reflecting their use for scratching and digging. The hind toe is larger and more functional in groups, such as the cracids, that spend much time in trees; it is smaller in the more terrestrial groups, but in none has it been lost, as it has in terrestrial birds of some other orders.

The short, rounded wings, powered by strong breast muscles (the white meat of the chicken), are indicative of the need for short, rapid bursts of flight, such as the escape from predators. Although no galliform is flightless, none is capable of long flights. The tail varies from extremely short (*e.g.,* in painted quail) to strikingly long; in many male pheasant the tail may be more than two-thirds of the bird's total length. The tails of some pheasant and of most megapodes are vaulted, having an inverted V-shape in cross section.

Ornamental plumage of the male

Male ornamental plumage is often remarkable in shape and coloration, combining spots or bars of silver, green, or purple iridescence with areas of brilliant orange, yellow, or white. Sculptured, fleshy wattles on the faces of male pheasant and grouse are often coloured a bright blue or red. In some male pheasant, such as the firebacks (*Lophura*), impeyans (*Lophophorus*), and peafowl, the head is ornamented with a small tuft of modified plumes, forming a tiny fan. Many cracids have patches of bare skin on the face or throat, usually red, yellow, or blue. Males of many curassows and guans possess head ornaments in the form of a brightly coloured fleshy knob or a bony casque (helmet) on the top of the head.

CLASSIFICATION

Distinguishing taxonomic features. The limits and interrelationships of galliform families have been determined on the basis of general body proportions, muscle and bone configurations, plumage, clutch size and egg characteristics, the appearance of the young, and some aspects of behaviour. Recent studies have utilized the biochemistry of egg white and blood proteins to indicate relationships.

Annotated classification. The classification presented below was established by the American ornithologist Alexander Wetmore, based on studies by many earlier workers.

ORDER GALLIFORMES

Suborder Galli

Family Megapodiidae (megapodes or mound builders)

All use heat other than body heat to incubate their eggs. Large feet, small heads. Tail often vaulted. Medium to large birds, 25–65 cm (10–25 in.); sexes alike. One fossil, *Chosornis praeteritus,* from the upper Pleistocene; 7 Recent genera, 12 species; Australia and East Indies to central Polynesia.

Family Cracidae (chachalacas, guans, and curassows)

Tail moderately long and broad. Plumage black or brown, duller in female. Most species with bare skin between eyes and beak (lores), some with fleshy wattles or other ornaments on face or crown. Medium to large; length 52–99 cm (20–39 in.); lower Eocene to present; 11 fossil and 11 Recent genera, 34 Recent species; New World tropics and subtropics, from southern Texas to Paraguay.

Family Tetraonidae (grouse)

Distinguished by having lower leg (tarsus) and sometimes feet at least partially feathered; nostrils also feathered. Tail strong; ornamental in some species. Many with brightly coloured bare skin over eye. Medium to large; 30–90 cm (12–36 in.). Lower Miocene to present; 3 fossil and 9 Recent genera, 17 Recent species; North America and northern Eurasia.

Family Phasianidae (pheasant, quail, partridge, and relatives)

Nostrils, feet, and (usually) tarsus unfeathered; esophageal air sacs lacking. Many species with spurs on the back of the tarsus. Plumage, especially of males, bright in many species, often with ornamental feathers; sexes usually different. Small to large; length 13–200 cm (5–80 in.); lower Miocene to present; 11 fossil and about 40 Recent genera, about 178 Recent species; virtually worldwide, except southern third of South America, northern Eurasia, and some oceanic islands.

Family Numididae (guinea fowl)

Distinguished by presence of small whitish spots on dark bluish or slate body feathers; head and neck bare or slightly feathered, often brightly coloured. Legs and feet large; spurs present only in *Phasidus* and *Agelastes.* Medium to large; length 43–75 cm (17–30 in.). No fossil species; 5 genera, 7 species; Africa south of the Sahara and Madagascar.

Family Meleagrididae (turkeys)

Distinguished by metallic sheen on feathers, bare head with red and blue skin and wattles or caruncles. Tarsal spurs of male long, of female short. Size large, length 84–110 cm (33–43 in.). Upper Pliocene to present; 1 fossil genus (Pleistocene) and 2 Recent genera, each with 1 Recent species; eastern and southern United States, Mexico, northern Guatemala, British Honduras.

Suborder Opisthocomi

Family Opisthocomidae (hoatzin)

Long neck and small head, with prominent crest of long feathers; beak short, stout, laterally flattened. Wings large and rounded; tail long and broad. Brown above, marked with white and russet; buff below. Nestling with 2 free, clawed digits on each wing. Adult size large, length about 61 cm (24 in.). One fossil genus (*Hoazinoides,* middle Miocene); 1 Recent genus with 1 species; river systems of northern South America.

Critical appraisal. Although the classification presented here has broad acceptance, modern authorities disagree on the numbers of species and, especially, genera in many groups. Forms once regarded as distinct are now often considered to be geographical races of larger species. The problem is particularly acute where island populations are involved, for the usual biological criterion of free interbreeding cannot be applied, and the taxonomist must infer from external appearance whether or not two forms belong to the same species. The genus *Megapodius,* for example, was considered by the American ornithologist James L. Peters, in his 1934 volume of the classic *Check-list of Birds of the World,* to comprise nine species with 25 subspecies. Another authority, Dean Amadon, in a study published in 1952, recognized only three species, with 15 subspecies.

At the generic level, taxonomy is more subjective than at the species level, the boundaries of the genus being subject only to the general views of the taxonomist as to what constitutes a genus. Recent years have seen a drift toward "lumping," with the result that what were once regarded as discrete genera are now frequently merged (lumped), a family often having fewer genera but about the same number of species. Details of the anatomy, behaviour, and distribution of many galliform species remain unknown. As more information about galliforms accumulates, further changes in the lower levels of classification may be expected. (F.H.)

Gruiformes (cranes, rails, coots, cariamas, bustards)

The bird order Gruiformes comprises a rather loose assemblage of 12 families that are generally agreed to be related but that differ widely in many aspects. They are an ancient group with a rich fossil history, but many are now restricted in range and few in number. Members of the order occur on every continent, but the only family with worldwide distribution is the Rallidae (rails, gallinules, and coots), with 132 living species. Cranes (Gruidae) are found on every continent except South America, but many of the 14 species have small populations, some on the verge of extinction. The bustards (Otididae), with 23 species, have a wide distribution, limited to the Old World, but hunting pressures and modern agricultural methods have greatly reduced their numbers. The mesites (Mesitornithidae), however, are confined to Madagascar, and the kagu (*Rhynochetus jubatus*) to the island of New Caledonia. Other small families in the order contain the hemipodes, or button quails (Turnicidae), plains-wanderer (Pedionomidae), limpkin (Aramidae), trumpeters (Psophiidae), finfoots (Heliornithidae), sun bittern (Eurypygidae), and cariamas (Cariamidae).

Although man's impact on them is very great, gruiform birds, because of their scarcity, have a negligible impact on man. With the possible exceptions of the sandhill crane (*Grus canadensis*), which descends on the grainfields of the Canadian prairies during the autumn migration, causing some crop damage, and the brolga, or Australian crane (*Grus rubicundus*), which causes similar damage in Queensland, no gruiform can be considered harmful to man's interests; some of the larger species, in fact, are hunted for food or sport.

GENERAL FEATURES

Size and weight

Gruiform birds range in size from the tiny button quails (*Turnix*) and miniature rails, such as the North American black rail (*Laterallus jamaicensis*) barely 15 centimetres (six inches) long, to the stately sarus crane (*Grus antigone*) of India, standing nearly 1.6 metres (five feet) high. The enormous kori bustard (*Otis kori*) and the Eurasian great bustard (*O. tarda*) may weigh up to 18 kilograms (about 40 pounds) and are the heaviest modern flying birds. Gruiforms vary widely in structure; some are adapted for life in or near water, others are adapted for life on land. Some forms fly well; but a number of gruiform species are flightless.

As a group, the gruiforms are probably best known for their impressive and graceful courtship displays, the most famous of which, the dances of the cranes, are imitated and adapted by many native peoples. The Ainu of Japan have a crane dance in honour of the Japanese crane (*Grus japonensis*), and many African peoples imitate the dance of the crowned crane (*Balearica pavonina*). Less well known, but no less spectacular, are the striking wing display of the sun bittern (*Eurypyga helias*) and the strutting and booming of the larger bustards.

NATURAL HISTORY

Ecology. *Habitat.* Gruiform birds live in a variety of habitats, from water and marshes to arid plains. The most aquatic are the finfoots and coots (*Fulica*). The former live along slow-flowing streams where heavy overhanging vegetation affords them cover, the latter on more open water. Most rails live in saltwater or freshwater marshes. The limpkin (*Aramus guarauna*) is essentially a marsh bird; in Florida it inhabits the sawgrass marshes and cypress swamps of the Everglades. Cranes bridge the gap between marsh and dryland birds, nesting in marshes but occurring in open plains and cultivated fields on migration and in winter. The sun bittern prefers muddy, wooded riverbanks but also occurs in woods well away from water. Trumpeters, mesites, the kagu, and some rails live in forest and dense brush. The remaining gruiform families inhabit more open country: the cariamas of South America favour grassland or hot, dusty plains with scattered bushes; the Old World bustards, button quails, and the plains wanderer prefer open, grassy plains, although they will accept old pastures and cultivated fields.

Diversity of diet

Food habits. Corresponding to the wide variety of habitats utilized by the gruiforms is the great diversity of food taken by them. In general, more animal than vegetable food is taken, but as a group the gruiforms are omnivorous. Coots and gallinules consume much aquatic vegetation. Finfoots live largely on mollusks, frogs, and small fish. The limpkin has a more specialized diet, consisting chiefly of certain large snails, which are broken open at certain favourite feeding stations that contain telltale piles of broken shells. The limpkins' near relatives, the cranes, eat almost any animal food, including rats, mice, moles, lemmings, lizards, snakes, frogs, tadpoles, snails, and a variety of insects. On its wintering grounds in Texas, the whooping crane (*Grus americana*), an endangered species, lives largely on crustaceans. The sandhill crane includes berries and grass in its otherwise animal diet on the northern tundra and gleans some plant material from old potato and grain fields on its southern wintering grounds. The Asiatic cranes that winter in Japan (such as the hooded crane, *Grus monacha,* and the white-naped crane, *G. vipio*) glean grain in rice paddies, and Japanese cranes in Hokkaido are fed corn (maize) by the local farmers. Cranes use their powerful bills for digging in the ground to get at bulbs and roots below the surface, and a similar foraging action has been noted for the gray-necked wood rail (*Aramides cajanea*) of tropical America, which probes in ground debris, flicking it aside with the bill. Rails as a group, like cranes, are omnivorous, though the bulk of their diet consists of small marsh animals, such as snails, crustaceans, frogs, and water insects. The purple swamphen (*Porphyrio porphyrio*), a vegetarian, often has a feeding platform on which it stands and pulls up the surrounding water plants; it will also climb up reeds and eat the flower heads.

The other members of the order have a similar mixed animal and vegetable diet, though with the emphasis always on the animal side. Captive cariamas readily eat meat, and a captive kagu feasted on ground steak provided by its owner. Bustards are fond of grasshoppers, and their varied diet also includes dung beetles, termites, centipedes, grass, clover, vegetable crops, and even, in Africa, the gum from the trunks of *Acacia* trees. The sun bittern stalks insects as a heron stalks fish, stealthily approaching its prey with neck drawn in, then grabbing it with a sudden, stabbing thrust of the bill.

Dancing by cranes

Reproductive behaviour. *Courtship.* The breeding cycle of many gruiform birds begins with elaborate courtship rituals and displays. Cranes pair for life, and the strong pair bond necessary to maintain this partnership is initiated and continued by a series of displays that, since they often consist of two birds facing each other and leaping into the air, are generally known as dances. The ceremony frequently begins as two birds circle each other with a curious, formal step, the legs stiff and the head and neck held high. The next action is bowing or "head bobbing," in which the head is held horizontally, the neck curved down in a U, and in this position the head and neck are bobbed or pumped up and down. One bird may do

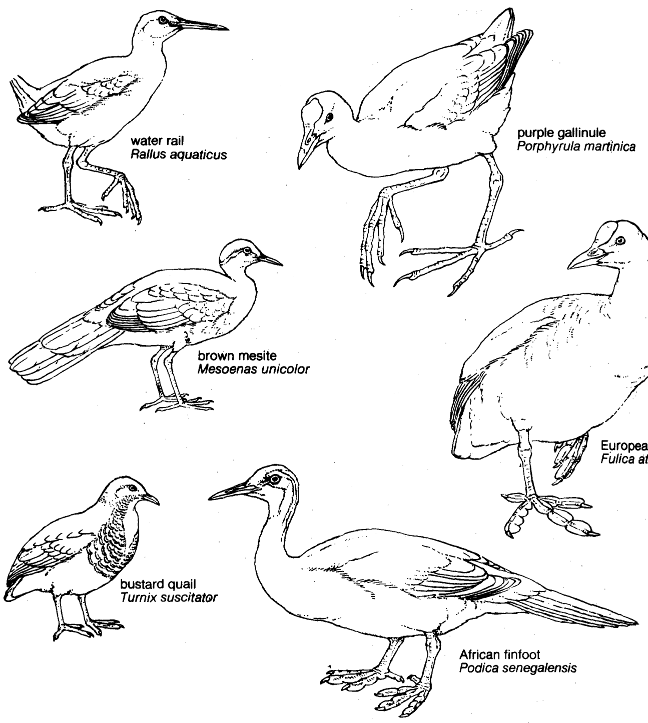


Figure 26: Body plans of some smaller gruiforms.
Drawing by R. Keane

this while the other bird looks on, or both may do it together. One bird (or both) then turns in a circle on the spot while continuing to bow. The momentum increases until suddenly both birds leap into the air and follow this by dancing. While dancing, the birds often pick up some object from the ground and toss it in the air as they leap. The object is usually something used in nest building, such as a stick, leaf, or tuft of grass, and the action may be related to nest-building drives. Again, while leaping in the air one bird may turn its back on the other. Another beautiful display involving a pair of cranes is the "duet." The birds first circle each other with the same formal step that initiates the dance, but instead of going into the dance they droop their wings, throw back their heads, and call in unison.

Although dancing intensifies at the beginning of the breeding season and is doubtless primarily connected with courtship and pair formation, it can occur at any time of year and may have other functions as well. Dancing often seems to be a method of releasing pent-up energy, as when a bird dances on its own or when a dancing pair sets off dancing in nearby individuals of a flock. So strong is the instinctive urge to dance that a five-day-old chick is recorded as leaping up and down and going through other motions of the dance, even though it had never seen another crane.

Vocalizations of rails

Pair formation in many rails is effected chiefly by voice; males establish territories and defend them vigorously with distinctive songs and calls while at the same time attracting females. Rails produce an amazing variety of noises. In North America, the clapper rail (*Rallus longirostris*) has a loud cackling call, the sora (*Porzana carolina*) an explosive whinny, and the yellow rail (*Coturnicops noveboracensis*) makes a noise like two small stones being clicked together. In Europe, the water rail (*Rallus aquaticus*) squeals like a stuck pig, and the corncrake (*Crex crex*) produces a rasp like a heavy comb being drawn over a piece of wood. The gray-necked wood rail greets the dawn with a ringing "Pop-tilly, pop-tilly, ko-ko-ro-ko-ko," which has given it the local name of "cocaleca" in Panama. In Africa, a large rail, *Himantornis haematopus,* of the Congo forests makes a pumping sound, and the black crake (*Limnocorax flavirostra*) in the papyrus swamps makes a curious gurgling sound. The tiny crakes in the genus *Sarothrura* have a variety of melodious calls, the buff-spotted crake (*S. elegans*) making a low moaning noise like the sound of a tuning fork. More familiar are the plebeian squawks and grunts of the wide-ranging coots and gallinules.

Rails also have courtship displays involving lowering the head, raising the wings, and fanning the tail, often while uttering some special call. Coots and gallinules display their colourful frontal shields and fan their tails to show off the white under tail coverts. Other species circle their partners in various postures. The display often ends with the male chasing the female, and the chase may end in copulation. In button quails the role of the sexes is reversed. The female is the most brightly coloured and courts the male, erecting her tail, puffing out her neck, and running around him while uttering a low crooning note. The male sun bittern selects an open spot, often in a patch of sunlight, where he spreads and raises his tail and wings until they meet in front of his head, exposing elegant patterns of red-brown, olive, gray, and black. In this posture he runs in a circle and may jump up in the air or bob his head.

In its aggressive display, the kagu stands erect, with the long feathers of the crest raised, the wings held out from the body, and the tail drooped. In this posture, it bounces at the adversary. In a playful mood the kagu will toss sticks and stones around with its bill, in a manner reminiscent of cranes. A captive cariama has been seen to run at a tree with lowered head, jerking its tail and giving a short cluck, then striking the tree with both feet. In spring wild birds have a bustard-like display (see below) accompanied by loud yelping calls.

Vocal displays

Trumpeters, named for their loud, resonant cries, have a cranelike dance involving strutting around on the ground and leaping into the air. Males of the larger bustards, the

Drawing by R. Keane

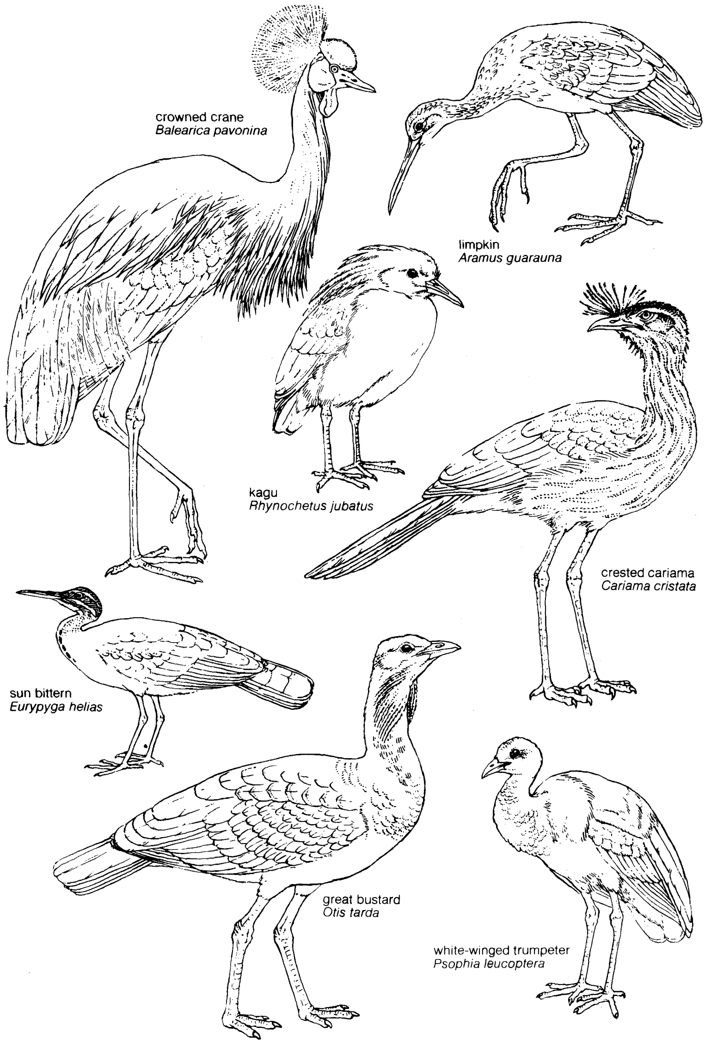

Figure 27: Body plans of some larger gruiforms.

great and kori bustards, for example, develop a special pouch in the neck during the breeding season with which they produce loud, booming calls. The Australian bustard (*Ardeotis australis*) "booms" with closed beak, producing a sound somewhat like the distant roar of a lion. Special display feathers that grow on the head, neck, and breast are molted after the breeding season. A large bustard in full breeding regalia, with all feathers puffed out, is scarcely recognizable; the head is immersed in an immense ruff, and the wings and tail are raised until they meet over the back, the total effect being that of an enormous feather ball. The ball then struts around in front of a female, who feigns indifference. Smaller bustards have somewhat different displays. The crested bustard (*Lophotis ruficrista*) of Africa has an aerial display flight in which it rises about 100 feet into the air and then planes steeply back to earth.

Nesting. Gruiform birds nest both on the ground and in bushes and trees. Of the ground nesters, button-quails and the plains wanderer nest in a grass-lined hollow, often building a domed roof and side entrance. Cranes raise up a pile of vegetation in open shallow water, and the limpkin builds a concealed nest in dense marsh grasses. Marsh-dwelling rails build simple nests of grass and aquatic plants, often in a thick tuft of grass, the blades of which they pull down over the nest to conceal it. The kagu builds a nest of sticks and leaves in a depression in the ground. Bustards scarcely have a nest at all, the eggs being laid on bare ground, sometimes beneath a bush or clump of grass for concealment. Finfoots and the sun bittern prefer a nest site on a branch of a tree, and finfoot nests generally overhang water. Of the two species of cariamas, one nests on the ground and the other in bushes. Trumpeters are variously reported as nesting on the ground and in holes in trees. Mesites place their simple stick nests a metre or two up in a tree. Being flightless, they must always find a site where a connecting series of branches leads from the ground to the nest, enabling them to hop up to it.

Sandhill cranes (*Grus canadensis*) leaping into the air as part of the courtship dance characteristic of this family of birds.

Incubation of the eggs

Clutch sizes vary widely within the order, from the single egg of the kagu to over 10 in some rails. Exceptional clutches of 15–20, recorded for some coots and gallinules, may be due to more than one female laying in the same nest. The eggs are usually white or buff, sometimes pale gray or pale green, immaculate in a few species, but usually with brown spots or blotches at one end. The incubation period is typically about three weeks, extending to four weeks in the cranes and larger bustards. Both sexes incubate the eggs and care for the young when hatched in all families except bustards, trumpeters, and button quails. Button quails are polyandrous (an individual mating with several members of the opposite sex), and the tasks of incubation and care of the young are performed entirely by the males. In bustards and trumpeters, the female does all of the incubating and caring for the young. Young gruiforms are downy, plain black in rails and dark brown in limpkins, variously patterned in most other groups. They leave the nest immediately or very soon after hatching, except for those of the sun bittern, cariamas, and bustards, which are cared for at the nest for a short time. There is some evidence that in the trumpeters, which habitually travel in flocks in the adult state, several pairs may pool their young and look after them communally.

Molt. The sequence of molts and plumages is very poorly known except in cranes, the young of which have a brown or gray juvenile plumage, with white-tipped or blackish feathers in some species. The juvenile feathers are gradually replaced at each successive molt with the white or gray feathers of the adult, but the last browntipped feathers do not completely disappear until about the third summer, when the bird is a little over two years old. Adult cranes, at least those nesting in northern temperate zones, molt in two stages; many of the wing and tail feathers are molted in early summer, at which time the birds may be flightless for a while; the rest of the plumage is gradually molted between August and October.

Migration and locomotion. Most gruiforms are nonmigratory. Bustards, button quails, and the plains wanderer migrate locally, following the rains to feed and nest. Only the birds nesting in the North Temperate Zone are true migrants; this group includes many cranes, some rails, and the Eurasian bustards. The spectacular migrations of cranes have excited man's interest since earliest times. The peoples of eastern Asia welcome the return of the cranes as symbolic of the coming spring, and in fall the farmers of Japan welcome the birds back to the rice paddies where they spend the winter. In Japan, the cranes return every year to the same traditional wintering grounds, where they are given strict protection. The last remaining whooping cranes in North America are likewise carefully looked after and are counted at the Aransas National Wildlife Refuge in Texas on their return from the north. Most cranes cover great distances on migration. Sandhill cranes travel 4,000 miles from their nesting areas in Alaska and eastern Siberia to southern United States, and common cranes (*Grus grus*) and demoiselle cranes (*Anthropoides virgo*) cover similar distances in the Old World.

When the northern marshes freeze over in winter, rails are forced to head south. Amazingly, these birds that fly so weakly across a marsh, with floppy wings and dangling legs, are able to travel thousands of miles each year on migration. The corncrake, nesting in Scotland, may winter in South Africa, and the sora rail of North America regularly crosses 800 miles of ocean to reach Bermuda.

The Eurasian bustards travel shorter distances, going only far enough to escape bitterly cold weather. Some species form large flocks at migration time. Bustards are great walkers, and local migrations in Africa are for the most part performed slowly on foot.

Travel on foot

Gruiform birds have a predilection for travel on foot. Many only fly when pressed, and some, like the mesites, have become flightless or nearly so. Many oceanic islands have been colonized by rails, which then evolved flightlessness in the absence of predators. The subsequent advent of rats, cats, pigs, or goats on such islands, usually with accidental or intentional assistance from man, has resulted in the extinction of a number of such rails. Rails typically sneak away on foot in thick vegetation, and button quails are equally loath to fly, preferring to walk away with their quick, nervous gait, stopping every so often to raise their heads and look around for danger. Trumpeters run fast and can even swim. Finfoots spend most of their life in water and prefer to hide in thick riverside bushes when disturbed, rather than fly. On the ground, gruiform birds move efficiently and even elegantly. The sun bittern walks gracefully with slow, precise steps, its neck outstretched. Cariamas run swiftly over the plains. Rails have a very characteristic walk in which the tail is flicked up with each step, and both the limpkin and the kagu share this tail-flicking action. Even such fine fliers as the cranes prefer walking, and there is no more elegant sight in the avian world than a tall and stately crane walking with deliberate and dignified gait across the prairie. In flight, cranes and the limpkin have a charcteristic wing action—a slow downstroke followed by a quick, flicking upstroke.

FORM AND FUNCTION

Gruiform birds vary greatly in shape and size and exhibit a broad range of morphological characteristics. Their plumage is predominantly brown or gray. Some have brightly coloured soft parts such as the bare, red skin on the head and neck of some cranes, used in displays, and the bright red and yellow bills and frontal (forehead) shields of gallinules. The crowned crane has a curious crest of stiff, golden feathers. The sexes are alike in most groups, except among the button quails, in which the female is more brightly coloured, and the bustards, where the males are more colourful.

The wings are rounded and often long, although in the nearly flightless mesites they are greatly reduced. The length of the tail varies, being proportionately short in button quails, rails, and trumpeters and rather long in mesites, finfoots, and the sun bittern. Cranes have very long inner secondary feathers (those of the inner wing or "forearm"), which extend beyond the end of the tail, giving the impression of a long-tailed bird. The bill is generally long and slender, particularly so in cranes, many rails, and the limpkin, although the cariamas have hooked bills which are doubtless used in tearing up mammalian prey. The legs are rather long, reflecting a preference for walking. The toes vary greatly—in the finfoots and coots they are lobed for swimming, in rails and the limpkin they are long and slender for walking on lily pads and other aquatic vegetation, but bustards and cariamas have short toes for running on hard surfaces. The hind toe, when present, is usually elevated.

Special anatomical features

Some groups have anatomical features peculiar to themselves. The mesites possess five pairs of powder down patches, far more than any other group, and the function of these is uncertain. Cranes, and the adult male limpkin have an extremely long trachea, or windpipe, that is coiled in several convolutions. These convolutions of the trachea probably give added power and resonance to the voice, which can carry for distances of a mile or more. Rails have a laterally compressed body, which gives rise to the expression "thin as a rail," enabling them to sneak between reeds and blades of grass without telltale movements of the vegetation. Most young rails have a claw at the tip of the alula (the "bastard wing" or "thumb") that enables them to clamber around on marsh vegetation. Finfoots have a sharp spur of uncertain function at the bend of the wing. The kagu, like the mesites and some rails, is flightless, a condition that may lead to its extinction by the dogs, cats, pigs, and rats that have been introduced on New Caledonia. Males of great and kori bustards have a gular (throat) pouch during the breeding season that opens into the mouth under the tongue and can be inflated at will. It is used by the birds to produce booming calls during courtship. The Australian bustard has no gular pouch, producing its calls by filling the esophagus with air. The esophagus is similarly used in sound production by the button quails and by rails of the genus *Sarothrura.*

EVOLUTION AND PALEONTOLOGY

Gruiform birds have the best fossil record of any avian order, going back to the Late Cretaceous, nearly 100,000,000 years ago. Fourteen fossil families are known, divided into 86 genera and 146 fossil species. In addition, 39 extant species are also known as fossils.

The oldest gruiform bird is the crane-sized *Laornis* from the Upper Cretaceous of New Jersey, recently shown to be closely related to the rails. *Telmatornis,* from the same epoch, formerly considered a gruiform, is now placed closer to the thick-knees (Burhinidae) in the order Charadriiformes.

Next in age are two families from the Paleocene (about 60,000,000 years ago), the Gastornithidae and the Diatrymidae, the latter containing some fascinating giant species—*Diatryma steini* stood about seven feet tall and had a massive head and bill—but it is in the Eocene, starting about 54,000,000 years ago, that gruiform birds first became abundant and the first representatives of modern families appeared: rails, cranes, and a bustard. In the Oligocene the limpkins and the suborder Cariamae had their beginnings. The Cariamae are represented today by only two living species, but their fossil history shows that in earlier epochs they were a more widespread and successful group. They include a number of flightless giants, the best known of which are several species of *Phororhacos* from the lower Miocene of Patagonia. These were powerful birds, the largest in excess of 2.2 metres (seven feet) in height. The best known form, *P. longissimus,* must have been a formidable predator, having a massive skull 65 centimetres (two feet) long and 25 centimetres (10 inches) high, with a hook at the tip of the beak.

With the exception of the above, and a single *Turnix* from the Pleistocene of China, the smaller modern gruiform families have no fossil records. Nevertheless, the abundance of fossils shows what an amazingly successful group the gruiforms were. They are known from all six continents, and for every fossil species discovered there must have been tens or even hundreds that are unknown. Today, however, gruiform birds are on the decline. Of the 12 gruiform families, fully eight are represented by three species or less, and four have only a single species. The only one that is at all numerous is that of the rails, with about 130 species. Many gruiform birds appear in the "Red Data Book" of endangered species, published by the International Union for the Conservation of Nature. Five of the 14 extant cranes are listed as in danger, the best known being the whooping crane. Seven rails are listed as in danger and 15 more have become extinct since about 1600. Many of the extinct rails lived on small islands and a number had become flightless, making them vulnerable to man and his animals. Nevertheless, the Gruiformes had been declining long before man entered the scene, apparently because the ecological conditions that favoured them in the past are less available to them today.

Endangered species

CLASSIFICATION

Distinguishing taxonomic features. The order Gruiformes is a heterogeneous group bound by taxonomic characters that are largely anatomical, and hence not readily evident on the live bird. Few are common to all members of the group, and no single character serves to separate the Gruiformes from all other orders. Some of the features that have been used in classifying the order are: the condition of the feet and toes; the type of palate, osteologically; the type of pelvic musculature; the number of carotid arteries; the presence (eutaxy) or absence (diastataxy) of the fifth secondary flight feather in the wing; the number of wing and tail feathers; the number of cervical vertebrae; the type of nostrils; the presence or absence of an aftershaft (a small "second feather" attached to the shaft of a body feather); and the behaviour of the young.

Annotated classification. The classification presented here is based on work by the ornithologists Alexander Wetmore, Pierce Brodkorb, and Joel Cracraft. Groups indicated by a dagger (†) are known only as fossils.

ORDER GRUIFORMES

Primarily marsh-dwelling birds of medium to large size. Toes not webbed (lobed in a few genera). Hallux (hind toe) usually elevated, sometimes absent. Two carotid arteries usually present. Aftershaft usually present. Crop lacking. Young usually nidifugous (precocious).

Suborder Mesitornithides

Distinguished from other suborders by reduced clavicles (collarbones) and presence of five powder-down patches.

Family Mesitornithidae (mesites). No fossil record. Superficially dovelike, but with characters of order and suborder. Hallux well-developed and functional. Three species; terrestrial, in forest and dry brush; confined to Madagascar; length 25–27 cm.

Suborder Turnices

Principal difference from other suborders is the possession of a well-developed basipterygoid process (a projection at the base of the skull).

Family Turnicidae (button quails). Pleistocene (one specimen) to present. Small and quail-like; short legs, no hallux;

beak short, slightly downcurved. Unique in the order in having only one carotid artery. Female larger and more brightly coloured than male. Eggs roundly oval. Eutaxic. Fifteen species; in grasslands and brush; southern Europe, Asia, Africa, and Australia; body length 11–19 cm.

Family Pedionomidae (plains wanderer). No fossil record. Similar to button quails, but differs in the following details: hallux present; two carotid arteries; wing diastataxic; eggs pointed. One species, confined to dry plains of Australia; body length about 16 cm.

†Suborder Gastornithes
Fossil only.

†*Family Gastornithidae.* Upper Paleocene of Europe; five species; large, flightless.

†*Family Diatrymidae.* Upper Paleocene to middle Eocene; North America and Europe; four species; large flightless predators.

Suborder Grues
Adults with down feathers in both pterylae (feather tracts) and apteria (areas between tracts); hallux present and variable; oil gland present and tufted.

Superfamily Gruoidea (cranes, limpkin, and trumpeters)
Only gruiforms with supraorbital furrows (*i.e.,* above the eye); distinguished from others by pelvic muscle formula. Ten to twelve tail feathers.

†*Family Geranoididae.* Fossil only; lower to middle Eocene; North America; seven species known.

†*Family Bathornithidae.* Fossil only; lower Oligocene to lower Miocene; North America; eight species known.

†*Family Eogruidae.* Fossil only; upper Eocene to upper Miocene; eastern Asia; two species known.

Family Gruidae (cranes). Lower Eocene to present. Bill long and straight; neck and legs long; hallux small and elevated. Head usually partly naked in adult. Wing diastataxic. Caudofemoral muscle present (except in *Balearica*). Twenty-one fossil and 14 Recent species; plains and marshes of the world, except South America; length about 79 to 150 cm.

†*Family Ergilornithidae.* Fossil only; lower Oligocene to lower Pliocene; eastern Europe and Asia; three known species.

Family Aramidae (limpkins). Lower Oligocene to present. Bill long; neck long and slender; head feathered. Hallux large and functional. Caudofemoral muscle absent. Swamps and marshes of New World tropics and subtropics; five fossil and one Recent species; length 58 to 71 cm (in Recent forms).

Family Psophiidae (trumpeters). No fossil record. Bill short. Separated from Gruidae and Aramidae by nostril shape, eutaxic wing, absence of occipital foramina (perforations at the base of the skull). Three species, in lowland forest of South America; length 43 to 53 cm.

Superfamily Ralloidea
Lack occipital foramina and supraoccipital furrows. Hallux well-developed and functional; cervical vertebrae fewer than in Gruoidea.

Family Rallidae (rails, gallinules, and coots). Upper Cretaceous to present. About 56 fossil and 132 Recent species; principally in marshes; worldwide; length about 14 to 51 cm.

†*Family Idiornithidae.* Fossil only. Upper Eocene to lower Oligocene of Europe and North America; eight species known.

Suborder Heliornithes
Distinguished from all other gruiforms, except coots (*Fulica*), by possession of lobed feet; by pelvic muscle formula, type of flexor tendons, and possession of 18 tail feathers.

Family Heliornithidae (finfoots). No fossil record. Three species; slow-flowing streams in tropical areas of Central and South America, Africa, and India and Southeast Asia; length 30 to 62 cm.

Suborder Rhynocheti
Large aftershaft; powder downs occurring as scattered groups of feathers. Large operculum (covering flap) over nostrils. Young nidicolous (dependent).

Family Rhynochetidae (kagu). No fossil record. One species, confined to forested highlands of New Caledonia; length about 56 cm.

Suborder Eurypygae
One pair of powder-down patches. Oil gland nude. Eighteen cervical vertebrae. Young nidicolous.

Family Eurypygidae (sun bittern). Beak medium length, straight, sharp; neck slender. Tail of medium length. One species; margins of woodland streams in Central and South America; length about 46 cm.

Suborder Cariamae
Distinguishing features in palate structure; talon-like nail on second toe; and type of flexor tendons.

†*Family Cunampaiidae.* Fossil only. Lower Oligocene of Argentina; one known specimen.

†*Family Brontornithidae.* Fossil only. Lower Oligocene to middle Miocene of Argentina and Uruguay; two species known.

†*Family Palaeociconiidae.* Fossil only. Lower Oligocene to middle Pliocene of Argentina; four species known.

†*Family Prophororhacidae.* Fossil only. Lower Pliocene to lower Pleistocene of Argentina; three species known.

†*Family Phororhacidae.* (Phorusrhacidae of some authors). Fossil only. Lower Miocene to lower Pleistocene; 10 species, nine from Argentina, one from Florida. Medium to large flightless predators.

†*Family Psilopteridae.* Fossil only. Lower Oligocene to middle Pliocene of Argentina; nine species known.

Family Cariamidae (cariamas or seriemas). No fossil record. Moderate-sized cursorial birds; legs long, feet small; tail long; beak broad, moderately long, slightly decurved. Forehead and back of neck crested. Two species; in grassland and brush, respectively, of east-central South America; length 76 to 92 cm.

Suborder Otides
Oil gland absent. Scales on tarsus (lower leg) hexagonal; hallux absent. Sternum with two pairs of notches. Wing with 11 primary flight feathers. Egg-white protein structure (of Otididae) unlike those of other gruiforms.

Family Otididae (bustards). Cursorial, but strong flying birds of open plains of Eurasia, Africa and Australia; three fossil and 23 Recent species; length 37 to 132 cm.

†*Family Gryzajidae.* Fossil only. Lower Pliocene of the Ukranian S.S.R.; one species known.

Critical appraisal. The great diversity in the order Gruiformes is reflected in the uncertainty of taxonomists about gruiform relationships. The most widely accepted classification is that of the American paleontologist Alexander Wetmore, used above, with 12 Recent families in one order. Some authorities place the plains wanderer (*Pedionomus*) in Turnicidae. A German ornithologist, Erwin Stresemann, underlining the differences between the gruiform families, divided them into ten orders, most of them monotypic (*i.e.,* with only a single form). A British anatomist, P.R. Lowe, dismayed by the wide variety of characters in the Gruiformes, eliminated the order altogether, distributing the families among other orders, a decision later repeated by a French worker, R. Verheyen, who divided the families among five orders, some of which are not recognized today. Verheyen's order of Gruiformes contained only the Psophiidae, Aramidae, Gruidae, and Otididae. In an attempt to resolve this confusion, an American biochemist, H.T. Hendrickson, studied the egg-white proteins of 10 of the 12 gruiform families (he had no material for Pedionomidae or Mesitornithidae) and found that a close group was formed by five families—Eurypygidae, Heliornithidae, Rallidae, Turnicidae, and Psophiidae. The Aramidae bridge the gap between this group and the Gruidae, but the remaining families (Rhynochetidae, Cariamidae, and Otididae) seemed to be very different, the last so different that they may be of independent origin from the rest of the order. (G.S.Ke.)

Charadriiformes (plovers, sandpipers, gulls, terns, auks)

The order Charadriiformes comprises the shorebirds, gulls, auks, and their relatives. These birds form an important and familiar segment of the avifauna of the world's coasts and inland waterways, of the Arctic regions, and of the oceans and their islands. They are mostly strong-flying birds of open country or open water, nesting on the ground and feeding on animal food in or near water. The order is worldwide in distribution, and some species perform the most extensive migrations of any birds.

GENERAL FEATURES

The order is a heterogeneous assemblage of 16 families, linked by similarities in anatomical features (especially skeleton and plumage) and developmental pattern. Better known members of the order fall into three groups,

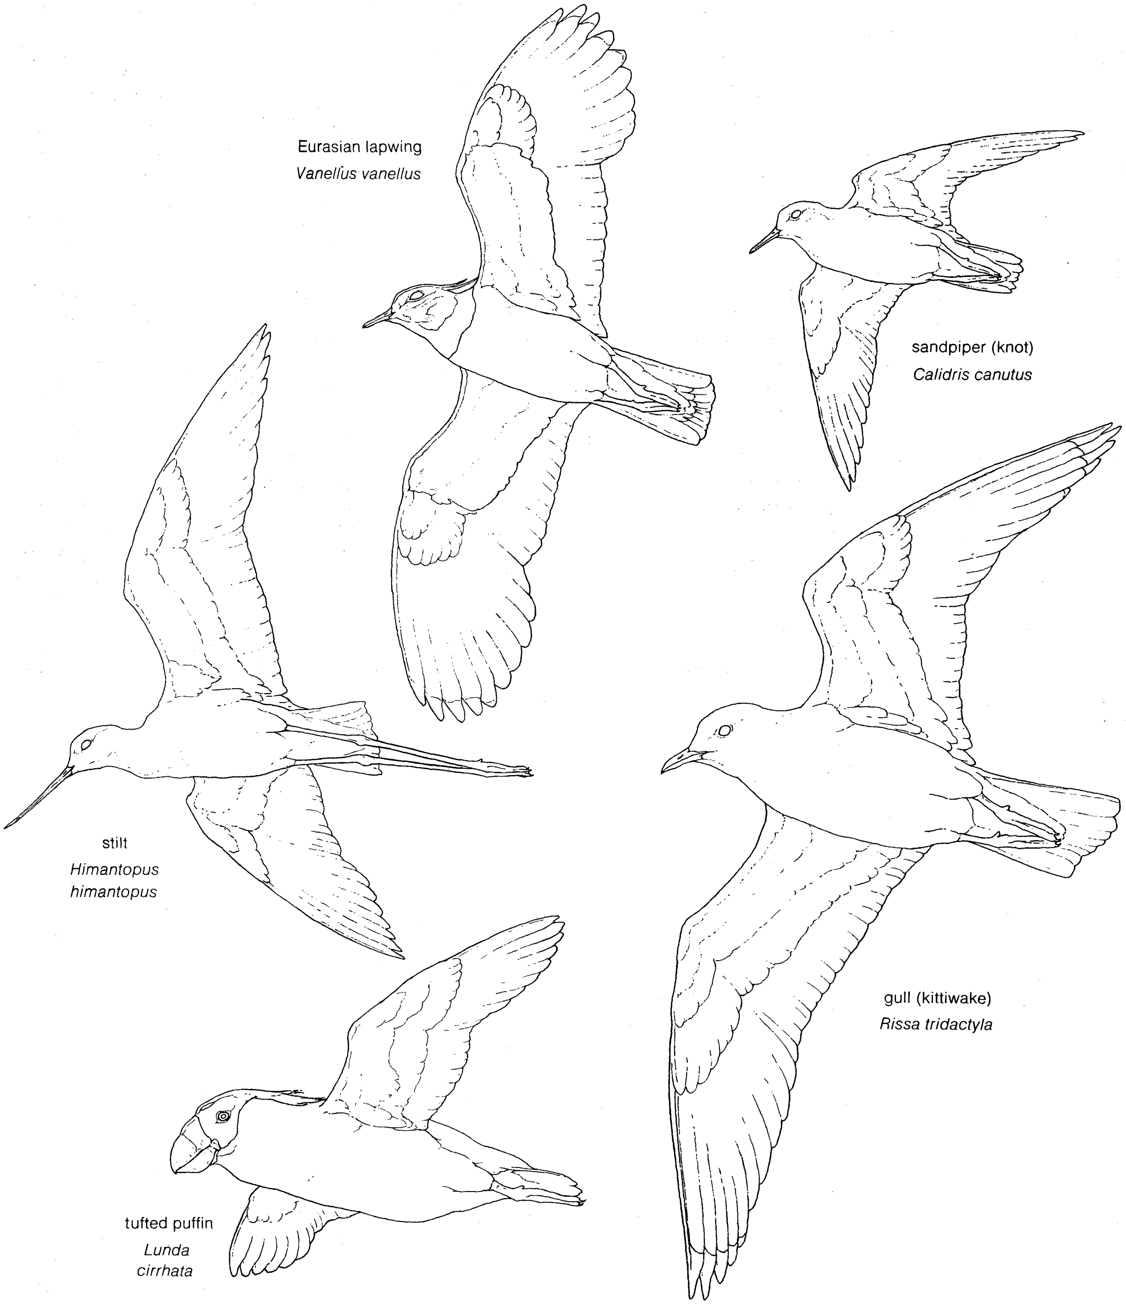

Figure 28: Body plans of typical members of major charadriiform groups.
Drawing by G. Tudor

easily recognized on the basis of general body plan. The first of these (the suborder Charadrii), collectively known as shorebirds or waders (Figure 28), includes sandpipers, plovers, lapwings, snipes, stilts, and some less familiar forms. They are primarily birds of shorelines and other open areas, and they walk or wade while feeding. There are about 200 species, varying in size from the least sandpiper, a sparrow-sized bird of about 20 grams (slightly under an ounce), to large curlews of about 640 grams (1½ pounds, near the body size of a small chicken). A second group, the suborder Lari, contains 92 species of gulls, terns, skimmers, skuas, and jaegers. They are long-winged, web-footed birds, the smallest of which is the least tern (*Sterna albifrons*), weighing about 43 grams (1.5 ounces), with a wingspread of about 50 centimetres (20 inches). The largest, the great black-backed gull (*Larus marinus*), weighs about 1,900 grams (a little over four pounds) and has a spread of about 165 centimetres (65 inches). The third and smallest suborder, Alcae, contains 21 species of auks, murres, guillemots, and puffins, all in a single family, Alcidae. They are compact, streamlined, marine birds with short, narrow wings and webbed feet. Alcids are adapted for swimming on the ocean surface and underwater.

Most charadriiforms have plumage patterns in white, grays, browns, and black, and many have bright red or yellow feet, bills, wattles, eyes, or mouth linings. A few species have both dark and light plumage phases.

Distribution

Each of the larger families (Laridae, Charadriidae, Scolopacidae) is practically worldwide in distribution, although none of the Scolopacidae breeds in Australia. The skuas and jaegers (Stercorariidae) are found in high latitudes of both hemispheres and are wide-ranging through the world's oceans. Auks and their allies (Alcidae) are widespread in the oceans, islands, and seacoasts of the Northern Hemisphere. They are not related to their similar counterparts of the Southern Hemisphere, the diving petrels and penguins. The oystercatchers (Haematopodidae) are found on coasts of all continents except Antarctica and occur inland in Europe and Asia. A group of families occurs in tropical (or tropical and temperate) regions of the Eastern and Western hemispheres: jacanas (Jacanidae), painted snipes (Rostratulidae), avocets and stilts (Recurvirostridae), thick-knees (Burhinidae), and skimmers (Rynchopidae). The coursers and pratincoles (Glareolidae) occur throughout tropical and temperate regions of the Old World, and the crab plovers (Dromadidae) are limited to shores of the Indian Ocean. Seed snipe (Thinocoridae) are found in southern South America, and northward in the Andes; sheathbills (Chionididae) occur on islands of the southern Atlantic and western Indian oceans and on the southern coast of South America and adjacent Antarctica. Phalaropes (Phalaropodidae) breed in northern regions, and two species winter at sea.

Importance to man. The eggs of murres, puffins, gulls, terns, and lapwings have long been harvested for food. These birds are particularly suitable for such use because many nest in enormous colonies, and because they replace the clutch if the first is taken soon after laying. Several hundred thousand eggs, and sometimes over a million, may be taken from a locality in a single year. Certain colonies, especially those of gulls and terns, have been raided without regard to the future of the colonies, but carefully controlled egging has long been conducted in the Faeroe Islands, Iceland, Greenland, and other northern regions. Adult puffins and other alcids are also harvested with long-handled nets on the Faeroes and in Iceland.

Extravagant exploitation of the great auk for food on its North Atlantic nesting islands by sailors, and later slaughter for the feather trade, probably caused its extinction in the 1840s. Other charadriiform birds, especially terns and gulls, assumed a sudden economic value for decorating women's hats in the latter half of the 19th century, and raiding of breeding colonies in North America almost extirpated several species. Aroused public opinion, hastened by the activities of the newly formed Audubon societies, brought protection to gulls, terns, and other species.

Charadriiform birds have had considerable economic impact in various other ways. California gulls are credited with saving the pioneers' crops in Utah during a plague of locusts, and today gulls habitually follow the farmer's plow, consuming exposed grubs and mice. Flocks of noddy terns and other birds serve to guide Hawaiian fishermen to schools of tuna, and the numbers, kinds, and behaviour of the birds may also indicate the size of the fish and the size and depth of the school. Certain shorebirds were once extensively killed for food or sport (causing near extinction of the Eskimo curlew); today woodcock and snipe are hunted under regulation.

Gulls and shorebirds are occasional hazards at airports, where airplanes have been damaged by collisions.

The order as a whole has been the subject of much scientific investigation, leading to important studies on speciation, ecology, ethology, migration, anatomy, and physiology.

NATURAL HISTORY

Locomotion and feeding behaviour. Most shorebirds inhabit open areas and are strong fliers, some performing extensive migrations that cover long distances over water. A ruddy turnstone (*Arenaria interpres*) banded in the Pribilof Islands was recaptured in the Hawaiian Leeward Islands, 3,770 kilometres (2,325 miles) away, four days later. Gulls, terns, skimmers, skuas, and jaegers spend much of their time on the wing, both in migration and in moving within the breeding or wintering grounds. Immature sooty terns (*Sterna fuscata*) spend several years flying at sea before first coming to land to breed, and Arctic terns (*Sterna paradisaea*) fly each year to and from Antarctic waters after breeding in the Arctic. Gulls are given to soaring and gliding more than the others and are the only members of the suborder Lari that spend considerable time swimming or resting on water. Of the three major charadriiform groups, the alcids spend the least time on the wing, but they are strong, fast fliers for short distances. Outside the breeding season they are pelagic (*i.e.,* living on the open ocean).

Food habits of shorebirds

The feeding habits of the charadriiforms are as varied as their external appearance. Jacanas inhabit pools and lakes thick with water lilies and other aquatic vegetation. They run agilely on lily pads with prancing steps, supported by their remarkably long toes and claws. While foraging, they turn over lily pads in search of snails, arthropods, and other small animals.

Plovers (Charadriidae) and the crab plover (Dromadidae) usually forage on open ground, relying on sight to locate the invertebrates on which they feed. The foraging bird runs a few steps, pauses with head cocked, then pecks at possible prey or runs again. Most plovers feed during the day, but the crab plover feeds mostly at twilight. Oystercatchers (Haematopodidae) feed largely on mussels, oysters, and marine worms. Depending on the type of mussel bed being exploited, the bird either tears loose a mussel and hammers a hole in the shell or, finding the mussel in water with its shell open, drives the knifelike beak into the open shell, cutting the adductor muscle and preventing the shellfish from closing.

Sandpipers and their relatives (Scolopacidae) use their slender bills as forceps to pick up surface invertebrates or (especially in the calidridine sandpipers) for probing in mud. Curlews use their long, downcurved bills for probing crustacean burrows on beaches and worm burrows on mudflats, and for picking up insects and berries on tundra or grassland. Woodcock (*Philohela* and *Scolopax*) also probe, but in woodland soils and leaf litter, feeding extensively on earthworms. Turnstones (*Arenaria*) habitually flip over vegetation, debris, soil, and stones with the straight upper edge of the bill, eating the animal life thus exposed.

Avocets and stilts (Recurvirostridae) feed in shallow water by sweeping the opened bill from side to side over the bottom (avocets) or near the surface (stilts). Stilts also feed by pecking and probing. The ibisbill (*Ibidorhyncha*), a recurvirostrid with a downcurved bill, inhabits Himalayan lakes and rivers and feeds by reaching under rocks in water for insects, mollusks, crustaceans, and worms, sometimes while wading belly-deep. Phalaropes (Phalaropodidae) habitually feed while swimming and sometimes stir up prey by spinning around.

Coursers and pratincoles (Glareolidae) are insectivorous birds of open country. Coursers feed most actively at night, taking termites, black ants, and other terrestrial arthropods by short dashes. Pratincoles hawk insects on the wing in the manner of swallows.

Sheathbills (Chionididae) inhabit Antarctic regions, where overdependence on one type of food may be disastrous. They subsist on algae; limpets and other mollusks; crustaceans; fish; the eggs and nestlings of penguins, cormorants and other birds; afterbirth and droppings of seals; and human refuse.

The food habits of seed snipe (Thinocoridae) are unique within the order. These chunky, terrestrial birds eat primarily vegetable matter, such as seeds, buds, shoots, and leaves, for which their short, stout bills are well suited.

Food habits of gulls and relatives

The gulls and their relatives (suborder Lari) are more dependent on flight for obtaining their food than are the shorebirds. The strongest fliers are the skuas and jaegers (Stercorariidae), which are gull-like in general proportions but with hooked bills. Stercorariids harass terns, gulls, boobies, and other seabirds until the latter drop or regurgitate food, which is retrieved by the "pirates." On their Arctic or Antarctic breeding grounds these birds prey on insects, rodents, small birds, and the eggs and young of other seabirds.

The diet of gulls (Laridae) is highly varied, including fish, small birds, and rodents, and a wide range of invertebrates, taken by active predation, as well as carrion of all sorts, garbage, and some vegetable material. Many of the larger gulls are not beyond piracy, stealing food from other birds (including members of their own species), and some prey heavily on the eggs and young of other seabirds. Sometimes they hawk insects or break open shellfish by dropping them from a height.

Most terns are smaller than gulls. All have straight, sharp bills and feed chiefly on the wing, by hovering over the water and plunging in for surface fish and crustaceans, by swooping low to pick fish from the water in flight, or by hawking insects over land.

Skimmers (Rynchopidae) feed by day or night. The bird flies over the surface of calm water at speeds up to 30 miles per hour with the long, knifelike lower mandible cutting the water. When the mandible strikes a fish or shrimp, the head doubles under the body and the bill clamps shut. The bird flies upward and swallows the fish in the air or carries it to the nest.

Food habits of alcids

Alcids (family Alcidae) are the only charadriiforms adapted for swimming underwater, which they do by propelling themselves with half-open wings. The larger alcids (puffins, murres, auks, and guillemots) feed on small fish and invertebrates, the smaller ones (murrelets and auklets) almost entirely on invertebrates, especially on tiny, free-swimming (planktonic) crustaceans, such as euphausids.

Breeding habits of shorebirds

Reproduction. The modes of reproduction in the charadriiforms are only slightly less diverse than the food habits. Nearly all are ground nesters, laying few eggs (two to four in most families; up to six in jacanas) often with little or no nesting material. Usually the eggs are protectively coloured. Some species nest in crevices or burrows, a few in trees. Many are colonial, with aggregations running to over a million pairs. Sex reversal, in which the female is more brightly coloured than the male and takes a dominant role in courtship, while the male incubates the eggs and rears the young, is found in most jacanas, painted snipe, and phalaropes.

Female jacanas are larger and more aggressive than males; after laying, females of some species show no interest in the nest or young, leaving incubation and care of chicks to the male. The nest is a shallow, sodden pile of vegetation that floats among aquatic plants. Chicks are downy and run well when a day old. Both chicks and adults may dive to escape danger and remain submerged (probably clinging to vegetation) with only the bill exposed. Adults have been known to take chicks up to 12 days old under their wings and carry them to a safer location. Jacanas perform injury-feigning displays and other striking displays, sometimes with their broad wings stretched aloft, and they attack other species near the nest.

The female of the Old World painted snipe (*Rostratula benghalensis*) is larger and more brightly coloured than the male, whereas the South American species (*Nycticryphes semicollaris*) shows little sexual dimorphism, although females are slightly larger. As in some jacanas, the female of *Rostratula* is more aggressive in courtship, displaying with spread wing and tail, and she leaves incubation and care of the chicks to the male. The nest is a shallow platform of bent reeds in which the four eggs (two in *Nycticryphes*) are incubated for about 19 days. The downy young take to the water readily.

Phalaropes nest in open tundra, marsh, or sedges near water. Females take the lead role in courtship and aggression, and several may vie for a male and fight among themselves. Copulation occurs on the water. There is no pronounced territorial behaviour around the nest, but a female may drive other females away from her mate. Incubation and care of the brood is performed by the male, and females leave the nesting grounds with the onset of incubation. The chicks are aquatic, swimming within an hour of hatching, and they perform the spinning habit commonly used by adults when feeding in water.

Oyster-catcher communal display

Oystercatchers (Haematopodidae) are noisy, stocky birds of coasts and shores. They are highly gregarious and even perform sexual displays within the flock. One such display is the piping performance involving a number of birds that run toward a central point, holding the bill and neck down and the bill open, uttering a loud piping. Groups also pipe and posture (lowering the bill and neck) in flight. Before copulation the male circles the female in a crouching pose with tail and bill lowered, while the female indicates readiness by raising her tail. All behaviour patterns (except the precopulatory ones) are common to both sexes. Oystercatchers have no strong territorial behaviour at the nest, often tolerating strange birds nearby, but they may return to the same spot with the same mate in successive years. Although pairs separate from the flock to nest, they periodically rejoin communal displays during breeding. The two or three eggs are incubated by both parents. Downy young move to the water's edge, where they remain on a feeding territory for at least six weeks and are fed small worms by the parents, who forage within sight in shallow water.

Avocets and stilts (Recurvirostridae) resemble oystercatchers in basic breeding behaviour, although the specific display patterns are different. Avocets nest in small colonies of up to a few hundred pairs, in grassy salt- or freshwater marshes that have substantial areas of shallow open water. Both sexes incubate the four eggs and protect the young. Stilts are somewhat colonial in their nesting, sometimes sharing a marsh with avocets. Stilts perform group displays in the breeding season. The ibisbill lays its eggs among the rocks of glacial streams. When alarmed, it bobs its tail and pumps its head up and down.

Most plovers nest in open areas, relying on their coloration to protect them while incubating or brooding. The solid colour of the back in the true plovers (*Charadrius*) matches the ground, and one or more black bands on the breast and face break the outline of the bird.

Many plovers are somewhat colonial but also exhibit territorial and aggressive behaviour. Some perform song flights during the breeding season, and many have melodious, whistled calls and bob when alarmed. The nest is a scrape or hollow with scant lining, in which four eggs are laid. Incubation is usually shared by the pair and takes from 20 to 30 days, depending upon the species. The chicks feed themselves but are usually protected by both parents by means of alarm calls that elicit crouching in the chicks. Often, parents will feign injury to divert a predator from their young. Many species occur in large postbreeding flocks and migrate great distances.

Crab plovers (*Dromas ardeola*) breed colonially in burrows in sand banks and fashion a nest chamber at the end of the narrow, three-to-five-foot tunnel. Here the bird lays a single, relatively large, white egg. The downy young is fed in the burrow by both parents.

Most pratincoles and coursers nest like plovers. Pratincoles breed in scattered groups, laying two or three eggs in an unlined scrape. They have a distraction display at the nest. The Egyptian plover (*Pluvianus aegyptius*) buries its egg in sand by day and incubates at night. Most glareolids lay two eggs, but the double-banded courser (*Rhinoptilus africanus*) lays only one, often located near antelope droppings, for concealment on otherwise bare ground. In that species, incubation by both sexes lasts about 26 days, and eggshells are removed. The chick has sparse down and is fed for about six weeks, until nearly fledged. A second egg may be laid before the first chick is independent. Adults and young combat the desert heat by panting, and adults also raise dorsal feathers and expose their legs during incubation.

The thick-knees frequent dry open ground but within reasonable distance of water. They are cryptically coloured and spend much of the day squatting on their heel joints ("knees") or resting flat on the ground with the legs drawn under the body. On hot days the legs may be extended behind the resting bird, perhaps for heat dissipation. They have large eyes and are active and noisy from dusk until dawn. Their displays include spread wing and tail postures. The one or two eggs are laid on bare ground and are incubated for 25–27 days by the female or by both birds. Both parents attend the downy chicks, which run from the nest a day after hatching and fly when six weeks old.

Sheathbills are the most gull-like of the Charadrii. Their feet are not webbed, but they swim well and fly strongly at sea hundreds of miles from land. Males bow, bob, strut, and coo during courtship. They build bulky nests in holes, burrows, or rock crevices. Their two or three eggs are laid more than a week apart, but incubation begins with the first. As a result, the chicks are of different sizes and rarely does more than the largest one survive. This seemingly wasteful system is an adaptation that allows the sheathbills to fledge the maximum number of young permitted by their fluctuating food supply.

Most members of the Scolopacidae (the largest family of the shorebirds) construct nests on the ground, but several species use the abandoned nests of other birds, in trees or on the ground. Most of the calidridine sandpipers have courtship songs given in flight and are monogamous, but the ruff (*Philomachus pugnax*) is notable for social courtship, performed on the ground, and for promiscuity. Males have a prominent collar of feathers of the head and neck (the "ruff") that are of different colours and patterns in different individuals. They assemble at communal display grounds (the arena or lek) where each bird occupies and defends a site during the day; occasionally, an "apprentice" male may be permitted to share an occupied site. Females visit the lek briefly and copulate with one or more birds. There is no pairing, and females assume all domestic responsibilities.

Woodcock and snipe (subfamily Scolopacinae) nest on the ground in dry woods (woodcock) and marshes (snipe). The males of most species perform courtship flights in which some or all of the "song" is produced by specialized wing or tail feathers. Woodcock are largely solitary and nocturnal and are known to fly to safety with a chick carried between their legs.

The subfamily Tringinae is the most diverse of the subgroups of the Scolopacidae. The breeding behaviour of the greenshank (*Tringa nebularia*) includes many features common to a number of shorebirds and provides a useful model for comparison with the behaviour found in the Lari and Alcae.

Breeding behaviour of the greenshank

From their winter quarters throughout much of the Old World temperate regions, greenshanks usually return north each year to the same breeding territory and often to the same mate. Males usually precede females to the breeding grounds, but sometimes they arrive together. Their nesting grounds are in northern Europe and Asia, in flat meadows or swamps near lakes, or in bogs with clusters of trees. The nesting territories vary in size from 100 to 700 acres, and nests may be three to eight kilometres (two to five miles) apart, or as close as a half kilometre. When the territories are relatively small, singing and fighting reaches a high pitch. In aggressive displays, opposing males lean forward with tails fanned, meeting bill to bill. They may then flutter over one another with legs dangling, in leapfrog fashion. Potentially dangerous intruders are met with violent scolding calls, flicks of the open wings, or shaking the half-raised wings. Anxiety is expressed by bobbing and curtseying or stretching the neck.

Flight songs are performed frequently during courtship and territorial adjustment, intermittently throughout incubation, and less regularly later. The tempo is quickest in unmated birds, which fly high (sometimes out of sight), singing, on downward glides and upward flight, while soaring and circling, sustained bursts of "too-too-too," with other calls interspersed. Unmated males chase other birds in the air. Upon landing the male gives an aggressive display toward other individuals. Males return the display, but females fly off, with the male in wild pursuit, sometimes attaining a great height and ending in a spectacular dive. The female may glide on bowed wings while the male rises and dips over her, dangling one or both legs, or he may flutter over a standing female in leapfrog display. The female invites copulation by tilting forward and squatting, and the male approaches and mounts, sometimes while waving his wings. Copulation is attempted repeatedly by the male before the female becomes receptive.

The male escorts the female to various parts of the territory, but she chooses the nest site and makes a scrape by lowering the breast, turning, and scratching with her feet; she also brings nearby plant material in her bill. A former nest may be reused for three or more years. The site is usually close to a landmark such as a boulder, stump, or tree. On occasion a single male greenshank may command two females that nest four to 250 metres apart or that occasionally lay in the same nest, where they may incubate side by side.

A clutch of four speckled and cryptically coloured eggs is laid in late April or early May and is incubated for 23 or 24 days. The eggs are laid at any time of day, and the female is accompanied by the male to the nest during the laying of at least the first eggs. Both members develop incubation patches (featherless areas of skin abundantly provided with blood vessels) on the sides of the breast and across the abdomen, and both share in incubation, although occasionally the male defaults. Duty shifts are most frequent at early morning and evening hours, and males generally incubate at night. The free individual spends its time at feeding grounds—usually a lake or marsh up to eight miles away, where it feeds, preens, or rests, or it may engage in song flights over the territory. The incubating bird sits tightly, even in the presence of danger, but it may spring off the eggs and perform an injury-feigning display. An egg knocked out of the nest is drawn back in by rolling it with the underside of the bill.

When the eggs are pipped the male spends much time perching near the nest. Chicks pipe inside the eggs and the hen calls back; she may or may not enlarge the egg hole by pecking. Immediately after the hatching the adult carries the shells some 50 to 500 metres and drops them, or occasionally eats them. The chicks, covered with protectively coloured down, leave the nest during their first day, running rapidly on relatively large feet. They scatter and squat at the alarm call and rally to gutteral clucking by the parent. The female herds the chicks toward the lake, preceded by the male, who acts as sentry. Chicks may have to cross streams or rivers and survive cold rains, but they are brooded during storms and at night for about two weeks. They are sometimes taken by weasels, gulls, hooded crows, or other predators. Sometimes the family separates, each parent taking one or more chicks, or one parent may depart, leaving all responsibility to the other. The chicks are feathered and fly at about 26 days of age but stay near the parents until they are experienced fliers.

Breeding behaviour of herring gull and relatives

The members of the suborder Lari are quite different in breeding behaviour from those of the Charadrii. The herring gull (*Larus argentatus*) is typical of many of the better known gulls. It inhabits subarctic and temperate regions of the Northern Hemisphere. It is not strongly migratory, but most birds shift southward after breeding, and some go as far as Panama, the Hawaiian Islands, the central African coast, northern India, Southeast Asia, and the Philippines.

In winter herring gulls have a daily routine of flying from their social sleeping grounds to the feeding grounds, near which they may rest and preen, returning to the roosting area in the late afternoon. Storms may flood the broad beaches or sandbars that they require for roosting, forcing them to shift many miles in search of a new area.

As spring approaches, the birds drift north to their breeding grounds, over which they may wheel one day only to disappear and return on another day. Eventually the birds land on the dunes or rocky coast that has been their traditional colony. Some stand in pairs, while others are in small groups known as "clubs." Old birds have already paired in February, and they return to their former territories, which are about 30 to 50 metres in diameter. The gulls establish or defend their territories by a number of aggressive displays, which may occasionally lead to fierce fighting.

Threat display of one bird may be met by threat, by anxiety or appeasement postures, or by retreat. The individual is usually dominant on its established territory. One aggressive display is the "oblique with long call," in which the neck is stretched obliquely forward and upward, the wings held slightly out from the body, and a loud, long-drawn call given with the bill wide open. In the silent "upright" threat posture the head is raised, the bill angled downward, the wings held stiffly apart from the body. A bird that approaches an intruder in this posture may increase its speed to a charge, half running and half flying. The intruder usually retreats to his own territory, where he, in turn, will perform the upright threat posture. Another aggressive action is "pecking the ground," in which the bird pecks and often tears out moss or grass, which it holds or tosses aside. Tugging at grass is strenuous and occasionally results in a backward tumble. A third threat posture, called "choking," often used by both members of a pair to intimidate another pair, consists of standing with legs bent, breast lowered, head pointed down, and the tongue lowered, while rhythmically jerking the head and uttering a deep call. These displays are effective in intimidating intruders, but occasionally fights break out in which birds peck or hold each other with their bills and pummel each other with their wings. Threat and fighting subside after territories have been established, and groups of neighbours recognize and tolerate each other.

Younger birds, not yet paired, settle in clubs. Here they doze or preen, and sometimes threaten or chase newcomers. Young males perform the "oblique with long call" display, causing other males to avoid them and females to land near them. Females approach males with the neck drawn in and the body and head horizontal, sometimes "head tossing" and uttering a liquid call. Instead of threatening, the male may be induced to walk off with such a female. Aggressive feelings are lessened by a display called "facing away," in which one or both birds, with neck stretched up, abruptly turn the head to the side away from the other bird. Together they make incomplete nest-building movements in a posture that resembles choking. The male may regurgitate half-digested food, which the female takes from his mouth and eats. This courtship feeding is repeated during pair formation but becomes less frequent as copulation becomes more frequent. Copulation is preceded by head tossing and begging calls by both members. The male stretches his neck and mounts the female's back while uttering a hoarse rhythmic call. The female continues to toss her head or may reach up to touch the male's breast while he waves his wings to maintain balance.

Courtship feeding

Copulations, choking, and courtship feeding may occur at the club, but eventually the pair walks off to establish a territory. They make several hollows (scrapes) with their feet, and begin to build a nest at one of them. Both collect bits of straw and moss, which they bring to the nest and which they may deposit while sitting in the nest with a sideways movement of the head. They scrape and turn in all directions to shape the nest.

The female lays three eggs at two-day intervals. With the first egg one bird (or both) stays at the nest, sitting or standing guard. They incubate in turn, relieving each other after periods of about two to five hours and often bringing new nest material. The arriving bird may call or "choke" and may have to push its reluctant mate off the eggs. If an egg is knocked out of the nest the bird rolls it back in, precariously balancing it with the thin lower edge of its bill. An incubating bird recognizes its returning mate by call even amid the clamour of the colony. Herring gulls apparently do not recognize their own eggs but return first to the nest site, even if the eggs are placed outside nearby. Incubation lasts about 30 days, including the three-day hatching period after the egg is first cracked. As part of the overall adaptations for concealment of eggs and chicks, gulls defecate at some distance from the nest and carry off the eggshells at hatching.

Defense of the brood lasts several weeks and consists of swoops at intruders, with one or both feet lowered. The alarm call of one bird in the colony alerts the others, but gulls learn not to react to alarm calls of individuals that tend to give false alarms. The chicks are brooded for about three days. They soon peck at the red spot on the adult's bill, which induces the parent to regurgitate food (usually worms) that is held for the chick to eat. Other activities of the chicks are preening, yawning, stretching, scratching, and crouching at the alarm call; later they run from the nest before crouching. Chicks that wander near other adult birds may be pecked to death.

After the chick's juvenile feathers have replaced the down and the bird approaches adult size and shape, its own parents may react aggressively toward it. The chick then adopts a submissive posture—with head withdrawn and body horizontal—similar to that of a female approaching a prospective mate. Full-grown young beg for food by head-tossing and high-pitched calls, but they are ignored or rejected as they become independent.

Herring gulls have concealingly coloured eggs, and their nests are widely spaced. The mobbing reaction in which many birds may participate is usually effective in distracting or repulsing a predator before it can extensively damage the colony.

The elaborate display repertoire of the herring gull during the breeding season is duplicated in other species, with some variations, additions, or deletions. The "hooded" gulls, exemplified by the black-headed gull (*Larus ridibundus*) and laughing gull (*L. atricilla*), have a striking "swoop-and-soar" aggressive flight display, and a ground display (called the "forward") wherein the neck is lowered, the head withdrawn and angled upward, and the wings held out from the body.

Several species of gull nest on narrow cliff ledges where they gain protection from predators but have limited space and face constant danger of the eggs or chicks falling off. In the kittiwake (*Rissa tridactyla*) adaptations against predation are reduced—alarm calls are rare, chicks are not camouflaged, defecation occurs on the nest rim, and eggshells are not carried away. Security against falling is achieved by a deep nest cup, smaller clutch (two eggs), and strong claws. The chicks crouch in the nest rather than running out.

The kittiwake is pelagic after breeding, and the swallow-tailed gull (*Creagrus furcatus*) of the Galápagos is semipelagic and nocturnal. The gray gull (*Larus modestus*) flies inland to waterless Chilean deserts to breed.

Breeding behaviour of terns

Terns are, in general, smaller than gulls. Most are coastal or pelagic during the nonbreeding season, returning to breed in large colonies on islands, offshore bars, isolated beaches, or on Arctic tundra. The common tern (*Sterna hirundo*) and royal tern (*Thalasseus maximus*) and their relatives nest on the ground, whereas noddies (*Anous*) nest in bushes or on cliff ledges, and the fairy tern (*Gygis alba*) deposits its single egg on the limb of a tree or bush. Nests of *Sterna* and *Thalasseus* may be so closely spaced that neighbouring birds spar with their bills as they incubate.

Displays of terns are more aerial than those of gulls and include "fish flights" in which one bird postures while carrying a fish. Ceremonial transfer of fish occurs during displays on the ground that are important in courtship and for maintenance of the pair bond.

Unlike gulls, most terns do not regurgitate food for the chicks but bring a fish back to the colony; there it is fed to the chick, which energetically pecks at the adult's bill. Chicks of royal terns band together soon after leaving the nest and may take to the water when predators approach. Terns are fierce in their mobbing attacks on predators. Like gulls, they often peck and kill chicks that trespass on their territories. Sooty terns (*Sterna fuscata*) have attracted considerable attention from biologists because on Ascension Island in the South Atlantic they breed every 9.6 months and on Christmas Island, in the Pacific Ocean, every six months. Elsewhere they have an annual cycle.

The breeding pattern of skimmers is ternlike. They breed on sandbars in rivers and estuaries in tropical and subtropical regions, forming loose colonies of about 100 to several thousand pairs. The nests are mere hollows in the sand. The eggs usually number three or four and are incubated chiefly by the female. The chicks are fed by both parents, mainly on small fish. In the presence of danger the chicks lie flat or burrow into the sand and may even kick sand onto their backs. Their mandibles are of nearly equal length until after fledging, enabling them to pick up fish brought in and dropped by the parents.

Although not strongly colonial in their nesting habits, numbers of skuas (*Catharacta skua*) may nest on the fringes of penguin colonies; in Iceland they nest in clumps of vegetation on great outwash gravel plains. Jaegers (three species of *Stercorarius*) nest on the tundra, where both sexes share in incubating the two eggs. Some species have light and dark phases. They are pelagic and solitary after breeding.

Breeding behaviour of alcids

Alcids breed in island colonies along Arctic and north temperate seacoasts, with the exception of a few murrelets that breed inland on mountains. Even these must remain within flying distance of the sea. The breeding behaviour of the pigeon guillemot (*Cepphus columba*) is fairly typical of the family. This species breeds on islands and coasts of the North Pacific, south to central California. It nests between rocks or in holes in cliffs, uses burrows of other birds, or digs its own tunnels with its bill and feet. Occasionally it nests on an open ledge or in tall grass. Unlike some other alcids, guillemots walk quite well on land.

Birds land at their breeding colonies in British Columbia in early April, at which time they stay only briefly in the early mornings. In general, birds return to the same mate and nest burrow for many years. Full attendance is achieved by the end of June, but even then many birds leave the colony in the afternoon to go to their feeding grounds—shoals that may be several miles distant. Only incubating and brooding birds spend the night at the colony. They drive other birds away from their burrows before egg-laying but are more tolerant later in the season when feeding young. The pair also defends a perch site away from the nest burrow, usually a rock close to the water. On this site, which is used in successive years by the same pair, copulation occurs and the nonincubating bird may rest and preen. About 30 percent of the birds at the colony consists of nonbreeding individuals—yearlings or two-year-olds that were hatched at the colony but are unpaired.

Communal water displays

During the pre-egg stage, which lasts about 30 to 60 days, the mated pairs spend much time at the perch sites, but they occasionally visit the nest site or cliff top and join in communal water displays. Their display repertoire includes several alarm reactions—the flight intention call, bill dipping (in water), and a scream delivered with the neck straight up and the bill agape. Among the aggressive and sexual displays are a silent lunge on water or land with bill somewhat open, chases that may be in flight or underwater, and a "hunch-whistle" on shore or water, with tail cocked, the head drawn back, the bill agape, accompanied by piping. A display that may represent appeasement is the "twitter-waggle" in which the bird twitters with the tail raised, wings loose, and head and neck outstretched and wagging sideways. The communal water dances, which occur in the pre-egg stage, involve many birds. Pairs are not always together or both present. The birds move rapidly under water or at the surface propelled both by wings and feet. This behaviour is interspersed with "hunch-whistles" and "twitter-waggles."

Pair formation is indicated by mutual "billing," in which the birds waggle their heads but rarely touch bills, while uttering a twittering trilled song with the bill open, revealing the bright red mouth lining. Copulation is initiated by billing, followed by the male's waddling in a circle, first in one direction, then in the other. The female crouches and the male mounts, resting on his tarsi and fluttering his wings to keep balance; the female may gape, scream, or utter an alarm call. She then rises, throwing off the male, and the birds bill or preen.

The pair cleans debris out of the nest cavity and piles up pebbles, without making a well-defined nest. A normal clutch is two eggs (rarely one), and the birds' brood patches will not accommodate more than two eggs. The second egg follows the first by three days. Incubation lasts for about 32 days, including a two-day interval between cracking and hatching. Steady incubation during the day begins one day after the clutch is complete, but incubation at night may not begin for one or two days more, at which time a single bird begins to sit all night until the early morning exchange. The incubating bird may leave the burrow briefly to defecate, preen, bathe, or drink, but it will not go to the feeding grounds until its mate arrives at the burrow. The downy chicks are fed, beginning the day after hatching, by both parents during their 35-day nestling and fledging period. Their food is mostly fish, including many blennies, sculpins, and sand lances, brought in the parent's bill throughout the daylight hours. The chicks may reject fish that are awkward to swallow or that have sharp spines. Fledged chicks eventually desert the burrow by night and may be coaxed out by a fish dangling in the parent's bill. The young are then independent and they disappear offshore to feed without the parents, who may remain to loaf about the colony during morning hours for several weeks.

Behaviour patterns like those of the pigeon guillemot run through many species with various modifications. Many alcids are burrow nesters, and some (*Uria*) habitually nest on narrow ledges of vertical cliffs, where they rest on their tarsi facing the rock wall. Some murrelets (*Brachyrhamphus*) nest in rock crevices above the timberline on mountains, and in trees of the taiga zone. Both sexes incubate the one or two eggs and feed the young at the nest site until it is nearly or completely fledged. Other murrelets (*Synthliborhamphus*) are truly nidifugous (precocious), their downy chick taking to the sea within two days of hatching. Many alcids nest in immense colonies of mixed species, which segregate in part according to their specialized needs for nesting and feeding. They migrate to pelagic winter feeding grounds by swimming.

FORM AND FUNCTION

Most members of the Charadriiformes are clearly recognizable as belonging to a particular suborder. Major structural variations occur in the beak and legs, correlated with the mode of feeding and size of food.

Adaptations for flight. Gulls, terns, and skimmers have long, narrow wings, low wing loadings (the ratio of weight to wing area), slow wing beat rates and flight speeds, and moderately developed flight muscles. Alcids, on the other hand, have proportionately shorter wings, high wing loadings, rapid wing beat rates and greater speed (45–55 miles per hour), and large flight muscles. Their wing bones are flattened in adaptation to underwater "flight." The shorebirds lie between the other suborders in flight adaptations; their wings are not adapted for soaring, but they are strong fliers and cover great distances in continuous flight.

The evolution of the wing in the Alcidae has been influ-

Drawing by G. Tudor

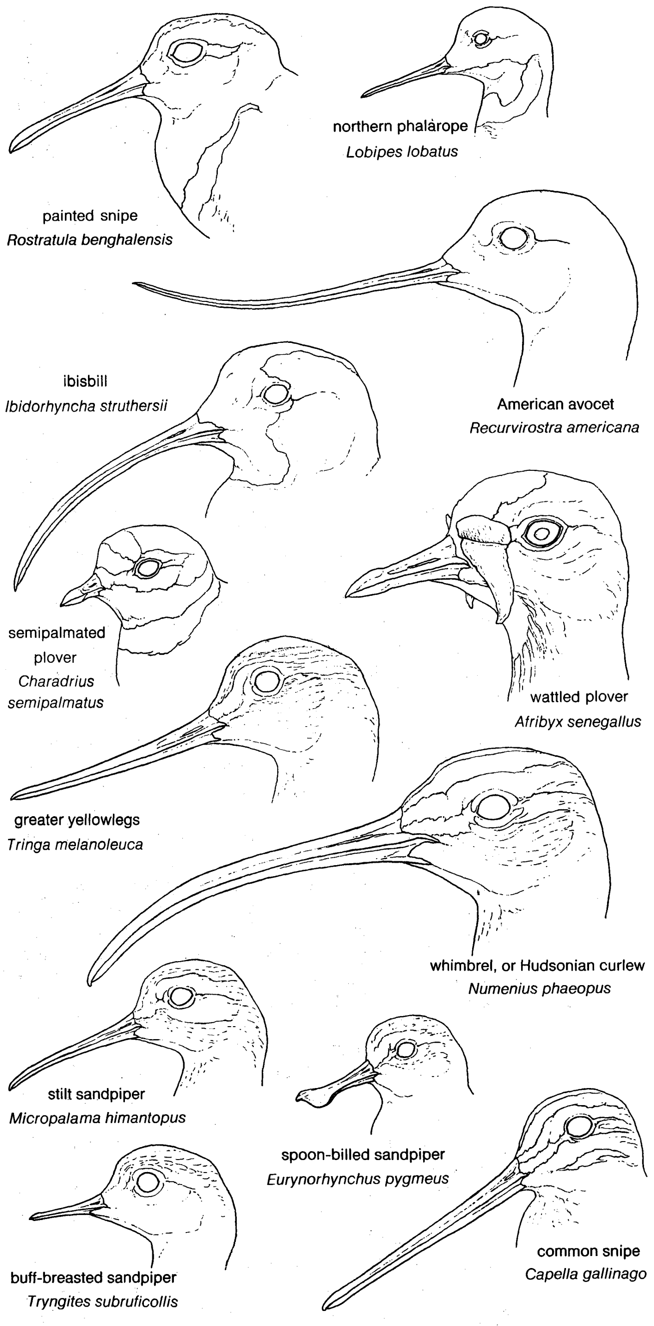

Figure 29: Bill variations among several shorebirds.

Aquatic use of wings

enced by the fact that it serves both as an aquatic paddle and as an aerial wing. The wing is partly folded underwater, reducing its area and increasing its mechanical advantage. It is used not to provide lift but to propel the bird in pursuit of prey. To support a bird in air, however, a wing must be larger than the optimum paddle size. This is especially critical in large birds, as body weight is proportional to the cube of linear dimensions and wing area to the square. Body size and flying ability are therefore limited by the need for a small effective paddle. In flightless aquatic species the wing can be relatively small and the bird can be much larger, as in the great auk and in penguins.

Molt. Most Charadriiformes have two molts between breeding periods, which are on an annual cycle in all except some populations of the sooty tern (*Sterna fuscata*). A partial body molt generally precedes breeding, and a complete molt follows breeding. In some species flight feathers of the wing and tail are molted before the fall migration; in others they are retained through the fall migration and molted on the wintering grounds. Still other species stop along the migration route to molt. The ruff (*Philomachus pugnax*) is exceptional in having one complete and two partial molts between breeding cycles.

Major flight feathers of most species are lost gradually and in sequence so that flight is not impaired. Flight feathers of the wing in most Alcidae, however, are molted simultaneously after breeding, with temporary loss of flight but no hindrance to underwater locomotion. One jacana (*Actophilornis*) is also flightless for a brief period.

Adaptations for feeding. As in other birds, the upper jaw as well as the lower jaw can be moved up and down. The lower jaw has special regions of flexibility enabling it to be widened by bowing outward and allowing passage of large prey into the throat in Lari and Alcae.

The shape of the bill varies greatly within the order, in accordance with special feeding methods. The hooked tip in gulls and jaegers facilitates grasping and tearing of food, which cannot be managed by the straight-billed terns. Some species such as the Atlantic puffin, rhinoceros auklet, and fairy tern are able to carry several fish crosswise in the bill while capturing still more. They do this by holding the fish against the roof of the upper jaw with the spiny tongue. The shorebirds exhibit a wide variety of bill types (Figures 29 and 30). Most bills in this group are long and slender, and straight or curved up or down. In the Scolopacidae, the bill is usually slender and flexible; in the Charadriidae, somewhat stouter and less flexible, often slightly swollen at the tip. Among the specialized probers (sandpipers, snipe, and allies), the upper jaw is rigidly attached to the cranium and has a mobile tip with a concentration of tactile sense organs under the rhamphotheca (the horny covering of the beak). The tip of the upper jaw is controlled by jaw muscles and serves to grasp worms or larvae underground and to inch them along the bill before swallowing.

In one plover (the wrybill, *Anarhynchus frontalis*) the bill curves to the right; in the spoonbilled sandpiper (*Eurynorhynchus pygmeus*) the tip of the bill is broad and spatulate. Oystercatchers have laterally flattened bills, with the tips forming a vertical blade. Seed snipe have short, conical bills not unlike those of sparrows. Pratincoles have short bills and wide mouths, like those of swallows and swifts.

The Lari show few bizarre modifications of the bill, feathers, or feet. One oddity is the bill of skimmers, in which the upper mandible is streamlined in cross section and laterally compressed. The lower mandible is knifelike and protrudes well beyond the upper. The sharp upper edge of the lower mandible fits into a groove in the upper when the bill is closed (see Figure 31).

Many alcids acquire bill ornamentation or head plumes during the breeding season. The functions of elaborate bill modifications are poorly understood but are believed to involve courtship and species recognition. The highly coloured plates on the bills of puffins (*Lunda* and *Fratercula*) are shed when the birds molt following the breeding season. In alcids that feed on zooplankton (tiny, free-floating animals), such as the least auklet (*Aethia pusilla*) and the dovekie or little auk (*Plautus alle*), the bill is relatively wide, the tongue large and fleshy, the palate broad with numerous horny projections, and the throat provided with an expandable pouch.

Many charadriiform birds drink saltwater. The ionic balance of their blood is maintained not only by the kidneys but by supraorbital glands (called nasal or salt glands) that lie in grooves in the skull over the eyes, discharging their salty excretion through the nostrils.

EVOLUTION AND PALEONTOLOGY

The earliest known Charadrii are represented by miscellaneous bones from the Upper Cretaceous rock layers of Wyoming, considered to constitute a family, the Cimolopterygidae, of the Charadrii. These bones, comprising two genera and four species, show closest resemblance to the avocets. Of similar age, but extending into middle Eocene times, are the Paleotringinae of the Scolopacidae, known from fossil deposits in New Jersey and Wyoming. These consisted of five species in a single genus of poorly known, large shorebirds, represented by fragmentary limb bones. Other probable relatives of the avocets, the Presbyornithidae, appear in the lower Eocene rocks of Utah. They are thought to be heavier bodied and more aquatic than present-day avocets, and to represent an ancestral stock from which the avocets and stilts descended. An extinct genus of the Rostratulidae and the modern genus *Limosa* are reported from the middle and upper Eocene of Europe. In the Oligocene are found extinct species in the modern sandpiper genus *Tringa,* in the plover genera

Drawing by G. Tudor

Charadrius and *Vanellus,* and in extinct genera of the Scolopacidae and Charadriidae. Possible relatives of the jacanas were the Rhegminornithidae from lower Miocene times of Florida; features of the tarsometatarsus suggest that these birds had a large hind toe. Other discoveries from the Miocene are extinct genera of the Scolopacidae, Charadriidae, Haematopodidae, and Burhinidae, and extinct species of four contemporary genera. Pliocene finds include the Recent *Bartramia* and *Micropalama* and an extinct genus of oystercatcher. Pleistocene deposits have added extinct species of four living genera, extinct genera of Scolopacidae and Charadriidae, and many examples of species still living today.

Within the Lari, extinct genera of the Laridae are reported from the Paleocene, Oligocene, Miocene, and Pleistocene, and an extinct genus of tern occurred in the Pleistocene. *Larus* and *Sterna* first appear in Miocene deposits—*Stercorarius* in the Pleistocene. Numerous modern species of Lari have been found in Pleistocene deposits.

The earliest of the auklike birds known at present were members of the alcid subfamily Nautilornithinae from the lower and upper Eocene of Utah. Represented by wing and leg bones, these birds are inferred to have had longer limbs than present forms and to have been less well adapted for flight underwater than are contemporary species. The Miocene produced the first known species of *Uria* and *Cerorhinca,* and an extinct genus of alcid. The murrelet genus *Brachyrhamphus* and the auklet genus *Ptychorhamphus* first appeared in the Pliocene, along with an extinct genus. Fascinating finds from the Pliocene are some very flattened wing bones (humeri) that exhibit features at both ends resembling those of penguins. These birds, the Mancallinae, were undoubtedly flightless and more specialized for underwater wing propulsion than was the now extinct great auk.

From this record of fossil Charadriiformes it appears that considerable adaptive radiation (diversification) has occurred and disappeared in the past. Modern families probably had their origins in Paleocene times or earlier, and many modern genera were well represented by the Oligocene and Miocene. Modern species date chiefly from the Pleistocene, and many facts concerning the distribution and differentiation of northern subspecies and species are explainable in terms of isolation during the periods of Pleistocene glaciation.

CLASSIFICATION

Features used in classification. The order Charadriiformes can be characterized by a variety of anatomical, behavioral, or other features, not all of which necessarily apply to any one species, genus, or family, and no one of which is necessarily found throughout the order. One set of characters may evolve rapidly in one group, another set in another. It is impossible to reflect all of these relationships in a single classification, and one must expect continued change in any classification with increasing knowledge of living birds and of fossils.

Annotated classification. The classification below follows that of the American ornithologist Alexander Wetmore. Groups indicated by a dagger (†) are known only as fossils.

ORDER CHARADRIIFORMES

Palate schizognathous; upper jaw schizorhinal (except Burhinidae and *Pluvianus*); lachrymal bone fused to ectethmoid; cervical vertebrae 15 or 16; dorsal vertebrae opisthocoelous or heterocoelous; two carotid arteries (except *Synthliborhamphus*); oil gland feathered; syrinx (vocal organ) tracheobronchial; wing diastataxic (except *Philohela*); aftershaft present; down feathers present on adults. Eggs usually pyriform (*i.e.,* somewhat pointed at one end). Chicks downy and nidifugous, pseudonidifugous, or nidicolous. About 312 species; worldwide.

Suborder Charadrii

Hypotarsus complex (with canals), coracoid bones usually separate, depressions for supraorbital grooves usually small or absent; basipterygoid processes and occipital foramina usually present; furcula without hypocleideum; adult downs on pterylae only. Young nidifugous (precocious).

†*Family Cimolopterygidae*

Fossil only. Known only from Upper Cretaceous strata of Wyoming. Four species; medium-sized shorebirds.

Family Jacanidae (jacanas)

Small to medium birds with showy plumage, moderately long, straight bills, and long legs. Some with wattles or lappets, a horny forehead plate, and wing spurs. Extremely elongated toes and long, straight claws. Occipital foramina and supraorbital grooves lacking; coracoids overlapping; rectrices 10. Females larger than males. 7 species; worldwide tropical and subtropical; length about 16–53.5 cm (6–21 in.).

†*Family Rhegminornithidae*

Fossil only; lower Miocene strata of Florida. One species; medium-sized birds.

Family Rostratulidae (painted snipe)

Small birds with cryptically patterned plumage, long slender bill, and moderately long legs. Female larger and brighter than male. Occipital foramina present; sternum narrow, with single pair of notches. Crop present in *Rostratula;* trachea convoluted in female. Two genera; one in southern South America, one in Africa, southern and eastern Asia, Australia; length 19–24 cm (7½–9½ in.).

Family Haematopodidae (oystercatchers)

Medium-sized birds with black, brown, or white plumage in bold patterns, or solid blackish brown. Bill long and wedge-shaped, bright red; legs moderately long, stout. Three toes. Supraorbital grooves large; tarsus covered with small, hexagonal scales. Four species, inhabit most temperate and tropical seacoasts, and inland water bodies in Europe and Asia; length 38–51 cm (15–20 in.).

Family Recurvirostridae (avocets, stilts, and ibisbill)

Moderately large birds with long bills, legs, and necks. Plumage in bold, simple patterns of black and white, gray, chestnut, or buff. Bill straight, recurved, or decurved. Toes webbed in *Recurvirostra.* Legs covered with reticulate scales. Plumage of underparts dense. 7 species worldwide in temperate and tropical regions, one species in Himalayas; length 29–48 cm (11–19 in.).

†*Family Presbyornithidae*

Fossil only. Two genera of large shorebirds from the lower Eocene of Utah.

Family Charadriidae (plovers, lapwings)

Small to medium-sized birds. Mostly with bold (but often concealing) plumage patterns of solid blacks, gray, browns, and white; many with one or two chest bands. Some with wattles and wing spurs. Bill usually short, with a swollen tip. Legs moderately long to long, with reticulate scale pattern. Hind toe usually absent. About 61 species; worldwide; length about 15–40 cm (6–16 in.).

Family Scolopacidae (snipe, woodcock, sandpipers, turnstones, and allies)

Small to medium-sized birds, mostly finely patterned in buff, browns, chestnut, black, gray, and white. Bill moderate to very long and slender; straight, decurved, or recurved; one with spatulate tip. Legs short to long, usually with transverse scales front and back. Hind toe usually present and elevated. About 82 species; worldwide; length 12.5–61 cm (5–24 in.).

Family Phalaropodidae (phalaropes)

Small, densely feathered birds with straight slender bills, moderately long legs, lobed toes, and flattened tarsi. Females larger and brighter than males. Three species; Arctic to temperate regions of Northern Hemisphere; winter at sea and in South America; length 19–25 cm (7½–10 in.).

Family Dromadidae (crab plover)

Medium-sized bird of white and black plumage. Legs long and covered with reticulate scales. Bill strong, laterally compressed, and pointed. Nostrils pervious; basipterygoid processes absent; 15 cervical vertebrae; dorsal vertebrae heterocoelous. One species; coasts of Indian Ocean and southern Red Sea; length 38 cm (15 in.).

Family Burhinidae (thick-knees)

Medium-sized birds with cryptically patterned plumage of brown, gray-brown, black, and white. Bill stout, short to moderately long. Tarsus reticulate. Upper jaw holorhinal; basipterygoid processes and occipital foramina absent; coracoids overlapping. Large eyes. Nine species; temperate and tropical regions of Eurasia, Africa, and Australia; New World tropics; length 35–52 cm (14–20 in.).

Family Glareolidae (pratincoles and coursers)

Pratincoles short-billed, long-winged, with medium-long legs and forked tails; coursers have longer bills, shorter wings and tail, long legs. Plumage patterned in olive, brown, gray, chestnut, black, white. Legs have rectangular scales front and back. Occipital fontanelles absent; basipterygoid processes absent in adult; dorsal vertebrae heterocoelous; 15 cervical vertebrae. 17 species; Africa, southern Eurasia, and Australia; length 15–25 cm (6–10 in.).

Family Thinocoridae (seedsnipes)

Small to medium-sized birds, cryptically patterned in brown, buff, gray, white, and black. Bill short and conical, legs short, wings long and pointed. Nostrils operculate; crop present; vomer broad; basisphenoidal rostrum thick; no basipterygoid processes or occipital fontanelles. Four species; southern South America and north in Andes; length 17–28 cm (7–11 in.).

Family Chionididae (sheathbills)

White birds of moderate size, short legs, and stout bill, with horny sheath over nostrils. No occipital fontanelles or basipterygoid processes; large supraorbital grooves; thick plumage; short carpal spurs on wing. Two species; inhabit islands of extreme southern Atlantic and Indian Oceans; length 35–43 cm (14–17 in.).

Suborder Lari

Hypotarsus simple (grooved but without canals); coracoids in contact (except in Stercorariidae); supraorbital grooves large; basipterygoid processes absent (present but small in young); occipital foramina absent in adults; furcula with hypocleideum; adult downs on both pterylae and apteria; anterior toes usually fully webbed, hind toe absent or minute; young tardily nidifugous (leave nest when half grown).

Family Stercorariidae (skuas, jaegers)

Medium-sized to large birds of solid brown, or brown, white, and black plumage. Bill moderately long, stout, hooked, with a horny dorsal plate. Wings long and pointed; tail with elongate central feathers in some. Legs rather short, toes webbed. Ceca well developed; coracoids not overlapping. 4 species; Arctic and Antarctic; length 43–61 cm (17–24 in.).

Family Laridae (gulls, terns)

Small to large birds, with solid plumage patterns of white, gray, black or sooty brown. Legs, eyes, and bill often brightly coloured in red or yellow. Wings long and pointed; tails of terns often long and deeply forked. Legs moderate to short. Bill short to moderately long; stout and somewhat hooked in gulls, more slender and pointed in terns. Front toes webbed. Sternum with two pairs of notches, ceca small. Rhamphotheca simple (without horny plates). About 85 species; worldwide; length 20–76 cm (8–30 in.).

Family Rynchopidae (skimmers)

Medium-sized birds with long, pointed wings, short legs, and a large bill. Bill deep and extremely flattened, lower mandible knifelike and longer than upper. Plumage black or blackish brown above, white below. Bill red or yellow, sometimes with black tip. Front toes webbed. Pupil closes to vertical slit. Three species; irregularly distributed in tropical and temperate rivers, lakes, and seashores; length 37–51 cm (14½–20 in.).

Suborder Alcae

Large supraorbital grooves with intervening space narrowed to ridge; basipterygoid processes absent in adults; occipital fontanelles present; haemapophysis of dorsal vertebrae large; sternum long and narrow with long, rounded metasternum. Anterior toes fully webbed, hind toe absent. Wing bones flattened. Young downy, nidicolous or nidifugous.

Family Alcidae (auks, murres, puffins and relatives)

Small to large, dense-plumaged, short-winged, aquatic birds. Plumage black, gray, or brown, usually white below. Many have ornamental bill and head plumes. Legs set far back; tail short. 21 species; coasts of northern oceans; length 16–76 cm (6–30 in.).

Critical appraisal. The Charadriiformes are thought to be related to the Gruiformes and to the Columbiformes. Certain intermediate or aberrant families have been removed from or added to the Charadriiformes by various taxonomists. The Belgian ornithologist R. Verheyen considered the Thinocoridae with the Pteroclidae (sand grouse) as a suborder of the Turniciformes, which he placed between the Columbiformes (pigeons and doves) and Galliformes (pheasants and relatives). It has been argued on behavioral and morphological evidence that the Pteroclidae are charadriiform rather than columbiform, but most authorities retain them in the Columbiformes on anatomical grounds. Verheyen allied the Jacanidae with two gruiform families (Rhynochetidae, Eurypygidae) as an order related to the rails and Charadriiformes. P.R. Lowe united the charadriiform and gruiform birds into a single order—the Telmatomorphae—placing the Thinocoridae as a link between the gruiform and charadriine members. Other families that have been variously placed in the Charadriiformes or Gruiformes are the Otididae (bustards, see *Gruiformes,* above), Burhinidae, and Glareolidae.

With undue emphasis on similarities resulting from convergent evolution taxonomists at times have allied the Lari with the Procellariiformes, and the Alcae with other diving birds (penguins, diving petrels, grebes, and loons).

Within the widely accepted limits of the Charadriiformes as presented here there are different opinions about the rank (superfamily, family, subfamily, or tribe) of various groups and about their internal relationships. Pending further evidence from comparative anatomy, physiology, biochemistry, and behaviour, the major groups within the suborders are here given family rank. (R.L.Z.)

Columbiformes (sand grouse, pigeons, doves, dodoes)

The order Columbiformes comprises the pigeons, doves, dodoes, and sand grouse. The suborder Columbae embraces the extinct dodo and solitaires in the family Raphidae and the extinct and living pigeons and doves in the family Columbidae. The names pigeon and dove are synonymous and imply no biological distinction. The sand grouse are given a distinct suborder, Pterocletes. The pigeon family is a natural and homogeneous assemblage of about 285 species of readily defined birds, unique in producing, for feeding their young, a nutritive secretion from the crop wall. Pigeon's milk is similar in composition to mammalian milk and is also induced by the secretion of the hormone prolactin from the pituitary gland. Pigeons also are distinctive in their unusual manner of drinking, in which water is sucked in as a continuous draft, the process being assisted by muscular contractions of the esophagus, whereas other birds take a sip of water and then tip back the head to swallow. It is frequently stated that the sand grouse share this typically pigeon habit; in fact they suck and then tip back the head to swallow, repeating the process four to 10 times during any drinking session.

GENERAL FEATURES

Adaptive radiation

With the exception of some highly specialized ground-living forms, all pigeons are readily recognizable. They range in size from birds the size of a starling (the diamond dove of Australia) to some as large as a female turkey (the crowned pigeons of New Guinea). The skeleton and body form is usually unspecialized, enabling pigeons to feed and roost arboreally yet also collect food from the ground. Adaptive radiation has been either toward a more specialized arboreal life or toward ground-feeding forms, some of which (quail doves) convergently resemble partridges. Sand grouse also resemble gallinaceous birds, although they cannot run, and have become adapted to desert and semidesert conditions in the Afro-Asian region. From the rock dove man has bred the various races of domesticated dovecote pigeons, racing pigeons, and other fancy breeds, while the domesticated form of the African collared dove (the so-called Barbary dove, sometimes erroneously given specific status) has long been a popular cage and dovecote bird. Because many pigeons are extremely well adapted to grain-eating and grazing habits, some conflict with man's agricultural activities and are considered pests.

Distribution and abundance

Pigeons are virtually cosmopolitan, being absent only from the Arctic, Antarctic, and some oceanic islands. Five species have become extinct since the late 17th century, at which time the dodoes and solitaires also vanished. The best known example is that of the passenger pigeon (*Ectopistes migratorius*) of North America, which was remarkable for its extreme gregariousness, a factor that helped the early settlers to exploit it ruthlessly; it was exterminated by the end of the 19th century. With the exception of several Pacific island races considered rare or endangered, other species have spread and increased, particularly as a result of man's agricultural activities. Since 1930 the collared dove has spread 1,000 miles northwest from the Balkans.

IMPORTANCE TO MAN

Throughout the world, agricultural development has effectively provided a "super-habitat" for many seed-eating pigeons, enabling them to thrive and spread: the collared dove (*Streptopelia decaocto*) in India in relation to cereal production, the spotted dove (*S. chinensis*) in Southeast Asia in relation to rice paddy, and the laughing dove (*S. senegalensis*) throughout Africa, Arabia, and India, associated with native crops. Any species that can profit from agricultural expansion must be extremely well adapted—in a sense, preadapted—to such conditions and is likely to achieve pest status. Damage by the wood pigeon in Britain has been estimated at £2,000,000 to £3,000,000 annually, but it is unlikely that it justifies expensive remedial action

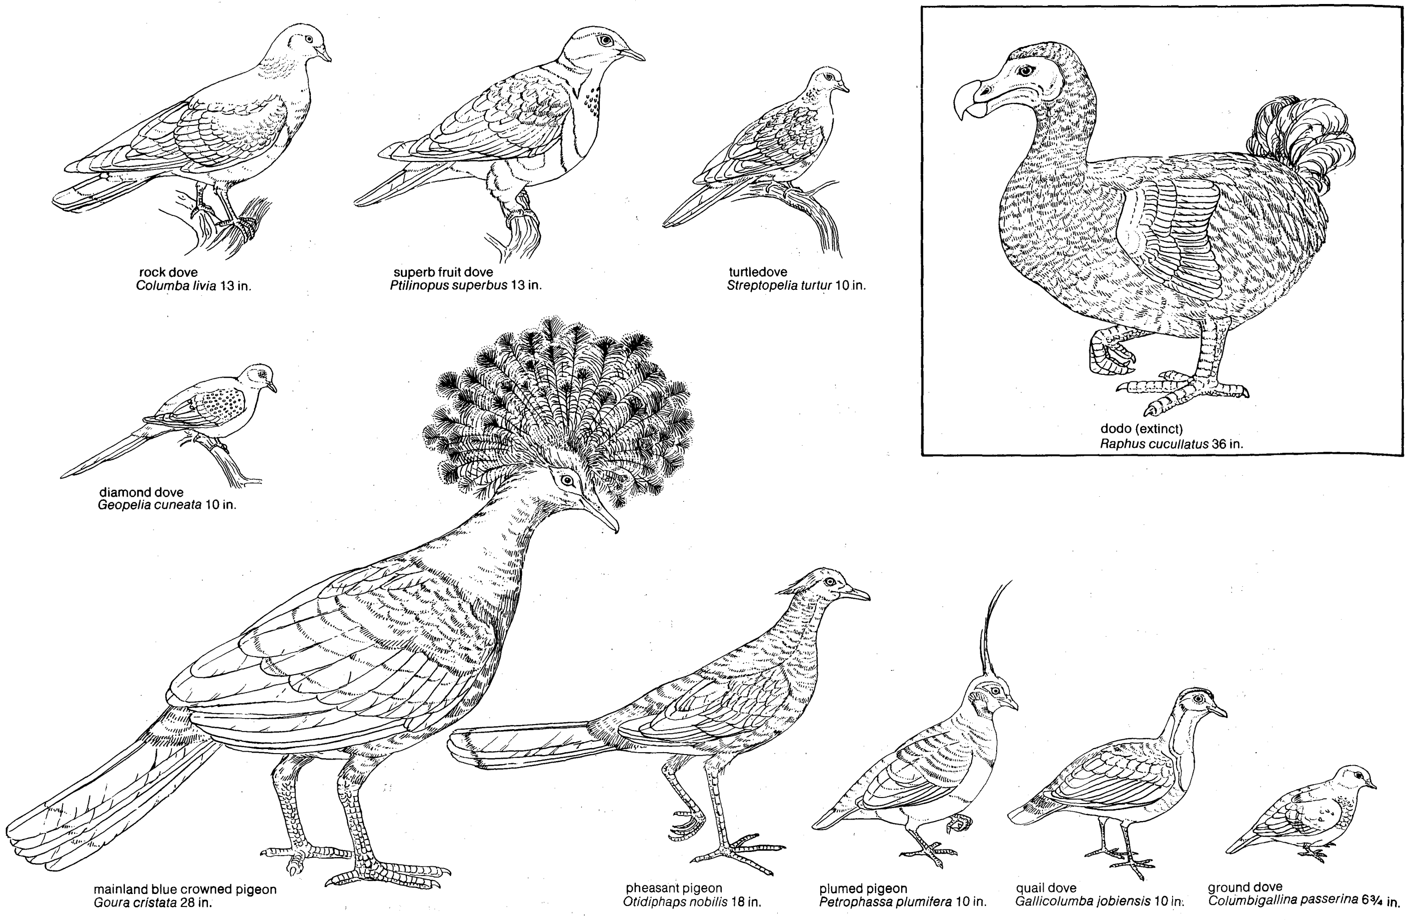

Figure 32: Types of columbiform birds.

on a national scale; the cost of cereal spillage before and at harvest exceeds this amount. Indeed, it has been shown that artificial population control, employing conventional methods such as shooting, is not feasible at a national level and that bonus schemes do not improve control operations. Emphasis is now placed on providing remedial action, relying often as much on scaring as killing, only in the precise locality where damage is occurring or is imminent. The use of more extreme control methods (for example, poisoning) is ruled out in densely populated areas because of the risks to people and livestock. In addition, the risk to other wildlife is now recognized, and there is a widespread desire, public as well as official, not to upset the balance of nature for the sake of immediate but marginal benefits. Any damage caused by the mourning dove to cereal farming in the United States pales in comparison with the value of the species as a sporting bird.

Nesting colonies of the rock dove (*Columba livia*) were farmed by Neolithic husbandmen for food, and gradually the process of rearing young in confinement led to the production of domesticated strains. Evidence for domestication extends back to 4500 BC in ancient Iraq, and the bird was sacred to the early Middle Eastern cultures, being associated with Astarte, the goddess of love and fertility; later, in ancient Greece, it was sacred to Aphrodite and in Roman times to Venus. By the Middle Ages dovecote populations were kept as a source of food on virtually every manorial estate in Europe. From the domesticated pigeons have been derived the various fancy breeds, such as tumblers and pouters, and many genetic aberrations that have given pleasure to countless enthusiasts. From the same source have come racing pigeons. Belgium, at the top of the international league table, has more than 165,000 pigeon fanciers. Carrier pigeons were used to relay news of the conquest of Gaul to Rome, brought news of Napoleon's defeat at Waterloo to England, and were used extensively for message carrying in the two world wars.

Urban pigeons

The popularity of the dovecote pigeon declined in the late 19th century as farmers realized that it was more efficient and brought greater financial reward to supply nations with bread than to convert corn inefficiently into this intermediate form of protein. The release of thousands of pigeons, together with escapes, established the feral populations in numerous European towns, in North America (where it is often known simply as the "city pigeon"), and other parts of the world as far away as Australia. Being naturally adapted to rocky ravines, sea cliffs, and barren sites, the bird has readily accepted the sides of buildings, bridges, and other man-made "cliffs." In towns it is fed and protected by an indulgent and benevolent public, at the same time being cursed by public health inspectors and those concerned with its depredations on stored grains. To a large extent problems connected with food storage can be remedied by adequate proofing of buildings and control of spillage.

The importance of feral pigeons as a reservoir and means of transmission of disease is becoming increasingly recognized, even though there are few cases where the transmission of disease can be proved. Feral pigeons appear to harbour ornithosis (psittacosis) to a sufficient extent to provide a potential human risk. Up to three-quarters of various local pigeon populations examined in Paris were found to be infected, and the virus also has been isolated in pigeons in Liverpool, London, and elsewhere. Virulent strains of *Cryptococcus neoformans,* which causes a fungal disease of the skin, as well as cryptococcal meningitis (a disease of the lungs and central nervous system), have been isolated in pigeon excreta in various cities.

NATURAL HISTORY

General habits. The evolution of the crop has been of vital importance to the pigeons. This bilobed diverticulum (a blind pouch) of the esophagus, located just posterior to the buccal cavity, serves as a storage organ for food. Subsisting for the most part on seeds, buds, leaves, and fruits, foods of low protein content and nutritive value, pigeons must consume large quantities during each feeding day. The rate of food intake can be higher than the digestion rate would otherwise allow, the surplus food accumulating in the crop to be digested after the birds have gone to roost. The ability to store food has enabled some pigeons to be represented among the small list of birds—geese and certain galliform birds are other examples—that can live as efficient grazers, occupying a leaf-eating niche in wooded country, either in the tree canopy or on the forest floor. Some, such as the wood pigeon (*Columba palumbus*), have secondarily adapted to more open country to exploit the food supplies created by agricultural expansion. This pigeon is typical of the many that obtain their food partly in trees and partly on the ground. In midwinter it can subsist entirely on clover leaves and spends 95 percent of the day collecting the leaf fragments at 60–100 pecks per minute. By such intensive feeding, a single bird can collect 35,000 clover leaf fragments (45 grams, dry weight) per day. In spring this diet is supplemented with tree buds and flowers and also pasture-weed seeds; in summer the diet is chiefly cereal grain; in autumn declining corn stocks on the stubbles are supplemented with tree foods such as acorns and beech mast.

The mourning dove (*Zenaidura macroura*) of North America and the turtledove (*Streptopelia turtur*) and stock dove (*Columba oenas*) of Europe rarely take green vegetation, do not feed in trees, and so are examples of the trend toward complete ground feeding. These doves subsist almost entirely on seeds collected from low herbage or the ground. In winter such food sources become unproductive, so the turtledove and the mourning dove, in the northern part of their respective ranges, migrate southward. Turtledoves migrate from northern Europe to winter in central Africa. The ancients were well aware of this movement: "They shall hasten as a bird out of Egypt, and as a dove out of the land of Assyria" (Hosea 11:11).

Adaptation to ground feeding

Adaptation to ground feeding has progressed much further in various tropical genera, though the ecology of the species involved barely has been studied. In the New World a series can be traced from the typical *Zenaida* pigeons, through the ground doves (*Columbina, Claravis, Metriopelia* and *Scardafella*), which are mostly compact with short tails, and the *Leptotila* doves of South America, with longer legs suitable for running over the ground, to the New World quail doves (*Geotrygon* and *Starnoenas*). The last are relatively long-legged and partridgelike, spending most of their time on the forest floor. In the Australasian region there is a similar series, from scrub-country doves resembling *Zenaida* and *Streptopelia*—here represented by *Geopelia*—through the emerald doves and bronzewings (*Chalcophaps* and *Phaps*), to the Old World quail doves (*Gallicolumba* and various derivatives). Most of these quail doves live on the forest floor, collecting fallen seeds and fruits and seeds from low herbage, but in Australia a few are found in open country. Some aberrant species have evolved even further toward ground living, an extreme case being the pheasant pigeon (*Otidiphaps nobilis*) of New Guinea and adjacent islands, which resembles a pheasant. Evolution toward ground-living forms in Australasia and South America may have been helped by a paucity of mammalian carnivores that would normally be predatory on ground-living birds, which may partly explain why the extreme development of such forms has not occurred in Africa. In arid regions of Africa and central Asia, however, the various sand grouse (*Pterocles* and *Syrrphaptes*) occupy this niche.

The radiation of pigeons into fully arboreal, fruit-eating types also is most apparent in Australasia, with the brown fruit doves (*Phapitreron*), green pigeons (*Treron*), and the fruit doves (*Ptilinopus* and *Ducula*). Within these genera there are a large number of sympatric (coexisting) species differing by a wide variety of species-specific colour patterns that serve for mate recognition and hence species isolation. Nevertheless, the predominant colour of most fruit pigeons is green, which ensures effective camouflage when the birds are, as usually, among tree foliage. The success of fruit pigeons in this region may have resulted from the absence of competition from monkeys—important fruit eaters in Africa and South America. Fruit pigeons are adept at perching on slender branches and have large mouths that allow them to swallow large fruit. In tropical forests appropriate trees with ripe fruit tend to occur sporadically, so that most of the fruit pigeons move through large areas of country in flocks to seek out their food.

Sand grouse rely on cryptic coloration to protect them from predators yet are powerful fliers when disturbed. Long primary feathers facilitate considerable flights to water sources for some species, round trips of up to 80 miles being made daily in some areas. The desert species usually fly to water at dawn, those of bush country at dusk. At either time several thousand birds may congregate at a traditional watering place. Their drinking habits are unique. Only five to 10 seconds are required for drinking, an adaptation believed to reduce the risks from the diurnal predators that collect around waterholes in anticipation of the birds' arrival. Up to 15 millilitres (about 0.6 ounce) of water may be imbibed by a sand grouse. Water is carried back to nestlings in the crop and alimentary canal and on specially modified abdominal feathers. When not breeding, sand grouse are nomadic wanderers in their desert home, but some species undergo periodic irruptive dispersals that may involve long-distance movements, usually when good breeding leads to a high population and subsequent food scarcity.

Drinking habits

Behaviour. When feeding on the ground a pigeon must be looking downward for much of the time and therefore is vulnerable to predators such as foxes. The widespread habit of feeding in flocks has probably not evolved as an antipredator device but rather to help the birds to locate their food. Many species possess signal marks that become prominent in sudden flight, just as some rabbits display the white underparts of the tail. The wood pigeon has white wing bars that flash on takeoff, the Nicobar pigeon (*Caloenas nicobarica*) a white tip to the tail.

A consequence of feeding in a flock is that differences in individual attributes are more readily manifested, and this finds expression in a strongly developed social hierarchy (peck order). In competitive situations submissive individuals are frequently supplanted by more dominant individuals, and efforts to avoid conflict result in their getting less food. During times of shortage they are the first to die, other flock members remaining perfectly healthy. There is no evidence that social behaviour has evolved as a mechanism whereby populations can achieve self-regulation of their numbers, as has sometimes been suggested.

Reproductive behaviour

In most pigeons, a male in reproductive condition acquires a territory, which it proclaims with an advertisement call, usually a variant of the typical pigeon "coo" sound. Intrusion from other pigeons is prevented, at first by threat displays involving sleeking the plumage, stretching the head forward, and partially raising the wings. If these displays of aggressiveness are ineffective the male then attacks the intruder, pecking at the opponent and delivering sharp blows with the carpal joint of the wing. Females behaving submissively are gradually tolerated, particularly by unpaired males, enabling pair formation to proceed. In pigeons that build their own nests in scrub and open woodland, territories may be large, but in some hole- and cavity-nesting species, such as the rock dove, only the area around the actual nest site is defended. A shortage of suitable sites forces the latter to be semicolonial. Many pigeons perform display flights in and near the territory to attract unmated females. Such displays frequently involve exaggerated movements, slow wing beating, and, in some, loud clapping noises produced by the wings. The underparts of the tail, and sometimes other areas of the plumage, may have contrasting light and dark patterns that are displayed during flight.

Ronald K. Murton

Courtship behaviour.
One aspect of the wood pigeon's, or ringdove's (*Columba palumbus*), courtship is the prolonged, gentle rubbing of one bird's beak, usually the male's, through the head feathers of his mate.

Display flights

Pair formation has been well studied in the rock dove and Barbary dove. A sexually mature male typically approaches a submissive member of the same species with the bowing display (in most pigeons this occurs within a previously acquired territory, but not invariably). Bowing is primarily an aggressive display, involving tendencies to advance and attack and to mount and copulate. It is usually accompanied by vocalization—the bow call. Females normally retreat from the bowing display and exhibit submissive postures but if receptive sink to the ground with lowered wings and tail. This may result in the male mounting immediately; if not, he gradually becomes less aggressive and commences the nest-demon stration display. Being a submissive display, this reduces any female fear and attracts her closer, leading to a state where the pair now accept each other's presence. Displays that cement the pair bond involve mutual nibbling of each other's feathers, particularly those of the head and neck. At this early stage of the cycle the female exhibits juvenile behaviour, begging food from the male who, in turn, feeds her. This is the normal stage at which the female solicits and copulation occurs, interspersed with displacement preening. The female gradually assumes a more assertive role as she ceases to fear her partner and will attempt to push him off the nest site and occupy it herself. The male is now stimulated to search for nest material, which he brings back to the sitting female, and one or both incorporate the material into a nest.

Secretion of "pigeon milk"

The specific acts of seeing her mate build a nest and of being involved herself stimulate the female's neuro-endocrine system so that estrogen secretion rises, causing the oviduct to develop about five days before eggs will be laid. Seeing and incubating eggs, or seeing another bird doing so, stimulates prolactin secretion causing the crop gland to become secretory, so that "pigeon milk" is available when the eggs hatch. From this time onward the crop gland gradually regresses so that by the time they are ready to leave the nest, the young are fed almost entirely on environmental supplies. The production of a highly proteinaceous milk enables these seed- and fruit-eating birds to be independent of animal food when the young need maximum nutrition. The limitations of crop-milk production also have doubtlessly set the limit to the maximum number of young that can be reared, so that no pigeon ever lays more than two eggs, and many fruit eaters lay only one.

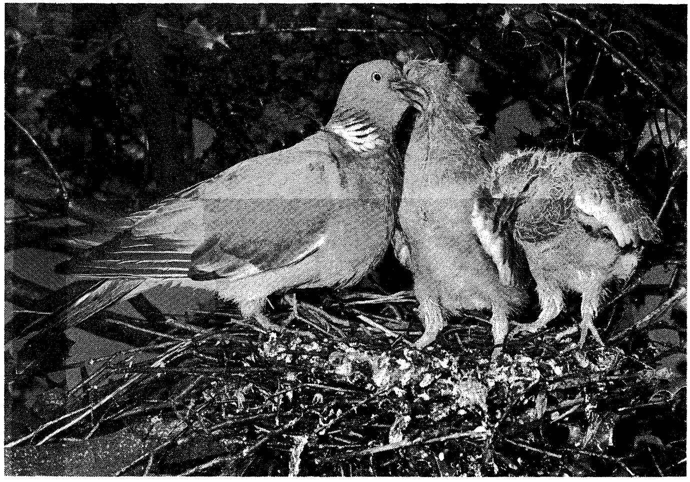
Most pigeons are multibrooded and have long breeding seasons, timed to correspond with the period of high food availability for both adults and young. Temperate zone pigeons, like other temperate zone birds, use proximate (immediate) environmental signals to insure attaining reproductive maturity at the appropriate time, one of the major signals being the seasonal changes of day length. The neuro-endocrine apparatus of British wood pigeons is stimulated by the day lengths of March; the gonads become active at that time and remain in breeding condition until September, when day lengths once more fall below the stimulatory threshold. This period of activity is appropriate to the season during which actual reproduction is feasible. The turtledove is stimulated into breeding condition in April during its migration north and lays its first eggs in late April and early May. The gonads spontaneously regress in August, inhibiting further activity, even though environmental conditions are good and breeding success is at a peak. The onset of reduced breeding activity in the presence of day lengths that were stimulatory in April is a safety mechanism; by reducing the physical strains associated with breeding, it enables the adults to accumulate the energy reserves needed to replace the flight feathers (vital for successful long-distance migration) and to lay down fat reserves for migration. Many pigeons, however, molt throughout the breeding season.

Nesting

Most pigeons build their own nests, simple flat platforms of twigs, in scrub or woodland. Some tree-nesting species occasionally nest on the ground, others regularly do so. White eggs are particularly attractive to predators so that, presumably to reduce these risks, some of the ground-nesting pigeons (*e.g.,* Old and New World quail doves) lay brown or cream-coloured eggs. In many pigeons, once the eggs are laid both members of the pair share the duties of incubation, changing over on or near the nest site, so that the eggs are normally not left uncovered. In contrast, sand grouse almost invariably lay three cryptically coloured and spotted eggs in a scrape on the ground; sometimes a few grass stems may serve as a lining. The male incubates by night, the female by day.

A few pigeons have adapted to nesting in crevices and holes, reducing the risks of egg predation but increasing the chances that the adult will be cornered on the nest by a predator. The clutch almost invariably consists of one or two eggs. The newly hatched young are at first continuously brooded but later are left for long periods while the parents seek food. The larger pigeons usually visit the nest only twice a day, bringing a crop full of food if feeding conditions are suitable. The young, called squabs, beg for food by pushing at the parent's breast, at the same time emitting a squeaky hunger note. They insert their bills in corners of the parent's mouth and are then fed by regurgitation. Although a pigeon is capable of rearing an artificial brood of three young, only two squabs can be fed at a time, and natural broods of three are extremely rare. In several species so far studied, when the nestlings are about three-quarters grown the parents begin a new cycle, building a new nest nearby and laying eggs.

Stephen Dalton—Natural History Photographic Agency



Feeding.
The unfledged squab of the wood pigeon (*Columba palumbus*) is nourished with "pigeon milk," a curdy substance regurgitated from the parents' crops.

Unguarded young are less subject to predation than are eggs. This is the case partly because of the squabs' more cryptic colouring, but primarily it is because they are capable of making a marked threat display. At the approach of danger they inflate their crops with air, causing them to become much bigger, and thrust their heads towards the enemy, at the same time hissing and snapping the mandibles together.

Ecology. Many temperate zone pigeons show marked population declines during the year. The high numbers resulting from breeding in temperate species can at first be maintained by extensive summer food supplies, especially in populations that depend on man-made food sources, such as barley or rice. But as food stocks decline in autumn and winter, reaching a critical level in relation to the population, juveniles suffer a high mortality, competing relatively unsuccessfully with adults. The change in population size from year to year thus depends primarily on the survival rate of juveniles through the period of food shortage, this being the key factor responsible for annual fluctuations. Long-term population trends, up or down, result from changes in the suitability of the habitat and are reflected in the number of adults that can settle to breed in an area. The average expectation of life for a British wood pigeon after reaching maturity is 2.25 years, which means that an average of 36 percent of the adult population dies each year. Whatever number of young 100 adults produce, only 36 need reach maturity to keep the population stable, and the rest are surplus. The juvenile mortality rate varies between 60 and 80 percent. Turtledoves are smaller and more at risk from predators; they also face the dangers of long migratory flights. Their adult mortality rate is nearer to 50 percent per annum, comparable to the 56 to 58 percent found in the North American mourning dove, which also is extensively shot for sport.

Population variability

FORM AND FUNCTION

Distinguishing characteristics. Pigeons are of compact shape, usually plump because of well-developed pectoral muscles, and with relatively small heads. The wings are long and often pointed in species that are highly migratory and in those that obtain most of their food in trees. A few island or montane species that fly less have reduced wings. A long, pointed tail, as in the extinct passenger pigeon and the masked dove (*Oena capensis*), is probably correlated with a high degree of manoeuvrability, necessary during a rapid escape from the ground in woodland. The partridge-like pigeons have short rounded wings and a short tail. These are mostly birds of woodland, keeping to the cover of trees and bushes, but in Australia there are species that live completely in the open and nest on the ground. One, the flock pigeon (*Phaps histrionica*), makes long flights to its feeding and drinking places and has long wings, in many respects apparently living like the sand grouse of Afro-Asian regions.

Pigeons generally have short legs, but in those that resemble game birds the legs are lengthened for more effective terrestrial locomotion. Three toes point forward and one backward. The bill is usually small and soft and may be overhung by the fleshy operculum (cere), which is enlarged in some of the fruit pigeons and domesticated forms of *Columba livia.* The bill shape is associated with feeding habits, slender bills being typical of seed eaters and deeply hooked bills of fruit eaters, especially those like *Treron,* which feed on large hard fruits such as figs. This trend in bill development is seen to an exaggerated extent in the ground-feeding tooth-billed pigeon (*Didunculus strigirostris*), whose bill resembles that of the extinct dodo, a bird that may have had similar feeding behaviour. It tears and nibbles its food into small pieces in a manner reminiscent of the parrots, taking berries, fruit, and mountain plantain.

Plumage

Pigeons have dense and soft plumage, the region in the vicinity of the eye often being bare. In most species the female is slightly duller than the male, but in some the sexes are identical, and in a few species there are marked differences in colour. One kind of sexual dimorphism, in which display plumage is confined to the male, is correlated in most other birds with a tendency toward polygamy; but it is not clear whether this is true in pigeons. Another kind of dimorphism involves the sexes' being rather differently coloured. Thus the male of the orange dove (*Ptilinopus victor*) is brilliant orange, the female green; the male ruddy quail dove (*Geotrygon montana*) is purplish chestnut, the female brown. This trend seems to be associated with making the female, who does most if not all the incubation in these cases, more cryptic.

With the exception of *Treron,* most fruit pigeons have a broad, short intestine and can void intact the stones from fruits they have eaten. Seedeaters have stronger gizzards and long, narrow intestines.

The sand grouse also are compact, with thick underdown, tough skins to resist desiccation, and frequently elongated central tail feathers. The legs are short and the toes sometimes slightly webbed, aiding progression on soft sand.

Physiology and biochemistry. Domesticated pigeons and the Barbary dove have long served as subjects for avian physiological research, and knowledge related to their body functions is extensive. They appear to exhibit no remark-

Production of prolactin

able specializations, compared with birds in general, with the exception that the crop becomes glandular in response to small amounts of the hormone prolactin. Prolactin was first discovered in pigeons by O. Riddle, and pigeons still serve in the bioassay of this hormone from other sources. Prolactin also is produced by other birds. Among other functions, it reduces aggressive behaviour during the incubation and early brood-care stages of the reproductive cycle. It apparently is involved in the molting process and in mechanisms associated with preparation for migration. Pigeons are unique only in having secondarily evolved a new target organ responsive to the hormone.

The sense of taste, as with most other birds, is poorly developed, and it is probably not an important factor in selecting food. Shape and tactile characteristics and, to a lesser extent, colour are much more important. The average number of taste buds is only 37, confined to the soft area at the base of the tongue and palatine region (in contrast, man has about 9,000 and the rabbit about 17,000). Pigeons can, however, exhibit a surprising sensitivity to certain substances, such as acids; only at extremely low concentrations are acetic acid solutions accepted as readily as pure water. The olfactory organs are well developed; but smell seems to be of little significance in the daily lives of pigeons, and experiments to demonstrate their olfactory abilities have yielded conflicting results. Visual acuity is highly developed, as in most other birds, although training experiments demonstrate that pigeons can attain an acuity little better than humans.

EVOLUTION AND PALEONTOLOGY

Dodoes and solitaires

By the time they appear in the fossil record the Columbiformes are already so well differentiated that their phylogenetic relations cannot be determined with certainty. The sand grouse and pigeons resemble each other anatomically, but this may have resulted from convergence towards a similar mode of life. The dodoes and solitaires were highly specialized island forms that doubtless arose in the Mascarene Islands and were peculiar to those islands. Three species are known, the dodo (*Raphus cucullatus*) on Mauritius, the Réunion solitaire (*Raphus solitarius*), and the Rodrigues solitaire (*Pezophaps solitaria*). A fourth species, the white dodo (named as *Victoriornis imperialis*), may have existed on Réunion but, if it existed, was probably a colour phase of the Réunion solitaire. The dodoes and solitaires became extinct in about 1681, 1746, and 1791 respectively, as they fell easy prey to marauding sailors and could not compete with pigs and other introduced livestock. They were pigeon-like birds that had lost the power of flight in the safety of their predator-free island existence and had become large (as big as a turkey), heavily built birds with strong bills and feet. The wings had become rudimentary, and the sternum possessed only a small keel.

The earliest known sand grouse are of the modern genus *Pterocles* and date from the upper Eocene of France (about 40,000,000 years ago). The earliest known pigeon is *Gerandia calcaria* from the early Miocene of France (25,000,000 years ago), although the suborder probably arose in the Australasian region, where the greatest variety of modern columbiforms is found. Other fossil pigeons are known from the Pleistocene (2,000,000 years ago).

CLASSIFICATION

Distinguishing taxonomic features. The most important features distinguishing the Columbiformes are the structure of the skull, sternum, and furculum. The several species have close thick feathers set loosely in the skin, lack the fifth secondary feather of the wing, and possess a crop. The structure of the bill and nostrils, the arrangement of the sterno-tracheal musculature, and the presence or absence of intestinal ceca distinguish the suborders. Behavioral characteristics are of doubtful validity in relating suborder relationships because the similarities may have arisen by convergence. Blood-antigen relationships may be considered more reliable.

Annotated classification.

ORDER COLUMBIFORMES

Birds in which the palatine processes of the maxillae do not meet in the midline (schizognathous) and with vomer absent or vestigial. Palatine and pterygoid bones articulate with basisphenoid rostrum. Basipterygoid processes present, except in family Raphidae. Sternum with large lateral and smaller inner incisions, these often fused to fenestrae. Furculum U-shaped and with hypocleideum little or not developed. Nares separated by a complete internasal septum. Hypotarsus complex. Plumage, close and thick, feathers loosely set in skin. Pterylosis essentially similar in the 2 suborders. 5th secondary quill absent (diastataxic). Oil gland naked or absent. Well-developed crop present.

Suborder Columbae (pigeons, doves, and dodoes)

Miocene to present. Intestinal ceca absent or minute, syrinx with sterno-tracheal muscles asymmetrical. Young altricial (helpless); hatched blind without real down. Basal part of bill soft and covered with a swollen skin that envelops the slitlike nostrils as a cap (operculum). External nasal opening into skull tapers behind into a narrow cleft running back into nasal bone (schizorhinal); 14–15 cervical vertebrae. 11 primary feathers, the outermost much reduced. Usually 12–14, and exceptionally 16–20, retrices. Crop bilobed. Nest in tree holes or caves or build flimsy platform of sticks on trees or ground. Eggs usually white, except in some quail doves brown or cream, mostly 2 in number, but 1 in some genera.

Family Columbidae (pigeons and doves)

Pleistocene to present. Characteristics of suborder. Length 15–80 cm; weight 45–4000 g. Wide range of colours, from grays and browns to striking orange, green, or purple. Worldwide except subpolar regions and some oceanic islands. About 285 species.

Family Raphidae (dodoes and solitaires)

Extinct but with no fossil record. Flightless, with much reduced furculum and wing, fused coracoid and scapula and no basipterygoid processes. Large; weight probably exceeded 10 kg. Limited to Mascarene Islands. 3 species.

Suborder Pterocletes.

Long intestinal ceca, symmetrical sterno-tracheal muscles, young nidifugous (precocious) and covered with down. Bill resembles that of game birds, not soft at base. Sternum with very high keel and ribs broad, cervical vertebrae number 15 to 16; tarsus short and feathered, toes wide and short, soles covered with hexagonal or rounded scales. Nostrils not schizorhinal and covered by feathers except in front. 11 primaries, outermost much reduced, and 14–18 retrices. Pterylosis as in pigeons but feather tracts wider. Oil gland small and naked. Large crop, not bilobed. 2 to 4 eggs laid in mere scrape in ground in open steppe or desert.

Family Pteroclididae (sand grouse)

Late Eocene or early Oligocene to present. Characteristics of the suborder. Coloration buff, reddish or grayish brown, barred or spotted with black, brown, yellow, or white; sexually dimorphic. Habitat sandy plains, open brush, or deserts of temperate to equatorial Eurasia and Africa. Length 23–40 cm (variation mostly in tail length); weight 120–300 g. 16 species.

Critical appraisal. On anatomical grounds, the sand grouse resemble the pigeons and are therefore placed in the same order. Their drinking behaviour only partly resembles that of the pigeons, and other behaviour in which the two groups are similar is not unique to either. G.C. McLean suggested that the sand grouse are nearer to the plovers (family Charadriidae, order Charadriiformes), and D. Goodwin also took this view. The subordinal limits of the Columbae seem well defined, although J. Lüttschwager suggested that the Raphidae bear closer affinity with rails (order Gruiformes). The gruiform line diverged early from the stock that eventually produced the Columbiformes and Charadriiformes, so if closer to the Gruiformes the dodoes would be closer to presumed pigeon ancestors, rather than, as usually believed, relatively recent offshoots from established Columbae stock. The pigeons and doves comprise a natural group, which most authors treat as a single family. This seems the best arrangement, but separate family rank is sometimes given to the pheasant pigeon, crowned pigeons, tooth-billed pigeons, and even to the fruit pigeons. These are probably best treated as the subfamilies Otidiphapinae, Gourinae, Didunculinae, and Treroninae. (R.K.M.)

Psittaciformes (parrots, lories, cockatoos)

The avian order Psittaciformes contains more than 300 species of generally brightly coloured, noisy, tropical birds, Early association with man

to which the general name parrot may be applied. Various species are known as keas, cockatoos, cockatiels, lories, lorikeets, parrotlets (or parrolets), parakeets, budgerigars, rosellas, conures, lovebirds, amazons, and macaws. Although the first accurate written reference to a parrot is frequently credited to the Greek historian Ctesias, of the 5th century BC, who described clearly what is now called the blossom-headed parakeet (*Psittacula cyanocephala*) of India, there is no doubt that parrots were associated with man much earlier, for aborigines on all continents had parrots as pets when first visited by explorers. Parrots of many kinds have been long transported to Europe for zoos and private collections. Affluent citizens of early Rome often kept parrots in their homes and even esteemed them as delicacies of the dinner table.

GENERAL FEATURES

Bodily proportions. Parrots vary in total length from eight to 100 centimetres (three to nearly 40 inches), the latter in long-tailed forms. The short neck and sturdy body, along with the stout feet and thick bill, give them a bulky appearance. The broad wings are often pointed; the tail is highly variable in both length and shape. In some species the tail is short and rounded or square; in others, such as the macaws (*Ara*), it is long and pointed. In numerous species the central tail feathers are very long, surpassing the body in total length. In the five species of racket-tailed parrots (*Prioniturus*) the central tail feathers are longer than the others and are spatulate, the middle part of the feather shaft being bare. No parrot has a forked tail. Pointed wings and a long tail usually are found in species that fly great distances; rounded wings and blunt tails typify the more adept climbers. Most parrots are swift on the wing, although they normally fatigue quickly.

Extinction of Carolina parakeet

Distribution. Parrots are primarily birds of the tropics. Their distribution encompasses the tropical and south temperate regions of the world, including Madagascar, New Zealand, and the West Indies. In Asia they occur throughout almost all of India but extend northward only to the Himalayas and southern China. They are absent from Europe. In the early 1970s in North America they ranged north only to the extreme southwestern United States (one species, the thick-billed parrot, *Rhynchopsitta pachyrhyncha*). Prior to the early 1900s, however, the Carolina parakeet (*Conuropsis carolinensis*) inhabited most of the eastern United States; it was brought to extinction by human persecution. The last captive died in the Cincinnati Zoological Garden in 1914, but the last generally accepted observation in the wild was a flock seen in Florida in 1920, although it has been claimed that they existed in South Carolina until 1938. In the Southern Hemisphere a number of parrots range to Tasmania and New Zealand, and in South America one species is found on Tierra del Fuego, but none are found on the southern tip of Africa.

Although parrots are found in most parts of the three southern continents (excluding the Sahara), they are not evenly distributed. Of the 81 genera recognized in a 1937 revision of the taxonomy of parrots, the Neotropical region (South and Central America) has 28, not one of which is found elsewhere. The Nearctic region (temperate and arctic North America) has had only the now-extinct genus *Conuropsis.* The Australo-Papuan region, which encompasses Australia, New Zealand, New Guinea, Celebes, and many of the Pacific Ocean islands, has 44 genera, three of which are shared with the Oriental region. The Oriental region, which, in addition to Asia, includes the Philippines and most of Malaysia, has nine genera, including the three shared with the Australo-Papuan region and one shared with the Ethiopian region. The Ethiopian region, comprising Africa, Madagascar, and nearby islands, has only six genera, one of which is the extinct *Mascarinus* from Reunion Island, 650 kilometres (400 miles) east of Madagascar. The Palearctic region (Europe and northern Asia) has none. Most parrot genera contain only a few species; only six include more than 10 species, four of which occur in the Neotropics.

Parrots as pets

Importance to man. The qualities of parrots, especially the ability of many species to imitate human sounds, make them popular as pets. The African gray parrot (*Psittacus erithacus*) and some species of amazons (*Amazona*) from the New World tropics are particularly good mimics. There is no evidence to suggest, however, that talking parrots realize what they are saying. Another appealing attribute of parrots is their display of affection, not only to others of their own species but also to man. Pairs of many species, especially the lovebirds (*Agapornis*), are together almost constantly, nibbling each other's feathers with seeming affection; if one bird disappears its mate sometimes dies, apparently of loneliness. Many parrots seem to delight in being petted and scratched, which is rare among birds. Parrots have extremely powerful jaws, however, and an indiscriminate attempt to pet them can result in a severe bite. The use of the toes for climbing and food handling, in much the same manner as man uses his hands, also makes parrots appealing. Their longevity, bright colours, intent gaze, ability to learn tricks, and willingness to remain on a perch instead of fluttering about contribute to man's fondness for various kinds of parrots as pets. Finally, most species are vegetarians and thrive on a varied diet. This circumstance, as well as the fact that their droppings typically are dry and compact, means that parrots require little care.

Most species of parrots have been kept in captivity at one time or another, and most have been bred, with the exception of the pygmy parrots (*Micropsitta*). A large zoological garden may have more than 100 species on display at one time. No parrot has been domesticated in the sense of gallinaceous birds and waterfowl, although in recent decades breeders have produced a variety of

Drawing by G. Tudor

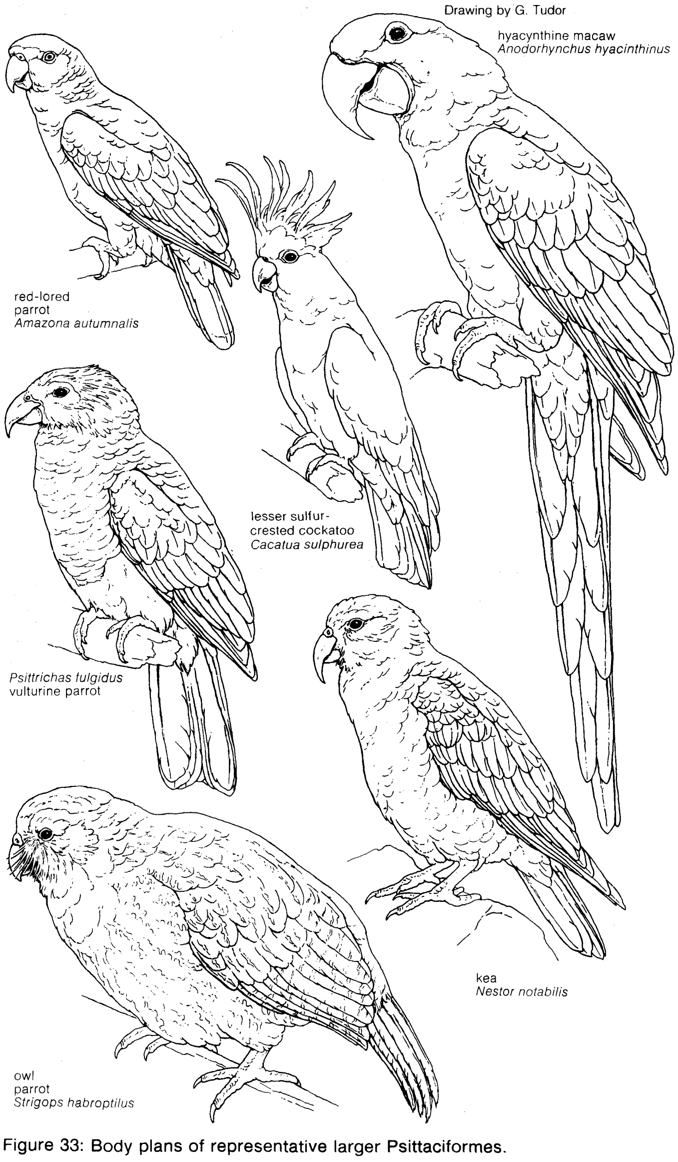


Figure 33: Body plans of representative larger Psittaciformes.

Longevity in parrots

colour strains of the budgerigar (*Melopsittacus undulatus*), commonly called shell parakeet. In the mid-1950s "budgies" became popular household pets in the United States; within a decade more than 5,500,000 people had at least one in their homes. Captive parrots, especially the larger species, are long-lived. Claims of 80 or even 100 years are frequent and perhaps true, although thus far impossible to document. A convincing record of a 56-year-old greater sulfur-crested cockatoo (*Cacatua galerita*) exists.

In the early 1930s the importation and sale of parrots in the United States was drastically curtailed by quarantine laws designed to combat psittacosis, or parrot fever (better called ornithosis, as the disease by no means is restricted to psittacine birds), a respiratory virus that can infect humans. Antibiotics now available reduce the severity of the disease, and most of the restrictions on the parrot trade have been relaxed.

The primary economic importance of parrots derives from their popularity with aviculturists. So popular are some species that the Australian government has found it necessary to pass laws forbidding export of the birds because wild populations were being decimated. Unfortunately, only a few of the many individuals captured ever reach the comparative safety of a comfortable cage, because of mishaps en route. Some parrots, especially certain of the Australian seed-eating species, damage crops and therefore are hunted and killed.

NATURAL HISTORY

Habitat and food choice. Most parrots inhabit forests, although a few live in grasslands. Of the forest-inhabiting species many forage along the forest edge and on the ground. Some parrots live in mountains, especially in the Himalayas and Andes; the New Zealand kea (*Nestor notabilis*) is a mountain inhabitant but obtains much of its food in forested valleys; it nests either in high elevation forests or near the forest edge. Many Australian parrots, such as members of the genera *Neophema* (grass parakeets) and *Psephotus,* are found in dry, open grasslands, typically where trees are scattered through the habitat. The budgerigar and the rare night parrot (*Geopsittacus occidentalis*) also are Australian grassland birds.

Drawing by G. Tudor

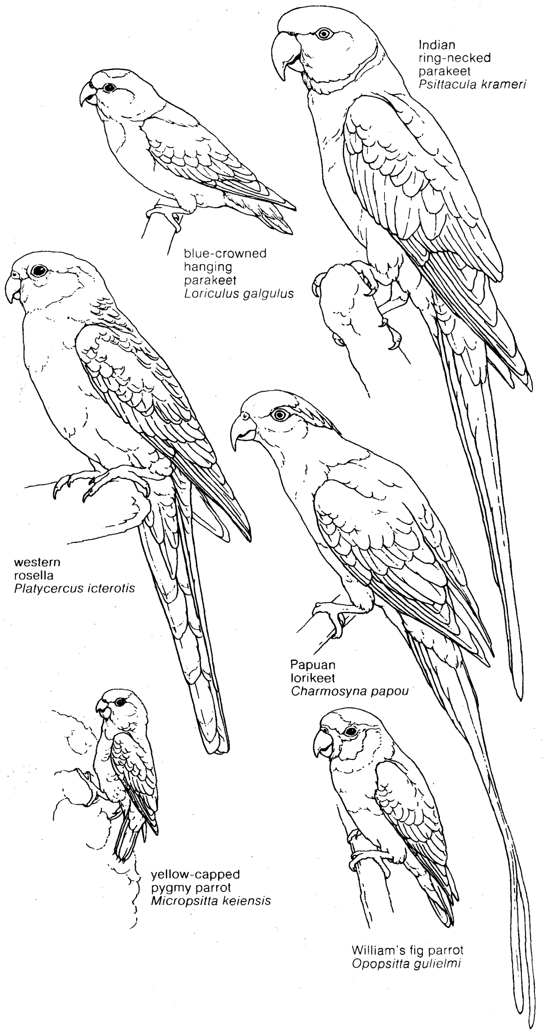

Figure 34: Body plans of representative smaller Psittaciformes.

Parrots feed almost entirely on plant materials. The smaller species tend to utilize grass seeds, berries, fruits, and the juices of blossoms; the larger forms obtain fruits and nuts from trees, and bulbs, tubers, and roots from the ground. When digging, many parrots also capture larval and adult insects, and raven, or black, cockatoos (*Calyptorhynchus*) gnaw through bark to obtain wood-boring beetles. Many kinds of nectar-eating birds suck juices through tubelike tongues, but brush-tongued parrots feed on nectar by crushing flowers and licking the juices. The tiny pygmy, or woodpecker, parrots feed on fruit, arboreal termites, and fungi. The kea feeds on dead sheep and carrion and will attack sick, injured, or trapped individuals but rarely will it harm healthy sheep.

Aggregations of parrots

Social behaviour. Typically, parrots are gregarious and noisy, often forming small groups—sometimes huge flocks—flying rapidly high overhead and screeching. Their seemingly conspicuous bright colours are somewhat misleading, for a group of parrots in foliage is difficult to discern. The grassland-inhabiting parrots are nomadic and often occur in flocks of tens or even hundreds of thousands. The development of agriculture in the interior of Australia, particularly the increased availability of water, has resulted in larger populations of several species, such as the corella (*Cacatua sanguinea*) and budgerigar.

The vocalizations of most parrots are loud, raucous screeches; generally the larger the species the more ear-splitting the calls. The voices of some of the smaller ones include chattering and twittering notes pleasant to the human ear. About 12 different calls, each announcing a different mood, have been identified for the greater sulfur-crested cockatoo. The amazing mimetic abilities of many parrots mentioned above are expressed only in captivity.

Reproduction. Parrots are monogamous. Some species breed colonially; others space themselves through the nesting habitat. Based on the fewer than 10 species that have been studied extensively, courtship and behaviour to maintain the pair bond may include vocalizations, bill-caressing, mutual preening, bowing, wing-raising, tail-spreading, and feeding the mate.

Nesting habits

With few exceptions, parrots nest in holes in trees. Some species add nest material such as leaves, fibres, and bark strips; others lay their eggs on the floor of the cavity. Some lovebirds cut leaves into strips, which are then tucked into the feathers of the back for transportation to the nest. Several parrots, including the pygmy parrots and the orange-fronted parakeet (*Aratinga canicularis*), hollow out cavities in termite nests. Exceptional in the family is the monk parakeet (*Myiopsitta monachus*) of South America, which builds a communal stick nest in trees. Several species nest in rock crevices or earthen caves; examples include the burrowing parrot (*Cyanoliseus patagonus*), kea, night parrot, and the flightless owl parrot (*Strigops habroptilus*). The ground parrot (*Pezoporus wallicus*) lays its eggs in a shallow cup on the ground.

Parrot eggs are white and usually nearly spherical. Generally the larger species lay only two eggs and produce one brood per year; the smaller species lay up to six or even eight or nine eggs and may breed two or three times per year. Incubation time, which generally varies directly with size, ranges from 16 to 30 days in the few species for which there is documentation. Either both parents or else only the female may incubate the eggs. The young hatch naked or with very sparse down. They are altricial—that is, they are helpless and require complete parental care—and they are also nidicolous—that is, they remain in the nest for some time after hatching. The young are fed by regurgitation, typically by both parents. In some species at least, care of the young may continue for several weeks after they have left the nest.

FORM AND FUNCTION

The yoke-toed foot

Foot structure. Parrots can be distinguished from other birds by the structure of the feet and bill. Most birds have the four toes arranged with three directed forward—the inner (II), middle (III), and outer (IV)—and one backward, the hallux (I). This condition, called anisodactyl, literally means without equal toes, referring to the unequal arrangement. Parrots have two toes (the inner and middle) directed forward, and two directed backward; this arrangement is called zygodactyl, which literally means yoke-toed and refers to the occurrence of toes in pairs. Zygodactyly also occurs in woodpeckers and their allies (Piciformes), cuckoos (Cuculiformes), and some other birds. The proximal (upper) bone of a bird's foot, the tarsometatarsus (commonly considered the lower leg), lies between the elevated heel joint and the toes. In parrots it is short and stout, and at least one toe is always longer. It is the characteristic short, thick tarsometatarsus—or tarsus, as the entire region is called—and the zygodactylous, long, strong toes that enable parrots to climb and manipulate objects so ably. The entire foot is encased in tough skin covered with small scales.

Bill and skull. The most distinctive morphological trait of parrots is the strongly hooked, powerful bill. Superficially the bill resembles that of the hawks and owls, but the upper and lower mandibles of parrots normally have a stronger and more uniform curve. Often the anterior edge of the lower jaw is broad and truncate. The under surface of the upper bill usually possesses transverse or oblique file-like corrugations where the lower jaw occludes. These file-like ridges, along with the highly manipulative tongue, assist in holding seeds as the bird uses the chisel-shaped cutting edge of the lower bill to peel away a seed cover.

The use of the bill for manipulating objects, cracking hard nuts, and as a third "foot" in climbing are all possible because of a highly kinetic (movable) upper jaw. Most living birds have such a kinetic upper jaw, which is connected to the skull dorsally by a hinge, and is able to be moved independently by swinging on this hinge, but nowhere among birds is this kinesis better expressed than in parrots. The raising of the upper jaw can be described as follows: all movement of the upper jaw originates at the point of attachment between the skull and the quadrate bone, which forms the hinge between the skull and the lower jaw. Two series of bones (the quadratojugal-jugal series and the pterygoid-palatine series), both of which lie in the roof of the mouth, are situated between the quadrate and the upper jaw. When the quadrate is swung forward, the two series of bones slide forward, causing the upper jaw to swing upward on its hinge with the skull.

The short, thick, and fleshy tongue of parrots shows a variety of specializations at the tip; one found in several groups is a brushlike fringe. Primarily, the tongue functions to manipulate and hold food. Those parrots with brushlike terminal papillae (nipple-like projections) on the tongue use them to hold juices, as a brush holds paint.

All parrots possess a cere, an area of soft skin surrounding the nostrils; it may be naked or covered with small, soft feathers. In adult budgerigars the cere is blue in males and tan in females.

The orbits (eye sockets) of some, but not all, parrots are ringed with bone. Other features of the parrot skeleton include a prominent keel on the sternum (breastbone), except in the flightless owl parrot of New Zealand, and a highly variable furcula (wishbone), which may be normal, weak, unfused medially, or absent.

Plumage coloration

Skin and plumage. Parrots have relatively few feathers, which are hard in texture and normally gaudy in colour. Many species are bright green with patches of red, orange, yellow, blue, or white; the plumage of others is predominated by the latter colours. A few parrots are brown or all green. Sexes are alike or nearly so, with a few notable exceptions. One, the eclectus parrot (*Lorius roratus*), was for many years thought to be two separate species until it was noted that only males were known for the predominantly green "species" and only females for the wine-red "species." The head is crested in a few parrots, especially among the cockatoos (Cacatuinae).

Powder downs, which occur in a variety of birds including some parrots, are specialized feathers, usually found in well-defined patches, that produce a powdery substance used to clean and waterproof the other feathers. They are well developed in cockatoos, in which they occur primarily as a pair of lateral rump patches.

Skin glands, which are abundant in mammals, are almost entirely lacking in birds, with the exception of the oil gland. The oil produced in this gland—also known as the uropygial gland because of its location at the base of the tail and as the preen gland because of its function—is used, like the powder down, to clean and waterproof the feathers. Oil is squeezed from the gland, and birds either use the bill to apply it to the feathers or rub their heads directly over the gland. The nipple of the gland, which protrudes through the skin at the base of the tail dorsally, is surrounded by a tuft of feathers in parrots. Not all parrots have an oil gland; for example, it is absent from the *Amazona, Brotogeris,* and *Pionus* parrots and greatly reduced in some others.

EVOLUTION AND CLASSIFICATION

The extinction of island species

Evolution. Dispersed on a multitude of small islands, parrots have always been vulnerable to extinction, and in recent times the group has suffered increasingly in this regard. From 1680 to the early 1960s at least 16 species disappeared entirely, and another 14 became endangered. Most of the extinct species lived on small islands or on large islands in the West Indies; only the Carolina parakeet had an extensive continental range.

The place of evolutionary origin of the parrot family is not known. The greatest structural diversity is exhibited by parrots from the Australo-Papuan region, but the greatest number of species occur in the Neotropical region. Some authorities doubt that either was the original home of this group, although it probably did arise in the Old World. The scanty fossil record is of no assistance in determining the original home of parrots, but it does provide an indication that the group is very old. Typical parrots are known from fossils from the Miocene epoch (about 20,000,000 years ago) of France and from North America. The fact that the Old and New World share no genera and that five of the six Ethiopian genera are not found elsewhere supports the antiquity of the group. An American biologist, Philip J. Darlington, has suggested that parrots and pigeons (Columbiformes), which show similar characteristics of distribution, may have been dominant everywhere before the rise of perching birds (Passeriformes), which may now be replacing them.

Annotated classification. The following classification follows the scheme proposed in 1959 by the German ornithologist Hans von Boetticher. He treated the parrots, as did most of his predecessors, as one family, with seven subfamilies, the two largest of which are further subdivided into tribes. Boetticher reduced the 81 genera recognized by U.S. ornithologist James Lee Peters in 1937 to 75, a figure that reflects the modern view of broader genera.

ORDER PSITTACIFORMES (parrots and allies)

Chunky, primarily tropical birds, with short necks, tarsi, and wings. Distinctive bill, short and strongly hooked, the upper mandible extending down over the tip of the upcurved lower mandible. Feet zygodactyl. Most brightly coloured; often gregarious; highly vocal. About 75 genera, 310–320 species; length 8 to 100 cm; found in the tropics and subtropics of the world and the temperate regions of the Southern Hemisphere.

Family Psittacidae

Characteristics of the order.

Subfamily Nestorinae (kea and kaka)

Bill rather long, narrow, less curved than in other parrots. Plumage greenish-brown. Two species: kea (*Nestor notabilis*) and kaka (*N. meridionalis*); length about 45 cm; New Zealand and adjacent islands.

Subfamily Psittrichasinae (vulturine parrot, or bristlehead)

Bill rather elongated, but more curved than in Nestorinae; face largely devoid of feathers, those present stiff and narrow. Plumage dark brown to black, with large patches of red. One species, *Psittrichas fulgidus;* length about 45 cm; New Guinea and adjacent islands.

Subfamily Cacatuinae (cockatoos)

Bill strongly curved (and massive in the palm cockatoo, *Pro-*

bosciger aterrimus); lower mandible wider than upper. Plumage black, gray, pink, or white, sometimes tinged with yellow or pink; often a prominent erectile crest, sometimes yellow or red. Four (or 5) genera, about 16 species; length about 30–80 cm; Australo-Papuan region and Philippine Islands.

Subfamily Micropsittinae (pygmy parrots)

Tiny parrots. Tail feathers short, with stiff shafts and pointed tips. One genus, 6 species; length about 8 cm; New Guinea and adjacent islands.

Subfamily Trichoglossinae (lories and lorikeets)

Bill relatively small; tongue brush-tipped. Mostly brightly coloured and gregarious. Feed on fruit, buds, pollen, and nectar; may be important pollinators of trees. Two tribes, Psittaculirastrini and Trichoglossini, about 14 genera, 62 species; length 11–32 cm; Australo-Papuan, Polynesia, Indonesia, and the Philippines.

Subfamily Strigopinae (owl parrot or kakapo)

Large, flightless parrot with soft greenish plumage and an owl-like facial disk. Nocturnal and vegetarian. One species, *Strigops habroptilus;* length about 60 cm; New Zealand.

Subfamily Psittacinae (all other parrots)

Range of characteristics encompasses that of order. About 52 genera, 234 species.

Tribe Platycercini (rosellas and allies). Most with long tails, many with bright plumage colours. Twelve genera, 31 species; length about 17–40 cm; Australo-Papuan, especially in interior of Australia. Tribe includes budgerigar (*Melopsittacus*), grass parakeets (*Neophema*), rosellas (*Platycercus*), night parrot (*Geopsittacus*), and ground parrot (*Pezoporus*).

Tribe Loriini (wax-billed parrots). Bill typically smooth and waxlike. Many species with bright plumage, sexes often differing. About 14 genera, 47 species; length about 14–45 cm; Australia and southern Asia to Africa and Madagascar. Tribe includes racket-tailed parrots (*Prioniturus*), ring-necked parakeets (*Psittacula*), the eclectus parrot (*Lorius*), and lovebirds (*Agapornis*).

Tribe Loriculini (bat parrolets or hanging parakeets). Small, short-tailed, green parrots. Rest hanging upside down. One genus (*Loriculus*), 9 species; length about 12 cm; India to Philippines and New Guinea.

Tribe Psittacini (blunt-tailed parrots). Medium-sized parrots; many brightly coloured, especially in green. Many are good mimics, especially in genera *Psittacus* and *Amazona.* Twelve genera, 66 species; length about 16–65 cm; New World tropics (majority), Africa and Madagascar.

Tribe Araini (wedge-tailed parrots). Tail usually graduated (*i.e.,* centre feathers longest, side feathers progressively shorter), often long and pointed. Some, especially the macaws (*Ara*) and blue macaws (*Anodorhynchus*), brilliantly coloured in red, yellow, and green, or blue. Many species with bare skin around eyes. Thirteen genera, 81 species; length about 12–100 cm; New World tropics. Three genera collectively include 54 species: *Pyrrhura* and *Aratinga* (conures and parakeets) and *Ara* (macaws).

Critical appraisal. With the present paucity of knowledge about the evolution of the orders of birds, any asserted or supposed relationships of the Psittaciformes, which are highly specialized, are necessarily purely hypothetical. Various authors have suggested, with little supporting evidence, relationships to such groups as the hawks (Falconiformes), owls (Strigiformes), game birds (Galliformes), pigeons (Columbiformes), woodpeckers (Piciformes), and cuckoos (Cuculiformes), especially the turacos (Musophagidae).

Relationships within the parrot order have proved just as perplexing. In the 1890s British ornithologist Alfred Newton commented on the state of knowledge of parrot classification in *A Dictionary of Birds* by writing:

> It is a reproach to ornithologists that so little satisfactory progress has been made in this direction, and the result is all the more disheartening seeing that there is no group of exotic birds that affords equal opportunities for anatomical examination, since almost every genus extant, and more than two-thirds of the species, have within recent times been kept in confinement in one or another of our zoological gardens, and at their death have furnished subjects for dissection.

Since Newton's time at least six classifications of the order have been proposed, many of which show basic similarities, but his statement was still basically true in the late 20th century. (G.E.W.)

Cuculiformes (turacos, cuckoos, roadrunners)

The bird order Cuculiformes is a cosmopolitan group containing two very distinct families, the cuckoos, Cuculidae, and the turacos, or plantain eaters, Musophagidae. Discussion of their relationship has led authorities increasingly to give the turacos ordinal rank. The family Cuculidae is much the larger group, containing about 127 species, found in the tropical and temperate zones of all the continents except Antarctica and on many oceanic islands; the Musophagidae contains 20 species, found only in Africa.

The cuckoos are an ancient group with uncertain phylogenetic affiliations and no living near relatives, even the turacos being quite distinct and with no intermediate, or connecting, species. The cuckoos are of unusual biological, especially ethological, interest because many species are brood parasites; *i.e.,* they lay their eggs in the nests of

Drawing by R. Keane

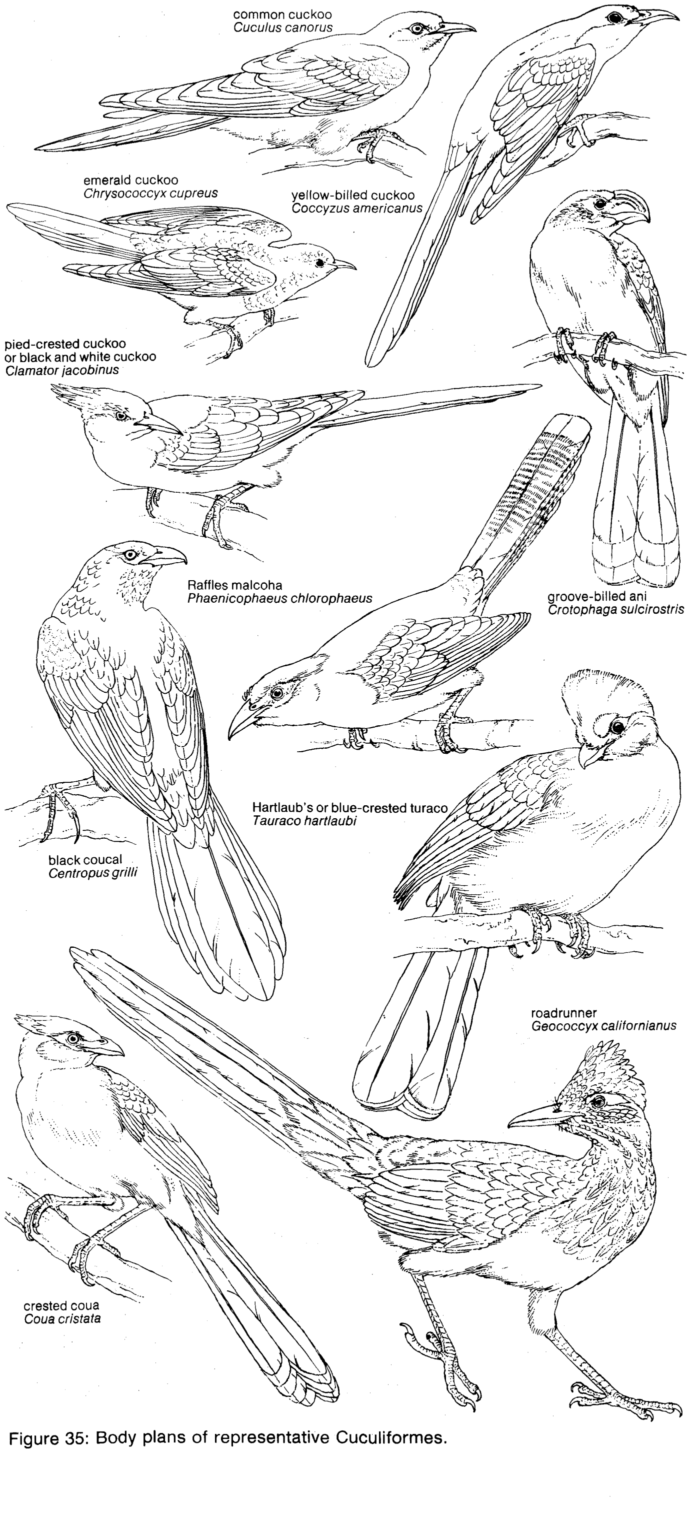

Figure 35: Body plans of representative Cuculiformes.

other species, which then rear the young cuckoos. Other cuckoos make their own nests, in which they incubate their eggs and rear their young as do most birds; and still others (*Crotophaga* and *Guira*) build communal nests. Some cuckoos are among the few birds that feed extensively on hairy caterpillars.

GENERAL FEATURES

Size ranges

The cuckoos cover a great range in size, from the small glossy or emerald cuckoos of the genus *Chrysococcyx,* which are about 15 centimetres (six inches) long, to the large ground cuckoos (*Carpococcyx*) and the larger species of coucals (*Centropus*), which reach nearly 90 centimetres (three feet), including the tail, which is often strikingly long. Most cuckoos have fairly loose-webbed feathers, varying in colour from subdued browns, grays, olive, and black, to brilliant, iridescent greens and purples and bright yellow. The beak is of moderate length and often slightly downcurved. The turacos are all sizable birds, the smallest species having a total length of about 37 centimetres (15 inches) and the largest attaining a length of almost 75 centimetres (30 inches).

Structural diversity in cuckoos

In keeping with the greater number of their included species and their worldwide distribution, the cuckoos show far more diversity in structure than do the relatively homogeneous turacos. The cuckoos include the arboreal "typical" cuckoos of both the Old World and the New World, the terrestrial roadrunners (*Geococcyx*) of southwestern United States and Mexico, and the more compact but also largely terrestrial coucals (*Centropus*) of Africa and Australasia.

DISTRIBUTION

Although the family Cuculidae is virtually worldwide in temperate and tropical regions, most of the subfamilies are restricted to one hemisphere or the other. Three (Cuculinae, Centropinae, and Couinae) are limited in distribution to the Old World; the subfamily Crotophaginae is wholly New World; the Neomorphinae is mostly New World, with one genus in Southeast Asia; and the sixth subfamily, Phoenicophaeinae, is represented in the tropics of both hemispheres. Many cuckoo genera are peculiar to certain parts of the world; others are cosmopolitan. Three genera (*Rhamphomantis, Caliechthrus,* and *Microdynamis*), for example, are known only from New Guinea; *Dasylophus* and *Lepidogrammus* occur only in the Philippine Islands; and *Saurothera* (lizard cuckoos) are found only in the West Indies. Some other genera are wide ranging: the typical cuckoos of the genus *Cuculus* are found in Europe, Asia, Africa, and Australia; the small, brightly coloured *Chrysococcyx* species occur in Africa, Asia, Australia, and some Pacific islands; and the coucals (*Centropus*) live in Africa, Asia, Australia, and adjacent islands.

Most cuckoos are solitary, often furtive birds that are inconspicuous even when relatively common. They do not form large flocks or even, except for the communal nesting anis (*Crotophaga*), small parties. The turacos, some of which form loose bands, are often conspicuous because of their bright colours, large size, and loud voices.

NATURAL HISTORY

Habitat utilization. As a group, cuckoos are forest birds, often inhabiting dense thickets that may make them difficult to observe. Some species, such as many of the genus *Cuculus,* inhabit rather open woodland. The guira (*Guira guira*) of South America and many members of the Old World genera *Clamator* and *Chrysococcyx* are found in open savanna (grassland), but only where trees are present. The roadrunners live in open scrub and cactus desert, often in the absence of any large vegetation.

The green and iridescent turacos (*Tauraco, Gallirex, Musophaga,* and *Corythaeola*) are primarily residents of dense, evergreen, broad-leafed forest; the grayer forms (*Crinifer*), most of which are called go-away birds (because the calls of some are "g'-way, g'-way"), are found in more open woodland, including savanna.

Food habits. Cuckoos are largely insectivorous, preying mostly on crawling insects. Orthoptera (grasshoppers, locusts, and mantids) are often taken. The greater, or North American, roadrunner (*Geococcyx californianus*) is reported to take flying grasshoppers by leaping after them from the ground. The larger cuckoos, such as the lizard cuckoos, roadrunners, and coucals, take substantial numbers of lizards, snakes, and other small vertebrates, sometimes including birds. Alone among the Cuculidae, the Madagascar couas (*Coua*) are reported to eat some fruit.

Musophagids feed almost entirely on fruit; only a few species are known to take insects and small vertebrates.

"Songs" of cuckoos

Vocalizations. Compared with birds generally, cuckoos must be considered a highly vocal group, a fact consistent with their forest habitat. A variety of songs, contact calls, and alarm notes are known for most species, some melodious, many harsh and discordant. The "song," associated with territorial assertion and courtship, is usually characterized by the repetition of loud, short notes, often on a descending scale or with a downward break in the middle. The individual syllables have variously been described as whistling, piping, cooing, tooting, laughing, grating, and clicking, depending on the species. The familiar clear, two-note call of the common cuckoo (*Cuculus canorus*) of Europe, Asia, and Africa is uttered by the male alone, the female giving a low bubbling call; apparently in most other species of cuckoos as well, the song is given by the male alone.

In addition to vocal sounds, at least one cuckoo, the North American, or greater, roadrunner, makes nonvocal sounds, clacking the mandibles to produce a rattling noise.

The calls of turacos are described as barking or laughing notes given in a series. A few species utter softer cooing notes.

Courtship behaviour. Except for features of parasitism, the behaviour of cuckoos is one of the least studied aspects of their natural history. A few species, in several subfamilies, have been observed closely, and some generalizations are possible. In territorial advertisement and in courtship, the singing male (in both parasitic and nonparasitic cuckoos) may posture, spreading the tail feathers, which are white tipped in most species, and drooping the wings. Courtship feeding of the female by the male has been observed in several species.

Courtship behaviour has been described for a few musophagids. In forest species, the male walks or leaps among branches with his tail fanned and with his wings half spread, displaying the crimson wing patches. Courtship feeding has also been observed, the male regurgitating fruit pulp or presenting whole fruit to the female.

Nesting. Two basic types of nesting behaviour are found among members of the order: parasitic and nonparasitic. About three-fifths of the Cuculidae and all of the Musophagidae mate, nest, and rear their young in the manner seen in most birds. About 50 species of cuckoos, including all of the subfamily Cuculinae (sometimes called "typical" cuckoos) and three species of the Neomorphinae, exhibit brood parasitism (*i.e.,* they lay their eggs in the nests of other species, which then rear the young cuckoos). Brood parasitism in the common cuckoo was recognized by Aristotle in the 4th century BC, and that of the koel (*Eudynamys scolopacea*) appears in the ancient Vedic literature of India, dating from about 2300 to 1800 BC, but the scientific study of this form of parasitism remained largely neglected until the late 19th century, when intensive study by many observers revealed a number of remarkable behavioral and physiological adaptations in the cuckoo.

Egg laying by the common cuckoo

In western Europe the common cuckoo is migratory, arriving at its breeding area in spring. The female establishes a territory and defends it against intrusion by other female cuckoos. The male is less restricted to an individual territory and more tolerant of other males; often more than one male will be in attendance on one female. Moving about within her territory, the female learns of potential host nests largely by watching their construction. Males of some species of cuckoos may accompany the females in searching for potential host nests. By the time she is ready to lay her eggs the female cuckoo has under surveillance several possible host nests and knows when the first eggs are laid by their owners. Most of the species parasitized by the common cuckoo are smaller than the cuckoo and lay their eggs at the rate of one each day until the clutch is complete, only then beginning incubation. Visiting when the hosts are away from the nest the cuckoo is able to place her egg in the nest after the host has started the clutch but before incubation has begun. It is well established that the common cuckoo lays eggs at 48-hour intervals, and apparently some glossy cuckoos lay one every 24 hours. The cuckoo places only one egg in each host nest and so must find a new nest for each of her 15 to 20 eggs. When parasitizing a species that builds a domed or globular nest, the female cuckoo clings to the outside of the nest and lays her egg through the opening without entering the nest. The repeated finding of cuckoo eggs in nests too small to admit a cuckoo or to bear her weight has led some authorities to maintain that the cuckoo lays the egg on the ground and carries it to the nest in her beak, but extensive observations have failed to substantiate this supposition. Some of the glossy cuckoos, however, parasitize nests so small and frail that mandibular egg placement cannot be ruled out.

In western Europe common cuckoos lay their eggs in the nests of many species, mostly songbirds (Passeriformes); more than 140 hosts species have been reported, including some that could hardly rear a young cuckoo successfully. Careful study of this and several other cuckoos indicates, however, that despite the wide range of hosts recorded, a few host species bear most of the load of raising the young of each cuckoo species. In some instances, such as two of the little Australasian glossy cuckoos (*Chrysococcyx*), the parasite relies mainly on a single host species.

Egg mimicry

Many birds react to a foreign object in the nest by deserting the nest, building another nest on top of the first, or removing the offending object. It is therefore of great advantage to a brood parasite to lay eggs that resemble those of its host, or, conversely, to parasitize species whose eggs are the same colour as its own. The utilization of several host species by a single population of cuckoos presents a difficult adaptive problem, for the host species may have many different egg colours. Early naturalists noted that there was often a marked resemblance between the egg of a cuckoo and those of the host, and a German ornithologist, Eduard Baldamus, in 1892 showed that the frequency and degree of similarity were too great to be coincidental. Subsequent studies by a number of workers, especially by an English naturalist, Edgar P. Chance, have revealed much of the basis for the resemblance, which is now called egg mimicry.

Each female common cuckoo lays eggs of a particular shape and coloration throughout her life, but the eggs of different females vary widely. Most authorities now agree that a given female normally restricts her parasitism to the single host species by which she herself was reared, and that the common cuckoo population is composed of numerous clans, called gentes, each of which parasitizes only one species of bird, for which the females of that gente have evolved egg mimicry. Only the gente of the female is important in egg coloration; the foster parentage of the male (*i.e.,* his gente) has no effect on his choice of females, and his genetic makeup apparently does not influence the coloration of eggs laid by his female offspring. Gentes are not given taxonomic designations but are sometimes known by their host species ("redstart cuckoo," "dunnock cuckoo," etc.). Evidence for this theory is largely circumstantial because of the difficulty in establishing the identity of individual cuckoos, but no plausible alternative theory has been proposed. The presence of cuckoo eggs in a wide variety of host nests in some small areas has been taken as evidence refuting the single-host hypothesis, but most of the nests with nonmatching eggs are found in areas in which the ecology has been seriously altered by human activity, with the result that female cuckoos have suddenly found themselves without adequate numbers of the proper host species and have been forced to utilize hosts for which their own egg colours are inappropriate. In the forested portions of northern Europe, where the habitat is relatively undisturbed and consists of homogeneous microecological areas (*e.g.,* reedbeds, birch forests), the common cuckoo parasitizes mainly a small thrush, the redstart (*Phoenicurus phoenicurus*), and both lay unspotted bluish eggs; in the reedbeds around Hungarian lakes the usual host is the great reed warbler (*Acrocephalus arundinaceus*), and the cuckoo eggs are strongly blotched with gray and black, like those of the warbler.

Studies of the reaction of the host to the presence of a cuckoo egg have indicated that egg mimicry is of considerable importance to the success of the parasite. Only about 5 percent of well-matched eggs are rejected by their hosts, as compared with up to 72 percent of mismatched eggs. Few cuckoos have been studied intensively in terms of egg mimicry, but the phenomenon is known to occur in at least some species. The great spotted cuckoo has an egg pattern mimicking that of the magpie (*Pica pica*), its usual host in southern Europe. In Africa, where it is apparently a recent colonist, this cuckoo exhibits what has been termed "evolutionary escape from specialization"; its new hosts, certain starlings, nest in holes, in which the semidarkness renders the dissimilarity of eggs less visible and hence unimportant. Among the 12 species of emerald cuckoos, the degree of host specificity and egg resemblance is variable, some species being highly host adapted, others less so. The genus as a whole shows no clear continuity of evolution in egg adaptation; individual species evidently have evolved their egg mimicry separately.

A notable feature of the egg of the common cuckoo is its small size; its weight is only about 2.5 percent of that of the adult cuckoo. The eggs of other parasitic cuckoos weigh more than 6 percent of the adult weight, and those of birds that rear their own young vary from 8 to more than 20 percent of adult weight. The adaptive value of small eggs is not well understood, but it is assumed to be related to the reliance of the common cuckoo on small hosts. Recent experiments have shown, however, that incubating birds show no adverse reaction to eggs significantly larger than their own.

Nest-mate eviction

Once the egg has been accepted and incubated by the hosts, the newly hatched cuckoo faces the problem of securing enough to eat from its small foster parents. The young cuckoo has evolved an astonishing form of behaviour, that of nest-mate eviction, that ensures that it will not have to compete with members of the foster brood for food. Within a few hours of hatching, the blind, naked, young cuckoo develops a strong urge to evict any objects, such as eggs or other nestlings, from the nest. It does this by working itself under the offending object and, aided by the presence of a depression between the shoulderblades, heaving the object over the rim of the nest. Within about 24 hours of hatching, the young cuckoo has the nest and the attentions of its foster parents to itself. The eviction habit is well developed in some parasitic cuckoos and seems to operate effectively in favour of the evictor but is surprisingly absent in many others, such as the crested cuckoos (*Clamator*).

Another habit that, like nest-mate eviction, tends to reduce the competition faced by the young cuckoo is the removal of one or more of the host's eggs by the female cuckoo, sometime before or after or at the time of the laying of her own egg.

The young cuckoo, while still in the nest, grows rapidly in response to the efforts of its foster parents, who regard it as their own. By the time it is ready to leave the nest, the young bird dwarfs its smaller hosts. Normally it does not receive attention from its real parents, but adult common cuckoos have occasionally been observed feeding young cuckoos; in the genus *Chrysococcyx* such behaviour appears to be more frequent than in other genera.

Social nesting in the guira and anis

Most of the nonparasitic cuckoos form stable pair bonds and defend territories, within which they build their nests and rear their own young. The guira and the anis are exceptional in that they live in flocks of five to 20 individuals, each flock defending a territory within which its members feed and nest. Several birds of the flock may cooperate in building a nest, in which two or more females may lay eggs and share incubation. Many members of the flock participate in feeding the young.

The nests of nonparasitic cuckoos are loose platforms of twigs placed in low vegetation or, rarely, on the ground. The coucals are unusual in that they build sizable domed nests of grass and twigs, on or near the ground, with side entrances.

The musophagids also build large twig nests, placed in trees often at considerable height. They lay unmarked whitish eggs, from which the young are believed to hatch completely covered with down; certainly they are downy from an early age.

Migration. Like most insectivorous birds in temperate climates, temperate-zone cuckoos migrate toward or across the equator for the winter. The migrations of some species are remarkable in that the young of the year travel completely independently of their parents and may cross up to 3,200 kilometres (2,000 miles) of open ocean unguided. Adults and young of some of the small Australasian glossy cuckoos separately migrate long distances to relatively small oceanic islands. It is obvious that the means of orientation and navigation must be unusually precise, but what they are remains as yet unknown.

FORM AND FUNCTION

In general body plan, most cuckoos resemble the "perching birds" (order Passeriformes). They are slender bodied, with medium to long wings and medium to extremely long tails, the latter sometimes constituting more than half the total length of the bird. The tail is usually graduated (the outer feathers shorter), and the individual feathers often are white-tipped.

The foot structure of cuckoos and musophagids is distinctive and at close range distinguishes these birds from any with which they might be confused. The foot of cuckoos is zygodactylous, or yoke-toed (*i.e.,* the outer toe is directed backward); that of musophagids is semi-zygodactylous, the outer toe being movable into either a forward or a backward position.

The cuckoo bill, although usually slender, is occasionally quite stout, as in the ground cuckoos and coucals, in which it makes a formidable weapon for subduing prey. In the anis the bill is heavy, with a strong ridge along the culmen (top), and, in the channel-billed cuckoo (*Scythrops novaehollandiae*) of Australasia, it is extremely large, almost like that of toucans. The bill is strong and rather short in the Musophagidae, usually with serrated edges. In the genus *Musophaga* it extends onto the forehead as a broad shield.

Most musophagids have prominent crests, a feature rare in cuckoos and well developed only in the genus *Clamator.* A number of cuckoos and turacos have bare skin, usually brightly coloured, around the eye or between the eye and the bill.

Turaco feather pigments

Perhaps the most distinctive feature of the turacos is the presence of two unique feather pigments. Turacin, a rich crimson pigment found in the primary flight feathers of *Tauraco* and *Musophaga,* is a copper salt of the pigment uroporphyrin III; and turacoverdin, the green pigment in turacos, is an oxidized derivative of turacin.

PALEONTOLOGY AND CLASSIFICATION

The order Cuculiformes is not well represented in the fossil record, but both cuckoos and musophagids apparently existed by the Early Tertiary Period, some 60,000,000 years ago. The dearth of fossil evidence is not surprising, in view of the group's preference for forest habitats; woodland animals, particularly small ones and particularly birds, are less frequently fossilized than those in open areas or aquatic habitats. Two species of musophagids have been described from the upper Eocene or lower Oligocene of France (about 40,000,000 years ago) and one from the middle Miocene (about 15,000,000 years ago). Three species of fossil cuckoos are known from North America, the earliest from the middle Eocene (about 45,000,000 years ago), and a fossil coua has been found in deposits from the Quaternary Period (the last 2,500,000 years) of Madagascar.

Although the cuckoos and musophagids are frequently united in a single order, as in the present article, most authorities acknowledge the distinctness of the two groups by placing them in separate suborders, Musophagi and Cuculi. The parrots (Psittaciformes) are often considered on osteological evidence to be the closest relatives of the cuculiforms, but even this relationship, if it exists at all, is not a close one. (He.F.)

Strigiformes (owls)

Owls constitute a homogeneous order (Strigiformes) of primarily nocturnal birds of prey, nearly worldwide in distribution. Their secretive habits, quiet flight, and weird calls have made them the objects of superstition and even fear in many parts of the world. The same characteristics have made the scientific study of them more difficult, with the result that the ecology, behaviour, and taxonomy of many species remain poorly understood.

GENERAL FEATURES

The size range of owls is about the same as that of their diurnal counterparts, the hawks (exclusive of the eagles and vultures), with lengths of around 13–70 centimetres and wingspreads around 30–200 centimetres. There are more owl species at the lower end of the size range. Owls apparently feed exclusively on animals. The most common prey is rodents; the smaller species, however, eat insects. All owls have the same general appearance: large head; hooked beak; large, forward-looking eyes; short tail; rather long, rounded wings; and large feet with sharp talons. Diversity occurs in size, in the presence or absence of decorative "ear" tufts, and in the extent of the facial ruff.

Owls are found on all continents except Antarctica and on most oceanic islands. Some, such as the barn owl (*Tyto alba*) and the short-eared owl (*Asio flammeus*), are among the most widely distributed of bird species; others, such as the Palau owl (*Pyrroglaux podargina*) and the Seychelles owl (*Otus insularis*), are endemic island species with small populations. Owls often attain higher population densities than hawks and have survived better in areas of human activity. Their nocturnal habits and inconspicuous daytime behaviour provide them some protection from shooting. The greatest densities are attained by small, territorial, insectivorous species, with pairs spaced about 200 metres apart in suitable woodland.

NATURAL HISTORY

Ecology. Owls utilize virtually all habitats, from grassland and tundra to dense woodland and rain forest. The distribution and density of most species apparently are limited by the availability of suitable nesting sites, rather than by the number of potential prey animals. In general the type of prey taken is governed by the size of the owl and by the relative abundance of potential prey species.

Hunting habits

Owls that hunt over grassland, such as the barn owl and short-eared owl, hunt by sustained flight, dropping into the grass to catch rodents. Many woodland owls secure prey by dropping from perches at the edges of forest openings. The Southeast Asian hawk-owl (*Ninox scutulata*) sallies from a perch to take flying insects. The whiskered owl (*Otus trichopsis*) takes flying insects in foliage. Owls of two genera (*Ketupa* and *Scotopelia*) are adapted for taking fish. Specialized forms of feeding behaviour are sometimes observed. The elf owl (*Micrathene whitneyi*) has been seen hovering before blossoms, scaring insects into flight with its wings and then catching them with its beak. A bay owl (*Phodilus badius*) has been observed stationed within a bat cave, catching bats as they issued forth at dusk. Although each species normally feeds on the type of prey for which it is adapted, a variety of owls may depend on a single prey animal when it becomes exceptionally abundant. Prey is generally swallowed whole, and indigestible material, such as feathers, fur, and bones, are regurgitated in the form of a compact pellet.

Vocalizations

Behaviour. Sound communication is important to owls, especially in mating and territorial defense. With their camouflage, immobile daytime stance, and silent flight, owls may be as difficult for each other to see as for natural enemies and human observers. Their characteristic sounds include snaps of the bill, claps of the wings in flight, and a variety of vocalizations, with pitch, timbre, and rhythm unique to each species and with pitch, at least, differing between sexes (the female higher). Although less melodious than the calls of some birds, the vocalizations of many owls are "songs" in the biological sense and may even be musical to the human ear. The song varies from deep hoots in some large species to chirps, whistles, or warblings in many small owls. When the nest is threatened, nestling burrowing owls (*Speotyto cunicularia*) emit a buzzing call that resembles the warning buzz of the rattlesnake, a frequent inhabitant of rodent burrows.

In the North American screech owl, a duet that seems to reinforce the pair bond starts with a special song by the male, eventually answered in kind by the female, often from a distance. After ten to 15 minutes of antiphonal (answering) singing, during which the two approach each other, the pair switches to a duet with a second song pattern, during which they meet. In the early spring this may be followed by precopulatory calls and posturing, then mounting. Other calls of the screech owl include: a note uttered by the female to stimulate the young to reveal their location after they have left the nest; a food soliciting call by the young; after the breeding season, barking calls, accompanied by bill-snapping, which indicate that the young are being ejected from the territory, or the adjustment of territorial boundaries.

Drawing by R. Keane (bay owl) and D. Malick (others)

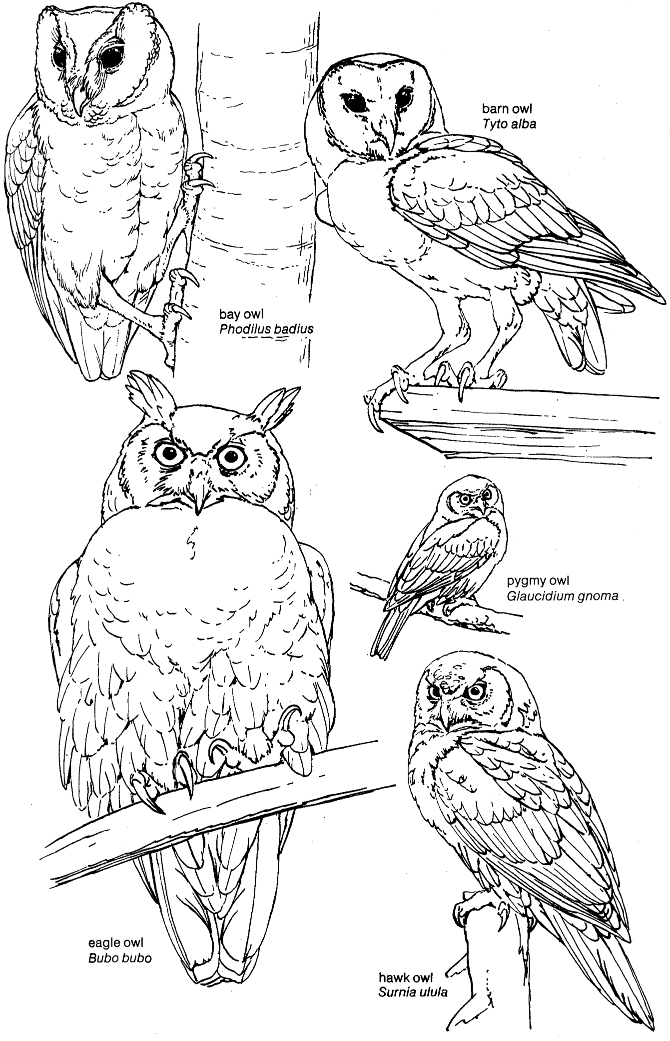

Figure 36: Variations in body plan among owls.

In many smaller species that do not normally sing duets, the male may sing all night from a single perch. The nocturnal routine of most owls involves peaks of activity at dusk and dawn. The owl leaves its secluded roost about dusk and moves to a perch overlooking the hunting area. There is a brief period of song, followed by about half an hour of foraging, then a longer period of song. Most of the darker hours of the night are spent inactively, with a period of alternating singing and hunting just before dawn.

Posturing by singing owls indicates that they communicate by sight as well as by sound. The male horned owl bows deeply with each song and raises the tail over the back. The wood owls (*Strix* species) engage in bowing, bobbing, and dancing, especially when courting. A defense display given by most large owls when threatened or when defending the nest involves increasing apparent body size by half spreading the wings and rotating them forward. The body feathers are raised and the fearsome appearance enhanced by snapping the bill and rocking the body from side to side. When seeking to avoid attention at its daytime roost (especially when being attacked by small birds), the owl compresses the plumage, elevates the ear tufts, and half closes the eyes. Combined with the barklike colour pattern of the plumage, this behaviour provides the appearance of a broken branch.

Nesting sites

Reproduction and development. Most owls nest in natural cavities in trees or cliffs or in woodpecker holes. The barn owls and the Eurasian little owls (*Athene* species) frequently use cavities in buildings. Some of the larger owls utilize old hawk or crow nests. Grassland and tundra owls nest on the ground, sometimes on an elevated hummock, and the burrowing owl digs a nest chamber in a rodent burrow. Frequently the nest cavity provides a daytime roost for one or both of the pair during the nonbreeding months. Most owls add no nesting material to the site, but the fur and feathers of accumulated prey remains and regurgitated pellets may provide some cushion for the eggs. When an open nest is used, leaves, grass, or other soft material may be added as a lining. The great gray owl (*Strix nebulosa*) occasionally constructs its own platform nest in a tree. In desert areas the smaller owls rely primarily on holes made by woodpeckers in large cacti. Intense competition has been observed among nesting birds, including owls, for occupancy of a limited number of nest sites. The invasion of the saguaro desert by the European starling (*Sturnus vulgaris*) has had a serious effect on small owls and other saguaro birds. The aggressive and abundant starlings occupy cavities before the other species have returned from wintering grounds and successfully defend the holes against native species.

Egg laying is timed so that the young become independent of their parents at a time when populations of prey species are greatest. At northern latitudes, many owls nest a month or two earlier in the spring than hawks of the same regions. An incubating owl is frequently covered by several inches of snow. Barn owls have been found nesting in every month of the year, even at the northern edge of their range, but the peak of nesting is in the spring. Owls lay more eggs than most diurnal raptors, with clutches of up to 12 (in the snowy owl, *Nyctea scandiaca*). In years of lemming abundance, snowy owls attain higher nesting densities, nest earlier, lay more eggs, and have higher fledging rates than when lemmings are scarce. The eggs of owls are more nearly spherical than those of any other bird group, the long diameter averaging only about 1.2 times the short diameter. They are laid at one- or, more typically, two-day intervals, and incubation begins when the first is laid. The result is that the oldest and youngest nestlings of a large brood may be hatched two or three weeks apart. If the prey populations are inadequate for the adult owls to support the entire large brood, the younger nestlings starve, while the more aggressive older ones are able to maintain normal growth rates and are strong at fledging.

Plumage succession

While in the nest, young owls grow two successive coats of white natal down. In the smaller species, the down is replaced by the immature juvenal plumage of softer, lacier texture than that of the adult. At this age, about two-thirds of the way to fledging, the young owls may leave the nest and spend the day several metres from it. In the screech owl, the juvenal plumage has fine barring, unlike the streaking of the adult. The first flight feathers, which appear about the same time, are like those of the adult but are more pointed. In the fall, only a few weeks after its acquisition, this plumage is replaced in a complete molt that introduces a plumage identical to that of the adult. In the larger owls that have been extensively studied (several species of *Bubo*), the juvenile plumage resembles the adult except that in *B. nipalensis* and *B. sumatranus* it is mostly white, with a different pattern of black marking from the adult.

Locomotion. Most owls use their feet only for perching and grasping prey. The burrowing owls, being terrestrial, can run rapidly over the ground and rarely perch in vegetation. The typical perch of other owls is a horizontal branch in a tree. The bay owl habitually perches on the vertical trunk of a tree, with the legs reaching sideways, one foot above the other. The body is held in a vertical position as though the owl were perched on a horizontal limb.

The flight of owls is a steady flapping on a straight path, ending in a short upward glide to the perch. Hunting, usually done from a perch, rarely involves extensive flight, requiring only a short burst of speed to surprise the prey on the ground. Forest owls rarely fly above the canopy of the foliage, but the Southeast Asian hawk-owl has been observed high in the air, flapping—or, on one occasion, soaring—in circles through swarms of bats, apparently without catching any. A few grassland and tundra owls hunt in sustained flight and have proportionately more wing area than their forest-dwelling relatives. The short-eared owl flaps slowly, the large area of the wings causing the light body to bob up and down, and sails for a brief period of time with the wings held in a high V over the back.

FORM AND FUNCTION

All owls share the same general body plan. The wings are long and rounded, the tail short. The legs and toes are of medium length and exceptionally strong for the size of the bird. Each toe is provided with a needle-sharp, curved talon. The outer toe is reversed in perching and is normally directed outward or backward in taking prey, providing the maximum possible toe spread.

The head is broad, to accommodate the exceptionally large eyes. The owl eye is elongated forward and encased in a tube made up of joined bony elements. The eye is virtually immovable, rigidly encased in the bony socket. Remarkable flexibility of the neck compensates for the immobility of the eyes; an owl can turn its head more than 180° in either direction and can thus look directly backward. The vision is binocular, and depth perception is often enhanced by moving the head away from the central plane. Owls that are mostly active at night have only rods in the retina, resulting in an absence of colour vision but a great increase in visual acuity and light sensitivity. Contrary to popular opinion, owls are not blind in strong light. The pupils, which operate independently, can be greatly reduced, protecting the sensitive retina and providing better daytime vision than that found in man.

Hearing

The ear is large and is surrounded by a ruff of papery feathers that serve to concentrate the sound. The feathers covering the ear opening are lacy and permeable to sound. A movable flap (operculum) on the anterior margin of the opening may function as a baffle to focus sounds. Some owls can locate and capture prey in total darkness, relying on their ability to localize the rustle of a mouse in leaves and to fly to that spot. In many owls the relative position of the ear opening is asymmetrical, being above a so-called blind cavity on one side of the head and below it on the other. The asymmetry is thought to be related to the sensitivity of each ear to sounds of various frequencies and provides the owl with the ability to localize sound sources in two planes simultaneously.

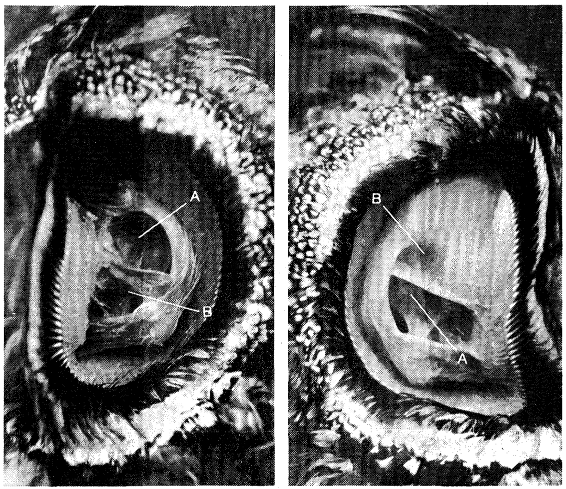
Many owls have erectile tufts of feathers ("ears" or "horns") above the eyes. In some cases the tufts give the owls a feline appearance and might frighten potential predators, but it is more likely that the erect "ears" serve to break the rounded outline of the head, adding to the concealment gained from colour and pattern.

The plumage of owls is soft, dense, and loose. A thick layer of down provides northern owls with insulation against cold. The upper surfaces of the flight feathers of most species are provided with a nap that makes the flight perfectly noiseless, allowing the owl to hear prey without interference of flight sound.

Owls vary in coloration from white through many shades of tan, gray, brown or rufous to deep brown. A few are solidly coloured, but most are cryptically patterned, with streaks, bars, or spots, often resulting in the bird's being almost invisible against bark. The concealing bark pattern is well exemplified in the small owls of the genus *Otus*. The soft brown, rufous, buff, or gray ground colour of each breast feather is adorned by a blackish bar, shaft streak, or combination of both, sometimes outlined in white or rufous. In some widespread species, such as the Eurasian scops owl (*O. scops*) and the screech owl, geographic variation is so great that the more divergent races are more different than some full species. In the far north there is only a faint pattern on a whitish background; in humid, temperate forests a bold pattern on a sooty background; in desert areas a medium to fine pattern on pale gray; in arid tropics a fine pattern on rufous; and in humid tropics a coarse pattern on fulvous. Size variation is also present, with northern birds weighing about twice as much as those of southern races. The horned owl (*Bubo virginianus*) exhibits similar variation. Screech, scops, and whiskered owls may be either gray or rufous; the ground colour apparently is determined by a single gene. Such dimorphism in ground colour is found in only certain populations of each species: the southern in the whiskered owl and the eastern in the North American screech owl and the Eurasian scops owl. In each case, interbreeding between the uniformly coloured monomorphic and sexually distinct dimorphic populations is limited. J.T. Marshall, Jr., regards the dimorphic strains as "incipient species." The mechanism by which natural selection maintains colour dimorphism, *i.e.*, its selective advantage, is poorly understood. Moreover, little is known about the type and degree of predation on small owls. The red phase of the screech owl may have survival value in the predominantly deciduous forest of eastern North America, blending with the foliage of summer and autumn, in which reds and browns are strongly represented.

Colour dimorphism

Heinz Meng



Asymmetry of the ear canal in the long-eared owl (Asio otus). In the left ear (left), the opening of the ear canal (A) is above the transverse fold and the blind cavity (B), below. In the right ear, the situation is reversed.

PALEONTOLOGY AND CLASSIFICATION

Fossil history. The earliest recognizable fossil strigiform is *Protostrix* from the Eocene of Wyoming. A number of genera from the later Tertiary have been assigned to Recent strigiform families. Some early owls reached far greater size than their modern descendents. A giant barn owl, about twice the size of the modern *Tyto alba,* inhabited Puerto Rico in the Pleistocene. Another large owl, *Ornimegalonyx oteroi* from the Pleistocene of Cuba, apparently was flightless. Both owls must have exceeded the modern eagle owls in size.

Distinguishing taxonomic features. The owls form a homogeneous group readily distinguished from all other orders by their general body plan, soft plumage, and osteological peculiarities. To determine relationships within the Strigiformes, taxonomists utilize the osteology of the skull and the sternum, relative specializations of the eye and ear, and the development of the facial disk. Within some genera the taxonomy is very complex, relying on general proportions, behaviour, voice, and ectoparasites (Mallophaga or feather lice).

Annotated classification.

ORDER STRIGIFORMES

Nocturnal predatory birds with hooked beaks; nostril marginal to fleshy cere; broad skull, facial disk, with forwardly directed eyes; reversible outer toe; talons for securing prey. One fossil and 3 extant families.

†Family Protostrigidae.

Fossil. Known only from lower Eocene of Wyoming.

Family Tytonidae (barn owls and grass owls).

Lower Miocene to present. Medium-sized owls (30–54 cm long) with heart-shaped facial disk completely encircling face; bill relatively long and slender; legs rather long, middle claw with comb. One pair of sternal notches, clavicles separate and not fused to sternum. One genus (*Tyto*), about 9 species. Worldwide, except in polar and subpolar regions and on some oceanic islands.

Family Phodilidae (bay owls).

Miocene and Recent. Like a small *Tyto,* but clavicles fused to sternum, which has 2 pairs of notches. Facial disk differs from *Tyto* in forming 2 movable lappets that can be focussed at sound, like mammalian ears. Disk interrupted at forehead. Wings short, broad. Legs and toes shorter and thicker than in *Tyto.* Voice, syrinx, behaviour, and ecology differ from both Tytonidae and Strigidae. One Recent genus (*Phodilus*), with 1 species widespread in Southeast Asia, and another (known only from a single specimen) in central Africa.

Family Strigidae (typical owls).

Upper Eocene to Recent. Clavicles fused to sternum, which has 2 pairs of notches. Facial disk consists of a semicircle on each side. Middle claw without comb. About 22 Recent genera, 125 species. Length about 13–70 cm. Worldwide, except Antarctica and some oceanic islands.

Critical appraisal. Most recent taxonomists have divided the Recent Strigiformes into two families, Tytonidae and Strigidae. The bay owl (*Phodilus*) has been placed in the Tytonidae by some authorities and in the Strigidae by others. F.E. Beddard, in 1898, suggested that the distinctive characteristics of the bay owl justified separation in a monotypic family, Phodilidae, a view recently endorsed by J.T. Marshall, Jr., after observations in the field.

Within the Strigidae, most current taxonomic problems are concerned with the placement of certain genera within the family and with the specific status of some populations of complex genera, such as *Otus.* Some of these problems await the development of new information on species-isolating mechanisms, especially vocal behaviour. (J.T.M.)

Caprimulgiformes (nightjars, frogmouths, potoos, oilbird)

The order Caprimulgiformes includes about 100 species of soft-plumaged birds, the major groups of which are called nightjars, nighthawks, potoos, frogmouths, and owlet frogmouths. The order also includes the aberrant oilbird of South America. Most are twilight or night-flying birds. Many produce sounds that are startling, strange, or weirdly beautiful and are surrounded by an aura of mystery richly endowed to elicit interest and sometimes fear from man. The name of the type genus *Caprimulgus,* "goatsucker," derives from an ancient belief that the birds seen flitting about the goats at dusk, actually preying on the insects disturbed or attracted by the goats, were taking milk from the goats' udders, a misconception no doubt fortified by the birds' uncommonly large mouths. There is now a tendency to replace the name goatsucker with the more appropriate term nightjar, derived from the birds' voices.

The caprimulgiform birds are sparrow- to raven-sized (14–55 centimetres) birds with enormous gapes, cryptically coloured and patterned plumage, short legs and, for the most part, long wings.

Comparison with owls

All caprimulgiform birds are rather similar in general appearance, but each family has certain peculiar characteristics both in form and in habits. Their closest relatives are the owls (Strigiformes), which they resemble in many ways, but there are numerous differences between them. Many of these are internal, but among those externally apparent are the bill and feet, which are not raptorial; the flatter head with eyes placed laterally rather than in a frontal facial disk; the relatively shorter tarsi and longer tails. Closer inspection reveals differences in the number of primary feathers in the wing and usually of secondaries and tail feathers as well. The nightjars also share some features with the swifts (Apodiformes), but these seem to be more superficial and coincidental than indicative of close phylogenetic relationship.

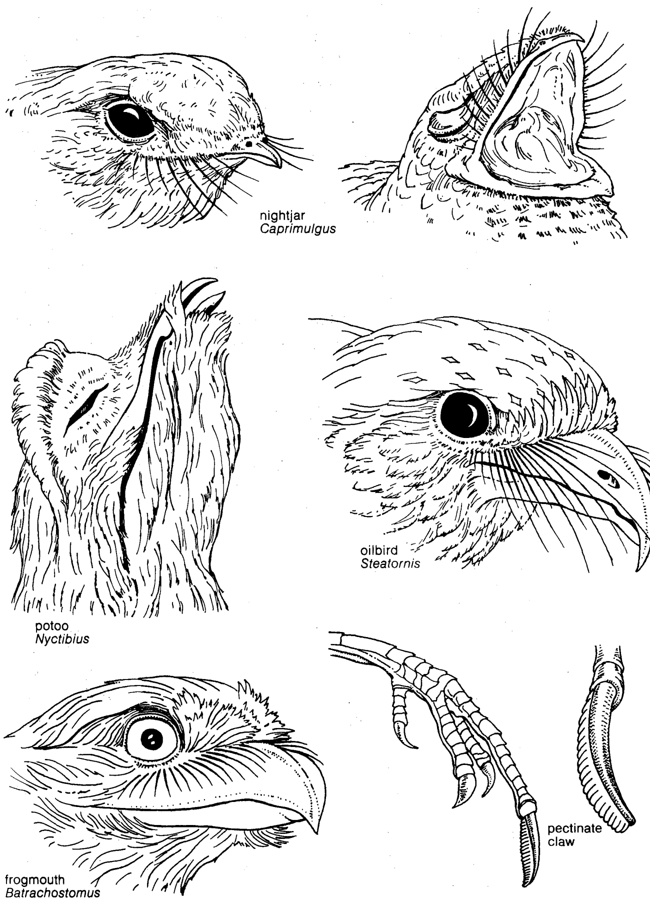


Figure 37: Beak and claw structure of representative Caprimulgiformes.

Drawing by E.J. Pfiffner

Although the true nightjars (Caprimulgidae) are amply distributed throughout the world, the other families are more restricted. The order is absent from New Zealand and some oceanic islands.

NATURAL HISTORY

The caprimulgiform birds are primarily crepuscular, their activity being largely limited to the periods of dawn and dusk, although they are also nocturnal when there is sufficient illumination, especially by moonlight. Some species may become active on dark, cloudy days, and a few are somewhat diurnal. Oilbirds possess a system of echolocation that permits them to fly freely in total darkness, an adaptation related to their roosting and nesting in caves, and are thus implicitly well equipped for nocturnal life. They leave their caves at dusk and return at dawn and are highly gregarious in their foraging behaviour as well as in roosting and nesting. The other members of the order are more or less solitary. Some nightjars that are migratory behave gregariously during migration and to some extent while in their "wintering" regions.

Although aerial feeders, most of the true nightjars roost on the ground, rocks, or fallen trunks, but some prefer horizontal branches of trees, in which case they usually perch lengthwise along the branch. Some ground roosters, however, will seek higher perches as singing or foraging posts; these are often slender branches or vines and the birds sit on them crosswise. Some species may even roost so perched. Unlike the nightjars, the frogmouths, potoos, and owlet frogmouths are arboreal. The last normally sit crosswise on a branch and fairly upright, both when active and at rest, resembling small, long-tailed owls. Potoos and frogmouths frequently sit crosswise and upright when actively foraging and also appear very owllike, although at rest they may perch quite differently. The potoos are noted for a peculiar stance, perching usually at the top of a stump, broken branch, or at a knob on an upwardly inclined limb. When alarmed in daylight they slowly flatten their plumage and stretch their bills upward in a stiff posture with the eyes nearly closed and the bill slightly open. Frogmouths adopt a similar broken-branch alarm posture.

During the day, the oilbird perches horizontally on ledges inside caves, usually on its nest. Ledges are limited and mostly occupied by nests. On its forays outside it has been observed to perch on the bare parts of tree branches. Its mien is rather hawklike, but its crouching stance, unique in some ways, is more like that of a nightjar.

Habitat. The caprimulgiform birds exploit ample food sources that are almost uniquely theirs. There are no other primarily frugivorous nocturnal birds to compete with the oilbird, its distribution being limited by the availability of suitable caves in regions providing the proper fruit for food.

Competition between species

The nightjars, by far the largest and most successful group, have no effective avian competitors for the great numbers of night-flying insects except among themselves; and the different nightjars have come to occupy almost all habitats, from semidesert to very humid regions and from sea level to 4,000 metres in altitude, with further advantage by preferring the more open areas: savannas, grasslands, and forest clearings. When woodland dwellers, they live in the more open forests or brushwood growths, and many use the woodlands only for diurnal concealment or nesting, doing most of their feeding at the edge or in clearings.

Competition between the nightjars and potoos is reduced because the latter hunt mostly from higher perches in open country or exploit the space above the great forests, a vast niche occupied by practically no other nocturnal bird.

Frogmouths and owlet frogmouths inhabit forested savannas, forest edge, second growth, and the more open forests. Thus their chief competitors are the insectivorous owls. As with the nightjars, differences in food preferences and methods of hunting minimize this competition. The hole-nesting owlet frogmouths, however, have to contend not only with owls but also many diurnal species for suitable nesting sites, and this may explain why they are apparently the least successful family in the order, as suggested by their limited distribution and paucity of numbers.

Food habits. Except for the oilbird, caprimulgiform birds are insectivorous, with some of the larger species occasionally carnivorous. Many of the nightjars and nighthawks feed in continuous hawking flight, which may be rather erratic as they pursue their prey. Others of the order make short sallies from arboreal or terrestrial perches in the manner of flycatchers, frequently taking advantage of the increased visibility afforded by roads. Many nightjars take crawling insects by swooping from arboreal perches or by running along the ground, being far more agile on their feet than is generally believed. Almost all insects are taken, but beetles predominate in the food of many species. Also important are moths, the winged forms of termites and ants, and mosquitos; even small birds are taken. There seems to be little difference between the general kinds of food items taken by the New and Old World nightjars (subfamily Caprimulginae), but the Old World species rely more on foraging in continuous flight than do most in the New World, where aerial foraging is largely limited to the nighthawks (Chordeilinae).

Potoos sally from exposed arboreal perches, sometimes fairly close to the ground, to feed on essentially the same types of insects as the nightjars. The prey of frogmouths is mostly terrestrial. In short sallies from elevated perches, frogmouths capture large, crawling arthropods on the ground or on branches. Snails, frogs, mice, small birds, and occasionally fruit also are taken. Owlet frogmouths feed mostly on terrestrial prey, much in the manner of the frogmouths, but also sally from a perch to take flying insects.

The frugivorous oilbirds

Aberrant in so many ways, oilbirds are the only nocturnal, exclusively frugivorous birds. The fruits eaten are primarily of various trees of the palm, laurel, and bursera families and have large hard seeds. The firm, fleshy pericarp of the fruit is exceedingly rich in protein and oily fats. The fruits are swallowed whole and the seeds later regurgitated. D.W. Snow has found that oilbirds apparently possess an efficient olfactory sense, suggesting that they employ scent in locating certain of the fruit-bearing trees. The fruits of palms, however, are not aromatic and are no doubt located by sight. The actual collection of the fruit seems to depend on sight. In feeding, the birds reach out with their bills and pluck the individual fruits while hovering. When feeding on large compact bunches of fruit they sometimes cling briefly with their feet.

Males of most, if not all, nightjars have patches of white feathers that serve as signals in mating. These patches are concealed when the bird is at rest but flashed in courtship displays. Males of several species in Africa and South America develop elongated wing or tail feathers that function in courtship and are lost following the breeding season.

Drawing by E.J. Pfiffner

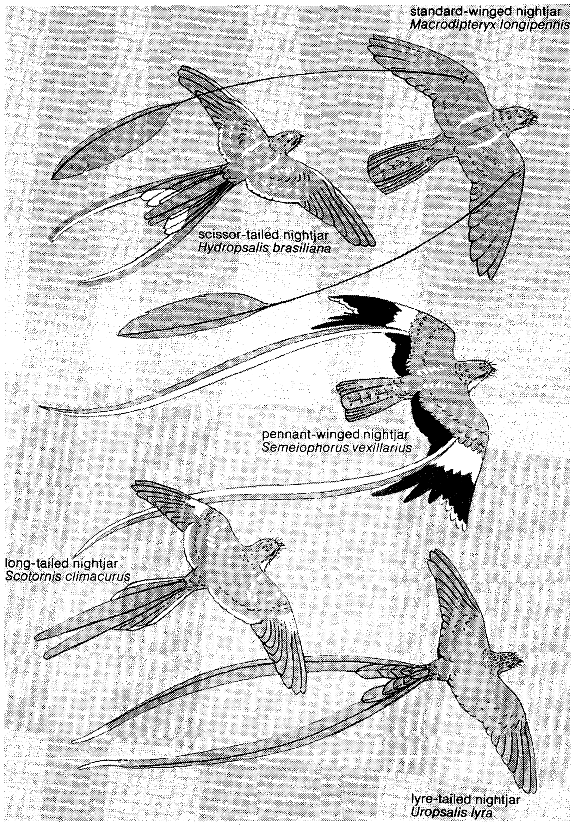

Figure 38: Specialized feathers in male Caprimulgiformes.

Vocalizations. The primary signals for mating and territorial purposes in most caprimulgiforms, however, are vocal and mechanical sounds. The voice is usually well developed, often having such distinctive patterns that the birds are named onomatopoeically (whippoorwill, chuck-will's-widow, etc.). The almost human lament of the common potoo (*Nyctibius griseus*) in South America has in some places earned this species the name "poor-me-one," and both it and the grotesque bawl of the great potoo (*N. grandis*) have been the source of many superstitious beliefs and legends. Frogmouths sing with various nasal booming, hooting, or croaking sounds, and the little known owlet frogmouths are reported to give owl-like whistles, churring calls, and a loud hissing note. Among the true nightjars, some species produce slowly or rapidly repeated churring sounds, in some cases rather toadlike, while others produce a warbled or whistled song, not at all disagreeable. Whistled phrases may be repeated hundreds of times without a break. Many different types of calls are used in different contexts, but the primary song, different for each species, appears to be the most important mechanism for species recognition. Besides vocal sounds, many species produce mechanical sounds in displays, such as claps and whirrs of the wings. In some species the vocalizations are given primarily in flight, in others primarily when perched; still others have different calls or songs when flying than when perched.

Echolocation by the oilbird

Oilbirds produce a variety of sounds, from clucking calls, apparently used to maintain contact, to harsh snarls and screams, when excited. They seem to have no primary song, which may be superfluous to their gregarious and specialized mode of life. Of greatest interest are the rapidly pulsated clicks that are emitted in shorter or longer bursts and that D.R. Griffin has found are used by the oilbird for navigation in total darkness on the principle of echolocation. These clicks are in the range of 7,000 cycles per second and thus audible to humans, in contrast to the ultrasonic pulsations used by bats in their system of echolocation. So far as is known, the only other birds to employ echolocation are some of the cave-swiftlets (*Collocalia* species). To what extent oilbirds use echolocation outside the caves is not known. As do their relatives in the order, they have large, sensitive eyes and probably navigate visually outside their caves.

Reproduction. Nesting habits are diverse among caprimulgiform families. Nightjars make no nest, depositing their eggs directly on the ground or on the leaf-covered floor of woodland. Occasionally they use a slight natural depression or scratch out a place among the debris. Populations of a few species (notably the North American nighthawks) have adapted to urban life and nest on flat gravel-covered rooftops. The one or two slightly glossy eggs may be cryptically coloured (profusely marbled with pink, buff, brown, or gray) or contrast markedly with their surroundings (white to buffy, usually with slight lines or blotches of colour). Incubation lasts about 19 days and may be by both adults or only by the female, there being considerable variation in this behaviour even within some species.

In contrast to the simplified nesting of nightjars, frogmouths construct nests on the horizontal forks of trees. In the genus *Podargus* the nest is of twigs and other plant matter and the two or three eggs are white; in *Batrachostomus* the nest is a pad of the birds' own down, bound and camouflaged externally with cobwebs and lichens, one white egg being laid. Both sexes are believed to incubate, the period being about 30 days. Owlet frogmouths nest mostly in hollow trees but also in tunnels in banks. They lay three or four white eggs, usually on a mat of leaves or fur. The incubation period is as yet unknown. The potoos are the most highly restricted nesters, for they must find a branch or stub with a suitable depression or crevice of just the right size to accommodate the single egg they lay. The egg is flat white, marked with brown and gray, and is incubated by both parents for 30 to 35 days.

On ledges in the caves they inhabit, the oilbirds build up a shallow nest rim of viscous, regurgitated fruit matter, which sets to a firm structure. As the accumulation of seeds raises the level inside the nest, the rim is constantly added to, so as to maintain a slight depression. The nests are used year after year and gradually grow to low mounds. Inevitably some seeds and the feces of very young nestlings contribute to the fabric of the rim. Two to four eggs are laid (white, subelliptical, slightly rough surface); both sexes incubate, the period being about 33 days.

Behaviour of the nestling

The chicks of nightjars are semiprecocial: they are down covered (buffy to brownish, plain or mottled, highly cryptic), fed by both parents, capable of opening their eyes on the first day (normally keeping them closed for several days), capable of walking on first day, and able to hop or run very well by third or fourth day. They usually run with wings raised, resembling young ducklings in gait. From the beginning chicks may solicit feeding by walking to the front of the adult, reaching up, and pecking at its bill. During the first days they are fed a regurgitated whitish viscous substance but later only partially digested insects. As early as the second day, although sometimes not until a week later, the chicks are led to different resting sites, at first only a metre or so at a time, but gradually much greater distances. Some of this moving may result from the chicks' own wanderings, for they are often restless and leave the covering adult.

In many cases both parents brood the chicks, in others only the female does so, and rarely the male assumes the primary role. By about two weeks the young are well feathered and too large for successful brooding; they rest at first near a parent but later quite alone.

Undisturbed young birds fly voluntarily at from 22 to 28 days; disturbed young may fly much earlier. About the time they are able to fly they begin a certain amount of feeding on their own but are still largely dependent up to 40 to 50 days. When two young hatch, one of them frequently develops more slowly and most often disappears during the second week. If it survives, however, it may require up to 40 days to reach the state of voluntary flight.

The nestlings of frogmouths, potoos, and owlet frogmouths are semidependent, covered with whitish down, fed by both parents, and remain in the nest until fledged. One observer noted that a young common potoo began wandering over the boughs of the nest tree at about four weeks. This same nestling first made trial flights at 47 days and finally left the nest tree when 50 days old. Other reports indicate the nestling period of potoos to be of 40–45 days, that of frogmouth to be about 30 days. The young are brooded only during the first half of this period, by which time young potoos have attained the juvenile plumage (whitish mottled with brownish) and are already accomplished in assuming the "broken branch" posture of adults.

On the whole, the caprimulgiform birds, like most birds, breed solely or mostly at the time of maximum abundance of food supply. Oilbirds may nest to some extent throughout the year, but the maximum nesting takes place during that time of year when the greatest number of appropriate trees are fruiting. Baby oilbirds are helpless (altricial), hatched blind and virtually naked, with only a little sparse down. They have an exceedingly slow rate of development. A thicker coat of down replaces the initial one after three weeks, and the adult plumage begins to appear at five weeks, there being no special juvenile plumage. The nestlings are apparently fed semidigested fruit pulp during the first days. At about two weeks there is a gradual change to whole fruits, regurgitated by the adults into the mouths of the young. As a result of the oil-rich fruit diet, young oilbirds build up extraordinary deposits of fat, which has led to economic exploitation. The fat can be boiled down to a high quality, durable oil, suitable for cooking and lighting. For this reason oilbirds were once subject to heavy predation by their human neighbours, a practice that continues even today, on a much reduced scale because of a general trend toward protection. The fat buildup reaches its maximum at about 70 days, at which time a young oilbird may weigh half again as much as an adult. By this time the plumage is well developed but not fully grown. The weight decreases as the feathers grow, until at an age of 100–120 days the young leave the nest, flying well and looking like adults. Both parents participate in feeding and brooding, the latter ceasing after about four weeks.

Migration. A number of tropical caprimulgiforms are sedentary, but the widespread cosmopolitan nightjars exhibit all degrees of migration. These migrations may be short, even local, or quite long. Some populations of the common nighthawk (*Chordeiles minor*) of North America and the European nightjar (*Caprimulgus europaeus*) migrate south to Argentina and South Africa, respectively. Actually, transequatorial migrations in both directions occur, as birds take advantage of the general alternation of seasons, and hence of food supply, on opposite sides of the Equator.

Lowering of body temperature in torpor

Hibernation. Some nightjars are able to cope with temporary food shortages by entering into periods of torpidity, a faculty they share with some swifts, hummingbirds, and a few others. The only known instances of apparently regular, prolonged annual hibernation in these birds, however, are reported for the poorwill *Phalaenoptilus nuttallii,* a nightjar. A banded individual was observed hibernating in the same small hollow in a rock during several successive winters. The bird was inert, with respiration and heart rates reduced to almost immeasurable levels and body temperature about 22° C below normal. Subsequent laboratory experiments have shown that several species of nightjar have the ability to relax into a torpid state under abnormal conditions. Such an efficient means of conserving energy may be more generally possessed than is presently realized throughout a family whose habits largely limit the birds to two brief periods of feeding a day, causing them to be especially vulnerable to involuntary fasting if inclement weather should prevent feeding during those periods.

FORM AND FUNCTION

Members of this order are easily recognized by their extremely wide mouths, large eyes, short legs and small, weak feet, and, except in the oilbird, soft plumage, in which browns and grays predominate.

The size of the gape is astonishing. When the bird opens its mouth, the opening seems to span the entire head, which is nearly the case. The beak, always somewhat hooked, is large and horny in the oilbird and frogmouths but reduced to a small projection in the remaining families. In body proportions, caprimulgiforms often appear chunky on account of the fluffiness of their plumage, but their actual bodies are proportionately no stouter than most songbirds. The tail is of medium length, except in males of those species with ornamental tail features. The wings are medium to long, and rounded in most species, pointed in a few, especially the nighthawks.

The plumage of all forms presents unexcelled examples of natural camouflage. Coloured in rufescent to ochreous browns, grays, white, and black, the species are variously patterned in greatest accord with their normal surroundings during daytime rest. Those nightjars that roost inside woodlands are streaked and spotted in a way resembling fallen leaves and other detritus on the forest floor. Those that dwell on gravelly terrain are speckled or otherwise patterned. The latter often contrast rather than blend with the soil, appearing like one of the many stones scattered about. The owlet frogmouths appear as clusters of dead leaves. Potoos and frogmouths are streaked and mottled like bark so that in the daytime alarm posture they appear most effectively as dead stubs.

Red and gray colour phases

Caprimulgiform species are frequently dichromatic, having grayish and reddish phases. These appear to be randomly distributed in some cases and sex-linked in others, there being several species of nightjars in which males are more grayish, females more reddish.

Except for possible freaks, the iris colour is brown in nearly all members of the order. Yellow occurs in the irises of some potoos, and yellow, orange, and ruby in frogmouths. Contrary to some reports, oilbirds do not have blue irises nor are any nightjars known to have yellow eyes.

CLASSIFICATION

Distinguishing taxonomic characters. The most important characters used to define the caprimulgiform birds are the type of plumage, structure of the feet and legs, form and structure of the bill, palatal structure, arrangement of the pelvic muscles and flexor tendons, shape of dorsal vertebrae, meristic characters such as the number of primary and secondary feathers and rectrices, presence or absence of intestinal ceca and of an oil gland, location of syrinx, presence and type of rictal bristles, powder down patches, carotid artery relationships, and a few other anatomical details. Variations in some of these same features characterize the different subgroups.

Annotated classification. The arrangement presented is the same as that proposed by A. Wetmore (1918) in a modification of R. Ridgway (1914). The group was then considered a suborder Nycticoraciae of the order Coraciiformes. The subsequent shift to ordinal level with the name Caprimulgiformes has long been accepted.

ORDER CAPRIMULGIFORMES

Soft plumaged (except Steatornithes), cryptically patterned birds with relatively weak anisodactyle feet and very short tarsi; deeply cleft gape (except Steatornithes); pelvic muscle formula AXY (XY in Steatornithes); flexor tendons fused (synpelmous); 10 primaries; 11–13 secondaries; 10 rectrices; aftershaft small but present; 2 carotid arteries and oil gland present (except in *Podargus* and *Nyctibius*).

Suborder Steatornithes

Dorsal vertebrae opisthocoelous (concave behind); gape not exceptionally deeply cleft; rostrum movably articulated with skull; plumage firm.

Family Steatornithidae (oilbird)

No fossil record. Locally distributed in Guyana, Venezuela, Colombia, Ecuador, Peru, and Trinidad. Desmognathous palate (maxillopalatine bones fused), palatines narrow and not expanded posteriorly; large, strong bill with hard rhamphoteca (horny covering) and subterminal tooth, surrounded by long vibrissae; bronchial syrinx; 15 cervical vertebrae. One species, length 40 centimetres.

Suborder Caprimulgi

Dorsal vertebrae heterocoelous (saddle-shaped); deeply cleft gape; rostrum fixed; plumage soft.

Family Podargidae (frogmouths)

No fossil record. Confined to Australasian (except New Zealand) and southern Oriental regions (including extreme southern India). Desmognathous palate; palatines broad throughout, slightly expanded posteriorly; wide, strong bill with hard rhamphotheca; bronchial syrinx; 13 cervical vertebrae; well-developed, powder-down tufts on either side of rump; oil gland absent in *Podargus,* very small in *Batrachostomus;* one carotid artery (left). Twelve species, length 20–40 centimetres.

Family Nyctibiidae (potoos)

Upper Pleistocene to present. Neotropical region. Schizognathous palate (small vomers and separate maxillopalatines); palatines narrow anteriorly, greatly expanded posteriorly; small, weak bill but with prominent horny angular projection on maxillary tomium midway between tip and rictus and tomium very broad, horny, and strongly convex from that point to rictus; extremely short tarsi; toes unusually wide basally, forming a broad flattened sole; tracheobronchial syrinx; 14 cervical vertebrae; large powder down patches on sides and breast; no oil gland; one carotid artery (left). Five to seven species, length 20–55 centimetres.

Family Aegothelidae (owlet frogmouths)

No fossil record. Australasian region (except New Zealand). Desmognathous palate; bill similar to Podargidae but shorter, weaker, and largely hidden by forehead feathering; bronchial syrinx; unique in the order in lacking ceca. Eight species; length 16–25 centimetres.

Family Caprimulgidae (nighthawks, nightjars)

Earliest probable fossil Oligocene, earliest modern fossil *Caprimulgus* in Pliocene (Europe). Worldwide in tropical and temperate zones; absent from northernmost Eurasia and America, southernmost South America, New Zealand, and some oceanic islands; subfamily Chordeilinae (nighthawks) restricted to New World. Schizognathous palate (except *Chordeiles* and perhaps other Chordeilinae); palatines narrow anteriorly, greatly expanded posteriorly; small, weak bill; well-developed rictal bristles (except *Eurostopodus* and Chordeilinae); small, weak feet; lateral toes much shorter than middle toe, fourth toe with only four phalanges (segments; five is normal for this order), middle claw with inner edge pectinated; hallux very short and directed inward; tracheobronchial syrinx; 14 cervical vertebrae. Seventy to eighty species; 14–40 centimetres (without ornamental feathers).

Critical appraisal. The major divisions of the caprimulgiform birds are clearly defined and their composition remarkably homogeneous so that there are no apparent taxonomic problems above the level of genus. The rather aberrant oilbird has traits similar to owls, but evidence places it in this order. Studies of the egg-white proteins by C.G. Sibley show that it is clearly caprimulgiform. These studies indicate a close relationship between the nightjars and the owls but do not support one to the swifts. Within the order the main taxonomic problems relate to re-evaluation at the generic level and clarification of species limits. These are likely to be settled only with the aid of field studies utilizing bioacoustical methods along with other disciplines. (P.A.S.)

Apodiformes (swifts, hummingbirds)

The order Apodiformes contains two groups of birds that are very different from one another in general appearance and way of life: the swifts and the hummingbirds. The two groups, considered suborders, are Apodi, which contains two families, Hemiprocnidae for the tree swifts (also called crested swifts) and Apodidae for the true swifts; and Trochili, which contains the single large family Trochilidae for the hummingbirds. The most obvious common characteristic of the two groups is a superb mastery of the air; both swifts and hummingbirds are agile fliers and share, in this connection, some peculiarities of wing structure. Some ornithologists believe that these anatomical resemblances are convergent (the result of the same type of natural selection acting on unrelated organisms) and that the true relationships of hummingbirds and swifts lie with other groups, not with each other.

GENERAL FEATURES

Importance to man. Man has long been fascinated by hummingbirds. From the time the first specimens arrived in Europe from the newly discovered American tropics, the brilliant, iridescent colours and diminutive size of hummingbirds have made them favourites of both scientists and the public. Stuffed hummingbirds were in great demand for display in homes and museums and for decorating ladies' hats. South American Indians brought hummingbirds from hundreds of miles around to great market centres such as Bogotá, Colombia, and Cayenne, French Guiana. Even today, some species and subspecies of hummingbirds are known only from these "trade skins," and their actual range has never been discovered by ornithologists. The commerce in hummingbird skins has almost completely vanished, and collectors now capture hummingbirds alive for exhibition in zoos and aviaries. Although some species are surprisingly hardy in captivity, the proper care of hummingbirds is not simple, and few of the birds that leave the jungle survive.

Bird's nest soup

In most parts of the world, swifts, little known to the average person, are often confused with swallows, which, although unrelated, are generally similar to swifts in size, proportions, and aerial habits. In Southeast Asia, however, one group of swifts is of major economic importance. The swiftlets of the genus *Collocalia* comprise a group of species, most of which live in caves. They build nests composed of varying amounts of plant and animal substances (*e.g.*, leaves, moss, hair, feathers) held together and fastened to the cave wall with a mucilaginous secretion of the salivary glands. The nest of one species, the edible-nest swiftlet (*C. fuciphaga*), is composed almost entirely of concentric layers of this salivary cement. These nests and, to a lesser extent, those of some other swiftlets are gathered commercially in the East Indies and form the base for the famous bird's-nest soup of the Orient.

Size range and diversity of structure. The smallest of living birds are included among the Trochilidae, the smallest known species being the bee hummingbird (*Mellisuga helenae*) of Cuba, which is barely 62 millimetres (two and one-half inches) from bill tip to tail tip. Even the largest member of the family, the giant hummingbird (*Patagona gigas*) of western South America, has a body only about the size of that of a large sparrow, although the bill and tail extend this length by about 35 and 85 millimetres (one and one-half and three and one-half inches), respectively. There is relatively little structural diversity among hummingbirds except in the size and shape of the bill and the ornamental feathers. The bill may be very short or, as in the sword-billed hummingbird (*Ensifera ensifera*) of the Andes, may exceed the rest of the bird in length. The bill may also be straight or curved to varying degrees, usually downward, but, in a few species, upward. In most hummingbirds, the tail feathers are relatively unspecialized; but in some others they are greatly elongated, either straight or curved, in others wirelike with spatulate tips. Brilliantly iridescent feathers are found somewhere on the body of most hummingbirds, often with an especially colourful gorget on the throat; a few genera have dull coloration. Sexual dimorphism (difference between sexes) varies, with females being either indistinguishable from males or less colourful or ornate.

Variety of swifts

The true swifts have a somewhat greater size range, from such tiny species as the five-gram (0.2-ounce) pigmy swiftlet (*Collocalia troglodytes*) of the Philippines to some of the large and powerful members of the Old World genus *Apus,* 30 times heavier. Beyond the size differences, the most obvious morphological variation among swifts is in the conformation of the tail. The spine-tailed swifts, a group that includes the familiar American chimney swift (*Chaetura pelagica*), have the central shaft of the tail feathers extended beyond the vanes (flat, expanded part) into pointed spines. In other swifts, with less specialized tail feathers, the tail itself may be square ended, moderately forked, or deeply forked (swallow-tailed). Less conspicuous structural variations that are used in swift taxonomy include the position of the toes and the amount of feathering on the legs. The four species of tree swifts that comprise the family Hemiprocnidae are rather uniform, differing mainly in size, proportions, and plumage pattern.

Hummingbird distribution

Distribution and abundance. Although there are unrelated Old World birds, such as the sunbirds (Nectariniidae), that superficially resemble hummingbirds, the family Trochilidae is confined entirely to the Americas. Of approximately 320 known species, most are tropical, and the greatest numbers of these are found in northwestern South America (Colombia and Ecuador). Several species have become adapted to temperate conditions, some by having extended their distributions north or south of the tropics, others by their occupation of high-altitude habitats in South and Central America. In North America only one species, the ruby-throated hummingbird (*Archilochus colubris*), is normally found east of the Great Plains. About

Drawing by Christian D. Olsen

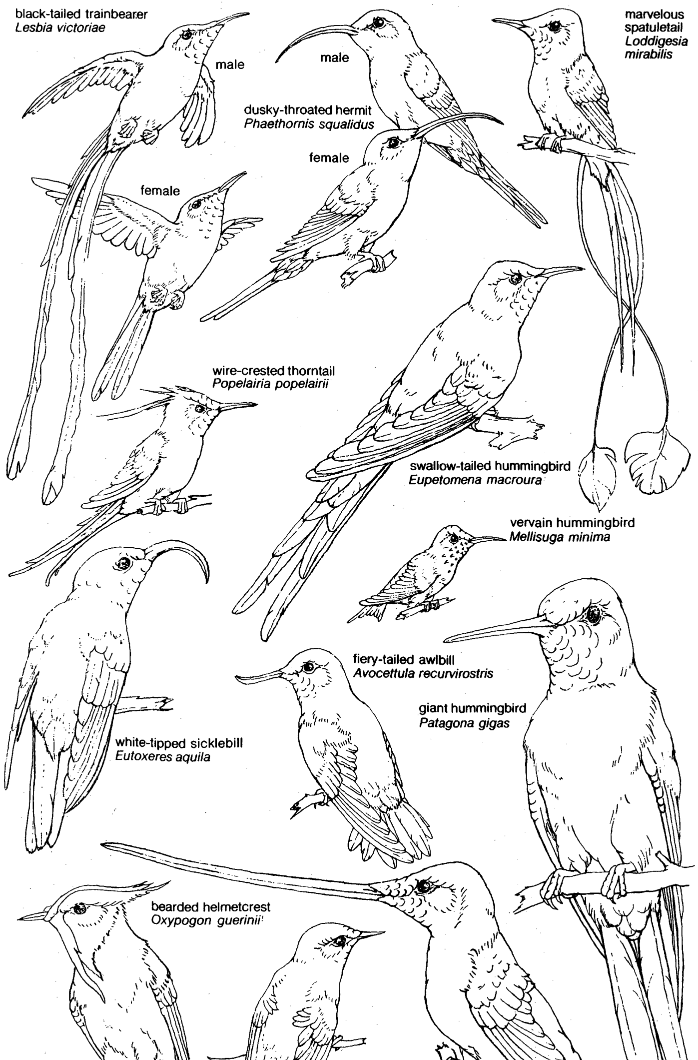

Figure 39: Body plans of hummingbirds.

a dozen occur regularly in the western United States; one, the rufous hummingbird (*Selasphorus rufus*), reaches southern Alaska.

The family Hemiprocnidae is confined to Asia, from India south and east through the East Indies, with one species reaching as far as the Solomon Islands. The Apodidae are much more widely distributed, occurring in both the Old and New Worlds. There are approximately 70 to 80 species, but the features that distinguish closely related species are often so subtle that there is little agreement about swift classification at either the genus or species level. Virtually nothing is known about some species other than their existence as evidenced by museum specimens; such birds may be rare, shy, or both. Others, such as the chimney swift, the European swift (*Apus apus*), and the house swift (*Apus affinis*) of India, are familiar inhabitants of towns and have been extensively studied by biologists.

NATURAL HISTORY

Behaviour and locomotion. In such overwhelmingly aerial birds as swifts and hummingbirds, locomotion is an inseparable part of behaviour. Although both groups depend on their flying ability to obtain food, the actual feeding methods are quite different. Swifts feed exclusively on flying insects, sharing with the unrelated swallows several morphological adaptations for this habit (*e.g.,* the short, weak bill, large mouth, and long, narrow wings). The feet of the true swifts are much weaker in proportion to body size than are those of swallows or hummingbirds, and the former are unable to perch on twigs, wires, or other similar landing places. In their normal resting posture the true swifts cling to vertical surfaces except when sitting on the nest. The tree swifts are somewhat less specialized and are fully capable of perching; in fact, their usual foraging method involves launching after flying prey from the vantage point of a high perch. Swifts drink by swooping down at the surface of a body of water, and nesting material may be picked in midair, as in the case of drifting feathers or plant material, or snatched in full flight, as are dead twigs and grass stems. Most courtship displays that have been described for swifts are wholly aerial, and copulation is known to take place in full flight.

Some species of swiftlets (*Collocalia*) that nest in total darkness deep in caves have the ability to orient themselves in flight by echolocation (reflection of sound waves back to the emitter), a phenomenon otherwise known, among birds, only in the oilbird (*Steatornis caripensis,* of the order Caprimulgiformes). The swiftlets emit a rattling call consisting of a succession of clicks, which, unlike the calls used by bats for the same purpose, are fully audible to the human ear. A few species of swiftlets lack this ability and nest only where some light penetrates the caves.

Feeding behaviour of hummingbirds

Hummingbirds are less constantly aerial than swifts and often spend long periods quietly perched. In foraging, however, most species depend upon their unique ability to dash from place to place and then to hover, motionless except for beating wings and darting tongue. They can even fly backward or upside down for short distances. The basic food is flower nectar, and the shapes of hummingbird bills are sometimes closely correlated with the shapes of the flowers from which they feed. The long, tubular tongue serves also for sucking up dew or rainwater as needed. Hummingbirds also eat small insects and spiders, which usually appear to be captured with the bill rather than with the tongue. Although hummingbirds perch, they share with swifts the lack of walking ability or other nonflying locomotion. They may sometimes sidle on a perch, just as swifts may crawl up a wall, but normal locomotion is by flying, even for short distances.

Prenesting, or courtship, behaviour is varied in hummingbirds; territoriality is completely absent in some species; others fiercely defend nesting or feeding territories. Hummingbirds in general tend to be aggressive and may attack vastly larger potential predators, such as crows and hawks. Leks, areas of communal male displays, have been described in some tropical species. Most displays are aerial, and some are spectacular; in other species, such as the plainly coloured hermits of the genus *Phaethornis,* singing forms an important part of display behaviour.

Reproduction and life cycle. The nests of tree swifts are tiny cups, barely large enough to hold the single egg. They are placed on small limbs, high up in trees, where they are subject to being moved about by the wind. The egg is glued to the bottom of the nest with the sticky saliva of the parent; this prevents the egg from being turned during incubation (as is done by virtually all other birds), and it is thought that the waving of the nest branch in the wind may in some way act as a substitute, moving the egg's contents within the shell. One of the true swifts, the palm swift (*Cypsiurus parvus*) of the Old World tropics, also glues its egg into the nest, but the nest is very different. This species utilizes feathers and plant material and attaches the nest, little more than a flat pad, to the underside of a hanging palm leaf, where it, too, is subject to agitation by the wind.

Figure 40: Body plans of swifts.

Variations in swift nesting habits

For such a relatively uniform group in a structural sense, the true swifts show a surprising variation in nesting habits. The New World palm swifts (*Tachornis*), like those of the Old World, place their nests under palm leaves, but the nest itself is more elaborate, being a sack entered from below through a tubular tunnel. Most other swifts nest either inside a crevice or hole (*e.g.,* in the ground, in a tree, between rocks), where they build a shallow cup of feathers and plant material as a flooring, or inside hollow trees, caves, or such man-made structures as buildings, wells, and tunnels. The nests may be circular cups placed on ledges or semicircular brackets attached to the walls. The bracket nests are fastened to vertical surfaces with a sticky secretion from the large salivary glands; in the swiftlet genus *Collocalia,* this substance may comprise most or all of the nest material itself. One species, the white-naped swift of Mexico, builds no nest at all but lays its eggs in a depression on bare sand on ledges deep inside caves.

Clutches in the true swifts vary from one to about six white eggs, with the higher numbers being found among some of the more northern species of the genera *Chaetura* and *Aeronautes.* Incubation is by both sexes. The young are hatched completely naked. Young swifts are left unattended for longer periods than is true of most altricial (helpless) nestlings; the adults spend a substantial amount of time foraging for the relatively small insects on which they feed, in order to capture a sufficient number to warrant a trip back to the nest. In bad weather, when few insects are flying, the young may be left unbrooded for hours. In some birds, this would normally lead to chilling and, perhaps, death, but young swifts maintain an essentially poikilothermic (cold-blooded) condition for the first few weeks of life, the body temperature dropping to near that of the environment without harming the young bird. In one genus, *Cypseloides,* the young develop a coat of downlike semiplumes (fluffy feathers) prior to the appearance of the juvenile pennaceous (smooth) contour feathers, and this fluffy coat also appears to aid in thermoregulation.

Many species of swifts are colonial nesters, and even those that are relatively solitary during the breeding season appear to be highly gregarious at other times of year. Night roosts of some species may number hundreds of individuals, and foraging flocks may include several species. The northernmost species, such as the European swift and the chimney swift, are long-distance migrants. The winter home of the latter species was a mystery for many years, until Indians in the upper Amazonian forests of Peru were found to have in their possession numbered aluminum bands that had been placed on the legs of chimney swifts by the United States Bureau of Biological Survey. Migration is also known to occur in some of the tropical species, notably in Africa.

The Indian population of the house swift has two breeding seasons per year and is one of the few birds in the world in which this phenomenon has been demonstrated. Adult males are in full breeding condition in late January and again in May and June; eggs are laid in January and February and again in June to September. The molt cycle, however, appears to be independent of the breeding cycle, and the flight feathers are renewed only once a year.

Nest design among hummingbirds

Unlike swifts, hummingbirds are largely polygamous. Males may build nests, but they are not used by the females. Most hummingbird nests, saddled on a branch, are composed of fine vegetable fibres, spider webs, fragments of bark, and lichens. Among the most interesting exceptions are the nests constructed by the hermits. They are long, slender, woven baskets of plant fibres and down, suspended from a strip of vegetation attached at only one side of the nest. The weight of the incubating female and, later, the weight of the young is counterbalanced by pebbles or clods of hard earth at the bottom of the dangling nest. The usual hummingbird clutch is two white eggs, and the female alone incubates and cares for the young in most species, although this is difficult to determine in the species that are not sexually dimorphic. In the sexually dimorphic species, the juveniles usually resemble the adult females, although some genera have a distinctive juvenile plumage that resembles neither parent. The young are fed by the parent thrusting its bill deep within the young bird's throat and regurgitating food.

Like the northern swifts, the hummingbirds that breed farthest north are the most highly migratory. The ruby-throated hummingbird was known to make annual nonstop flights across the Gulf of Mexico long before physiologists understood avian metabolism well enough to determine how this could be possible for such a tiny bird. Migration takes place among some Southern Hemisphere hummingbirds, such as the giant hummingbird and the green-backed fire crown (*Sephanoides sephanoides*); the latter reaches Tierra del Fuego and is thus the southernmost hummingbird, but there is little information about the nature and extent of these movements.

Ecology. The distribution of both swifts and hummingbirds is strongly influenced by the specialized nature of their foods. Swifts are found virtually worldwide but are limited to areas where flying insects are found in sufficient numbers to sustain adults and young. Food of this kind is presumably more abundant in the tropics, and the family is primarily a tropical one; it is chiefly in the tropics that sympatric species (*i.e.,* those whose ranges overlap), sometimes closely related, may be found. Although there may be some altitudinal and other ecological separation of sympatric species, virtually nothing is known about possible partition of environmental resources among swifts; as many as three closely similar species of *Chaetura* can be seen foraging together in Trinidad. Swifts also forage with swallows.

Hummingbirds are more specialized in their feeding habits, in that their bill shapes are, in many cases, correlated with the shapes of the most commonly utilized flowers. Because hummingbirds are restricted almost entirely to feeding at flowers, their distribution is affected by flowering periods, and the virtually seasonless tropics, where flowers of some kind may be found the year round, are, not surprisingly, the home of the most species. Despite the degree of specialization found, a flowering tree in the tropics may attract six species of hummingbirds simultaneously. In some cases feeding areas are strongly defended territories; in others the birds feed side by side, apparently ignoring each other completely.

Lowered metabolic levels in resting birds

Torpor. Swifts and hummingbirds are among the few groups of birds that have been shown to be capable of energy conservation through a reduction of their body temperature and entry into a torpid (sluggish) condition. The extremely high metabolic rate of active hummingbirds suggests that the value of torpor to the birds lies in energy conservation while roosting at night. In the swifts, whose normal metabolic rate approaches that of other birds, the lowered body temperature is an energy-conserving mechanism during what may sometimes be long periods of fasting, at times when foraging for flying insects is not possible.

Evolution, paleontology, and classification. *Fossil history.* As might be expected of such fragile birds, no fossil species of hummingbirds are known, although remains of Pleistocene origin (less than 2,000,000 years old) have been reported for two living species. Five fossil swifts have been described; two from the lower Miocene age (about 20,000,000 years ago) and one from the upper Miocene (about 10,000,000 years ago) have been assigned to modern genera. The extinct genus *Cypselavus* is known from two fossil deposits in France: one species from the lower Miocene, the other from the upper Eocene or lower Oligocene (35,000,000–40,000,000 years ago). Their identification as swifts does not seem to be questioned, but they throw no light on the origins of the family. The fossil family Aegialornithidae, sometimes provisionally assigned to the Apodiformes, is now usually considered to belong to the order Caprimulgiformes.

Classification. As presently constituted, the subdivisions of the order Apodiformes are summarized below.

ORDER APODIFORMES

Characterized primarily by the shape and proportions of the wing. The humerus (bone of the upper arm) is short, the hand is strikingly long, and the primary flight feathers (attached to the hand) are much longer than the secondaries (attached to the forearm). Other anatomical characteristics shared by swifts and hummingbirds include the holorhinal (the posterior border of the internal openings rounded) and impervious (without external openings) condition of the nostrils; single (left) carotid artery (except in swifts of the genus *Cypseloides,* which have two); sternum without notches; and oil gland unfeathered.

Suborder Apodi

Bill short and gape (mouth) deeply cleft; tongue short; salivary glands large; crop absent; nostrils without opercula (coverings); 8–11 secondaries; 6–7 pairs of ribs.

Family Hemiprocnidae (tree swifts)

Hallux (hind toe) directed backward, not reversible, foot capable of perching; no claw on manus (hand). Hatched with natal down; a distinct juvenile plumage unlike that of adults; adult plumage with crests or plumes on head. One genus, 3–4 species.

Family Apodidae (true swifts)

Approximately 70–80 species; species limits, especially in *Collocalia,* highly controversial. Hallux lateral or nearly so, reversible in some; foot incapable of true perching; claw present on hand. Young hatched naked; juvenile little different from adult in plumage; no crests or plumes. One fossil and 8 to 14 Recent genera; 70–80 species.

Suborder Trochili

Bill slender, usually long, gape not deeply cleft; tongue long, tubular, and extensible; crop present in nestling; nostrils with opercula; 6–7 secondaries; 8 pairs of ribs.

Family Trochilidae (hummingbirds)

Characters of suborder. More than 120 genera usually recognized, but a further study will probably result in reduction. Approximately 320 species, nearly 30 of which are known only from trade skins; some may be hybrids.

Critical appraisal. The most fundamental question in the classification of the Apodiformes is whether the swifts and hummingbirds are, in fact, more closely related to each other than to any other birds. Some ornithologists believe that the resemblances in wing structure are convergent and that the other shared characters are relatively widespread among several orders of birds and of little significance in indicating relationships. These authorities argue that the differences between swifts and hummingbirds are so fundamental that the two groups could not have shared a common ancestor recently enough to warrant placement in the same order. Ornithologists holding this opinion would recognize a separate order, Trochiliformes, for the hummingbirds. The Caprimulgiformes (nightjars and allies) are usually considered to be the closest relatives of the swifts, but the placement of the hummingbirds is more difficult. Their closest living relatives, if not the swifts, must almost certainly be among the group of orders usually placed nearest to the Passeriformes (perching birds).

The tree swifts have sometimes been subordinated to the level of a subfamily of the Apodidae. Their many relatively nonspecialized anatomical characters indicate that, although indubitably swifts, they merit separate family status. Two subfamilies, usually Apodinae and Chaeturinae, are customarily recognized in the Apodidae but probably represent an exaggerated dichotomy. The African species *Schoudetenapus myoptilus* has been shown to combine certain characteristics of both subfamilies and may be a relict of an ancient and relatively primitive group of Apodidae. Additional studies may enable ornithologists to redefine subfamilies of swifts.

Problems of classifying swifts

The classification of swifts at the genus and species level is also fraught with controversy. Part of this represents the traditional battle between advocates of large, inclusive genera and those who prefer to use generic names to call attention to differences; in other classifications, one difficult species is transferred between what are otherwise generally accepted genera. Species limits are especially difficult to determine among the swiftlets (*Collocalia*); there is absolutely no agreement about how many species exist nor what names they should bear. The characters that have long been used to define species of *Collocalia* are mixed, and some have proved to be of no taxonomic importance. Important morphological characters have been overlooked; one swiftlet, first described as a subspecies, was found 26 years later to be the only three-toed form in the genus and was quite properly given species status. The type of nest construction and the presence or absence of the ability to navigate with echolocation appear to be fundamental characters within *Collocalia,* but this information is not available for many forms, and the taxonomy of the genus will long be in a state of flux.

Among the hummingbirds there are obvious groupings of related genera, but no discontinuities are marked enough to warrant the recognition of subfamilies. There are generally conceded to be too many hummingbird genera that are based entirely on characters found only in males, involving ornamentation used in species-specific displays. As yet, however, there has been no research that will permit the redefinition of hummingbird genera. (K.C.P.)

Coraciiformes (kingfishers and allies)

The birds of the order Coraciiformes include the kingfishers, todies, motmots, bee-eaters, rollers, hoopoes, and hornbills and are collectively referred to as roller-like birds. Among the members of the order that have attracted man's special attention are certain kingfishers that plunge headfirst into water for fish and are associated with classical mythology. According to the ancient Greeks, Ceyx and his wife Alcyone were shipwrecked at Delphi and changed into kingfishers. The Chinese used the shining blue feathers of some types of kingfishers to decorate picture screens. Bee-eaters (Meropidae) have been accused of preying on commercially valuable honeybees, and the North American belted kingfisher (*megaceryle alcyon*) is sometimes considered a pest at fish hatcheries because it preys on young game fish. The kookaburra (*Dacelo novaeguineae*) has a loud, laughing or braying voice that is commonly associated with the Australian outback, or back-country. To the biologist, the sealing of the female of certain species of hornbills in her nest during incubation and brooding is one of the most intriguing behavioral modifications among birds.

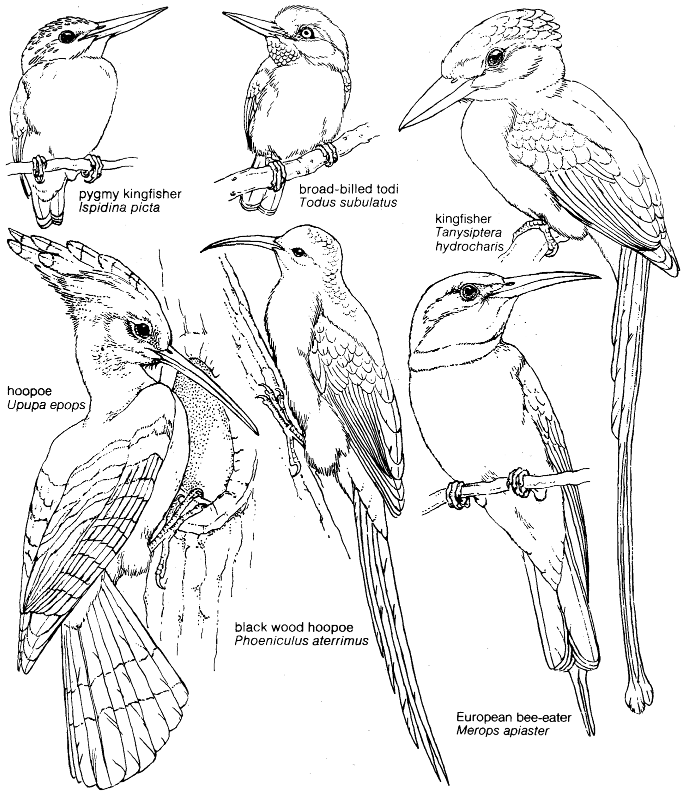

Figure 41: Body plans of smaller Coraciiformes.
Drawing by R. Keane

General features. The roller-like birds are active by day (diurnal) and range in length from the size of a small sparrow (about ten centimetres, or four inches) to over 100 centimetres (40 inches). They have compact bodies, short to moderately long necks, large heads, rather long bills, small feet, and ample wings. The tail varies from short to very long and may be forked, square, or graduated; the outer or central tail feathers are, in some species, pointed or spatulate at the tip. All of these birds regularly perch in trees, where some feed; others fly in search of food, and a few walk or hop on the ground. The group's food ranges from invertebrates (including insects) and small vertebrates to berries and fruit.

Distribution. Collectively, the ten families of the order are almost worldwide in temperate and tropical areas, with the greatest number and diversity in the warmer parts of the African, southern Asian, and Papuan areas. Many species are common and conspicuous, and a few tolerate human settlement, although their direct importance to man is minimal.

Families of coraciiform birds

Only the kingfishers (family Alcedinidae) are found in both Eastern and Western Hemispheres. The motmots (Momotidae) and todies (Todidae) are restricted to the New World tropics, the bee-eaters (Meropidae), rollers (Coraciidae), and the hoopoes (Upupidae) to temperate and tropical regions of the Old World, and the hornbills (Bucerotidae) to the tropics of Africa and Asia. The wood hoopoes (Phoeniculidae) are found only in tropical and subtropical Africa; the cuckoo roller (Leptosomatidae) and the ground rollers (Brachypteriacidae) are found only on Madagascar.

NATURAL HISTORY

Life history. Most species live permanently in one region, but temperate-zone species move nearer the tropics for the winter. In the Old World tropics that have a dry–wet seasonal change, local movements of bee-eaters sometimes take advantage of the related crops of insects. In East Africa, where there are two dry and two wet seasons, two periods of breeding may occur a year; however, the picture is not clear.

As a group, these birds are well endowed with voices, but their vocalizaions are usually referred to as calls rather than songs. Some are harsh; others are soft or are whis-

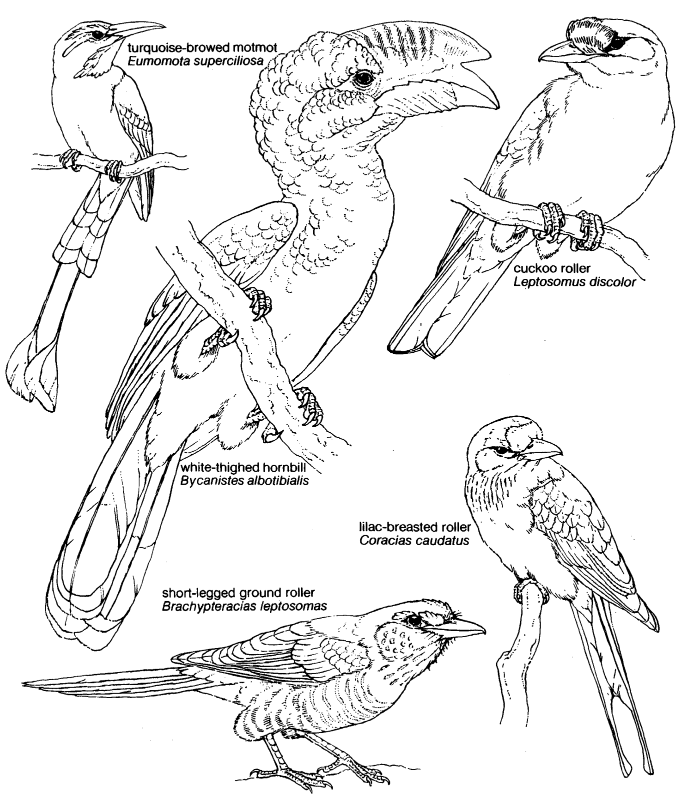

Figure 42: Body plans of larger Coraciiformes.
Drawing by R. Keane

tled or hissed. Some are given as single notes, others as series in a trill, a rattle, or a hooting, and still others as a cacophony or medley of notes. Some calls are given from perches; others are given on the wing. Certain utterances may be related to courtship and mating or to territory; others seem to be simply a part of the bird's general daily activity. Pairs are formed to the accompaniment of simple posturing displays and series of calls, ranging from harsh to soft. Certain rollers use tumbling display flights. Both sexes usually share in the nest duties.

Many roller-like birds are solitary in feeding and nesting, but some bee-eaters are gregarious and also nest in colonies. Hornbills and wood hoopoes move about in small parties most of the year, but they nest solitarily. The nest site is always in a cavity, which may be a hole or crevice in a tree, a bank, or a wall. The cavity may be among rocks or be a tunnel dug by the birds in the ground, or it can be an abandoned termite nest.

Walling in of the female hornbill

Normally, little or no nest material is added, except by the hoopoe (*Upupa epops*). In some (perhaps most) hornbills, however, the female enters the nest cavity before laying starts; the male brings mud and debris, which the female takes and plasters around the entrance until only a slit is left. The male passes food to the female through the slit until after the young are more or less grown. At that time she breaks out of the nest, and then both parents feed the young.

The members of the order lay two to nine eggs, with the tropical species laying the smaller clutches. Among the hornbills the larger species lay fewer eggs than do some smaller ones. The eggs are usually white but, in the hoopoe, may be olive, brownish, bluish, or greenish, and sometimes spotted. Incubation is performed by both male and female in kingfishers, todies, motmots, and bee-eaters and by the female alone in the hoopoe and hornbills when she is fed by the male. Incubation periods of 18 to 22 days have been recorded for some of the smaller members of the order.

The young are nidicolous (dependent upon the parents) and are naked, except for the hoopoe and some kingfishers that have varying amounts of down at birth. The recorded nestling period (25 to 28 days) of certain of the smaller species is only slightly longer than the incubation period, but large species have longer nestling periods, and the great hornbill (*Buceros bicornis*) has a total period (incubation to fledging) of three to four months. Except for the hoopoe and the walled-in hornbills, the young are fed by both parents. The male of these species brings food to the female, who passes it on to the young. The rate of feeding the young is apparently variable. In large species of hornbills, the male is recorded as making one trip per hour to the nest, during which he brings a gullet full of fruits and regurgitates them one at a time and passes them to the female. A much smaller species brings one item of animal food and holds it in his bill each trip and makes about six trips an hour.

Coraciiforms of several groups practice no nest sanitation, and regurgitated insects and other remains accumulate and are used to make a platform on which the young rest in later nest life. Hornbill nests are kept more or less clean, and, in one small species in which the female breaks out of the nest when the young are half grown, the young perform nest sanitation and also help to seal up the nest again after the female emerges.

When the young leave the nest, they are able to fly and usually are similar to, although sometimes duller or paler than, the adult in plumage. There is believed to be one molt a year, which occurs after the nesting season. In an unusual modification, the female of the African hornbill, walled in during incubation and throughout the nest life of the young, molts during this period, losing and renewing all of her flight feathers.

Locomotion and feeding. Coraciiform birds tend to perch in trees and shrubs when at rest. Some favour exposed perches on which they are conspicuous, others seek the protection of foliage or the shade of the forest. Lacking cryptic coloration—many are nearly uniform in colour or boldly patterned—they do not rely on concealment for protection. Their flight varies from weak and laboured to strong, well sustained, and direct. The flight of some, such as the rollers, is swift and graceful. Some species, such as the kingfishers, use little bipedal locomotion; others (*e.g.,* some hornbills) hop, walk, or scramble in the treetops, creep along branches (wood hoopoes), or walk or hop on the ground (hoopoe, other hornbills).

The food of the roller-like birds includes a wide variety of organisms. Among the animals taken are worms, snails, crustaceans, insects, fish, amphibians, reptiles, small birds, and mammals. Vegetable food consists chiefly of the fruits of trees, usually gathered in the trees but sometimes picked up on the ground.

Types of foraging behaviour

Some birds of this order seem to choose animal food more for its size than its type, and a single method of feeding tends to predominate in each family. Some families (Upupidae and Leptosomatidae) contain only one species; others are large and predictably diverse—*e.g.,* the hornbills (Bucerotidae), with 45 species, and the kingfishers (Alcedinidae), with about 90 species. Each family or group of families tends to have a characteristic pattern of feeding behaviour, and the foraging patterns fall into four categories, or feeding niches: (1) watchful waiting on a perch, (2) aerial—*i.e.,* spending much time on the wing, (3) searching on foot among branches of trees, and (4) walking on the ground.

The watchful waiters, the kingfishers, motmots, and todies, tend to sit quietly for long periods. When they see their prey on a leaf, a branch, the ground, or even in water, they fly out with swift, direct flight, seize the prey with the bill, and return to the perch. The todies catch more flying insects than do members of the other two families. A few kingfishers plunge headfirst into water from perches or from hovering flight, but these number only a few of the species-rich family Alcedinidae. The shovel-billed kingfisher (*Clytoceyx rex*) of New Guinea is partly terrestrial and is known to feed on beetles and earthworms; the latter are apparently dug from the soil of the forest floor with the bird's short, heavy bill. The ruddy kingfisher (*Halcyon coromanda*), widespread in Southeast Asia, eats many large land snails. It seizes a snail with its bill and beats it against a rock until the shell is broken and the meat can be extracted.

The term temperament, although tinged with human associations, seems applicable to certain traits that are common to many species within a family, as contrasted with members of another group. Kingfishers, motmots, and todies are stolid, phlegmatic birds that sit quietly for varying periods of time between sallies for food. Kingfishers often bob their heads and the forepart of their bodies when nervous or mildly alarmed; when startled into flight, some give sharp calls. Motmots have the habit of moving their tails from side to side.

Bee-eaters and rollers are aerial feeders but spend much time perched quietly, leaving their perches to make sallies for passing insects. Bee-eaters, especially, often spend long periods on the wing, gliding in circles while looking for insects, especially bees and wasps. Some forest bee-eaters perch in foliage and near flowers, securing their prey without flying. Rollers spend more time perched, but they too are graceful in flight and capture much of their food by hawking or by darting down to the ground. Members of both groups are often seen aloft, apparently not feeding but flying for diversion. The cuckoo roller (*Leptosomus discolor*) also flies above the forest canopy, but it is looking for large insects and small lizards in the outermost foliage. It may either seize them while on the wing or alight to capture them.

Feeding while clambering among the branches of trees is carried on by many of the larger hornbills and by the small wood hoopoes, but in quite different ways. The hornbills fly over or through the forest with strong, often noisy flight and, on alighting, scramble or hop among the branches reaching out for fruit, small animals, or both. The wood hoopoes have weak flight, and they do not fly much; they fly chiefly from one tree or clump of trees to the next, climbing about the trunks and branches of trees and lianas in acrobatic poses as they seek insects in crevices and on the bark surface.

Walking on the ground is the usual mode of feeding for the common hoopoe (*Upupa*), the ground rollers, and for a few hornbills. The hoopoe walks with quick steps, bobbing its head in time with the steps and pausing to probe with its long bill in the ground and in crevices, in search of large arthropods and small vertebrates. Its flight is strong and direct. When perched, it may quietly flash its long crest open and shut. The ground rollers, most of which are birds of the deep forest, also feed on the ground on food similar to that of the hoopoe. When disturbed, they fly or jump to low perches.

Social feeding by ground hornbills

The ground hornbills (*Bucorvus* species) exhibit a definite social organization when foraging. Three or four members of a group searching for insects and other small animals on the ground may keep near each other, with the result that prey frightened into activity by one bird may be caught by one of the others. Several other species of hornbills occasionally forage solitarily on the ground.

Habitat selection and ecological diversity. Coraciiform birds, diverse in their structure and behaviour, occupy a variety of habitats. Each species is restricted in distribution by requirements of feeding and nesting areas. A species may be considered to occupy a feeding and, during the breeding season, a nesting habitat, and these may or may not be contiguous. Some species, such as certain African kingfishers, which nest in cavities excavated in termite mounds and feed on termites and other insects near the nest site, may be said to nest within their feeding habitat. Aerial feeders, such as bee-eaters, which nest in burrows, may be considered to occupy two habitats, one for feeding and one for nesting.

The factors that influence habitat suitability are evident in a few cases. One bee-eater requires a cut bank in a grassland area for its burrow, but must be near a forest because it feeds over the forest and the forest edge. The importance of suitable perches is illustrated by observations made on an insect-rich region of East African grassland, from which kingfishers were absent until a road was built. With the roads came telegraph wires, which provided the perches.

Relative diversity of coraciiform families

The widest range of habitats occupied by members of the order Coraciiformes is found in Africa (including Madagascar), where eight of the 10 families are represented. These exhibit all four basic feeding modes, but on Madagascar some niches are occupied by families different from those on the African mainland. Ground feeding in the forest, for example, is limited to the ground rollers in Madagascar; in Africa this niche is occupied by the hoopoe (except in dense forest) and by birds of other orders. The four coraciiform families found in temperate Eurasia occupy only three niches: ground feeding (hoopoe), darting from a perch (kingfishers, some bee-eaters), and aerial hawking (other bee-eaters, rollers). In Australia only the last two niches are occupied by coraciiforms, and these are the same families that hold these niches in Eurasia. In the New World, where three families are found, only one feeding mode is used, that of darting out from a perch; but this mode is geographically and ecologically subdivided between the diminutive todies, which are limited to the Greater Antilles where neither the kingfishers nor the motmots are represented, and the kingfishers (with the exception of the pygmy kingfisher, *Chloroceryle aenea*), which are specialized fish eaters.

Social behaviour. A number of coraciiform birds are markedly social, feeding in small parties and nesting in colonies. Some wood hoopoes forage in conspicuous, noisy bands of five to 10 individuals. The acrobatic, climbing activity of a band is sometimes interrupted when the birds of a whole party bow and sway their bodies, pump their tails up and down, and join in a chorus of chattering calls. Moving from tree to tree, one bird follows another in weak undulating flight. Forest species of wood hoopoes are less social, and lone individuals sometimes call while perched high in a tree. Many hornbills may be seen flying through or over the forest, the beats of their broad wings giving a characteristic loud whooshing noise. They are usually found in small parties and actively move about in the branches, sometimes giving conversational notes. A study of a young captive hand-reared hornbill of a small species of *Lophocerus* (*Tockus*) has provided surprising data. This bird seemed to have a remarkably active, alert, intelligent personality recalling that of captive crows. It greeted its foster parents by raising its wings, pointing its beak upward, raising its head feathers, and chattering. It was jealous of attention given other animals, kept close to its foster parents when out of doors, and alighted on their shoulders. When accompanying them on walks, it flew from tree to tree. It was busy and mischievous, attracted by anything bright, and fond of picking at knots or holes. This young hornbill had a passion for pulling up seedlings and sometimes amused itself by darting in and tweaking the tail of a larger, more lethargic, young *Bycanistes* hornbill.

Relationships with other species. Certain types of social behaviour of the Coraciiformes involve other birds or unrelated animals. Although some of these interactions are occasional and opportunistic, others are regular parts of everyday life and may be called symbiotic—*i.e.,* one that brings mutual benefit to the different species involved.

Utilization of grass fires

The regular swarming of many bird species about grass fires to capture animals driven out of hiding by the flames is a phenomenon often related to human activity, for such events are often caused accidentally or deliberately by man. Among the birds that gather are both rollers and bee-eaters; they swoop down near the flames and into the smoke to seize fleeing insects. After the fire has passed, certain hornbills find good foraging on foot over the newly exposed ground.

More notable are a number of interspecific nesting relationships. Some bee-eaters make their colonial burrows in the same banks in which certain smaller swallows dig their burrows; there seems to be no conflict between the larger bee-eaters and the smaller swallows, despite the similarity in nesting and feeding habits. In southern Africa, the little bee-eater (*Melittophagus pusillus*) sometimes makes its nest burrow in the wall of the very much larger burrow of the aardvark (*Orycteropus afer*), and there is no further relationship between the bird and the mammal.

Sporadic incidents occur between species when one or both are foraging; a kingfisher may pilfer a food item from a dipper (*Cinclus*), and a savanna kingfisher will occasionally fly down to seize a grasshopper flushed by a man. Many associations are more frequent. Some bee-eaters in Africa often accompany large bustards, other large walking birds, and zebras and other game animals to feed on the insects roused from the grass by the animals. The bee-eater even uses the bustard's back as a perch. The bee-eater may also accompany an automobile driven through these grasslands to secure insects. There is also a regular association between hornbills and bands of monkeys in the treetops of African forests, with the birds seeking the insects stirred into activity by the fruit-eating monkeys.

In many parts of the Old World tropics, where large arboreal termite mounds are common and conspicuous, certain kingfishers usually excavate their burrows in them; in fact, some species are believed to nest only in them. The presence or absence of the termites might be expected to have an important effect on the populations of such kingfishers. The hoopoe commonly nests near buildings, especially in South Africa, and it is possible that the availability of such sites may affect the local abundance of the species. The presence of woodpecker holes used by hoopoes and wood hoopoes may also affect the size of their breeding populations.

Some African species of kingfishers, bee-eaters, hoopoes, and wood hoopoes are victimized by obligate social parasites, the honey guides (Indicatoridae, related to the woodpeckers). The honey guide lays its eggs in the host's nest and, with its bill or claws, often punctures the shell of the foster parents' eggs so they do not hatch. If the foster parents' eggs do hatch, the nestling honey guide usually disposes of the host's young by throwing them from the nest or by biting, crowding, or starving them to death. The honey guide's young are thus raised at the expense of the young of the host species. Apparently kingfishers, bee-eaters, hoopoes, and wood hoopoes are of great importance in the ecology of honey guides, and the frequency with which the roller-like birds are victimized by honey guides may be a serious factor in their population status.

A remarkable insect fauna has been found in the nest of an African hornbill. Though some nest sanitation is practiced by the birds, it is not complete. In one nest, more than 400 individual insects, mostly larvae, were found (about half were moth larvae); they represented eight species and were feeding on the droppings and debris in the nest cavity, which was remarkably clean and had little odour. The hornbill provides microhabitats for the insects (albeit scattered and seasonal), and the scavenging of the insects may be of advantage to the hornbill.

FORM AND FUNCTION

Size and plumage. The coraciiform birds are a rather heterogeneous order, united mainly by features of their internal anatomy. Some characteristics of the beak and feet serve to separate them from other orders, such as perching birds (Passeriformes) and the woodpeckers and their allies (Piciformes), which appear to be their closest relatives.

No single coraciiform family encompasses the entire size range of the order. The todies are the smallest, with lengths of nine to about 11.5 centimetres (3.5 to 4.5 inches), and the hornbills, from about 40 to 160 centimetres (16 to 63 inches), are the largest. The kingfishers are from 10 to nearly 46 centimetres long (four to 18 inches), the longest being those with extended tail feathers. Motmots and bee-eaters are in the same general size range as the kingfishers, but the smallest of them are larger than the tiniest kingfishers (*Ceyx, Ispidina*), and the largest motmots, although about 50 centimetres (20 inches) long, have not nearly the body bulk of the chunkier, but slightly smaller, kookaburras (about 45 centimetres, or 18 inches). The smaller families have, predictably, less size variation.

Ornamental coloration

The plumage of the roller-like birds is firm and often highly colourful. The bee-eaters are collectively and individually among the most brilliantly coloured of all birds; one individual may be marked with green, yellow, red, blue, and black. Many kingfishers are also brightly coloured, with a tendency toward metallic blues and blue greens. The beak is often bright red or orange. Most hornbills, with ornamentation frequently found on the beak, are strikingly patterned in black, white, and shades of gray and are sometimes accented with rufous or yellow; many have areas of bare skin, blue, red, yellow, or black in colour, around the face.

Morphological specializations. A few of the external features, such as modifications of the wings and feet for locomotion and of the beak for food handling, are obviously related to behaviour and habitat. Even in these important aspects of the body plan, the common heritage is evident in such features as the small feet and fusion of the front toes.

The most obvious adaptation to behaviour is the shape of the wing. The size and shape of the wing correlates well with the type of flight. Aerial feeders have the longest, most pointed wings; the most extreme forms are found in the bee-eaters, but they are also well developed in the rollers and the cuckoo roller. The birds that watch for their prey and fly out after it (*e.g.,* kingfishers) have moderate, rounded wings, while the ground feeders (ground rollers, hoopoes) have broad wings, as do those that feed on foot in the trees (hornbills, wood hoopoes).

The tail is highly diversified in length and shape. Forked tails occur only in the best fliers (bee-eaters and rollers), though some of these birds have square tails or elongated central tail feathers instead. Elongated central tail feathers also occur in the hornbills that practice direct flight and in ground rollers that fly little. The small kingfishers have the shortest tails. The exact shape of the tail does not correlate well with locomotion, nor does the presence of spatulate tips on elongated tail feathers in motmots, rollers, and kingfishers, which are perhaps of social importance.

The characteristic short tarsus (the lower leg) of the order and the fusion of the three front toes (except in the cuckoo roller) seem a heritage that has been modified but little with modification of behaviour. The foot is used only for perching in most family groups. In cases in which it is used extensively for terrestrial locomotion (ground rollers, hoopoe), the tarsus is lengthened somewhat in the former but not in the latter, and is also somewhat lengthened in the aberrant hornbill, known as the ground hornbill. The hornbills that feed in the tree branches have a broad pad on the toes, evidently an adaptation for perching. The wood hoopoes have long slender toes with long, sharp, curved claws, an obvious adaptation for the bark-climbing habits of these birds.

Drawing by R. Keane

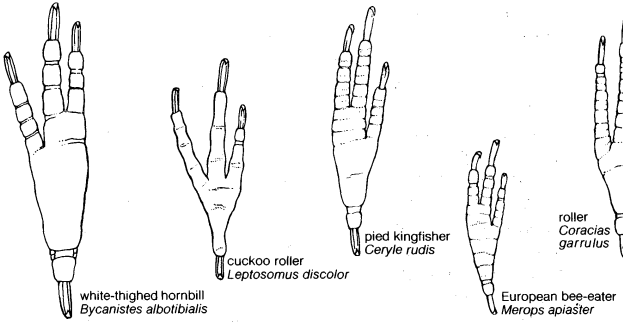

Figure 43: Feet of some Coraciiformes, plantar (bottom) view.

The most unusual foot in the order belongs to the cuckoo roller, whose outer toe is capable of being reversed. This makes a better perching foot for the bird that flies over the forest trees, scanning the branches for its prey, and alighting suddenly to seize a caterpillar, chameleon, or grasshopper.

Diversity in the bill

The bills show remarkable diversity in bulk and shape. Basically, the long stout bill so common in this order seems to be an adaptation for seizing and subduing active animal prey that is large in proportion to the size of the bird. This is true for rollers, ground rollers, cuckoo rollers, and motmots, all of which have only moderately long and stout bills. The larger, rather stouter, straight bill of the kingfishers is an exaggerated version in birds that often take small invertebrates. The hornbills, with their very large, laterally compressed bills, often somewhat ornamented with a prominent horny casque in the male (smaller in the female), seem to have carried bill size beyond the point of a strictly functional feeding organ. Species that feed largely on fruit plucked from branches as well as species that take lizards and snakes and dig in the ground for insects all have exaggerated bills.

An advantage of a long bill can be seen in hornbills that feed on fruits among the outer branches of forest trees; the long bill enables the bird to reach fruit on slender, outer twigs. There is also the probability, evidenced by the sexual difference in bill ornamentation, that the bill serves in courtship and perhaps in other social contacts within the small parties characteristic of hornbills.

Another type of long bill in the order is that of the hoopoes and the wood hoopoes, which is a slender and slightly, to strongly, downcurved bill. The former use the bill to probe in the ground while walking, the latter to poke into crevices and crannies of the barks and branches of trees.

Similarities to birds of other orders. The size of the birds of this order and their propensity to take rather large prey bring them into competition with many other species of other groups. It is perhaps instructive to compare certain Old World groups with representatives of different orders in the New World tropics (see above *Natural history*). The most striking parallel is seen between the toucans (Rhamphastidae, order Piciformes) and the hornbills, which, with their enormous bills, small feet, general diet, behaviour, and appearance, are remarkably alike. A similar degree of convergence is seen between the bee-eaters and the jacamars (Galbulidae, order Piciformes) of tropical America and also between some African wood hoopoes (*Rhinopomastes*) and American wood hewers (*Campylorhamphus*). Similar ecological conditions apparently have brought similar adaptations in external structure and behaviour between birds of quite unrelated orders, in widely separated areas.

EVOLUTION AND CLASSIFICATION

Evolution. The history and some of the family relationships within the Coraciiformes are obscure, so that any treatment of the evolution of the order must be considered speculative. The present distribution and abundance of the 10 families suggest an Old World origin, probably in the Ethiopian–Indian region, but the southern Palaearctic (Eurasia) may also have been involved; the limited number of fossils, consisting of a few hornbills from the Eocene (about 50,000,000 years ago) and Miocene (about 15,000,000 years ago), a roller from the upper Eocene or lower Oligocene (about 38,000,000 years ago), a possible wood hoopoe from the Miocene, and a kingfisher from the lower Oligocene, all have migrated from Europe. At the periphery of the Ethiopian region, the island of Madagascar has the endemic ground-roller and cuckoo-roller families, probably derived from separate colonizations of the early roller stock; the island was later colonized by the modern rollers, bee-eaters, kingfishers, and the hoopoe. Extending eastward through southern Eurasia, the modern hoopoe (*Upupa epops*) reaches Malaysia (making it the most widespread single coraciiform species); the hornbills have reached the Papuan area; and the roller, bee-eater, and kingfisher families have reached the Australian continent.

Kingfishes advancement in the New World

In the New World, the early arrival of a protokingfisher stock, via the Bering Strait, probably gave rise to the motmots of Central and South America and the todies of the West Indies. Later, a specialized, fish-eating branch of the kingfishers colonized the New World, evolving one species in the Nearctic region (North America) and several in the Neotropical region.

Considering the relative paucity of roller-like birds in tropical America and their comparative abundance and diversity in the Old World tropics, it seems likely that, by the time the coraciiform stock had reached the neotropics, many niches occupied by members of this order in the Old World were already filled by members of various piciform and passeriform families. The passeriform suborder Tyranni, with more than 600 New World species, is particularly diverse. The presence of highly adapted potential competitors, such as the toucans, jacamars, and puffbirds, endemic members of the Neotropical avifauna, may have retarded the colonization and evolution of the Coraciiformes in the New World.

Classification. *Distinguishing taxonomic features.* The external characteristics on which families are based are the size and shape of the beak and wing and the arrangement and amount of fusion (syndactyly) of the three front toes. The ten families are united, additionally, by features of the palate bones, the tendons of the leg, the configuration of the leg muscles, and the body pterylosis (pattern of feathers).

Annotated classification. The following classification is based on an arrangement used in 1960 by Alexander Wetmore, a U.S. ornithologist.

ORDER CORACIIFORMES (roller-like birds)

Small to medium-large land birds, with body lengths of about 10 to 160 cm. Most species conspicuously coloured. Beak prominent; straight, or slightly or strongly downcurved. Some syndactyly of toes (I, II, and III) in most families. Cavity nesters; young hatched blind and naked (except in Upupidae). Worldwide in temperate and tropical regions. About 191 species.

Family Alcedinidae (kingfishers)

Oligocene to Recent. Chiefly arboreal; short tarsus, small feet; syndactyl. Beak medium to long, straight, stout, usually spearlike. Wings short, rounded. Food: invertebrates and small vertebrates, including fish. About 90 species; distribution that of order, but greatest diversity in Indo-Australian Region; length 10–45 cm.

Family Todidae (todies)

Recent. Chiefly arboreal. Long, straight, flattened, blunt bill. Toes syndactyl. Wings short, rounded. Food: invertebrates, insects. Five species; West Indies; length 9–12 cm.

Family Momotidae (motmots)

Eocene to Recent. Chiefly arboreal. Moderately long, stout, pointed, slightly decurved bill usually with serrate cutting margins. Tarsus very short, toes syndactyl. Wing short and rounded. Food: invertebrates, lizards, and some fruit. About 8 species; South and Central America; length 17–50 cm.

Family Meropidae (bee-eaters)

Pleistocene to Recent. Arboreal and aerial. Bill long, compressed, tapering to a fine point, and slightly decurved. Tarsus short, anterior 3 toes slender, weak, and syndactyl. Wing long and pointed. Food: insects. About 24 species; Africa, southern Eurasia to Australia; 15–35 cm long, including elongated tail feathers.

Family Coraciidae (rollers)

Eocene to Recent. Chiefly arboreal and aerial. Bill stout, crowlike, slightly downcurved, terminally hooked. Tarsus short, foot strong; inner and central toes united at base. Wing long, moderately pointed. Food: chiefly insects. About 12 species; temperate and tropical parts of the Old World, greatest number of species in Africa; length 25–32 cm.

Family Brachypteraciidae (ground rollers)

Recent. Chiefly terrestrial in forest and desert brush. Roller-like birds with longer tarsus and short, rounded wings. Food: small animals of forest floor or desert brush. Five species; Madagascar; length 30–40 cm (including long, graduated tail of some species).

Family Leptosomatidae (cuckoo roller)

Recent. Arboreal and aerial. Bill moderately long, stout, slightly decurved, and terminally hooked. Tarsus very short and, unique in this order, toes semi-zygodactyl (the outer, anterior toe reversible). Wings long, moderately broad and somewhat pointed. Also unique in having a pair of powder-down patches, one each side of rump. Food: large insects, lizards. One species; Madagascar; length about 43 cm.

Family Upupidae (hoopoe)

Pleistocene and Recent; terrestrial and arboreal. Bill long, slender, slightly decurved. Tarsus short, slender; toes, long, with central and outer ones fused at base, claws short. Wing moderate, broad. Food: arthropods, and other invertebrates. One species; Africa, southern Eurasia, and Malaysia; length about 29 cm.

Family Phoeniculidae (wood hoopoes)

Miocene (Europe), Recent (Africa); arboreal. Bill long, slender, slightly curved to sickle-shaped. Tarsus very short; toes long, central and outer ones fused at base. Claws long, curved and sharp. Food: invertebrates chiefly. Six species. Length 22–38 cm.

Family Bucerotidae (hornbills)

Eocene (Europe) to present. Chiefly arboreal (1 species chiefly terrestrial). Large, slightly curved bill, often with casque or sculpturing (larger in males). Tarsus short to very short, toes syndactyl. Wings moderate to long and broad. Unique in order in having eyelashes. Food: insects, small vertebrates, and fruit. About 45 species; Africa, southern Asia to Papuan area; length 40–160 cm.

Critical appraisal. Paleontologists have called the order Coraciiformes a miscellaneous assemblage of birds with

Divergence among families

large bills and have pointed out that the anatomical differences between the families of birds within this and other orders are minor compared with differences found within some mammalian orders, such as the carnivores, which include both cats and seals. The classification of birds into higher categories is justified by expediency and tradition. The roller-like birds include ten groups of birds here called families, the largest, the kingfishers and the hornbills, containing 90 and 45 species respectively, the smallest, the hoopoe and the cuckoo roller, a single species each. Each family is fairly uniform within itself, but between families some anatomical characters have a disconcerting habit of lacking a common linkage. The order does seem to have a common heritage, however, judging from the sum of the characters that place them high in degree of specialization, just below the perching birds (Passeriformes) and the woodpecker-like birds (Piciformes). They have been variously said to be distantly related to the cuckoos, parrots, owls, and even the nightjars, depending on the relative weight given to characters such as the condition of the bony palate, the notching of the sternum, the arrangement of the toes, the thigh muscles and foot tendons, the structure and location of the syrinx (sound-producing organ), the development of the ceca (blind pockets in the digestive tract), and the arrangement of the intestines, the arrangement and type of feathers and down, and the type of nesting.

Some authorities would include rollers, ground rollers, and cuckoo rollers as subfamilies of the Coraciidae. There is also a question as to whether the hoopoes and wood hoopoes are more nearly related to the hornbills or the rollers.

The families fall into six or seven well-defined groups: (1) kingfishers, todies, and motmots, (2) bee-eaters, (3) rollers and ground rollers, (4) cuckoo rollers, (5) hoopoes, (6) wood hoopoes, which are sometimes united with the Upupidae, and (7) hornbills. (Au.L.R.)

Piciformes (woodpeckers, barbets, honey guides, toucans)

The bird order Piciformes includes the familiar woodpeckers, their relatives the piculets and wrynecks (collectively, the family Picidae), and the exotic tropical jacamars (Galbulidae), puffbirds (Bucconidae), barbets (Capitonidae), honey guides (Indicatoridae), and toucans (Ramphastidae). This arboreal group of about 370 species is distributed on all continents except Australia and Antarctica, but only the woodpecker family is widespread outside the tropics. Although the six families comprise the order, over half of the species represent one subfamily (Picinae, true woodpeckers) of the family Picidae. The order includes such familiar birds as the European great spotted woodpecker (*Dendrocopos major*) and green woodpecker (*Picus viridis*) and the American flicker (*Colaptes auratus*) and downy woodpecker (*Dendrocopos pubescens*). Piciforms are economically important because they include many insect-eating species. A few species are harmful in eating fruit (toucans) or damaging trees (sapsuckers, genus *Sphyrapicus*), but even these species eat some insects and other animals, and they of course serve as natural balances within the ecological systems of which they are a part.

Distribution of the order

The tropical distribution of most piciform families suggests that these represent specialized remnants of a once more numerous and diverse array of arboreal birds. Perhaps many elements of the order became extinct during the geologically recent burgeoning of the diverse, ubiquitous, and highly successful order Passeriformes, which the piciforms resemble in many ways. It has even been suggested that both groups be merged into one order.

Piciform species vary in size from about nine to more than 60 centimetres (3½ to 24 inches) in overall length. They vary greatly in the structure of their beaks and only slightly less in the rest of their morphology, some, such as the huge-billed toucans and the sturdy woodpeckers, being very specialized. The specialized habits of the wax-eating honey guides are unique among birds. The most numerous and widely distributed groups, the barbets (70 species) and the woodpeckers (about 203 species), excavate their own nesting cavities, thereby avoiding competition with other birds and, incidentally, providing homes for many other species of vertebrates.

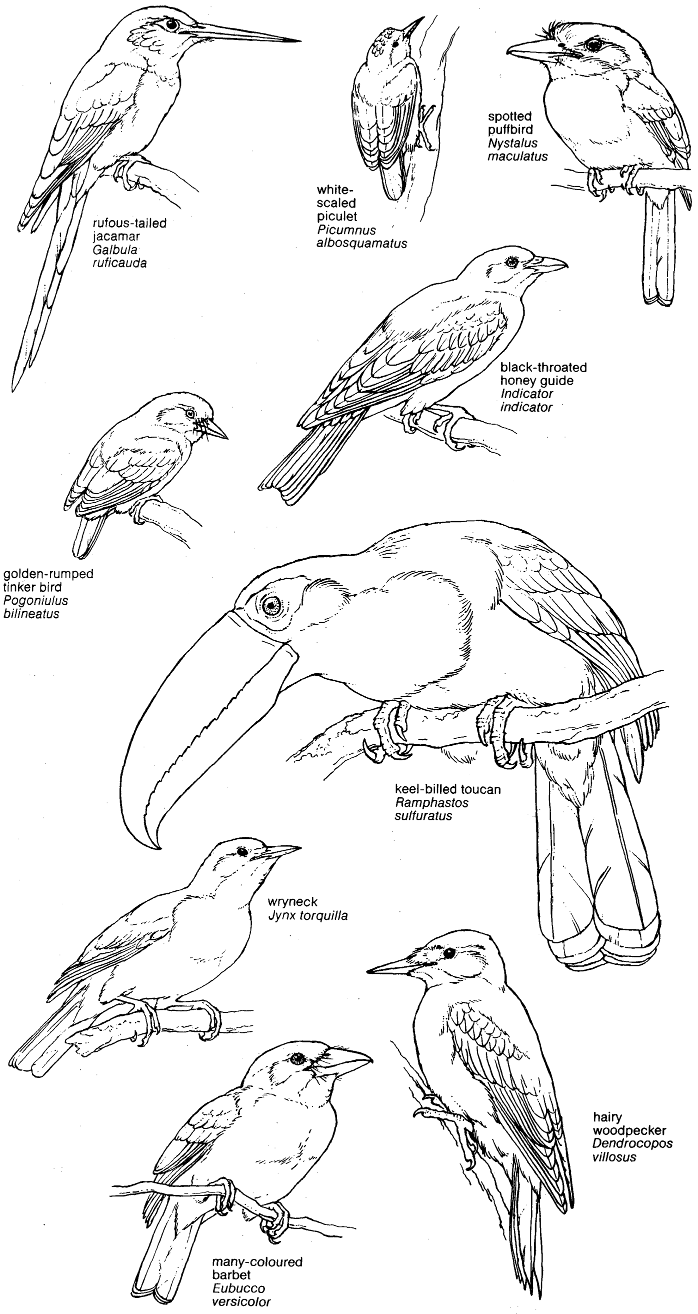

Figure 44: Body plan of representative piciform birds.
Drawing by R. Keane

IMPORTANCE TO MAN

Most piciform birds consume insects, some foraging in places (within bark) reached by no other birds. Thus, they are valuable in the control of insects, even helping to prevent the spread of tree diseases, such as Dutch elm disease, by destroying insect carriers. Fruit-eating barbets and toucans spread seeds of certain tropical trees, the seeds being passed through their bodies at distances away from the parent tree. Honey guides lead man, as well as other mammals, to sources of honey. Colourful toucans, barbets, and jacamars, and even the dull-coloured puffbirds delight both natives of and visitors to the tropics. Woodpeckers are conspicuous and often colourful species of the forest, and their actions have long elicited interest and admiration from man—their winter visits to suet feeders in the Northern Hemisphere are anticipated and enjoyed by millions of onlookers. The excavation of nesting and roosting holes by woodpeckers and barbets provides homes for countless birds of other species, which utilize the holes after the excavators are finished with them. Foresters in Europe frequently compensate for the lack of old woodpecker holes needed by valued insect-eating species by placing artificial nest boxes in their cultivated forests.

Artificial nest boxes

Fruit eating by barbets and toucans sometimes causes damage to cultivated fruit plants, especially near villages and towns. The few species of sapsuckers in North America and southern Asia occasionally destroy trees by creating openings through which disease agents may enter, although wounds in healthy trees rapidly heal. Piciform birds that excavate their nests usually choose dead or dying trees, but some excavate in live trees or cacti. The area around the excavation may be sealed off by scar tissue in some trees, especially cacti, resulting in no damage but diminishing the tree's value. Some woodpeckers damage fence posts and utility poles, particularly in open country, in well-kept woodlots, and near cultivated forests where dead trees are scarce.

NATURAL HISTORY

Distribution and ecology. Piciform birds are varied in their habits, although certain facets of behaviour relating to hole nesting, such as the snakelike hissing of young birds in the nest, are shared with some other hole-nesting birds. Jacamars and puffbirds, the fly-catching members of the order, are stolid, unsuspicious birds, allowing close approach by humans. Woodpeckers, toucans, and barbets are more wary, but the smaller species of piculets and woodpeckers sometimes can be approached closely.

Jacamars and puffbirds inhabit various portions of tropical American forests. Jacamars sit quietly on perches in openings and edges, flying infrequently, but often flicking their tails. Large insects, such as butterflies, are captured, taken to a perch, and usually beaten against it. The wings of the insects are removed if the prey are to be fed to the young.

Puffbirds are often found in farm areas, where they may be seen along the road looking something like dull-coloured forest kingfishers. They have a rapid, darting flight, and some species, such as the swallow-winged puffbird (*Chelidoptera tenebrosa*), spend much time making sorties after insects high in the trees. Others forage low in bushes, obtaining prey on the ground as well as in undergrowth. Tail-jerking movements are observed in some puffbirds (*e.g.,* the two-banded puffbird, *Hypnelus bicinctus*), as in jacamars.

The barbets are weak-flying, essentially resident birds inhabiting woodland and savannas, occasionally the fringes of deserts. They feed on insects, fruit, and even flowers and buds. The tiny African tinkerbirds (*Pogoniulus*), so named for their repetitive vocalizations, feed mainly or entirely on insects, foraging rapidly over bark and occasionally tapping with the beak, very much like piculets of the woodpecker family. Some barbets have serrated, or "toothed," edges of the bill, in the manner of toucans; these are apparently used for tearing open fruit.

Guiding by honey guides

Honey guides are nonmigratory birds, dwelling in pairs or alone in forests and savanna. They feed on insects, fruit, and beeswax. Only a few honey guides of the genus *Indicator* actually are known to "guide" certain mammals, including man, to bees' nests. Most honey guides are able to enter bees' nests without assistance, there to eat larvae and, primarily, wax, which is digested with the help of special bacteria within the birds' digestive tracts. Honey guides that "guide" use a peculiar chattering to attract the attention of an animal likely to follow. The greater honey guide (*Indicator indicator*) spreads its tail conspicuously and uses a peculiar undulating flight in attracting attention. It perches and calls again, then moves further on in another short flight, as the interested animal draws near. Upon reaching the bees' nest, the honey guide waits quietly in the vicinity until the animal has taken the honey and moved off. It then flies to the devastated nest and feeds on scattered pieces of wax and exposed larvae.

Toucans are strictly New World tropical-forest birds, although they may forage about farms. One group, the hill toucans of the genus *Andigena,* occurs in the Andes up into temperate forests. No toucans are geographically migratory, but some species make local movements up and down mountain slopes. Toucans eat much fruit, perhaps aided by their serrated beaks. Smaller pieces or small fruits are first held in the tip of the bill and then thrown back into the mouth. They also eat larger insects, birds' eggs, and even young birds. The colour patterns of the bill are distinct in each species and probably serve a behavioral function. Toucans have a peculiar habit of cocking the tail forward over the head, particularly while sleeping in a cavity; D'Arnaud's barbet (*Trachyphonus darnaudii*) also does this during displays.

The family Picidae is comprised of three distinct subfamilies. One, the Jynginae, contains two closely related species of wrynecks (*Jynx*), found in Eurasia and central Africa. Wrynecks, which have soft, unspecialized tails, forage for ants in trees and on the ground.

The piculets (Picumninae) comprise a second subfamily of soft-tailed, woodpecker-like birds. All but four of about 30 species live in forests and dry woodlands of the New World tropics. The major genus *Picumnus* is peculiarly distributed in having about 24 species in the New World and one species (*Picumnus innominatus,* the speckled piculet) in southern Asia, a pattern of distribution matched by the woodpecker genus *Celeus.* All the piculets are tiny, the largest—the peculiar Haitian piculet (*Nesoctites micromegas*)—being only sparrow sized. They feed in a woodpecker-like manner, tapping and probing usually on small branchlets and vines, and they allow close approach, continuing to forage under the eyes of an observer. Their food is composed mainly or entirely of insects.

Feeding behaviour of woodpeckers

The true woodpeckers (Picinae), with their stiffened tails, usually perch lengthwise on tree branches or trunks. Among the relatively few species that go to the ground, all hop, except for two species of flickers (campo flicker, *Colaptes campestris,* and Andean flicker, *Colaptes rupicola*) that walk. Foraging is by diverse modes. True excavating, which penetrates the substrate of the bark, is not as common as one would expect on viewing the woodpecker bill. Most woodpeckers forage mainly by gleaning items from the surface of a tree, by probing into cracks, and by occasional to frequent tapping, sufficient to break barely through the surface. Only the heavy-billed, so-called ivorybills (genus *Campephilus*) of the New World, some of their relatives, other similarly specialized Asian groups, and a few of the smaller woodpeckers (genus *Picoides;* some species of *Dendrocopos*) regularly chisel deep into trees. The food of woodpeckers is varied, mainly consisting of insects, but some species (especially of the genus *Melanerpes*) frequently eat fruits and berries. Ants are a favourite food, especially in tropical regions—fully half of the numerous tropical species feed largely or entirely on ants. Three woodpeckers (ground woodpecker, *Geocolaptes olivaceus* of Africa, the campo flicker, and the Andean flicker) are ground dwellers, feeding mostly on ants, while seven or eight other species frequently forage on the ground. The flight of woodpeckers is strong, with definite up–down undulations.

Most woodpeckers are permanent residents, the few exceptions including the North American yellow-bellied sapsucker (*Sphyrapicus varius*) and flicker, which are highly migratory.

Reproduction. The ability of most piciform birds to excavate their own nest holes is probably a major factor responsible for their success. With relatively diverse types of bills, the jacamars, puffbirds, and barbets excavate nesting cavities, as do the sturdier billed woodpeckers, although the former utilize a softer substrate such as earth or dead trees. Woodpeckers alone within the order have biologically "capitalized" on their adaptations for excavating nests, by various further specializations for nesting (even in hard, living trees) and for foraging on the surface and within the bark of trees. They have thus exploited niches unavailable to other birds, a fact that accounts for their success relative to other members of the order. Yet because of their specialized habits, only a limited number of kinds of woodpeckers can exist together, usually no more than five to eight species (more in some tropical environments), differing somewhat in size and habits.

Difficulties in the study of hole-nesting birds

Because of the concealing nature of the nest cavity, the behaviour of hole-nesting birds is more difficult to study than that of species building exposed nests. The nesting behaviour of most piciform families must be inferred from observations on a few examples, the woodpeckers being the only group that has been extensively studied.

Jacamars are usually resident wherever they occur and nest at diverse times of the year depending on the locality. Nests are excavated in banks or in steep hills. Both sexes dig with the beak, kicking out dirt with their feet. The tunnel is comparatively short, usually less than one metre (three feet) in depth. No lining is placed in the nest chamber at the end of the tunnel. Three or four white eggs are incubated by both sexes, with the female incubating at night. The incubation period of several species of jacamars is known to be from 19 to 21 days. The young are downy and hatch with their eyes closed. They remain for 20 to 26 days in their nest before leaving. Most of the food consists of large insects brought to the young by both parents. The parents do not clean debris and fecal material of the young from the nest, which becomes littered.

Puffbirds excavate their nests in the ground or in termite nests on the ground or in trees. The tunnel is usually deeper than that of a jacamar, often reaching a metre or more into the ground. Several pairs may nest close together, semicolonially. Both sexes excavate the burrow. Some species leave the chamber at the end of the tunnel unlined, while others may line it with grass or dead leaves. Several species, including the white-whiskered puffbird (*Malacoptila panamensis*), pile sticks and leaves at the mouth of the nest tunnel, effectively concealing it. Both sexes incubate the two (occasionally three) white eggs. The newly hatched young are naked and are fed by both parents.

Social nesting and roosting

Although the majority of barbets nest in isolated pairs, there is a marked trend toward sociality. Large numbers of one or several species may gather to feed at a fruiting tree. Some species are found in family groups, and displaying groups of several individuals may be seen during the onset of breeding. The most social of all are the plain-coloured barbets (genus *Gymnobucco*) of Africa, the brown barbet (*Calorhamphus fuliginosus*) of southeastern Asia, and some species of the genus *Megalaima* of southern Asia. These nest colonially and feed in gatherings of up to 50 or more birds (*Gymnobucco*). They are aggressive, noisy birds and may take over an entire dead tree for nesting, driving away other bird species. In some barbets of the genera *Semnornis* and *Megalaima*, communal roosting occurs, with numbers of birds spending the night together in the same hole. Nests are usually excavated in trees, but a few species burrow into the ground or into termite nests. Both sexes excavate the cavity, which typically has a nearly round entrance, small for the size of the bird. The same cavity may be used for several nesting seasons. No lining material is placed in the nest cavity. The shape of the barbet's bill, which is not at all chisel-tipped like that of a woodpecker, makes the excavation of cavities in trees a task requiring great effort, and it appears that only dead, well-rotted trees are used. Two to five white eggs are laid in the cavity; both parents then incubate the eggs for 13 to 15 days or more. Both also may spend the night in the nest. The young develop slowly, spending 30 or more days in the nest. The adults clean the nest, removing excreta. Often the young and adults continue to roost together after the young have left the nest, occupying a separate "dormitory" hole excavated for that purpose. On occasions, more than one pair of birds may use the same nest (white-eared tinkerbird, *Pogoniulus leucotus*).

Most, if not all, of the honey guides are brood parasites, laying their eggs in the nests of other species, especially those that nest in holes or in deep, covered nests. The host's eggs often are punctured by the female honey guide when she lays her own egg. Only a single egg is laid in each host's nest. Because of the parasitic habit, the incubation periods of honey guides are not well known, but periods of 12 to 16 days have been found in species of *Indicator*. The young birds spend a long time in the nest, 35 to 40 days or more. When newly hatched, they have hooks on the tips of their bills, which are used to injure and kill the young of the host species. These hooks later fall off.

Toucans nest in natural cavities or in old woodpecker nests. Smaller species may usurp a nest freshly constructed by woodpeckers. Old, well-rotted cavities may be enlarged slightly. One to four eggs are laid on the floor of the nest, which may be unlined or lined with a few leaves. About 16 days are required for incubation, performed by both sexes. The birds are shy about the nest and hence difficult to observe. The young, naked when hatched, bear large pads on their heels, on which they perch in the nest. The nestling period is generally long, up to seven weeks or more, varying with the size of the birds. Toucans, except the toucanets (genus *Aulacorhynchus*), do not maintain clean nests. Family groups may remain together for a long time, for small flocks are often seen throughout the year.

Wrynecks usually nest in natural crevices, old woodpecker holes, or old swallow holes in banks. They lay two to 14 eggs, and both sexes incubate. Like the American flicker and probably other woodpeckers, the wryneck is an indeterminate layer; *i.e.,* the bird produces eggs until a certain number have accumulated.

The nests of piculets are constructed in small trees, stubs, fence posts, and the like. The entrance is tiny and rounded, resembling a barbet nest entrance. Two to four eggs are laid and incubated for about two weeks. The initially blind and naked young grow for three weeks or more before leaving the nest for the first time. Both parents incubate and feed the young, and in at least some species they both remain in the nest at night. After fledging, the young may continue to roost in the nest at night with their parents for several months. Like the wrynecks and most other birds and unlike woodpeckers, the piculets often perch crosswise on branches.

The reproductive behaviour of woodpeckers is better known than that of most other Piciformes. The sexes are clearly marked by simple pattern differences, most commonly involving the presence or absence of red on the head. Observations at bird-feeding stations suggest that sexual recognition occurs throughout the year, with males dominant over females. Aggressive displays are conspicuous and numerous in woodpeckers, including various head postures centring on the bill, bill pointing, head turning, swinging of the head and body from side to side, bobbing and bowing of the head, wing flicking and spreading, tail spreading and turning, and even aerial displays. These displays exhibit the complex head markings, as well as the body, tail, and wing patterns found in most species. Many vocal and instrumental signals are used, including the widely prevalent tapping or drumming of the bill against a tree or, in cities, on tin roofing.

Displays of woodpeckers

Most woodpeckers actively defend territories, often throughout the year. This perhaps accounts for their strongly developed aggressive behaviour. Few species are markedly social, but members of the New World genus *Melanerpes* especially tend to be, even while nesting. Up to 11 different adults of the yellow-tufted woodpecker (*Melanerpes cruentatus*) were observed feeding young in three different nests in eastern Peru. Some of the adults fed young in two and even in all three nests. Andean flickers nest in loose colonies in banks and may be seen in groups of 10 or 12 birds. Otherwise, social gatherings of woodpeckers generally involve family groups during and sometimes after the breeding season. Most woodpeckers are aggressive toward others of their own species, even to some extent toward their mates and young. Aggressive encounters are most frequent between members of the same sex. When an intruding woodpecker invades the territory of a pair during the breeding season, it usually is attacked by the member of the pair that is of the same sex as the intruder. Conflicts between birds after the breeding period are more intense when the woodpeckers involved are of the same sex. Experiments with the North American flicker show that even paired birds recognize each other primarily by their sexual colour markings, for a female given an artificial black moustache stripe (characteristic of the male) was attacked and pursued unceasingly by her mate until the experimenter rescued the exhausted female and removed the "moustache." She was once again fully accepted by her mate.

Nests are excavated by the birds themselves, although a

Nesting of woodpeckers

few species will accept artificial nest boxes. Two species, the ground woodpecker and the Andean flicker, always nest in the ground, digging nests in banks, and the campo flicker of South America often does so. Other woodpeckers chisel holes in trees, fence poles, cacti, or similar sites. Usually both sexes construct the nest, but either sex may do most of the work, depending on the species. The nest cavity varies with the size of the bird. A flicker (30 centimetres, or 12 inches, long) was found incubating eggs in a tree stub only 12 centimetres (five inches) thick; so less space is required for nesting than one might expect. Nevertheless, the size of the stub or tree necessary for nesting is proportional to the size of the woodpecker. Also, the size and abundance of dead or dying trees influence the abundance and types of woodpeckers that can occupy an area.

From two to nine white eggs are laid on the bare floor of the woodpecker's nest cavity. Most species probably are indeterminate layers. By removing the freshly laid eggs as they appeared daily, one experimenter induced a female flicker to lay a total of 71 eggs. The incubation period of woodpeckers varies from 11 to 20 or more days. Both adults incubate the eggs, and typically the male alone occupies the nest during the night. The young are naked and helpless when hatched and spend up to 36 days in the nest. Both parents feed the young and keep the nest clean by removing excreta frequently. In some species the young are driven off by the adults soon after they can feed themselves; in others the family remains together longer, sometimes even until the next breeding season.

Vocalizations. The voices of Piciformes are rarely melodious and are often harsh or strident. The vocalizations of jacamars are squeaky, the notes sometimes being run together into a trill. Whistles or trills may be alternated or mixed, forming a simple song. Puffbirds are relatively quiet, producing thin whistles, peeps, and twitters. The vocalizations of toucans are loud and often harsh, especially those of the larger species, such as those in the genus *Ramphastos*. The calls of barbets are monotonous and repetitive, but some are bell-like and pleasing to the ear, especially those rendered antiphonally (*i.e.*, the birds alternating) or simultaneously by members of a pair. Displays may accompany this singing. With some colour patterns like their relatives the woodpeckers, barbets have similar displays, such as head swinging, head bobbing, bill pointing, and others.

Although the vocalizations of woodpeckers are individually less complicated than the songs of passeriform birds (the order that includes the songbirds), up to eight or nine different and varying calls may be used by some species (*e.g.*, the ladder-backed woodpecker, *Dendrocopos scalaris*). These function as "advertising songs" (usually repetitive, often harsh, "rattle" or "wick" calls), as aggressive or submissive calls associated with displays, and in other ways.

FORM AND FUNCTION

Adapted for diverse modes of life, piciform birds vary strikingly in their morphology and in their habits. The interpretation of differences is difficult in many cases especially considering that different structural means may achieve the same purpose. Thus, the fly-catching jacamars are exceptionally long-tailed, but the puffbirds, which feed similarly, are generally short-tailed.

Foot specialization

Characteristic of all members of the order is the yoke-toed (zygodactylous) foot in which the outer toe (toe IV) as well as the hind toe (I) points to the rear. This was long considered an adaptation to climbing or perching on the vertical trunks of trees, but recent studies have shown that this type of toe arrangement may really denote a generalized perching foot. Most of the strongly wood-pecking species of the Picidae that are four-toed spread the toes laterally and anteriorly—*i.e.*, up the tree that they are climbing, with no toes pointing to the rear. Three-toed woodpeckers, such as the northern three-toed woodpecker (*Picoides tridactylus*), which have lost the hind toe (hallux, toe I), climb with all three toes facing to the front and sides and swing the inner toe (II) backward when perching on a branch. The hallux tends to be small in those Picidae that have retained it, and its loss has occurred independently in several lines of woodpeckers and piculets.

Just as birds in general are structurally similar because of requirements imposed by flight, woodpeckers are structurally similar because of requirements imposed by wood-pecking habits. The special modifications responsible for their unique abilities are diverse. The tail feathers (especially the central one or two pairs) are stronger in woodpeckers, resisting the wear caused by their use in propping the bird's body as it hammers with the bill. The toe structure and associated arrangement of tendons and leg muscles form a functional complex of features enabling the woodpecker to climb tree trunks and to maintain its position while pecking the tree.

Another functional complex involves the skull, head musculature, bill, tongue, and associated structures of the woodpecker, collectively its food-gathering apparatus. The skull is unusually thick, and, in the most specialized wood-pecking species, it curves inward at the upper base of the bill, instead of meeting it directly, giving a built-in shock absorber. The head musculature is specialized to power the thrusts of the bill and to help absorb the shock caused by pecking. The long, distensible tongue is variously equipped with tiny barbs and coated with a sticky substance provided by often greatly enlarged and modified salivary glands. The horns of the hyoid apparatus responsible for the ability to extend the tongue are tremendously elongated, and when the tongue is retracted, they often extend around the back of the skull, over the top, and (rarely) even onto the bill and into a nostril (see Figure 45). The tongue can be extended into holes made by the bill and can be used both as a probe and as a "spear" (by means of the barbs and sticky mucus) to locate and extract insects far beyond the bill's reach. The bill of more specialized woodpeckers is chisel tipped, broad based, and very sturdy. The nostrils are slitlike, preventing sawdust and wood chips from entering. Other parts of the body may be modified for support or to prevent damage from the shock of pecking.

Drawing by R. Keane

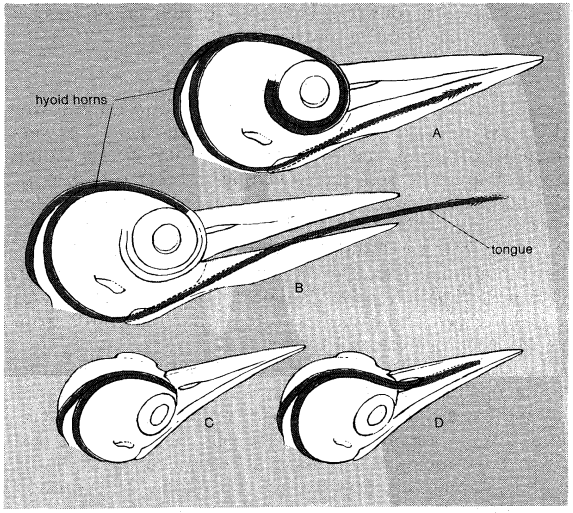

Figure 45: Position of hyoid bones (shaded) with tongue (A) retracted and (B) extended, shown in the hairy woodpecker (*Dendrocopos villosus*). (C and D) Other configurations of hyoids: C ending at the base of the beak; D entering the right nostril and lying within the upper mandible.

An advantageous side effect of their specialization is that woodpeckers are exceptionally tough-skinned and sturdy and thus are difficult to kill. Unfortunately, this has not saved the magnificent, highly specialized ivory-billed woodpecker (*Campephilus principalis*) and its close relative the imperial ivory-billed woodpecker (*Campephilus imperialis*), the largest of all woodpeckers, from extinction through destruction and modification of habitat. A remnant population of the former is known to exist in Cuba, but the future for both species is bleak.

Among woodpeckers, sexual difference in bill structure and other characteristics plays a role in allowing the members of a pair to utilize somewhat different types of food, presumably facilitating more efficient foraging.

Of the other piciform families, the Indicatoridae are specialized in features, such as their thick skin, relating to their beeswax eating and brood parasitism. Other peculiarities, such as the graduated long tail of the lyre-tailed honey guide (*Melichneutes robustus*) and the presence of but nine primaries (there is usually some trace of a tenth primary feather) in the wings of most honey guides, are more difficult to interpret functionally.

The toucan bill

The bill of the toucans, another specialized group, is something of an anomaly. Very large, with serrate edges and usually splashed with colour, it is peculiarly constructed within. Many crisscrossing, fine, bony fibres give it great strength for its size and light weight. The serrated bill may be effective in tearing open fruits, although the birds often feed on small fruits daintily picked, held at the tip of the bill, and thrown back into the mouth. Alternatively, the serrations may aid in securing insects or in plucking young birds out of nests. The colour patterns of the bill probably function as species-recognition signals or in some other way during displays. Yet the size of the bill seems greater than necessary for the serving of these functions. Studies of the feeding habits of the larger species may enable the solution of this point.

EVOLUTION AND PALEONTOLOGY

Fossil species of the order Piciformes are almost unknown. Many avian fossils identified long ago are in need of verification, including the early fossil "woodpeckers," some of which are now believed to belong in other orders. Fossil woodpeckers are now known only from the Pliocene Epoch (about 6,000,000 years ago). Except for a single specimen from the middle Miocene of Bavaria assigned to the Capitonidae, the other Recent families have no fossil records. A fossil family, Zygodactylidae, was erected in 1971 to receive three species of fossil piciform birds from the Miocene of western Europe.

The dearth of fossils leaves the evolution of existing groups open to speculation. If it is true that existing families of the order are only specialized remnants of a formerly more diverse assemblage, then the generalized groups that might have included common ancestors of some of the modern families are now extinct. Therefore, the evolution of the order must be interpreted from inferences based on the morphology of its existing families.

Little can be said about the puffbirds and jacamars. Both families are relatively uniform, and no existing species shows intermediacy or close resemblance between them. They must have evolved very early in the history of the order from a generalized, fly-catching ancestor. If the Galbulae and Pici are indeed closely related, their divergence from a common ancestor must have occurred long ago.

Ancestors of the woodpeckers and barbets

The families within the suborder Pici are definitely interrelated. The honey guides and barbets are morphologically similar, as are the toucans and barbets. The barbets are rather diverse, foliage and branch-foraging piciform birds. An ancient species of barbet, not greatly unlike modern barbets, could have evolved into the ancestral toucan and another such species into the ancestral honey guide. Woodpeckers and barbets share an ancestor probably dating from an earlier period than either the barbet–toucan or the barbet–honey guide ancestor. The peculiar wrynecks, and even the piculets, may represent relicts of early evolutionary radiations in the line leading to woodpeckers. Modern woodpeckers have radiated into many groups, some specializing for an arboreal wood-pecking existence, others remaining generalized, and still others becoming partially adapted to life on the ground.

CLASSIFICATION

Distinguishing taxonomic features. Various characteristics set the Piciformes apart from other orders and distinguish subgroups within this order. Among these features are the condition of the toes and their flexor tendons; the condition of the nostrils; the absence of basipterygoid processes at the base of the skull; the arrangement of the pelvic muscles; the size of the deltoid muscle; the condition of the syringeal muscles.

Annotated classification. The classification below is based generally upon those of a British ornithologist, P.R. Lowe, and an American, C.G. Sibley. The groupings are accepted generally among taxonomists, with disagreement centring about the taxonomic rank of the subcategories (*e.g.,* superfamily versus family) and whether or not to merge part of the order with the perching birds (Passeriformes). The family indicated by the dagger (†) is extinct.

ORDER PICIFORMES

Zygodactylous birds (toes arranged 2 in front and 2 behind); flexor tendons with a vinculum (a connecting strip), digits I, II and IV supplied by flexor hallucis, and flexor digitorum supplies digit III; nostrils impervious and holorhinal (not deeply cleft); eutaxic (5th secondary present), 9 to 11 primaries, 10 to 13 secondaries; 8 to 12 rectrices (tail feathers); aftershaft present; no down in adults; hole-nesting birds, laying all-white eggs. About 370 species.

Suborder Galbulae

Desmognathous (vomer bone of palate small or lacking; maxillopalatines connecting); nude oil gland; 2 carotid arteries; no gallbladder; 10 primaries, 10 to 12 secondaries, 10 to 12 rectrices. Catch food, usually insects, on wing; nest in ground or termite nest.

Family Galbulidae (jacamars)

Tropical and subtropical Central and South America. Bill long. Vomer lacking. Legs with long smooth scales behind and scutellate (small scales) in front. Moderately sized, long-tailed birds with iridescent plumage dominated by green. Feed by fly catching for large insects. Nest in burrows excavated in banks.

†*Family Zygodactylidae*

Middle and upper Miocene of France and Bavaria; 3 species.

Family Bucconidae (puffbirds)

Tropical and subtropical Central and South America. Distinguished by a shorter, wider bill than jacamars, with a decurved tip. Vomer present. Leg scales scutellate in front and behind. Moderate or small-sized, dull-coloured birds with an unusually large head, plumage lax and noniridescent. Feed by fly catching for insects and other arthropods and vertebrates as well. Nest in burrows in the ground, or in termite nests on the ground, or in trees.

Suborder Pici

Rarely desmognathous, usually aegithognathous (vomer broad; maxillopalatines not connecting) or saurognathous (vomer a delicate rod; maxillopalatines reduced, not connecting); oil gland usually feathered; 9 to 11 primaries, 10 to 13 secondaries, 10 to 12 rectrices. Nest in tree cavity, rarely in ground. Food diverse, secured by various means, but rarely by fly catching.

Family Capitonidae (barbets)

Tropical and subtropical New World, Africa, and Asia. Small to medium bill, not chisel-like; short, nonextensible tongue; nostrils opening onto bill surface without a fossa (depression); conspicuous bristles at base of bill. Small to medium, usually brightly coloured birds of stocky appearance. Food fruit or insects, often gleaned from tree bark or foliage. Nest hole in trees or termite nests, usually excavated by the birds.

Family Indicatoridae (honey guides)

Tropical and subtropical Africa and Asia. Small bill, not chisel-like; short, nonextensible tongue; nostrils opening onto bill in centres of large fossae, and without conspicuous bristles at base of bill. Small or medium, generally dull-coloured birds with smallish heads. Food beeswax and insects. Brood parasites, laying eggs in nests of other birds, especially piciform birds.

Family Ramphastidae (toucans)

Tropical to temperate Central and South America. Distinguished by a long and often deep and brightly coloured bill, with serrated edges. Tongue nonextensible but long and fringed. Medium to large, long-tailed and often brightly coloured birds. Food mainly fruit, also insects, even eggs and small birds. Nest in natural tree cavities or woodpecker holes, never excavated.

Family Picidae (woodpeckers, piculets, wrynecks)

Generally worldwide, except Australian region. Distinguished by a straight, usually chisel-like bill, long extensible tongue with elongated hyoid (tongue) apparatus, salivary glands secreting a sticky material that coats the tongue. Very small to large birds, often patterned in black, white, and bright colours. Forage on tree trunks and branches, rarely on the ground. Food chiefly insects, some fruit, rarely sap and seeds. Nest excavated (except wrynecks) in tree, post, cactus, or (rarely) in the ground.

Critical appraisal. Although recognizing the relationship of this order to perching birds (Passeriformes), most taxonomists prefer to keep the two groups separate as distinct orders, especially since clear evidence for relationship with a particular group of perching birds is lacking. No perching bird has the zygodactyl toe arrangement. The exact relationship between the suborders Galbulae and Pici has not been established. Lowe advocated relationship of the Galbulae with the Coraciiformes (kingfishers, bee-eaters, etc.), and the merger of the Pici in the Passeriformes. The suborder Pici is often considered to contain three superfamilies, for the toucans, the woodpeckers, and the barbets and honey guides, respectively. The above arrangement within the suborder Pici begins with the barbets, generally recognized as the least specialized group within the suborder and the most likely ancestral family. The honey guides are almost universally considered very closely related to barbets and are placed next. There is agreement that the specialized toucans, placed next, evolved from barbet-like ancestors. The exact relationship of the specialized woodpecker family with barbets is unknown, but it is likely either that woodpeckers evolved from barbets or that the two groups shared a common ancestor. No authority has suggested that woodpeckers are more closely related to toucans or to honey guides than to barbets. Various authorities have arranged these families diversely, but nearly all place the woodpeckers last. No single arrangement is universally accepted. (L.L.S.)

Passeriformes (perching birds)

Worldwide abundance of passerines

The order Passeriformes, the passerines, or perching birds, is the dominant avian group on Earth today. Considered the most highly evolved of all birds, passerines have undergone an explosive evolutionary radiation in relatively recent geological time and now occur in abundance on all continents except Antarctica and on most oceanic islands. Their rapid evolution and adaptation to virtually all terrestrial environments have resulted in a large number of species, some 5,100, compared to only about 3,500 species for all other birds.

The order Passeriformes is divided by most taxonomists into four suborders: Eurylaimi, Tyranni, Menurae, and Passeres. The first three, containing about 1,100 species, are considered more primitive and are often grouped informally as the "suboscines" for convenient comparison with the very large fourth suborder, the oscines, or songbirds (about 4,000 species).

GENERAL FEATURES

Size range and structural diversity. Passerines are small to medium-sized land birds, ranging from about 7.5 to about 117 centimetres (three to 46 inches) in overall length. Among the tiniest species are the New World flycatchers (Tyrannidae), New Zealand wrens (Xenicidae), titmice (Paridae), flower-peckers (Dicaeidae), tanagers (Thraupidae), and waxbills (Estrildidae). The heaviest are the lyrebirds (Menuridae) of Australia and the ravens (*Corvus*). The longest species, the ribbon-tailed bird of paradise (*Astrapia mayeri*), is actually not so large in body bulk but has extremely long tail feathers. Most passerine species fall within the range of about 12.5 to 20 centimetres (five to eight inches) in length and from 15 to 30 grams (0.5 to one ounce) in weight. A house sparrow (*Passer domesticus*), for example, is 12 to 15 centimetres (five to six inches) long and weighs about 26 grams (0.9 ounce); a cardinal (*Cardinalis cardinalis*) 20 to 23 centimetres (eight to nine inches) and approximately 44 grams (1.5 ounces).

Passerines have evolved a great diversity of feeding adaptations. The majority are insectivorous, at least at certain times of their lives. Members of the order have evolved many ways for finding insect food: swallows (Hirundinidae) are aerial feeders; New World flycatchers "hawk" insects by flying out from a perch; vireos (Vireonidae) glean insects from small twigs and foliage; woodcreepers (Dendrocolaptidae), nuthatches (Sittidae), and creepers (Certhiidae) search for insects in crevices in tree bark; and many other species pick and scratch on the ground and in leaf litter. More specialized passerines eat aquatic insects (dippers: Cinclidae), fish (some New World flycatchers: Tyrannidae), fruit (cotingas: Cotingidae; and many others), leaves (plantcutters: Phytotomidae), nectar (sunbirds: Nectariniidae), small land vertebrates (shrikes: Laniidae), and seeds (finches and many others). For these different food habits, various structural specializations have developed, especially in the bill and feet (see below *Form and function*).

Importance to man. *Aesthetic and economic importance.* Since prehistoric times people have enjoyed watching and listening to songbirds. The almost infinite variety of colours, patterns, behavioral traits, songs, and calls found in these birds appeals to man's aesthetic tastes. As objects of beauty and interest passerines have been incorporated into human culture, folklore, poetry, music, sculpture, and painting. Songbirds have also been used as symbols, such as the European goldfinch (*Carduelis carduelis*), which represented the Passion of Christ in Renaissance art, or the raven (*Corvus corax*), which sometimes has signified a messenger for the devil, an evil omen.

Songbirds as religious symbols

Passerines are widely kept as cage birds. The origins of this practice are lost in antiquity, but it is known that by the 5th century BC the Greeks kept a variety of songbirds, including finches, nightingales and other thrushes, magpies (*Pica*), and starlings (*Sturnidae*). Canaries (*Serinus canaria*) were brought to Europe from their native Canary Islands in the 16th century and have since been developed by domestication and breeding into many varieties. Other passerines now widely kept as pets are the cardueline and estrildine finches and the starlings (particularly Asian mynahs, *Gracula*). The magnitude of the cage-bird "fancy" is indicated by importation statistics on wild and semi-domestic birds: in one recent year alone, over 420,000 passerines (excluding canaries) were legally imported into the United States as cage birds, a number far exceeding that of parrots, the only other bird group whose members are commonly kept as pets. Many countries, including the United States and Great Britain, prohibit the capture and sale of nearly all native songbirds.

Songbirds are also economically important in other ways. Although seldom considered food in economically advanced areas, they are nonetheless important dietary items in many rural or heavily populated countries. China, Japan, and other Oriental countries, for instance, have highly developed techniques for catching small birds, and in cities such as Hong Kong and Tokyo passerines are commonly sold in food markets. In Italy, France, and Belgium the capture of migratory songbirds for the pot or for cage birds is still extensive. Laws against such activities are difficult to enact or enforce in areas in which the habit has become part of the culture; hence, for example, more than 10,000,000 passerines were still being caught annually in Italy in the late 1960s.

Fortunately, killing songbirds for their feathers is no longer as prevalent as it once was. Until the early 20th century, however, there were few protective laws, and the wearing of birds (especially on women's hats) was common. In 1886 a young ornithologist reported that he had counted feathers from no fewer than 40 bird species, including 22 kinds of passerines, on hats seen on two afternoon walks in a fashionable part of New York City.

Other cultures have used songbird feathers for personal adornment, but usually for men rather than women. This practice often came about not only for the beauty of the feathers themselves but also because the feathers were used as symbols of such bird qualities as speed and aggressiveness. Most noteworthy are the feathers of male birds of paradise (Paradiseidae) used as headdresses by tribesmen of New Guinea. An estimated 80,000 adult birds are still being killed annually for this purpose. Other ancient uses of passerine feathers have now largely been terminated, either because the birds are extinct (in the case of Hawaiian feather cloaks) or because more suitable modern substitutes have been found (Melanesian feather money).

Songbirds as agricultural pests

Some passerines, on the other hand, are serious economic pests. In areas in which one-crop agriculture is extensive, certain bird species have undergone population explosions because of almost unlimited food availability; in turn, their crop depredations can be serious. One example of this is in Africa, where immense flocks of a small weaver, the red-billed quelea, or Sudan dioch (*Quelea quelea*), numbering as many as 20,000,000 birds in one flock, do millions of dollars worth of damage to various small grain crops each year. Other serious pests are the Java sparrow (*Padda oryzivora*) in Asian rice fields and mixed flocks of New World blackbirds (*Icteridae*) and European starlings (*Sturnus vulgaris*) in grainfields in the United States. The same starling and the house sparrow, both introduced to the United States from Europe, have become urban pests by fouling buildings with excrement and blocking rain gutters and ventilators with their nests. Starlings occasionally also have been implicated in accidents; in 1960 a flock at the airport in Boston was sucked into a jet's engines and the resultant crash killed 61 people.

Ecological importance. The greatest importance of passerines is ecological. As the dominant form of birdlife in virtually all terrestrial environments, the perching birds are a major component of the world's ecosystems. They consume great quantities and varieties of food—grains, fruits, insects and other invertebrates, small amphibians and reptiles, and even small mammals—and in turn serve as food for other animals; they act as hosts for parasites and are occasionally parasitic themselves; they both propagate and distribute plants by pollinating flowers and carrying viable seeds to new locations; and they have the mobility (through migration) to utilize habitats that are available only at certain times of the year. A few aspects of the ecological impact of passerines are known, but, until the science of ecology has advanced, the true magnitude of their importance cannot be evaluated with precision.

NATURAL HISTORY

Types of territories

Reproduction. *Territoriality and courtship.* The breeding behaviour of passerines is diverse. Most species are solitary nesters, a single monogamous pair of birds maintaining a territory that is large enough to support all their activities during the breeding season: courtship, mating, nesting, and food gathering. Others have similar territories, but the birds forage outside the defended area for most of their food (*e.g.,* the North American redwinged blackbird, *Agelaius phoeniceus*). Still others are colonial nesters, defending only the nest site and a small area immediately adjacent to it. Some species build individual nests close together in a colony (oropendolas, Icteridae; some swallows; the house sparrow), and others construct massive communal nests in which the breeding pair defends only its own nest cavity (palm chat, *Dulus;* several weaverbirds, Ploceidae). In a few species polygynous (polygamous) males establish special display territories (leks) for courtship and mating in which no nesting takes place. In these courtship arenas the males, usually brilliantly coloured, attract females through song and posturing and sometimes by dancing, manipulation of objects, and other elaborate displays. The best known arena-displaying males are the cocks of the rock (*Rupicola*), manakins (Pipridae), birds of paradise, and bower-birds (Ptilonorhynchidae). After mating in or near the lek, a female leaves to build a nest and raise the young without assistance from the male. Still other species build no nest at all, but are brood parasites (some cowbirds, Icteridae; whydahs, Ploceidae); the female lays her eggs in the nests of other (usually smaller) species, and the young are raised entirely by the foster parents.

Nesting. Nest sites are varied: they include holes in the ground, trees, banks, and rock crevices; on ledges; on the surface of the ground; within the larger nests of other species (including nonpasserines) or near wasp nests (presumably for the protection the wasps afford); and in a wide variety of vegetation—grasses, shrubs, and trees.

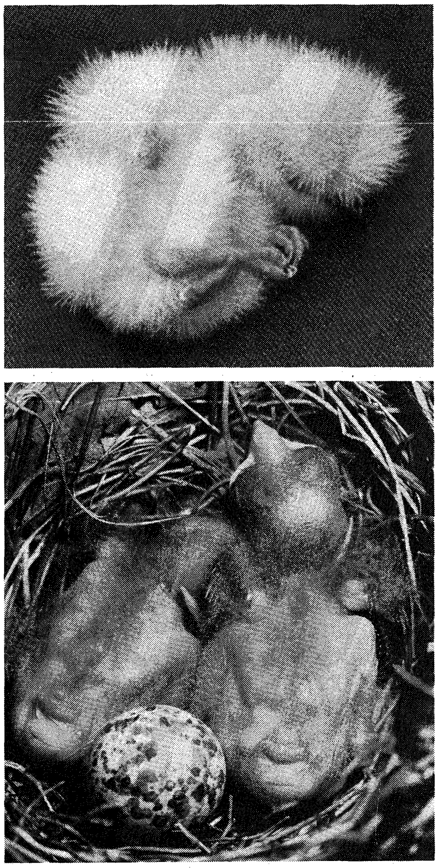
Nest materials

Passerine nests are usually elaborately constructed and may contain many different kinds of materials: mud, grasses, hair and feathers, strips of bark, plant fibres and downs, rootlets, twigs and sticks, leaves, string, spider webs, cast snake skins, lichens, and many other substances. Most species build open nests, usually cup-shaped. Others form domed or ball-shaped closed nests, with an entrance at the side (occasionally at the top or bottom). One of the most famous closed nests is that of the South American ovenbirds of the genus *Furnarius* (Furnariidae), whose name derives from its thick-walled mud "oven" nest, often built on top of a fence post or some other exposed site. The North American ovenbird, *Seiurus aurocapillus* (a wood warbler, Parulidae), also builds a domed oven-shaped nest, but of plant materials on the forest floor. Some species, especially members of the Icteridae, make soft hanging nests that range to two feet or more in length. The thorn birds (*Phacellodomus*), as well as many other Furnariidae, build huge nests of twigs suspended from the ends of tree branches; these nests, which may be more than two metres (nearly seven feet) long and contain many compartments, are used by only a single nesting pair, sometimes with nonbreeding helpers (probably the young of the previous season). These nests are often appropriated by troupials (*Icterus icterus*), which evict the owners, even destroying the eggs and young in the process. a few other species also take over nests for their own use, notably the piratic flycatcher (*Legatus leucophaius,* a tyrannid) and the bay-winged cowbird (*Molothrus badius*).

Woven nests

Nests of many passerines are constructed with amazing skill. The tailorbirds of Asia (*Orthotomus*) are noted for nests built in a pocket that the birds make by sewing together the edges of one or more leaves, using plant fibres or other materials. Some species, especially the weavers, are able to tie knots with strips of grass or palm leaves and thus weave an exceptionally tight and compact nest. Others build equally firm nests by felting the materials together. In contrast, a few passerines build flimsy nests (some Cotingidae), apparently as an adaptation toward lessened visibility to predators, for such nests are attended minimally by the parents, seemingly to draw as little attention to the site as possible. Other birds excavate their nests in soft earthen banks, use old woodpecker holes, or find natural crevices in trees or rocks. The type of nest built by the members of a single family may be varied (extremely so in the Furnariidae) or consistent: all woodcreepers nest in holes; all vireos weave a cup between the arms of a forked branch.

(Top) David W. Snow, (bottom) Root Resources—EB Inc.



Two main types of passerine young.
(Top) Downy young of the South American bare-throated bellbird (*Procnias nudicollis*). (Bottom) Naked young of the North American cardinal (*Cardinalis cardinalis*).

Incubation and parental care. Passerines lay clutches of one to 14 eggs, clutch size being unrelated to the size of the bird. The largest species, the two lyrebirds (*Menura*), lay a single egg; some of the smaller titmice (*Parus*) have been recorded with the biggest clutches. In most passerines the female incubates the eggs alone, but in some groups—such as the antbirds (Formicariidae), certain grosbeaks (*Pheucticus*), and others—the male shares equally in incubation. Males of most species help to feed the young. some passerines have only one nest per breeding season, but others may have two or more, especially if one nest is destroyed before the young fledge. The incubation period generally varies from 11 to 21 days depending on the species but is well over a month in lyrebirds. The hatchlings are typically blind, sparsely covered with down, and helpless; some species hatch completely naked, and a very few are densely covered with down at hatching (some cotingas, antbirds of the genus *Formicarius,* and some Campephagidae). The young remain in the nest for eight to 30 or 35 days (about 42 in the lyrebirds) but most commonly from 10 to 15 days. After they fledge, they require some days or weeks to become fully independent of their parents.

Variety of vocalizations among passerines

Sound production. An outstanding aspect of passerine behaviour is the ability to sing. Song is best developed in the oscines, which have a highly complex vocal organ or syrinx, but even the more primitive suboscines are capable of a variety of vocal sounds. The woodcreepers (Dendrocolaptidae), ovenbirds (Furnariidae), and antbirds (Formicariidae) sing relatively simple songs, consisting of a few notes or whistles, often repeated rapidly in a trill, roll, or rattle. Manakins (Pipridae) also utter simple trills or whistles: in addition, some species are capable of a loud nonvocal snapping sound, which is produced by specialized wing feathers. The cotingas sing a wider variety of songs, from quiet musical notes to the incredibly loud and far-carrying "gongs" of the bellbirds (*Procnias*). The New World flycatchers are well known for their range of distinctive call notes, and many species sing well and melodiously. In some groups (notably the *Empidonax* complex), the plumages of closely related species are so similar that the birds can be distinguished in the field only by their calls and songs. Both the lyrebirds and scrubbirds (Atrichornithidae) have syrinxes more like those of oscines and are known for their loud and complicated songs. They are also accomplished mimics; lyrebirds mimic the songs of almost all birds within their hearing, as well as many mechanical sounds. Many species of oscines have complicated and beautiful songs, notable examples being the nightingales (*Luscinia*) and some other thrushes, larks (Alaudidae), mimic thrushes (Mimidae), and wrens (Troglodytidae). The possession of the complex oscine syrinx does not guarantee a complex song, however, and many "songbirds," such as waxwings (*Bombycilla*) and swallows, utter simpler sounds than do many suboscines.

Only the male of most passerine species sings a true song, although the female can produce a variety of call notes and other sounds. In some species in which the female sings, she seldom does so during the breeding season unless it is a duet with her mate. Such duetting or antiphonal singing of paired birds is so well developed in certain species that it is difficult to determine that the song is coming from two individuals. In the African black-and-red shrike (*Laniarius barbarus erythrogaster*) the reaction time between the male's start of song and the female's response has been timed at 0.135 second.

Active versus passive anting

Interactions with ants. *Anting.* A characteristic but poorly understood behaviour pattern of passerines is the practice of anting. This peculiar ritual has two forms: active anting, in which a bird picks up worker ants in its bill and wipes them on its feathers in a stereotyped manner, and passive anting, in which the bird squats or lies down in a group of ants and assumes an exposing stance so that the ants will crawl up into its feathers. Birds may also apply ants to their plumage while passively anting, but species that use the active stance (the majority of recorded passerines) apparently never use the passive stance. Birds show definite discrimination in the type of ants used, avoiding stinging species and selecting those that exude or spray formic acid or other defense fluids (ants of the subfamilies Formicinae and Dolichoderinae of the family Formicidae). A great deal of controversy has existed over the function of anting. Some authorities have theorized that it is a form of self-stimulation, but British ornithologist K.E.L. Simmons has argued convincingly that it is a type of feather maintenance. Formic acid and other ant fluids are known to be insecticidal; dressing the feathers with ants would thus kill or deter avian parasites, such as lice and mites. Additional components of ant fluids include essential oils, which could be used by birds to supplement the oils from their own uropygial (preen) gland. After a bout of anting, birds often continue feather-maintenance activities by bathing, oiling (from the uropygial gland), and preening. Recent studies have shown anting to be most prevalent during molt, when the bird's skin is irritated by the growth of new feathers. Anting clearly is innate behaviour, and its remarkable uniformity in at least 30 passerine families, both oscine and suboscine, implies that it has real importance to the bird. Some individuals have been seen to ant with such things as cigarette butts, orange peels, mothballs, and smoke, apparently reacting to the pungent fumes of these objects as to the strong odours of ants. A few nonpasserines have also been observed going through motions that are similar to anting, but as yet true anting is known only in the Passeriformes.

Ant-following. Another specialized form of behaviour, also associated with ants, is the practice known as antfollowing. In the New World tropics, nomadic army ants move in huge troops, swarming over the forest floor in columns as wide as 10 metres (more than 30 feet) or more. Because the ants devour all the small animal life in their path, a moving column of them is edged by fleeing insects, spiders, millipedes, isopods, small frogs, and lizards. The ant columns are accompanied by troops of birds that seize the fugitives. Ant-following birds apparently do not eat the ants but only the insects and other small animals trying to escape. A number of passerine species, notably several antbirds, are believed to be entirely dependent on army ants for finding food. Many other birds also follow ants when they come upon them; these include woodcreepers, manakins, New World flycatchers, tanagers, wrens, and occasional ovenbirds. Even some nonpasserines may join a troop of ant-followers—motmots (Momotidae), tinamous (Tinamidae), and hawks—although the hawks may be more attracted by the ant-following birds than by the insects. The same ant-dependent species have also been known to follow large animals, including man, that stir up insects with their feet.

Association of passerines with large animals

A few passerines, although not ant followers, will escort large quadrupeds, such as cattle, buffalo, and deer, to catch the insects that fly up around them and to feed on the ticks and flies parasitizing the animals themselves; especially noted for this behaviour are the cattle tyrant (*Machetornis rixosa,* Tyrannidae) tickbirds or oxpeckers (*Buphagus,* Sturnidae), and several cowbirds. In Australia yellow robins (*Eopsaltria,* Muscicapidae) will follow the much larger lyrebirds as they scratch and feed along the ground.

A zebra covered by a large number of oxpeckers.

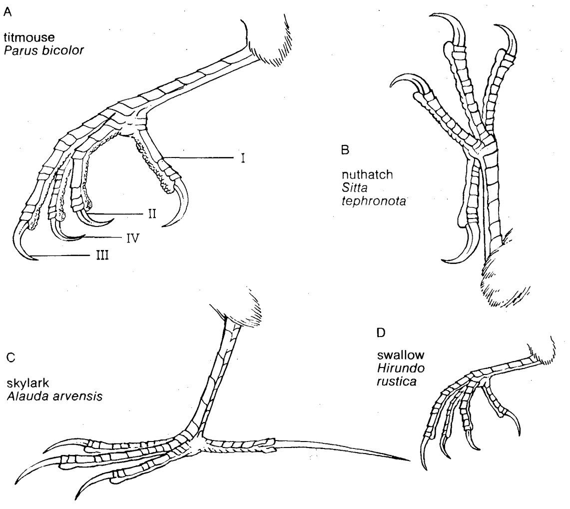

Figure 46: Modifications of the foot of perching birds, for (A) perching and clambering; (B) bark climbing; (C) ground walking; (D) perching only (weak foot). Right feet are shown.

Drawing by R. Keane

FORM AND FUNCTION

External features. *Feet and legs.* The single feature that distinguishes passerines from all similar birds is their "perching" foot. In this foot type, all four toes are well developed and free from one another; in some families (wrens and most suboscines) the front toes may be partially fused at the base, but the distal portions (extremities) are functionally free. The hind toe (hallux) is joined on the same level with the front toes and opposes them, so that the foot can grip a perch. The only exception to this passerine foot type is found in the well-named *Paradoxornis paradoxus,* or three-toed parrotbill (Panuridae), in which the outer toe is reduced to a short clawless stump, fused to the middle toe; other species of *Paradoxornis* have normal feet.

Modifications of the foot

Although all passerines can perch, not all do so habitually. A number of species (some tapaculos, Rhinocryptidae; larks; pipits, Motacillidae) are largely terrestrial and have feet modified for walking and running; the terrestrial foot is differently proportioned from the typical perching one, often with longer toes and longer, straighter claws (particularly on the hallux), probably as an aid in maintaining balance when running. The dippers, or water ouzels (*Cinclus*), are semi-aquatic, but although they successfully swim on the water surface and walk underwater searching for food on stream bottoms, they have retained the typical passerine foot. The single slight difference in the *Cinclus* foot is that the claw of the middle toe sometimes has a thin horny flap (of unknown function) on its inner border. Some other passerines, notably swallows, live a largely aerial life and have small and weak feet. The typical arboreal songbird has a well-developed foot, with the middle front toe longer than the others. Birds such as woodcreepers and nuthatches that often cling to vertical surfaces have strong, curved, sharp claws. Those that spend much of their time walking and scratching on the ground (although not limited to terrestrial activity) tend to have heavy, straighter, and rather blunt claws. Most passerines, however, have moderately curved sharp claws that are suited to grip a variety of rounded or rough surfaces.

The lower leg of passerines, the tarsometatarsus (usually called simply the tarsus), is normally covered by a horny sheath (podotheca). Exceptions include some swallows, which have feathered tarsi. Although the various different patterns of scale size and distribution of the normal unfeathered podotheca have been used by some taxonomists to differentiate families or groups of families, study has revealed so much variability in the tarsal patterns of certain families that it is no longer considered a reliable family character; it may still be useful as a generic or specific character. In most oscines the posterior (plantar) surface of the tarsus is bilaminate—*i.e.,* covered by two long plates, or laminae.

Evolutionary plasticity of the bill

Bill. The bills of passerines are extraordinarily diverse in size, shape, and proportions. This diversity was long thought to be indicative of the birds' relationships and so was used as a prime taxonomic character. It is now believed, however, that bills are evolutionarily plastic, reacting with relative ease to selective pressures, particularly to changes in feeding habits. Thus on a broad scale a passerine's bill shape reveals less about its family affinities than it does about its food preferences, and, although bill shape may be an aid to determining a bird's relationships, it must be considered in the light of other features and of the degree of variation found in the family. Two frequently cited examples of the adaptiveness of bills are the geospizine, or Darwin's finches (Fringillidae) of the Galápagos Islands, and the Hawaiian honeycreepers, Drepanididae (see EVOLUTION, THE THEORY OF). Each is a closely interrelated group of birds with different kinds of bills in the several species and genera. Those of drepanidids range from heavy, seedcracking, grosbeak-like bills through thin, pointed insectivorous types to the long, decurved (curved downward) bills of nectar feeders. These Hawaiian birds are now thought to be members of a single family of nine genera. On the basis largely of bill shape, they were once classified into four different families and 18 genera.

Most birds, including passerines, show little sexual dimorphism (difference between sexes) in bills except for minor differences in size (reflecting general body size differences) and sometimes in colour. The most outstanding exception is the extinct huia (*Heteralocha acutirostris,* Callaeidae), originally classified as two different species. The male of this New Zealand bird had a strong, chiselling bill, whereas the female had a long, decurved, pliable bill. Reportedly the two sexes fed cooperatively, the male digging in decaying wood and the female probing in crevices to extract grubs. The species unfortunately was prized by the Maoris, who used the white-tipped tail feathers in ceremonial headdresses, as well as by Europeans, and, after most of its habitat had been destroyed, the huia was hunted to extinction about the end of the 19th century.

Drawing by R. Keane

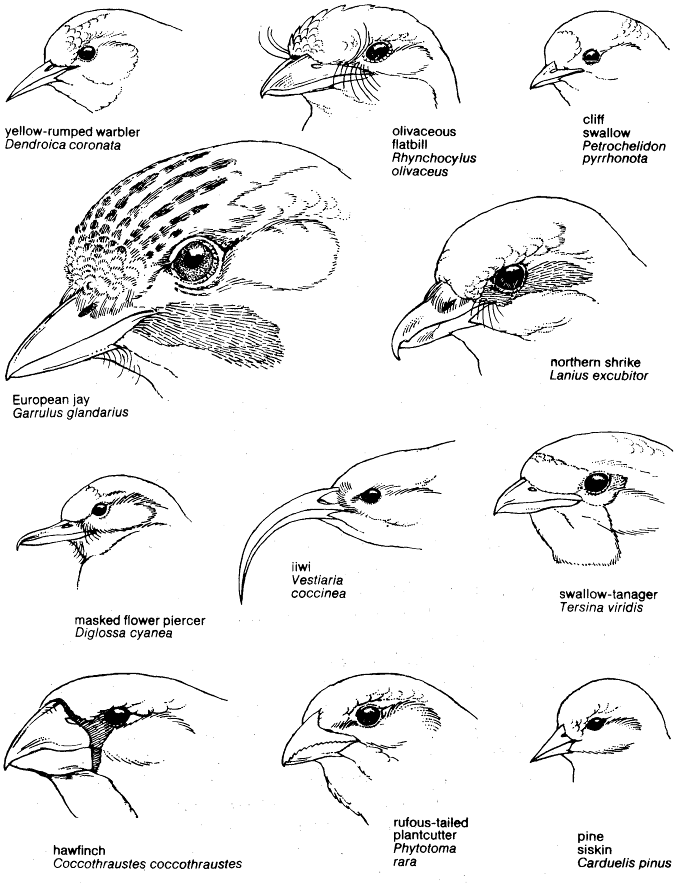

Figure 47: Types of bills found among passerine birds.

Specializations of the bill

Passerine bills may be broadly classified into eight morphological and functional types:

1. Insectivorous: a generalized type found in many passerines, ranging from relatively straight and pointed (as in the wood warblers, Parulidae), through bills with a slight or pronounced hook (some New World flycatchers), to those that are short, with a wide gape and usually surrounded by rictal bristles (stiff hairlike feathers)—*e.g.,* in aerial feeders, such as swallows. Most insectivorous bills are relatively light in build, but this depends on the type of insect usually taken by the species and also on how generalized a feeder it is.

2. Omnivorous: unspecialized in shape and function but usually strongly built, as in crows and jays (Corvidae).

3. Toothed: strongly hooked at the tip and with a "tooth" (notch) on either tomium (cutting edge) of the upper mandible; adapted to tearing up large, relatively soft prey. This is the typical bill of shrikes (Laniidae) but is also found in some unrelated birds, such as the Australian bellmagpies (Cracticidae) and some tanagers.

4. Tearing: a relatively light bill with a strong hook at the tip, for tearing open objects, such as flowers, to obtain the insects and nectar within. Found in flower piercers (*Diglossa,* Thraupidae).

5. Probing: relatively narrow and often downcurved; slender in species that probe flowers for tiny insects and nectar (sunbirds; some Hawaiian honeycreepers) but more heavily constructed in those that probe in wood or under tree bark (creepers, *Certhia;* some woodcreepers).

6. Frugivorous: variable but usually rather wide; ranges from lightly built with a wide gape for swallowing whole fruits (found in some cotingas, and in the swallow-tanager, *Tersina*) to more heavily built for tearing apart tougher fruits (some tanagers).

7. Serrated: conical, with a finely serrated edge, adapted for feeding on leaves, buds, shoots, and fruit. Found only in the plant cutters (Phytotomidae).

8. Conical: adapted for seed eating. Ranges from exceedingly stout and blunt (*e.g.,* the hawfinch, *Coccothraustes,* which can crack remarkably hard objects, such as cherry pits) to relatively small and pointed (siskins, *Carduelis*). Some forms specialized for particular kinds of seed extraction (*e.g.,* crossbills, *Loxia,* which feed on pine seeds).

Opportunistic feeding

This classification indicates morphological and functional types of bills, but it does not imply that a species with a particular type of bill will feed only on the food for which it is best adapted. Although some birds are extremely specialized in their feeding habits, most are opportunistic feeders, seizing upon whatever food is readily available and can be "handled" with the bill. Hence many basically granivorous or frugivorous birds catch insects, especially when feeding nestlings, and many insectivorous species exploit seasonally available plant food. Myrtle warblers (*Dendroica coronata*) and tree swallows (*Iridoprocne bicolor*), for example, feed on bayberries in fall and winter, and eastern kingbirds (*Tyrannus tyrannus*) and other New World flycatchers will eat a variety of fruits and berries in season.

The mandibles of passerines, like those of all other birds, are composed of bone covered with a horny sheath, the ramphotheca. The ramphotheca is worn down by normal use and, in most birds, is capable of growing to replace the lost material. In individuals with damaged bills or those (such as cage birds) that do not have the opportunity to wear down the constantly growing ramphotheca, the bills overgrow at the tip.

Plumage and pterylosis. The colours, patterns, and textures of passerine feathers are considered important taxonomic characters, especially in determining genera, species, and subspecies. Plumage is also occasionally used in a very broad way to indicate evolutionary levels. Spots, streaks, and dull colours are generally considered more primitive than bold or complicated patterns and bright colours, but there are many exceptions to this rule.

Passerines often are sexually dimorphic in their plumage, with adult males wearing brighter colours and more striking patterns than do females. In some families, notably tanagers (Thraupidae), wood warblers (Parulidae), and New World orioles (Icteridae), the temperate zone species show more sexual dimorphism than do tropical members of the same families. In addition, many species (especially those in temperate climates) are seasonally dimorphic, with a bright plumage during the breeding season and a dull one in winter. Juvenile plumages of both sexes tend to be cryptically coloured (*i.e.,* adapted for concealment), as is that of the adult female.

Colour varieties in passerines

Virtually any colour may be found in one passerine or another, and the order offers a wide array of specialized feather types, such as the waxlike tips on the flight feathers of waxwings (Bombycillidae); the tufts of stiff feathers in some honeyeaters (Meliphagidae); iridescent "spangles" in some manakins, sunbirds, and tanagers; and the almost unbelievable array of "wires," iridescent gorgets, velvety ruffs, racquet tails, and filamentous plumes of the birds of paradise.

Another taxonomically important character is the number and distribution of feathers (pterylosis) on the bodies of passerines. From external appearance all birds seem to be more or less evenly covered by feathers; in actual fact, however, most birds have their feathers growing from relatively narrow tracts (pterylae) in the skin. From the pterylae the feathers fan out and cover the remainder of the bird's body. In passerines, the feathers are arranged in eight distinguishable tracts, with apteria (relatively bare skin) between them. Variations in tract width and length and especially differences in feather number and distribution are often useful in determining relationships. Of particular interest are the occurrence of apteria within tracts and the configuration of the ventral tract. Also used in classification are the numbers of flight feathers. The remiges (flight feathers on the wings) of most passerines consist of 10 primaries on the "hand" (manus) and nine secondaries on the forearm (ulna). In all perching birds the tenth (outermost) primary is reduced to some degree, and in many families only nine may be found. The number of secondaries is more variable, with some species having as many as 14 (the satin bowerbird, *Ptilonorhynchus violaceus*). Tail feathers (rectrices) also vary; most passerines have 12, but the number ranges from six to 16.

Of importance in some species is the relative length of the primaries. This "wing formula" is often useful in distinguishing between species of such difficult groups as the New World flycatchers and the Old World warblers (Sylviidae).

Internal features. *Syrinx.* In a group of birds as vocal as the passerines, it is natural that the structure of the vocal apparatus should have evolutionary significance. Differing from the mammalian larynx in both location and structure, the syrinx consists of a resonating chamber at the lower end of the windpipe (trachea), with associated membranes, cartilages, and muscles. These modifications involve elements of the bronchi (the two tubes connecting the trachea with the lungs) as well as those of the trachea. Since the mid-19th century the basic subdivisions of the order Passeriformes have been based primarily on the structure of the syrinx. Some of the features of the syrinx long thought to be indicators of relationships have recently been shown to have little taxonomic validity. Other taxonomic characters now must be studied and evaluated before the classification can be adjusted.

Syringeal muscles are classified into two groups: extrinsic muscles, which connect the syrinx with other parts of the anatomy, and intrinsic muscles, which extend from one part of the syrinx to another. The number, shape, and attachments of the intrinsic muscles are likely to remain important in passerine classification. Those birds in which the muscles are inserted on the middle of the bronchial semi-rings (C-shaped cartilages that strengthen the bronchi) are sometimes called mesomyodian (most members of the suborder Tyranni) and those with the insertion on the ends of the semi-rings are acromyodian (Menurae, Passeres). The Eurylaimi and a few others have no intrinsic muscles. Further distinction is made in the number of pairs of intrinsic muscles, most importantly in the Passeres, which have four.

Vocal-organ specializations

The passerine syrinx exists in four basic types:

1. Unspecialized: relatively little modification of the tracheobronchial region; few, if any, cartilaginous spe-

cializations, and no intrinsic muscles; found in broadbills (Eurylaimidae), pittas (Pittidae), New Zealand wrens, asities (Philepittidae), plantcutters, most cotingas, and a few manakins and tyrant flycatchers.

2. Tracheophone: most of the specializations limited to the tracheal region; intrinsic muscles number zero to two pairs; pessulus (a bony bar lying at the junction of the bronchi) absent; found in all members of the Furnarioidea (South American ovenbirds, woodcreepers, antbirds, and tapaculos).

3. Intermediate tracheobronchial: various modifications of cartilages and membranes; one or two pairs of intrinsic muscles; pessulus present or absent; found in the sharpbill (*Oxyruncus*) and most manakins and tyrant flycatchers.

4. Oscine (acromyodean): complex musculature involving four pairs of intrinsic muscles (but three pairs in lyrebirds and scrubbirds); some cartilaginous specializations; pessulus present (except in larks).

Despite the rather extensive knowledge of the morphology of the syrinx and its importance in passerine classification, very little is known about how it functions to produce sounds. Several theories have been proposed, but none has yet been proved wholly satisfactory.

Skeleton. Of the many variations in passerine skeletal structure, only a few that are important in classification are mentioned here.

In the skull the bony palate, composed of a number of small bones, is termed aegithognathous; also found in swifts (Apodiformes), this palatal type is characterized by the shape and type of fusion of the small bones of the palate. Within this basic type the many minor variations in shape, size, and position of the component bones are useful in delimiting closely related groups of birds, especially suboscines.

Elsewhere on the head, variations in the hyoid apparatus, a complex of small bones that supports the tongue, have been used in passerine classification.

In the sternum (breastbone) the shape of the anteriormost spine (spina sternalis) and the number of notches in the posterior border are of great interest. The spina sternalis, which is short and forked in most passerines, is long and simple in the Eurylaimidae (one exception), the Philepittidae, and a few of the Cotingidae. All oscines and most suboscines have a single pair of posterior sternal notches; only the tapaculos and certain of the terrestrial antbirds (*Conopophaga, Pittasoma, Hylopezus, Myrmothera*) have two pairs. The sternum of lyrebirds differs from those of all others in the order in being very thick, long, and narrow; it may have no posterior notches at all, or it may have a single shallow pair.

From P.L. Ames in (A,B,C) *Bulletin of the Peabody Museum of Natural History*, no. 37 (1971), Yale University; (D) J.C. George and A.J. Berger, *Avian Myology* (1966), Academic Press

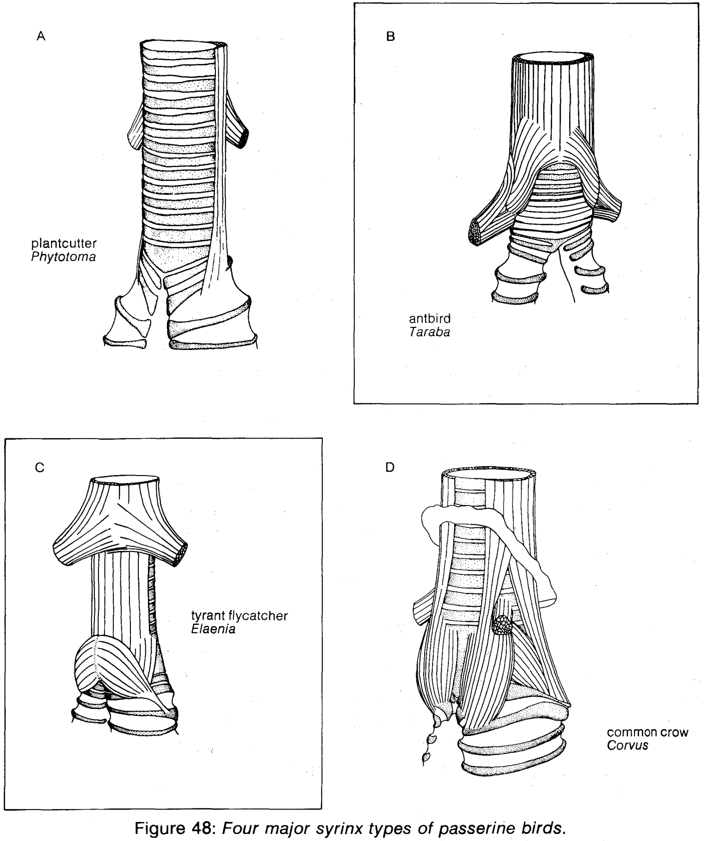

Figure 48: *Four major syrinx types of passerine birds.* Figures show lower trachea, upper bronchi, and attached muscles, seen from the ventral side. (A) unspecialized; (B) tracheophone; (C) intermediate tracheobronchial; (D) oscine.

Musculature. A number of different muscle systems have been important in passerine classification. Important examples, in addition to those of the syrinx, are the muscle complexes controlling the tongue, the jaws, the wings and pectoral girdle, and the legs and pelvic girdle. One character that has been used for over a century is the condition of the deep plantar tendons. These narrow straps extend from the bellies of the two deep flexor muscles on the leg, down the back of the tarsometatarsus, and attach to the toes. They act to close the toes (hence to grasp a perch). In the Eurylaimidae these tendons are connected by a short band (vinculum), but in all other passerines they are entirely separate. This difference has been used by some to divide the passerines into two major groups: the Desmodactyli (vinculum present) and the Eleutherodactyli (vinculum absent).

EVOLUTION AND PALEONTOLOGY

Origins of perching birds

Passerines, like other small land birds with fragile bones and arboreal habits, are rarely fossilized; hence the fossil record gives few clues to their evolution. Their origins, both in time and ancestral type, can only be guessed. Some authorities believe that passerines arose during the Early Cretaceous Era (about 120,000,000 years ago); others believe that it was much later, not until the Late Cretaceous or even Paleocene Epoch (perhaps 65,000,000 years ago).

The earliest known passerine fossils are from the upper Eocene Epoch (about 40,000,000 years ago). One of these is an extinct genus assigned to the modern family of tapaculos (Rhinocryptidae), another is thought to be related to the titmice (Paridae), and still another to the starlings (Sturnidae). *Palaeospiza,* a primitive oscine classified as a separate family (Palaeospizidae) between the larks and the swallows, is known only from the Colorado Oligocene Epoch (about 35,000,000 years ago). As drying conditions during the Miocene Epoch (26,000,000 to 7,000,000 years ago) reduced the forests and encouraged the spread of grasslands, bird families exploited the newly appearing drier and less forested habitats and radiated into them. There for the first time appear remains of crows (Corvidae), thrushes (Turdidae), wagtails (Motacillidae), shrikes (Laniidae), and wood warblers (Parulidae).

During the Pliocene Epoch (from 7,000,000 to 2,500,000 years ago) the warm, dry conditions continued, and most paleornithologists now believe that all of the living passerine families were in existence by its close. They also believe that most modern species of birds arose during the Pleistocene Epoch (about 2,500,000 to 10,000 years ago), a period of almost constant change during which there were four major advances and retreats of the glaciers. Most of the passerines in the fossil record are from the Pleistocene or Recent epochs and represent either living species or close relatives. Evolution since the retreat of the last ice sheet (about 11,000 years ago) has been mainly at the subspecies level.

With the lack of a significant fossil record, nothing is known of the type or types of birds from which passerines arose. Studies of the anatomy of modern forms have led to a general agreement that the perching birds developed from more than one ancestral type (polyphyletic origin). But until more evidence is unearthed, nothing further can be said.

CLASSIFICATION

Distinguishing taxonomic features. The classification of passerines is probably the single most vexing problem in avian taxonomy today. Few of the subgroupings (especially oscine families) have strikingly different characteristics,

Suborders Eurylaimi and Tyranni

black-and-yellow broadbill
Eurylaimus ochromalus
Eurylaimidae

straight-billed woodcreeper
Xiphorhynchus picus
Dendrocolaptidae

pale-legged ovenbird (hornero) with nest
Furnarius leucopus
Furnariidae

pearled treerunner
Margarornis squamiger
Furnariidae

black-crested antshrike
Sakesphorus canadensis
Formicariidae

rufous antpitta
Grallaria rufula
Formicariidae

purple-breasted cotinga
Cotinga cotinga
Cotingidae

saffron-crested tyrant-manakin
Neopelma chrysocephalum
Pipridae

blue-backed manakin
Chiroxiphia pareola
Pipridae

yellow-billed tit-tyrant
Anairetes flavirostris
Tyrannidae

d'Orbigny's chat-tyrant
Ochthoeca oenanthoides
Tyrannidae

rusty-backed antwren
Formicivora rufa
Formicariidae

suiriri flycatcher
Suiriri suiriri
Tyrannidae

rusty-margined flycatcher
Myiozetetes cayanensis
Tyrannidae

Thraupidae

Painting by R. Keane

the fossil record is inadequate to elucidate the complete evolutionary history of the order, and the order has undergone an explosively radiative evolution that has resulted in a large number of anatomically similar species. Classification is further complicated by the persistence of intermediate and relict forms and a high degree of convergence (similarity due to different lines' being subject to the same types of natural selection) among distantly related groups. It is therefore necessary to examine each passerine species in careful detail (including its anatomy) to be certain of its affinities. With some 5,100 species in the order, this is a monumental task, one that is by no means complete. Traditionally, passerine families have been defined on the basis of a careful (usually anatomical) study of only a few individuals; the great majority of the birds have been assigned to established families solely because they externally resemble the studied species in plumage, bill, leg, and foot characters, as well as in what is known of their life history, behaviour, geographical distribution, etc. It is unfortunate that in the early years of avian taxonomy there was a strong tendency to try to include each newly discovered species, regardless of its geographical range, in some previously defined palearctic family.

Re-evaluation of early taxonomic characters

In the mid-20th century, taxonomists began re-examining the generally accepted 19th-century groupings of birds into families. In these investigations some of the features on which earlier classifications were based have been found to be convergent or too variable to be useful in certain groups (*e.g.,* bill shape, tarsal scutellation). Consequently, passerine taxonomists have been left with a rather sparse body of morphological information upon which to base a classification. In recent years ornithologists have made a concerted effort both to augment some of the century-old work on passerine anatomy and to explore new avenues of morphology, behaviour, reproductive patterns, biochemistry, and zoogeography to help define and relate the many families of perching birds. Much of this work is still in progress and has not yet been incorporated into classification systems. Among traditional and newly studied taxonomic features are external characters—such as rictal bristles and other specialized feathers, colours and patterns of the fleshy parts of the mouth, morphology of the bill and nostrils, colour patterns of adults and young; internal anatomical characters—such as the number of cervical (neck) vertebrae, the condition of the deep plantar tendons, anterior and posterior spines and processes of the sternum, syringeal muscles, palatal and other bones of the skull, feather tracts, jaw and tongue musculature, hyoid (tongue) apparatus, aortic-arch system, pneumatic fossa (cavity) of the humerus, and types of spermatozoa; biochemical analysis of substances—such as egg white, eye lens, plasma proteins, and hemoglobins; and an array of behavioral traits—such as reproductive behaviour, nest building, methods of scratching, etc. Thus, although the current system is by no means satisfactory, improvement is in the offing, and it is hoped that in the near future modern studies will lead to a more firmly drawn passerine classification.

Annotated classification. The classification and sequence of families given here is essentially that proposed in 1971 by American ornithologist Oliver L. Austin, Jr., based on a 1960 classification by Alexander Wetmore, with certain changes (see *Critical appraisal*). Some of the traditional diagnostic characters have been omitted because they have proved unreliable or because preliminary restudy indicates that the old generalizations do not hold true.

ORDER PASSERIFORMES (perching birds, or passerines)

Land birds with a characteristic "perching" foot; 4 toes (never webbed) joined at the same level, with the 1st toe (hallux) directed backward and never reversible. Oil gland unfeathered. Wing eutaxic (no gap between the 4th and 5th secondaries), usually with 9 or 10 primaries. The young altricial—*i.e.,* hatched almost or completely naked of feathers (a few exceptions), helpless, and requiring a considerable period of parental care. Groups marked with a dagger (†) are extinct and known only from fossils.

Suborder Eurylaimi

Syrinx simple, tracheobronchial, lacking intrinsic muscles and cartilaginous specialization; pessulus present. Sternum with anterior spina sternalis long and simple (exceptions) and with one pair of notches in posterior border. Hallux weak but about as long as the other toes. Clavicles well developed. Usually 15 cervical vertebrae (all other passerines have 14). Deep plantar tendons of different type than all other passerines.

Family Eurylaimidae (broadbills). Generally brightly coloured, chunky birds, with large heads, short necks; 12.5 to 28 cm (5 to 11 in.) in length. Bill broad and flattened, covered with a crest in some; gape wide. Front toes partially joined; 10 or 11 primaries. Other characters as in subordinal definition above; 14 species, primarily in forests or cloud forests. Indo-Malaya, Africa, Philippines.

Suborder Tyranni (majority of suboscines)

Syrinx usually more complex; muscles variable; pessulus present or absent. Sternum with short spina sternalis, forked (exceptions noted below); posterior border with one or two pairs of notches. Hallux strong. Clavicles well developed.

Superfamily Furnarioidea

Syrinx complex, tracheal; pessulus absent. Pterylosis (distribution of feathers) variable. Sternum with one or two pairs of notches.

Family Dendrocolaptidae (woodcreepers). Characteristically slender arboreal birds, olive brown to rufous, usually streaked or barred; 14.5 to 37 cm (5½ to 15 in.). Strong probing bills, laterally compressed, short and straight to long and downcurved; nares holorhinal (see Furnariidae). Short legs, powerful feet; front toes partially joined at base. Tail stiff with spiny tips. Posterior border of sternum with one pair of notches. Syrinx with cartilaginous specializations and two pairs of intrinsic muscles. Pterylosis with distinctive ventral tract type. Forty-eight species, forest or brushland. Mexico through South America.

Family Furnariidae (ovenbirds). A large and extraordinarily diverse group, an excellent example of adaptive radiation. In South America, especially in the southern Brazil–Argentina–Chile region, this family has evolved to fill a broad range of ecological niches; various furnariids look and behave like wrens, thrushes, dippers, creepers, larks, wood warblers, titmice, nuthatches, and even the nonpasserine woodpeckers (Picidae) and sandpipers (Scolopacidae). If such diversity can be summarized, ovenbirds are generally small, dull brown birds, darker above and paler below; 12 to 28 cm (about 5 to 11 in.). One distinctive character is the shape of the external nares (nostrils), which are schizorhinal (slitlike) at their posterior border rather than holorhinal (rounded), as in other passerines. Front toes partially joined at base. Sternum with one pair of notches (some exceptions). Syrinx with two pairs of intrinsic muscles. Pterylosis distinctive within suboscines but of same type as many oscines. Approximately 215 species, wide variety of habitats; Mexico through South America.

Family Formicariidae (antbirds). A large and diverse family, with loose-webbed plumage, generally in browns, grays, black, and white. Overall size range 9.5 to 37 cm (less than 4 to nearly 15 in.), including several large terrestrial species with long legs but very short tails (hence a deceptively short "body length"). Bill strong, hooked to variable degrees. Front toes slightly joined at base. Sternum with one or two pairs of notches, the two pairs found in most but not all of the long-legged terrestrial species. Syrinx of two types: the first with one pair of ventrally originating intrinsic muscles (largely the arboreal species), the second with no intrinsic muscles. Pterylosis variable; dorsal tract with reduced or absent posterior element (primarily the arboreal species); several different dorsal types among the terrestrial species. Wings generally short and rounded, flight weak; about 231 species, largely in dense forests and brushland. Neotropical; Mexico to northern Argentina.

Family Rhinocryptidae (tapaculos). A small, little-known group. Plumage dull, generally in grays, browns, and black; 9 to 25.5 cm (less than 4 to more than 10 in.). Bill distinguished by a movable flap (operculum) over the nostrils. Legs, feet, and claws strong. Wings short and rounded, flight feeble. Sternum with two pairs of notches. Syrinx with one pair dorsally originating intrinsic muscles (some exceptions). Pterylosis distinctive in ventral tract (exceptions). Twenty-seven species, grasslands, scrublands, and dense forest undergrowth. Central and South America, especially Chile and Patagonia.

Superfamily Tyrannoidea

Syrinx tracheobronchial; pessulus present or absent. Pterylosis: dorsal saddle with full-length apterium (exceptions). Sternum with one pair of posterior notches.

Family Cotingidae (cotingas). An extremely diverse, probably composite family; ranges from plain-coloured flycatcher-like to bright, extravagantly adorned birds: 9 to 45.5 cm (about 4 to 18 in.). Some with extraordinary plumes and lappets (the crow-sized umbrella bird, *Cephalopterus*); others renowned for their loud voices, fleshy wattles, and white plumage (white being unusual in land birds). The family as traditionally constituted can no longer be characterized anatomically: the syrinx is of two types; the tarsal envelope is of several different kinds; the joining of the front toes is variable; the dominant artery of the thigh is either the sciatic or femoral; the spina sternalis is forked except in some bell birds (*Procnias*). Several species with powder downs, a specialized type of feather otherwise known in passerines only in the oscine wood-swallows (Artamidae); 91 species, forests. United States–Mexico border to Bolivia, Peru, and Argentina.

Family Pipridae (manakins). Most piprids are fairly uniform in external appearance; generally small (8.5 to 16 cm [3½ to 6½ in.]), rather stubby, with short wings and tail (a few long-tailed species). Most males black with patches of brilliant colour (red, yellow, blue, etc.); females are generally drab olive green. Several species, such as the broad-billed manakin (*Sapayoa aenigma*), are externally and anatomically unlike the majority of manakins and may not be properly included in this family. Bill short, rather broad at base, notched, with a slight hook at tip. Some species with specialized feathers, particularly in the wings (also true of some cotingas and tyrannids). Third toe partially fused at base to 2nd or 4th. Syrinx highly variable, as family is presently constituted; 59 species, tropical and subtropical forest. Southern Mexico to Paraguay and northern Argentina.

Family Tyrannidae (New World, or tyrant, flycatchers). Large family of generally (but not exclusively) arboreal birds with plumage in grays, browns, olive greens, some with black, white, and yellow, occasionally brighter colours. Many with erectile crowns or crests, often more colourful than the rest of the plumage; length 7.5 to 40.5 cm (3 to 16 in.). Bill extremely variable but commonly broad, somewhat flattened, and hooked at tip; nostril rounded without an operculum or narrow with membranous operculum; most species with well-developed rictal bristles (stiff hairlike feathers around the mouth). Feet weak except in the few terrestrial species; front toes variably but never strongly fused. Syrinx characterized by 1 pair of intrinsic muscles (none or 2 in some), generally variable in other features. About 367 species, with a wide range of habitats. Northern Canada and Alaska through North and South America to Tierra del Fuego, also Falkland and Galápagos Islands. (The family common name of New World flycatchers serves to distinguish it from the large oscine family of Old World flycatchers, Muscicapidae.)

Family Oxyruncidae (sharpbill). A single, rare, little-known species, sometimes placed in the Tyrannidae. Length about 17 cm (7 in.); externally very much like flycatchers, with the same basic syringeal structure. Differences include a long, straight, and sharply pointed bill, surrounded at the base with short, fine, stiff feathers (not rictal bristles). Nostril narrow, covered by a broad horny operculum. Feet strong. Locally distributed in humid forest from Costa Rica to southeastern Brazil and Paraguay.

Family Phytotomidae (plantcutters). A small family of finch-like birds, gray or brown streaked with black, with areas of rusty red; about 17 cm (7 in.) long. Bill distinctive, stout and conical with a finely serrated edge. Legs short, feet large and strong. Syrinx simple, similar to that of some Cotingidae. Pterylosis: flank margin of ventral tract oblique, contrasting with truncated margin in other New World Tyrannoidea; 3 species, open brush and cultivated regions (where it is often considered a pest). Peru to Argentina and Chile.

Family Pittidae (pittas). A relatively homogeneous family; stout-bodied, long-legged, largely terrestrial, 15 to 28 cm (6 to 11 in.); with a wide range of colours in the loose-webbed plumage: reds, greens, blues, as well as browns, black, and white. Wings short and rounded but strong; tail very short. Syrinx simple, lacking intrinsic muscles and cartilaginous modifications; pessulus absent in most species. Egg-white protein pattern differs from that of all other suboscines. Twenty-three species, Old World tropics in forests and scrublands. Africa through Malaysia, Australia, Solomon Islands.

Family Xenicidae (New Zealand wrens). Small birds, 7.5 to 10 cm (3 to 4 in.), look and act much like true wrens (Troglodytidae). Considered evolutionary relicts, 2 species are strongly arboreal, the other 2 terrestrial. One of the latter, the now-extinct Stephen Island rock wren (*Xenicus lyalli*), was markedly terrestrial and may have been flightless; if so, it would have been the only known passerine to have completely lost the ability to fly. The 3 extant species are very weak flyers, with short wings and very short tails. Legs long and slender; 3rd and 4th toes fused basally, and all toes (especially the hallux) with long claws. Forest and scrub; New Zealand.

Family Philepittidae (asities and false sunbirds). The two species of asities (*Philepitta*) are black or yellowish green, rather pitta-like, with stout bodies and long legs. The two false sunbirds (*Neodrepanis*) are very different externally, looking much like true sunbirds (Nectariniidae), with which they were long classified; small, blue, yellow, and greenish with short tails and long, slender, curved bills. All philepittids have bare skin or wattles or both around the eyes. Currently classified in the Tyranni, but the simple structure of the syrinx and the unforked spina sternalis have led some authorities to suggest they are more closely allied to the Eurylaimi. Forests of Madagascar.

Suborder Menurae

Syrinx tracheobronchial, acromyodian, with 2 or 3 pairs of muscles inserted on the ends of the bronchial semi-rings; pessulus present. Sternum with short, forked spina sternalis, 1 pair of notches or none. Hallux strong. Clavicles not well developed.

Family Menuridae (lyrebirds). Among the largest members of the order in length, 75 to more than 100 cm (30 to 40 in.), with some weighing over 1,100 grams (about 2½ pounds), lyrebirds are aberrant passerines in virtually all features. In size, brownish plumage, and terrestrial habits, they look much like pheasants. The tail of 16 feathers is extraordinary: in males of *Menura superba* the outermost pair of feathers is curved like a lyre, the next 6 pairs are light and filamentous, and the innermost pair is modified into narrow "wires"; the tail of *M. alberti* is shorter and simpler; females of both species have rather long but not extremely modified tails. The alula (free digit on the leading edge of the wing) on the short rounded wings has 6 feathers rather than the usual 3 or 4. Rictal bristles present. Legs and feet strong and heavy. Sternum long, narrow, and thick, unique within passerines; posterior border may be entire or with 1 pair of shallow notches. Syrinx of the oscine type, but with only 3 pairs of intrinsic muscles; it is capable of a remarkable variety of loud ringing calls and the birds are famous for their vocal mimicry. Two species, dense forests; Tasmania (introduced) and eastern Australia.

Family Atrichornithidae (scrubbirds). Wholly unlike lyrebirds in external appearance, rather like large wrens, long-tailed, brownish, and terrestrial; 16.5 to 23 cm (6½ to 9 in.). One species, *Atrichornis clamosus,* long thought to be extinct but recently rediscovered. Both species virtually flightless, with very small wings and clavicles small and separated (not fused into a furcula, "wishbone"), a condition unique within passerines. Sternum unlike *Menura,* with 1 pair of deep posterior notches. Legs and feet very strong. Rictal bristles lacking. Similar to lyrebirds in the quality of their strong voices, nesting habits, and basic syringeal structure. Scrubbirds, however, have only 2 pairs of intrinsic muscles in the syrinx. Two species, scrublands; in western and eastern Australia.

Suborder Passeres (songbirds, or oscines)

Syrinx with 4 pairs of intrinsic muscles. Sternum with spina sternalis short and forked, and posterior border with 1 pair of notches. Hallux variable in strength. Clavicles well developed. All with same complex of syringeal muscles, with only minor variations.

Family Alaudidae (larks). A distinctive and well-defined group, the only oscines with back of tarsus rounded and scaled instead of sharp and unsegmented. Syrinx also unique among Passeres in lacking the usual bony pessulus. Small ground birds, 12 to 23 cm (about 5 to 9 in.), usually cryptically coloured in browns and grayish buffs, plain or streaked, lighter below (several species black below); sexes similar. Bill usually pointed, slightly downcurved; wings long, pointed; legs rather long, hind toe usually with long, straight claw. About 75 species inhabit open fields, plains, beaches of Old World, with only one species, the horned lark (*Eremophila alpestris*), also in North America south to Colombia. Many species migratory. Food: seeds, insects, and other invertebrates. Sing beautifully, often a soaring flight song.

†*Family Palaeospizidae (Palaeospiza).* A single fossil species known only from Oligocene of Colorado.

Family Hirundinidae (swallows, martins). A distinctive family placed low on the oscine family tree because of primitive syringeal characters, particularly the double bronchial rings, unique in Passeres. Small birds, 9.5 to 23 cm (about 4 to 9 in.), with compact plumage, often with metallic sheen, usually lighter below; sexes usually alike or nearly so. Wings long, pointed, primaries reduced to 9. Tail medium to long, truncate to forked. Legs short, feet small, weak. Bill short, flat, but wide gape enhanced by rictal bristles. Walk with difficulty but fly strongly, feed on insects caught in flight. Voice usually a twittering or squealing, sometimes melodious. The river martins of Africa and Thailand differ by large, brightly coloured bills, stronger feet, and syringeal characters. The 79 living species are found worldwide except polar regions and certain oceanic islands; all or nearly all migratory.

Family Dicruridae (drongos). Small to medium-sized birds, 18 to 63.5 cm (7 to 25 in.), the longest being those with exceptionally long tails; usually black with purple or greenish sheen, some crested or with spangled neck and head feathers, iris of eye usually red; sexes alike. Bill stout, arched, slightly hooked and notched; long, strong rictal bristles; legs short, feet stout. Wings long; tail variable, of 10 or 12 feathers, usually forked; some species with racquet tails. Arboreal birds that fly well but seldom long or far. Food mostly insects caught on the wing. Voice varied, melodious; capable mimics. The 20 species range through Africa, southern Asia, Malaysia, northern Australia, east to Solomons, in woodlands, savannas, cultivated regions.

Family Oriolidae (forest orioles, fig-birds). Medium-sized birds, 18 to 30.5 cm (7 to 12 in.); brightly coloured, predominantly in yellows, greens, and black; sexes unlike, female duller, young streaked below. Bill strong, pointed, slightly hooked; long, pointed wings with 10 primaries; medium to long tail of 12 feathers. Strictly arboreal birds that feed on insects, fruit; 28 species in forest and open woodland across Eurasia, in Africa, East Indies, Australia, Philippines. Flight strong, undulating. Voices loud, with harsh calls, but melodious songs. For New World orioles, see below Family Icteridae.

Family Corvidae (crows, jays, ravens, rooks, choughs, nutcrackers, and magpies). Medium to large passerines, including the heaviest oscines, the ravens (*Corvus*); 17.5 to 70 cm (7 to 28 in.). Ten primaries, the 10th (outer) always much shorter than 9th, but longer than primary coverts. Bill strong, powerful, longer than rest of head or nearly so; nostrils usually covered with bristles. Crows (*Corvus*) and allies, large, black or black and gray or white; wings long, tail shorter than wing. Jays generally smaller, often coloured in blues, greens, yellows; wings rounded; tail sometimes two-thirds of total length. About 102 species, almost cosmopolitan (absent from southernmost South America, Antarctica, some oceanic islands, introduced to New Zealand); varied habitats, prefer woodlands, open brushlands. Voices harsh, loud.

Family Callaeidae (wattlebirds). Medium-sized, 25.5 to 53.5 cm (10 to 21 in.); black, brown, or blue-gray, with fleshy blue or orange wattles at the gape; sexes may differ in size, wattles, and bill shape. Weak fliers but hop strongly. Sternum weak; 10-primaried wings short, rounded; tail long. Bill stout and short to long and curved; legs long, feet stout. Eat fruit, nectar, insects. A variety of musical notes and whistles. Three species limited to primeval forests of New Zealand; huia (*Heteralocha*) extinct; wattlebird (*Callaeas*) and saddleback (*Creadion*) rare.

Family Grallinidae (mudnest builders). Ten-primaried oscines of medium size, 19 to 50 cm (7½ to 20 in.). Differ from most corvids in lacking nasal bristles. Legs long, strong; wings long and pointed to short and rounded. Black and white or dark gray; sexes alike or unlike. Four species limited to Australia, western New Guinea, in woodlands, marshes, cultivated lands, usually near water. Weak fliers with peculiar jumping gait; all build deep, open-bowl nests of mud, stiffened with hair, feathers, grass. Eat insects, snails, seeds, soft fruit. Melodious whistles, harsh and plaintive notes.

Family Cracticidae (bell-magpies). Ten species of medium to large oscines, 25 to 58 cm (10 to 23 in.). Most black, white, and gray; some have brown phase; sexes alike or unlike. Large, heavy bill, slightly to strongly hooked; nostrils bare. Wings long, pointed; legs strong, medium to long. Australia, New Guinea, and nearby islands; gregarious inhabitants of brushy plains, open forests, mangrove shores, cleared lands. Eat insects, small animals, some fruit and seeds. Fine singers with ringing, gonglike calls.

Family Ptilonorhynchidae (bowerbirds). Ten-primaried oscines of medium size, 23 to 37 cm (about 9 to 15 in.); sexes alike in a few, but males usually much brighter coloured, often with nuchal (neck) crest but never with plumes or facial wattles. Stout bill, straight to slightly curved; wings rounded; legs and feet stout, hind toe shorter than middle toe. Seventeen species, in forests of New Guinea and northern Australia. Solitary, largely terrestrial birds; eat berries, seeds, fruits, insects, small animals. Males of most species build elaborate stages or bowers for display and courtship. Loud ringing calls, good mimics.

Family Paradisaeidae (birds of paradise). Small to medium-sized, 10-primaried, 14 to 117 cm (about 5½ to 46 in.), greatest length due to streaming tail feathers; greatly varied colours, most males with spectacular plumes on head, flanks, wings, or tail; some with wattles or bare skin on the head; females plain browns or grays. Bill slender to rather heavy, hooked or sickle-shaped in some. Wings rounded; legs short; feet rather stout. About 40 species, New Guinea, northern and eastern Australia, Moluccas, and adjacent islands. Solitary forest birds, rather weak fliers; males of most species have elaborate courtship displays. Eat fruit, seeds, insects, small animals. Prolonged whistles, loud shrill calls.

Family Paridae (titmice and chickadees). Ten-primaried oscines with short to medium, rounded wings; tail short to long; bill rather stout, pointed, shorter than remainder of head; nonoperculate nostrils concealed by thick feathers. Small birds, 7.5 to 20 cm (3 to 8 in.), with thick plumage usually strongly patterned in grays, yellows, brown, black, or white, never streaked, barred, or spotted; sexes usually alike. About 64 species in forests and brushlands of the Philippines, Malaysia, Eurasia, Africa, and North America to Guatemala. Active, gregarious little birds; feed on insects, seeds. Chattering notes, whistled calls.

Family Certhiidae (creepers). Small, slender, climbing birds, 9.5 to 19 cm (3½ to 7½ in.), with curved bills as long as or longer than rest of head; operculate nostrils free of bristles or feathers; rictal bristles absent. Legs short, thin, outer toe always shorter than middle toe but much longer than inner toe; claws long, hind claw as long as or longer than hind toe; wings rounded or pointed; tail feathers long, stiff, with pointed tips. Brownish above, streaked with black or light brown, white below; sexes alike. Six species (with the inclusion of the African spotted creeper, *Salpornis,* a controversial point) in temperate woodlands of Eurasia, Africa, North America, south to Nicaragua. Solitary birds, spiral up tree trunks from base probing bark for insects; two species inhabit rocky cliffs. Soft calls, sweet but weak songs.

Family Sittidae (nuthatches). Small, stocky, climbing birds, 9.5 to 19 cm (3½ to 7½ in.), with thin, pointed, usually straight bills; rounded, nonoperculate nostrils partly concealed by feathers; short rictal bristles present; tarsus short; long, laterally compressed claws on large toes, hallux equal to outer toe, inner toe reaching only to second joint of middle toe; wings rather long, pointed; tail short, square, soft. Typically gray to blue above, white or brownish below; sexes alike or nearly so. About 22 species; typical nuthatches (*Sitta*) distributed across North America and Eurasia to Malaysia and the Philippines, aberrant forms in Philippines, Australo-Papuan region. Typically in forests, a few in rocky areas. Forage on tree trunks and large branches for insects, eat some seeds and small fruits. Simple call notes and songs.

Family Climacteridae (Australian treecreepers). Six species of small, creeper-like climbing birds, 12.5 to 17.5 cm (5 to 7 in.); of uncertain ancestry and affinities. Legs short; toes long, claws long, curved, strong, especially that of hallux; tail rounded, soft; bill long, somewhat downcurved. Grayish brown to black above, streaked below, often a lighter eye stripe and wing bar; sexes similar but with slight recognizable differences. Forests of Australia and New Guinea; rather solitary, sedentary birds; feed by spiralling up tree trunks, some forage for insects on ground. Voice high-pitched whistles.

Family Panuridae (bearded tits, parrotbills). Small, titmouse-like birds, 10 to 17.5 cm (4 to 7 in.), distinguished (with one exception, the bearded tit, *Panurus biarmicus*) from all other oscines by the strongly compressed bill, much shorter than head, markedly curved convexly, both tomia (cutting edges) sinuated; nostrils concealed by feathers; wings short, rounded; tail rather long, graduated. Plumage soft, fluffy, plain brownish above, lighter below; sexes alike or nearly so. About 19 species in brushy grasslands, scrublands, and thickets of temperate Eurasia; active, gregarious, travel in small flocks searching for seeds, insects, berries. Low twittering call notes.

Family Chamaeidae (wrentit). Small bird about 16.5 cm (6½ in.) long, with thick fluffy plumage; plain brown above, lighter and streaked below. Bill short, rounded, pointed, slightly downcurved; nostrils exposed, operculate; rictal bristles distinct; wings short, rounded; tail long, graduated; sexes alike. The single species ranges in brushlands and forest edges from Oregon to northern Baja California; usually in pairs. Eats insects, small berries. Voice: a loud whistle on one pitch. Often classified in the Timaliidae.

Family Timaliidae (babblers). A poorly defined, diverse group of more than 250 species, with uncertain affinities and lineage. Small to medium-large, 9 to more than 40 cm (3½ to 16 in.). Plumage soft, fluffy; bill highly varied, small and weak to long, straight, downcurved, often hooked. Wings short, rounded, fit close to body; legs rather large, strong. Mostly dull coloured, a few brightly coloured; sexes alike and unlike. In woodlands, scrub, and brushlands of eastern and central Eurasia, Africa, Madagascar, Philippines, Malaysia, and Australia; solitary or gregarious, usually arboreal, some terrestrial; all insectivorous, some also eat fruit, berries. Many species with noisy, harsh calls, musical songs.

Family Campephagidae (cuckoo-shrikes and minivets). About 70 species of small- to medium-sized, forest-living birds, 12.5 to 35.5 cm (5 to 14 in.). Africa, India to Japan, East Indies, Australia. Rather stout, slightly downcurved bill, notched, hooked at tip; nostrils partly concealed by short bristles; wings medium, pointed; long tail rounded or graduated; legs short, feet weak to strong. Feathers of back and rump usually with heavy shafts, thickly matted and loosely attached. Cuckoo-shrikes plain gray, black, or whitish birds, often with barred underparts; minivets brightly coloured in reds, yellows. Sexes often completely dissimilar. Eat insects, berries, small fruits. Noisy birds, with whistles and harsh calls.

Family Pycnonotidae (bulbuls). Medium-sized birds, 14 to 28 cm (5½ to 11 in.), with soft, fluffy plumage, especially soft on lower back and rump; many species with hairlike, vaneless feathers on nape of neck. Bill usually slender, slightly downcurved; rictal bristles well developed; feet and legs rather small; wings short; tail medium to long. Usually drably coloured in gray, brown, greenish, some with yellow, white, or red patches on head and under tail; sexes alike. About 119 species in Africa and across southern Asia to Japan, Philippines, Moluccas, Borneo; in woodlands, brushlands, cultivated regions. Eat berries, fruit, some insects. Noisy, some good singers, mimics.

†*Family Palaeoscinidae (Palaeoscinis).* A fossil species known only from the Miocene of California.

Family Irenidae (leafbirds, ioras, fairy bluebirds). Small to medium birds, 13 to 25 cm (5 to 10 in.); bill fairly long, slightly downcurved or hooked; legs short; wings rounded; tail square to rounded. Like bulbuls, some have hairlike feathers on nape and long fluffy rump feathers but are more brightly coloured, brown or black with contrasting yellow, green, or blue; sexes usually dissimilar. About 14 species in forests and cultivated lands from India to Philippines, south to Borneo, Java, Sumatra. Eat fruit, berries, buds, some insects. Good singers, musical whistles and fluty notes.

Family Cinclidae (dippers). The only largely aquatic oscines; small, 14 to 19 cm (5½ to 7½ in.), birds with plump bodies, short concave wings, short, square or rounded tail. Tarsi and toes long and stout. Bill slender, straight, pointed; nostrils with broad operculum; rictal bristles absent. Dense compact plumage plain gray, brown, or black, some with white patches on throat, breast, head; sexes alike. Four species, found along swift, rocky streams in Eurasia, North Africa, and North and South America, south to Argentina. Food: insects, aquatic larvae, and other organisms gleaned from stream bottoms. Have shrill penetrating whistled calls and chattering songs.

Family Troglodytidae (wrens). Small, 9.5 to 22 cm (3½ to 8½ in.), chunky birds, mostly brown, usually barred, spotted, or streaked, with white, black, or browns; sexes alike. Bill slender, medium to long, often downcurved; nostrils with operculum; rictal bristles usually indistinct but sometimes obvious with 1 or 2 well developed. Stout legs and feet, front toes partly joined at base. Wings short, rounded, well-developed 10th (outermost) primary, at least half as long as 9th; tail short, square to rounded, often carried cocked up. The 59 species range through most of North and South America; 1 also found in Eurasia and North Africa; inhabit brushlands, forests, forest edges, rocky slopes, deserts, grassy marshes. Most forage on or near ground in undergrowth for insects, worms, other invertebrates. Highly developed song, musical, variety of bubbling, flutelike to growling notes, harsh chattering calls; some species duet.

Family Mimidae (mockingbirds, catbirds, thrashers). Slender, medium-sized, 20 to about 30 cm (8 to 12 in.); bill medium to long, nearly straight to strongly downcurved; nostrils always exposed, with overhanging membrane; rictal bristles present, but few and somewhat weak. Legs rather long, feet strong, middle toe joined at base to outer toe but not to inner toe. Wings short, rounded; tail long. Coloured brown, gray, black, bluish, underparts usually pale, often white, spotted, or streaked, some solidly coloured, some with white in wings or tail; sexes alike. Exclusively New World, the 31 species range from southern Canada, the West Indies, Galápagos, to southern Argentina and Chile. Eat fruit, seeds, insects. Famous as fine singers and mimics.

Family Turdidae (thrushes, bluebirds, nightingales, wheatears, robins, chats). A large, almost cosmopolitan group of about 305 species of small- to medium-sized birds, 11.5 to 33 cm (4½ to 13 in.). Bill rather slender; legs and feet fairly stout, tarsus usually booted (smooth sheath, not divided into scales); 10-primaried wing rounded to pointed; tail medium, truncate or graduated, forked in a few. Colours brown, blue, gray, often blended, or in bold black, white, yellow, or red patterns; sexes alike or unlike; young usually spotted below. Virtually worldwide; absent originally only from New Zealand (now introduced there), some oceanic islands, Antarctica, and parts of the Arctic. Usually arboreal, many terrestrial, in varied habitats—forests, deserts, brushlands, grasslands, cultivated fields. Eat mostly fruit, insects, also seeds, leaves, worms, and mollusks. Most are fine singers.

Family Sylviidae (Old World warblers, kinglets). Typically small, 9 to 26 cm (3½ to 10 in.), with slender bill; longitudinal nostrils with an operculum; medium rounded wings of 10 primaries; short to medium legs. Plumage usually browns, grays, olive greens with little pattern; some streaked or barred; some brightly, boldly marked; sexes alike or similar, young never spotted below. Nearly 300 species, worldwide except in polar regions, South America, some oceanic islands, mostly in woodlands, some in brushlands, marshes. Food essentially insects; voices pleasant, varied, well-developed song in some.

Family Polioptilidae (gnatcatchers, gnatwrens). Dainty, slender, tiny, 10 to 14 cm (4 to 5½ in.), with long, thin, pointed bills, operculate nostrils partly exposed, and rictal bristles. Rounded wing with 10th primary much less than half as long as 9th; long, rounded tail constantly moving. Blue-gray or brown above, lighter below, most with white in outer tail feathers, some with black markings on head; sexes alike or nearly so. The 11 species are active arboreal birds of open forests and semi-arid deserts from southern Canada to Argentina. Food essentially small insects. Rather weak songs of trills and warbles, simple short call notes.

Family Pachycephalidae (whistlers, shrike-thrushes, thickheads). Small- to medium-sized, stout-bodied, 13 to 28 cm (5 to 11 in.); roundish heads, rather heavy bill sometimes hooked at the tip. Wings rather long, pointed, with very short 10th primary; tail medium long, usually rounded. A few species crested or with wattles or bare patches at base of bill. Most are greenish gray to brown above, lighter below, many with yellow or dull red markings; sexes alike, a few unlike; many juvenile plumages spotted or like that of female. About 42 species in Australo-Papuan region, Malaya, Philippines, Oceania; in forests, brushlands, mangroves, savannas. Diet predominantly insects with some fruit. Melodious fluty calls, pairs often duet.

Family Maluridae (wren-warblers, emu-wrens). Small-bodied birds, 7.5 to 25 cm (3 to 10 in.), that carry the long tail cocked up over the back. Bill small, weak; wings short, rounded; legs and feet medium. Emu-wrens (*Stipiturus*) have rectrices reduced to 6 loose-barbed shafts. Most species are brightly patterned in contrasting browns, reds, shiny blues, black, and white; sexes alike or unlike. About 83 species in Australo-Papuan region, including New Zealand; in forests, scrublands, heaths. Food largely insects and other invertebrates. Many are good singers, mimics.

Family Muscicapidae (Old World flycatchers). A large (about 340 species) family of small insectivores, 7.5 to 22.5 cm (3 to 9 in.); the paradise flycatchers (*Terpsiphone*) with long tails, to 53.5 cm (21 in.). Typically with flat, broad bills, well-developed rictal bristles; short, weak legs and feet. Wings short and rounded to long and pointed; tail short and narrow to long and fanned or with long central plumes. Varied colours, many plain browns, grays, some with bright blues, reds, and black and white; some crested or with facial wattles; sexes alike and unlike, young usually spotted. Eurasia from tree line south through Africa, Australia, and in Pacific Islands to Hawaii; forests, scrublands, cultivated and riverine areas. Voices usually weak, monotonous, but well-developed, song in a few.

Family Prunellidae (accentors, hedge sparrows). Small, drab, 12.5 to 17.5 cm (5 to 7 in.); slender, pointed bills, wide at base, culmen (ridge of upper bill) slightly rounded. Tarsus rather short, feet strong. Wings rounded to pointed with very short 10th primary; tail shorter than wing, square or emarginate. Colour browns or grays, usually streaked or spotted; sexes similar. Twelve species across Eurasia and northern Africa; various habitats, parks and gardens, brushlands, barren mountain slopes below snow line. Feed on or near ground on insects, berries, seeds. Thin chattering, twittering songs, metallic calls, often in flight.

Family Motacillidae (pipits, wagtails). Small, slender-bodied ground birds, 12.5 to 23 cm (5 to 9 in.). Pipits similar to larks in appearance but differ in having a bilaminate tarsus and pointed wing with 9 primaries. Wagtails have longer tails, brighter colours. Bill thin, pointed; legs long, slim, with elongated hind toe and hind claw (with some exceptions); tail usually edged with white or yellow. Plumage brown, streaked, mottled, sexes similar (pipits); or marked in bold black, white, or yellow patterns, sexes unalike (wagtails). About 53 species, worldwide except polar regions and some oceanic islands; in open grasslands, deserts, shores, cultivated areas. Feed on insects, spiders, mollusks, some vegetable matter. Simple repetitive song often given in flight, and short, sharp call notes.

Family Bombycillidae (waxwings). Small, arboreal, soft-plumaged, crested, 15.5 to 19 cm (6 to 7½ in.); distinguished by waxy red "droplets" at tips of secondary wing feathers of most individuals. Bill short, swollen, slightly hooked; nostrils almost concealed by feathers, rictal bristles absent. Long, pointed wing with rudimentary 10th primary; square to slightly rounded, short tail. Velevety plumage blended with browns, grays, and yellow; tail tipped with yellow or red; sexes alike. Three species in temperate Northern Hemisphere, in evergreen or birch forests. Eat berries, fruit, buds, flowers, insects. Weak chattering song, soft lisping calls.

Family Ptilogonatidae (silky flycatchers). Small, arboreal, crested, 18 to 24.5 cm (7 to 9½ in.). bill short, broad, deeply cleft; nostrils exposed, bordered by membrane, rictal bristles present. Wings and legs rather short; 10th primary well developed; tail long. Soft silky plumage of solid grays, black, brown, white spots in wings and tail, some with yellow markings. Four species, found from southwestern U.S. to Panama; in brush country, desert scrub, open forest. Rather shy, active birds that feed on berries and on insects caught in flight. Weak warbling song.

Family Dulidae (palm chat). Medium-sized, about 19 cm (7½ in.); deep laterally compressed bill, strongly curved culmen, circular nostrils wholly exposed. Wings rounded, 10th primary less than half as long as 9th; tail longish; legs and toes stout. Plumage stiff and harsh, olive brown above, yellowish-white streaked with brown below; sexes alike. The single species limited to cultivated areas and open woodlands of Hispaniola and Gonave Island, West Indies. Lives on fruits and flowers. Noisy, gregarious birds with harsh chattering notes.

Family Hypocoliidae (hypocolius). Medium-sized, 17.5 cm (7 in.); short, broad bill, moderately curved culmen, operculate nostrils; nasal bristles lacking and rictal bristles poorly developed. Tarsus rather short, heavily scutellated (scaled). Soft plumage blue-gray above, lighter below, with black facial, wing, and tail markings, white wing tips, slightly crested; sexes alike. The single species inhabits semi-arid scrublands, palm groves, gardens in Tigris-Euphrates valley of Iraq, wanders to Afghanistan, western India, Arabia, Red Sea coast. Fruit eater with low calls and weak song.

Family Artamidae (wood-swallows or swallow-shrikes). Chunky-bodied, medium-sized, 15 to 21 cm (6 to 8½ in.); unique among oscines in having powder downs. Bill stout; broad at base, moderately long, decurved, pointed; legs short; feet strong. Wings long, pointed; tail short, nearly square. Plumage compact, soft, in plain solid browns, grays, or black above, usually lighter below; sexes similar. Ten species in open lands, forest clearings, Australia east to Fiji Islands, north to Philippines, Indochina, India. Live on insects caught in flight. Voice a harsh nasal twittering.

Family Vangidae (vanga shrikes). Small- to medium-sized, 12.5 to 32.5 (5 to 13 in.), 10-primaried, arboreal oscines of varied aspect; some resemble flycatchers, thrushes, nuthatches, or typical shrikes. Bill stout, heavy, hooked, notched; with enlarged ridge in one, thin, downcurved in another; legs and feet strong; wings fairly long, rounded; tail square or rounded, moderately long. Plumage rather soft, loose, typically black or blue above, white below, some with brown or gray patches; sexes alike or unlike. Thirteen species, restricted to forests, scrublands, mangrove swamps, of Madagascar. Eat insects, small reptiles, amphibians. Chattering calls, harsh notes, shrill whistles.

Family Laniidae (shrikes). Rather small- to medium-sized, 15 to 36 cm (6 to 14 in.); 10-primaried, with proportionately large heads; stout, strong, sometimes toothed, sharply hooked bills; strong legs with sharp claws; tarsus scutellate anteriorly, lamellate (plated) laterally; wings medium; tail usually long, narrow. Plumage soft, black, gray, or brown above, usually paler below in true shrikes; yellows, reds, greens in some African bush shrikes; sexes alike or unlike. Essentially Old World, 64 species across temperate Eurasia, Africa, east to Philippines, and south to New Guinea and Timor; 2 species in North America to southern Mexico; usually solitary birds, in open forests, clearings, brushlands, cultivated areas. Food large insects, small vertebrates; some impale prey on thorns for storage and to tear apart. Voices varied, some with well-developed song, several species sing antiphonally.

Family Prionopidae (helmet shrikes). Medium-sized, 19 to 25.5 cm (7½ to 10 in.); distinguished from preceding family by their fully scutellate tarsus and stiff forehead feathers projecting forward, almost concealing the nostrils; most with conspicuous wattles surrounding the eyes. Bill stout, hooked; legs short, strong; wings and tail medium to long. Plumage black above, white or buffy below in bold patterns; sexes similar. Nine species, in brushlands, scrub, and forests of Africa, south of the Sahara. Gregarious arboreal birds that hunt in small flocks for insects. Harsh chattering notes, nasal humming sounds, snap bills audibly.

Family Sturnidae (starlings, mynas, oxpeckers). Stocky, medium-sized, 16.5 to 42 cm (6½ to 16½ in.); very short but visible 10th primary. Bill pointed, straight, or slightly arched, swollen near the tip in oxpeckers (*Buphagus*); tongue flat, not tubular (as in some relatives). Legs and feet stout, strong, tarsus with unbroken plates behind. Typically dark coloured with metallic sheen, some brown or gray with white, yellow, or red markings, some with facial wattles, a few crested; sexes alike or unlike. About 107 living, 4 recently extinct species in all types of wooded and agricultural lands; temperate Eurasia through Africa, northern Australia, East Indies, east to Tuamotu Archipelago; a few introduced widely elsewhere (*e.g.*, North America). Almost omnivorous; wide range of vegetable and animal foods. Garrulous, varied notes, calls, whistles, some excellent mimics.

Family Meliphagidae (honeyeaters). Small- to medium-sized, 10 to 40 cm (4 to 16 in.); long, protractile, brush-tipped tongue curled at the sides to form a tube. Bill slender, pointed, downcurved, upper cutting edge serrated; nostrils unfeathered, with leathery operculum. Wings long, pointed, 10th primary about half the length of 9th; tail medium to long. Legs short to medium, tarsus scaled anteriorly. Drab browns, yellows, grays, or bold patterns of black, red, white; sexes alike or unlike. About 168 living, 4 recently extinct species, from Australia and New Zealand through the Papuan region, north to Marianas, east to Hawaii, 2 species in southern Africa. Habitat forests, brushlands, cultivated lands. Food chiefly nectar, insects, some fruit. Voices loud, varied; musical song in many.

Family Nectariniidae (sunbirds, spider hunters). Small, 9 to 22 cm (3½ to 8½ in.). Long, slender, downcurved, pointed bill, finely serrated near tip; tongue not brush-tipped but partly tubular, projectile, divided at tip; nostrils rounded, open, operculate; no rictal or nasal bristles. Wings rounded, short, 10th primary variable in length but always present; tail square, medium to long, pointed, sometimes with elongated central feathers. Legs short, stout, tarsus with anterior transverse scales; hallux and claws short. Many sunbirds with vivid colours, metallic sheens, and bright patches in male; females much duller; other sunbirds and spider hunters dully coloured in both sexes. About 116 species, in forests, scrub country, mangroves; Asia and Africa south of Sahara, east to central China, Philippines, Solomons, south through Malaya to northern Australia. Active arboreal birds, sunbirds are Old World counterparts of New World hummingbirds but not as skilled fliers. Feed on nectar, insects, some small fruit. Weak call notes, faint songs.

Family Dicaeidae (flower-peckers, pardalotes, diamond birds). Small chunky birds, 7.5 to 18 cm (3 to 7 in.), with short necks, legs, tails. Bill usually short, stout, relatively straight; slender and curved in a few, edges of distal (outer) 3rd serrated; distal half of short tongue deeply cleft, the edges curled into 2 slender semitubular tips. Wings rather long, 10th primary usually vestigial, absent in a few. Bright-coloured males dark, glossy (rarely metallic) above, lighter below, often with red or yellow patches on crown, rump, breast; females usually much duller; some species dull-coloured in both sexes. About 58 species in forests, scrublands; India to southern China, Philippines, east through Solomons, and south to Australia. Active arboreal birds, feed around flowers on nectar, small insects, berries (particularly mistletoe). Sharp metallic twittering calls, a few have warbling song.

Family Zosteropidae (white-eyes). Relatively uniform group of little birds, 10 to 15 cm (4 to 6 in.) long, yellowish or reddish-brown to olive green above, lighter below, typically with a conspicuous white eye-ring; sexes alike. Bill short, slender, pointed, slightly decurved; tongue brush-tipped; rictal and nasal bristles absent. Wings short, rounded, 10th primary usually lacking; tail medium, square; legs and claws short, feet strong. About 90 species in forests, brush country, mangroves; Africa south of Sahara, across southern Asia to Korea, Japan, south to Australia, New Zealand, east to Carolines, Samoa. Travel in restless flocks, feed on nectar, insects, fruit. Weak voices, pleasant twittering, warbling songs.

Family Cyclarhidae (pepper-shrikes). Rather heavily built, medium-sized, 14.5 to 17.5 cm (5½ to 7 in.), with large heads; stout, strongly hooked, laterally compressed bills; nostrils rounded, exposed; rictal bristles present but weak. Wings short, rounded, 10th primary half length of 9th; tail medium; legs and feet strong. Loose-webbed plumage olive green above, yellow to buffy-white or gray below, rufous stripe over eye; sexes similar. One species southern Mexico to Guianas, Uruguay, northern Argentina; a second in Colombia and Ecuador; open forest, brushland. Weak fliers, travel singly or in pairs, moving deliberately through foliage. Eat large insects, fruit. Repetitive warbling song, harsh scolding calls.

Family Vireolaniidae (shrike-vireos). Small, poorly known; 14.5 to 18.5 cm (5½ to 7 in.). Rather stout, hooked bill; nostrils oval, exposed; rictal bristles inconspicuous. Wings short, rounded, 10th primary reduced to half length of 9th; tail short to medium; legs short, stout. Plumage silky, loose-webbed, greenish above, yellowish to white below, head marked with yellow, gray, blue, black, or white; sexes similar. Three species; in rain-forest treetops from southern Mexico to central Brazil. Food fruits, insects. Loud repetitive whistled song.

Family Vireonidae (vireos, greenlets). Rather plainly coloured, small arboreal birds, 10 to 17.5 cm (4 to 7 in.), mostly brownish-gray to olive green above, yellow, grayish, or white below; plumage never streaked or spotted; some with light eye-rings, eye stripes, wing bars; sexes alike. Bill fairly heavy, slightly hooked and notched; nostrils ovate, operculate, partly exposed; rictal bristles inconspicuous; legs short, strong. Wings long, pointed to short, rounded, 10th primary very short or vestigial. About 37 species in all types of woodlands from central Canada to Uruguay and Argentina. Usually solitary inhabitants of forest edges; seek insects on leaves and branches, eat some berries, fruit. Compulsive singers; songs of repeated, often melodious, phrases; harsh scolding notes.

Family Drepanididae (Hawaiian honeycreepers). Small forest birds, 11.5 to 22 cm (4½ to 8½ in.), limited to the Hawaiian Islands; 14 species living, 10 of them rare and local; 8 species are recently extinct. Bill extremely varied among species: short to long, thin to thick, straight to extremely downcurved, pointed to hooked, but never serrate or notched. Wings pointed, 10th primary vestigial or absent; tail medium, truncate or slightly forked; legs short to medium; feet strong. Plumage plain brown, olive green, yellow, red, gray, or black, never metallic or glossy; sexes unlike or similar with female smaller. Found solitary or in small flocks. Feed on nectar, insects, seeds, fruit. Warbling songs, clear calls.

Family Parulidae (wood warblers, bananaquits). Dainty, small, 10 to 18.5 cm (4 to 7½ in.); pointed wings of 9 primaries, medium 12-feathered tail. Bill usually slender, pointed, culmen slightly downcurved, flattened with pronounced rictal bristles in a few but never notched or hooked; tongue moderately slender, tip variably bifid (divided) or fimbriate (fringed). Legs medium, hind claw never elongated. Colours varied but never metallic or glossy; grays and olive browns dominant ground colours, often brightly patterned with yellows, reds, blue, black, or white; sexes alike or unlike. About 119 species in forests and brushlands from tree line of North America to southern South America. Active, arboreal (a few terrestrial); feed mostly on insects, occasional fruits, berries, seeds, 1 group (bananaquits) sip nectar. Voices typically weak, thin, high-pitched; a few with loud and well-developed songs.

Family Zeledoniidae (wrenthrush). The single species is small, 11.5 cm (4½ in.), with 9 primaries. Bill weak and flattened vertically; legs long, feet large, strong; wings and tail short, rounded. Plumage soft, olive brown above, slate gray below, crown black-bordered orange; sexes are alike. Resident in humid cloud forests of Costa Rican and western Panamanian highlands. Shy, retiring birds with weak, fluttery flight, seldom fly more than 20 m (65 feet), preferring to creep and hop on forest floor. Food consists mainly of insects. Voice thin, high-pitched, repetitive whistles.

Family Icteridae (orioles, troupials, oropendolas, caciques, blackbirds, grackles, cowbirds, meadowlarks). A heterogeneous group, medium to large, 16 to 54 cm (about 6 to 21 in.). Straight, pointed, unnotched, conical bill, with culmen extending more or less onto forehead; operculate nostrils, never concealed; rictal bristles lacking. Wings mostly long, pointed; tail short to rather long; legs and feet strong. Plumage often solid black with metallic gloss, or multicoloured in bold patterns of black and red, orange, yellow, brown; sexes usually differ, female smaller. About 88 species, throughout Western Hemisphere (except polar regions), in a wide variety of habitats. Many species gregarious; some colonial or semicolonial nesters. Eat a wide range of animal and vegetable foods. Usually loud-voiced, with harsh, whistling, or bubbling calls; well-developed song in some.

Family Tersinidae (swallow-tanager). Single tanager-like species, 15 cm (6 in.), differing from Thraupidae mainly in peculiar palate, expandable throat, and broad, flat, swallowlike bill; longer wings, shorter legs. Male shining turquoise with black throat, face, sides barred black, white below; female green with grayish-white barring. Lowland and mountain forests; Panama, Trinidad, south into Argentina. Somewhat gregarious; strong fliers; feed on insects, fruit. Voice monotonous chirps, almost no song.

Family Thraupidae (tanagers, euphonias, honeycreepers, and diglossas). Small to medium, compactly built, 9 primaries; 8 to 30 cm (about 3 to 12 in.), most under 20 cm. Bill with commissure (meeting of edges) not abruptly angled or bent at the base; mandibular tomium not distinctly angled (never toothed) near the base. Bill usually conical, short to medium, generally notched, toothed, or hooked at tip; rictal bristles present. Nectar-feeding species with specialized bill and brush-tipped tongue. Wings pointed, short to long; tail short to medium, truncate, emarginate, or rounded. Generally brightly coloured, in contrasting patterns of black, white, yellow, red, blue, green, brown; sexes alike or unlike. About 223 species in forests, brushlands; temperate North America to Brazil, Argentina. Arboreal birds; flight strong but not sustained in non-migratory species. Eat berries, fruit, insects, nectar. Voices varied, song well developed in a few but usually short calls and warblings.

Family Catamblyrhynchidae (plush-capped finch). Finchlike, 9 primaries, 15 cm (6 in.), with stubby, conical, slightly hooked bill and a distinctive patch of short, stiff, velvety tipped, orange-yellow feathers on the forecrown. Wings short, rounded; tail medium; legs stout, feet strong. Male bluish-gray above, chestnut below, nape and sides of head black; female similar but duller. Mountain forests of Colombia, Venezuela south to Peru, Bolivia. A little-known species of uncertain relationships and systematic position.

Family Fringillidae (New World seedeaters). Small, 9 primaries; 10 to 27 cm (4 to 11 in.), with short, stout, conical, pointed bills. Commissure distinctly angled or deflexed at the base, mandibular tomium elevated, often toothed, gonys (midline ridge of lower bill) more than half length of upper bill; rictal bristles usually obvious. Wings short, rounded to long, pointed; tail short to long, tarsus relatively long. Colours and patterns varied; sexes alike or unlike. About 315 species almost cosmopolitan (absent from Oceania, East Indies, Madagascar, Antarctica; introduced in Australia, New Zealand) in all terrestrial habitats. Gregarious or solitary, terrestrial or arboreal birds; food mainly seeds, some other vegetable matter, insects. Call a simple chirp, often well-developed song; flight song rare. Family includes buntings, juncos, towhees, grosbeaks, cardinals, longspurs, Darwin's finches, chaffinch, yellow hammer, most sparrows.

Family Carduelidae (goldfinches, siskins, rosefinches, redpolls, crossbills, bullfinches, hawfinches, canaries). Small to medium-sized, 10 to 25 cm (4 to 10 in.), with short, stout to slender pointed bills (mandibles crossed in one genus); gonys less than half length of upper bill. Wings somewhat rounded, medium length, 10th primary present but less than half length of 9th; tarsus relatively short. Colours variable but browns, reds, and yellows predominate; some streaked or mottled, some plain patterns; sexes alike or unlike. About 112 species in woodlands, brushlands, worldwide except Pacific Islands; introduced in Australia. Gregarious birds with strong, undulating flight. Eat seeds, buds, berries, some insects. Highly developed songs, sing in flight.

Family Estrildidae (waxbills, some finches). Small, 7.5 to 15 cm (3 to 6 in.), bill stout, short, pointed; gonys less than half the length of upper bill. Wings rounded, short to pointed, medium length; 10th primary present but almost vestigial; tarsus relatively short. Great variety of bright and somber colours and patterns; sexes alike or unlike. About 107 species; forest edges, clearings, grasslands, and marshes of Africa, southern Asia, East Indies, Australia, some South Pacific islands. Highly gregarious, active, ground feeders. Food: seeds, some berries, insects. Song poorly developed, weak chirps, chatterings, buzzes.

Family Ploceidae (weaverfinches). Small, stoutly built seedeaters, mostly 10 to 25 cm (4 to 10 in.), a few long-tailed species to 50 cm (males only). Short, stout, conical, pointed bills; gonys less than half length of upper bill; rictal bristles lacking; tarsus relatively short. Wings short to long, rounded to pointed, 10th primary present, much reduced; tail short to very long. Colours, patterns widely varied; sexes alike or unalike. About 156 species in all terrestrial habitats, mainly in Africa, also in Eurasia, Madagascar, Malaysia; a few (*e.g.,* the house sparrow, *Passer domesticus*) widely introduced elsewhere. Usually gregarious; food mainly seeds, some other vegetable matter, insects. Harsh, monotonous voices, song poorly developed.

Critical appraisal. The classification of the Passeriformes is currently in a state of flux. Of the several major works on the order since 1950, no two have agreed on the sequence of families, and each author has proposed innovations of his own. Ornithologists who are principally concerned with arranging museum displays, preparing national lists, or studying avian biology in the field may regard any change in classification as an unnecessary and unmitigated nuisance, and a few such workers have tried to prevent further change by having avian taxonomy formally "standardized." An attempt to do so at the XIVth International Ornithological Congress in 1966 failed in part because taxonomists opposed it vigorously and in part because its proponents could not agree on which of the several passerine sequences currently in use should be adopted.

Difficulties in preparing a lineal sequence

A main difficulty with any lineal sequence is the impossibility of making it reflect evolution's three-dimensional development, and it will be many years before enough

Parulidae (wood warblers)	Icteridae	Sturnidae	Estrildidae
Zeledoniidae (wrenthrush)	Tersinidae	Oriolidae	Fringillidae
Icteridae (New World orioles and allies)	Thraupidae	Dicruridae	Vireonidae
Tersinidae (swallow-tanager)	Catamblyrhynchidae	Callaeidae	Drepanididae
Thraupidae (tanagers)	Fringillidae	Grallinidae	Parulidae
Catamblyrhynchidae (plush-capped finch)		Artamidae	Emberizidae
Fringillidae (New World seedeaters)		Cracticidae	Icteridae
Carduelidae (goldfinches and allies)		Ptilonorhynchidae	
Estrildidae (waxbills)		Paradisaeidae	
Ploceidae (weaverfinches)		Corvidae	

evidence is in to satisfy all taxonomists. Most taxonomists place adjacent in the linear order those groups that they believe to be most closely related, but if three groups are believed to be equally interrelated, no linear sequence can express the relationship. The simplest solution for those who want a rigid, nonvarying sequence is to list all families alphabetically, and under each the genera and species alphabetically in turn. Even this system, which of course gives no indication of relationships, is not foolproof, for all scientific names are subject to change through the laws of priority as well as by inevitable changes in various taxa as more is learned about them. Hence it seems far better to retain the systems currently in use, leaving them fluid enough to be changed when changes are shown justifiable.

Since the late 19th century, when the many advances in taxonomic thought of the previous century began to crystallize and bear fruit, three main passerine sequences have dominated the world bird lists. The first, proposed originally by R.B. Sharpe of the British Museum in 1877, but based in part on the published and unpublished work of others, places the crows at the summit of avian evolution (hence at the end of a modern lineal sequence), ostensibly (although never so stated directly) on the basis of their alleged high intelligence. This sequence was adopted by the German ornithologist Ernst Hartert in his monumental *Die Vögel der paläarktischen Fauna,* published in 1903, and subsequently by most other European ornithologists.

The second sequence, placing the thrushes at the end, was in general usage, particularly in North America, until the late 1920s.

The third sequence, originally proposed in 1926 by two Americans, Alexander Wetmore and Waldron De-Witt Miller, but also based partly on the earlier work of others, places the crows, actually a rather generalized group, near the base of the oscine family tree, and in top place puts the so-called nine-primaried oscines, dominated by the seed-eating fringillids, because, as Wetmore explained in a 1960 paper (*A Classification for the Birds of the World*),

> this group is the modern expression of a main core or stem that through the earlier Tertiary periods has given rise to more specialized assemblages . . . . Further specialization is apparent in some parts of the existing fringilline assemblage that, if undisturbed, may lead to further differentiation.

This sequence immediately became standard for North American works and has remained so for these and certain international lists ever since, with only minor departures and rearrangements.

Within the suboscines, research is beginning to suggest that the three Old World families long included within the suborder Tyranni should be removed, leaving that suborder purely New World in distribution. It has been suggested that the asities (Philepittidae) may be more closely related to the broadbills, with which they share some features of the syrinx and sternum, than to the New World tyrannoid groups. The relationships of the asities, pittas, and New Zealand wrens will remain uncertain until further study can provide a better understanding of their biology and anatomy.

Nearly all recent classifications have grouped the eight to 10 families of New World suboscines in a suborder, Tyranni, based on syringeal features studied by the 19th-century anatomist A.H. Garrod. An American ornithologist, P.L. Ames, following a re-examination of the syringeal anatomy, suggested in 1965 that one superfamily of the suborder, Furnarioidea (the antbird-ovenbird group), should not be united to the other, Tyrannoidea (tyrant flycatchers and allies), on the basis of the syrinx but should be elevated to subordinal rank, a view supported by features of the pterylosis and sternal and cranial osteology. This suggestion, made initially in 1907 by a British anatomist, W.P. Pycraft, but without supportive evidence, was taken up in a classification by R.W. Storer in 1971 (see the Table).

As more suboscines are studied in detail, some genera may be found to have been misclassified; particularly vulnerable are certain forms in the woodcreeper–ovenbird (Dendrocolaptidae–Furnariidae), antbird–tapaculo (Formicariidae–Rhinocryptidae), and cotinga–manakin–flycatcher (Cotingidae–Pipridae–Tyrannidae) complexes. A group of small South American ground birds known as gnateaters and antpipits was separated from the antbirds in 1882 as a family, Conopophagidae, and generally recognized for nearly 90 years. Careful study in 1968, however, revealed that the family was an artificial one; one genus (*Conopophaga*) has been returned to the Formicariidae, the other (*Corythopis*) placed in the Tyrannidae. Recent studies of egg-white proteins by American biologist C.G. Sibley and colleagues suggest that the palm chat (*Dulus*) may be closer to the weaverfinches than to the waxwings; that the Cape sugarbird (*Promerops*) may be a starling rather than a honeyeater; and that the phainopepla (*Phainopepla*) may be most closely related to the solitaires (*Myadestes*), which are currently placed in the thrush family. A number of widely accepted oscine families invite similar examination. Only additional study will solve these problems and (it is hoped) provide a better understanding of the position of aberrant genera, such as *Rupicola* and *Menura.*

Within the oscines, one of the greatest problems is a satisfactory delineation and arrangement of the many superficially similar groups. Most taxonomists agree that the oscines contain three large groups (see the Table): (1) the crows, Old World orioles, birds of paradise, and allies; (2) the thrushes, babblers, Old World flycatchers, Old World warblers, kinglets, and allies; and (3) the finches, icterids, tanagers, and allies. Authorities disagree on how to subdivide these groups into "manageable" sections, precisely where to draw the lines between some families, and even whether to assign them familial or lesser taxonomic rank. Other groups, currently assigned family rank, are still of moot affinities and defy all efforts to place them in a linear sequence completely acceptable to everyone; among these are the larks, swallows, titmice, wrens, dippers, mimid thrushes, honey eaters, waxwings, and the palm chat.

As present-day students are delving more deeply into and reassessing the anatomical evidence on which most passerine families were erected a century ago, they are finding that much oscine classification was based originally on a few basic characters, weighted too strongly by the opinions of individual taxonomists. Bringing to bear such existing new lines of evidence as ethology, serology, parasitology, and protein analysis is helping to clear some of the long unchallenged beliefs that have clouded the main issues. It is hoped that these developments will encourage taxonomists to abandon some of their tenacious opinions—*e.g.,* that the crows represent the apex of passerine evolution. They should then be able to draw familial lines at the point at which the evidence indicates they should be, regardless of the relative size of each group.

(M.H.C./O.L.A.)

BIBLIOGRAPHY

General works. A.J. MARSHALL (ed.), *Biology and Comparative Physiology of Birds,* 2 vol. (1960–61), and D.S. FARNER and J.R. KING (eds.), *Avian Biology,* vol. 1–2 (1971–72; vol. 3–4, in prep.), two of the most thorough works on avian biology to date in English; A. LANDSBOROUGH THOMSON (ed.), *A New Dictionary of Birds* (1964), definitions and authoritative accounts of a wide variety of topics related to birds; R.T. PETERSON *et al., The Birds* (1963), a well-illustrated, popular account of birds and their biology; E. STRESEMANN, "Aves," in the *Handbuch der Zoologie,* 8 vol. (1927–34), a classic general work (in German); J. VAN TYNE and A.J. BERGER, *Fundamentals of Ornithology* (1959), an advanced, college-level text, especially noteworthy for its accounts of avian families; J.C. WELTY, *The Life of Birds* (1962), a college-level text crammed with general information on birds; H.F. WITHERBY *et al., The Handbook of British Birds,* 5 vol. (1938–41), a concise summary of knowledge of British birds; R.S. PALMER (ed.), *Handbook of North American Birds,* 3 vol. (1962–76) a compendium of information on North American loons, grebes, petrels, pelecaniforms, ciconiiforms, and flamingos (vol. 1) and waterfowl (vol. 2–3).

Fossil record and evolution: P. BRODKORB, "Catalogue of Fossil Birds," pt. 1–4, *Bull. Florida State Mus.,* 7:179–293 (1963), 8:195–335 (1964), 11:99–220 (1967), 15:163–266 (1971), a world list of fossil birds through the Piciformes; A. WETMORE, "A Check-List of the Fossil and Prehistoric Birds of North America and the West Indies," *Smithsonian Misc. Collns.,* vol. 131, no. 5 (1956), an account of North American fossil birds not included in the parts of Brodkorb's catalogue published up to the early 1970s; G.R. DE BEER, *Archaeopteryx lithographica* (1954), the most thorough account of this important fossil;

O.C. MARSH, *Odontornithes* (1880), the best available figures and descriptions of *Hesperornis* and *Ichthyornis;* K.C. PARKES, "Speculations on the Origin of Feathers," *Living Bird,* 5:77–113 (1966), arguments favouring evolution of feathers for flight rather than thermoregulation.

Taxonomic works: E. MAYR and D. AMADON, "A Classification of Recent Birds," *Amer. Mus. Novit.,* no. 1496 (1951), and A. WETMORE, "A Classification for the Birds of the World," *Smithsonian Misc. Collns.,* vol. 139, no. 11 (1960), two differing arrangements of the orders and families of birds.

Tinamiformes. PIERCE BRODKORB, "Catalogue of Fossil Birds," *Bull. Fla. St. Mus. Biol. Sci.,* 7:179–293 (1963), a checklist of fossil birds, stating that ratites and carinates could have arisen from a tinamou-like stock; DOUGLAS A. LANCASTER, "Biology of the Brushland Tinamou, *Nothoprocta cinerascens,*" *Bull. Am. Mus. Nat. Hist.,* 127:271–314 (1964), a study of species that inhabit the lowlands east of the Andes in northern Argentine, living in thorn woods—one of the few comprehensive life histories of the tinamous; W. BEEBE, "The Variegated Tinamou, *Crypturus variegatus variegatus* (Gmeln)," *Zoologica,* 6:195–227 (1925); KENNETH C. PARKES and G.A. CLARK, JR., "An Additional Character Linking Ratites and Tinamous, and an Interpretation of Their Monophyly," *Condor,* 68:459–471 (1966), showing that ratites and tinamous share a conformation of the rhamphotheca not found in other birds; A.K. and O.P. PEARSON, "Natural History and Breeding Behaviour of the Tinamou *Nothoprocta Ornata,*" *Auk,* 72:113–127 (1955), life history of a tinamou that lives in grass-covered hills of southern Peru at considerable heights in the Andes; H. SICK, "Tinamou," in A. LANDSBOROUGH THOMSON (ed.), *A New Dictionary of Birds* (1964), a survey of the principal characteristics of the whole group and EMMETT R. BLAKE, *Manual of Neotropical Birds,* vol. 1 (1977), with description, measurements, and distribution of the species.

Casuariiformes. D. FLEAY, "Nesting of the Emu," *Emu,* 35: 202–210 (1936), presents observations of this species in captivity. D.W. GAUKROGER, "The Emu at Home," *Emu,* 25:53–57 (1925), describes the nesting habits in the wild. A.L. RAND and E.T. GILLIARD, *Handbook of New Guinea Birds* (1967), is a summary of the biology and classification of cassowaries; and D.L. SERVENTY and H.M. WHITTELL, *Birds of Western Australia,* 4th ed. (1967), a summary of emu habits and statistics of kills. H.L. WHITE, "Notes on the Cassowary (*Casuarius australis* Wall)," *Emu* 12:172–178 (1913), presents field observations on habits and nesting in Queensland, with illustrations.

Podicipediformes. R.S. PALMER (ed.), *Handbook of North American Birds,* vol. 1 (1962), provides an up-to-date summary of information on North American species; K.E.L. SIMMONS, "Studies on Great Crested Grebes," *Avicult. Mag.,* 61:3–13, 93–102, 131–146, 181–201, 235–253, 294–316 (1955), is a classic study of grebe behaviour; R.W. STORER, "The Behavior of the Horned Grebe in Spring," *Condor,* 71:180–205 (1969), contains comparative material on several species, and "The Patterns of Downy Grebes," *Condor,* 69:469–478 (1967), is concerned with the colour patterns of grebe chicks. The same author's "Courtship and Mating Behavior and the Phylogeny of the Grebes," *Proc. 13th Int. Orn. Congr.,* pp. 562–569 (1963), and "Evolution in the Diving Birds," *Proc. 12th Int. Orn. Congr.,* pp. 694–707 (1960), provide insight into the evolution and classification of grebes.

Procellariiformes. Among the general works of value W.B. ALEXANDER, *Birds of the Ocean,* 3rd ed. (1955), remains a standard identification handbook; A.C. BENT, *Life Histories of North American Petrels and Pelicans and Their Allies* (1922); R.A. FALLA *et al., Birds of New Zealand* (1966), deals with some 56 tubinare species; J. FISHER and R.M. LOCKLEY, *Sea-birds* (1954), an introduction to the natural history of the sea-birds of the North Atlantic; R.M. LOCKLEY, *The Island* (1969), includes life-histories of Manx shearwaters and storm petrels, and homing experiments; *Man Against Nature* (1970), descriptions of New Zealand tubinares and muttonbirding; R.C. MURPHY, *Oceanic Birds of South America,* 2 vol. (1936), also many original papers by this noted field worker; R.S. PALMER (ed.), *Handbook of North American Birds,* vol. 1 (1962), contains much information about the species recorded from North America; V. SERVENTY, *A Continent in Danger* (1966), a description of muttonbirding and banding of shearwaters; H.F. WITHERBY (ed.), *The Handbook of British Birds,* vol. 4 (1949), detailed characters and life histories of tubinares recorded in the British Isles.

Notable monographs include: W.B. ALEXANDER *et al.,* "The Families and Genera of the Petrels and Their Names," *Ibis,* 107:401–405 (1965), a taxonomical reorganization of the order Procellariiformes; P.E. DAVIS, "The Breeding of the Storm Petrel," *Br. Birds,* 50:85–101, 371–84 (1957), follow-up of an earlier study by Lockley; J. FISHER, *The Fulmar* (1952), a classic monograph; W.S. JAMESON, *The Wandering Albatross* (1958), a readable account of the biology of the largest albatross; R.M. LOCKLEY, *Shearwaters* (1961), an edition of a classic monograph first published in 1942; R.C. MURPHY and L.S. MOWBRAY, "New Light on the Cahow, *Pterodroma cahow,*" *Auk,* 68:226–80 (1951), rediscovery of the cahow at Bermuda; B. NELSON, *Galapagos: Islands of Birds* (1968), contains an extensive section on the waved albatross; M.K. ROWAN, "The Greater Shearwater *Puffinus gravis* at Its Breeding Grounds," *Ibis,* 94:97–121 (1952); J. WARHAM, "The Biology of the Giant Petrel *Macronectes giganteus,*" *Auk,* 79:139–60 (1962); D.B. WINGATE, "Discovery of Breeding Black-Capped Petrels on Hispaniola," *Auk,* 81:147–59 (1964).

Sphenisciformes. JOHN SPARKS and TONY SOPER, *Penguins* (1967); and BERNARD STONEHOUSE, *Penguins* (1968), are well illustrated popular books. R.C. MURPHY, *Oceanic Birds of South America,* 2 vol. (1936), is a classic work with extensive information on 10 species of penguins. J.T. EMLEN and R.L. PENNEY, "Distance Navigation in the Adélie Penguin," *Ibis,* 106:417–431 (1964), is a short technical paper concerned with long-range movements. R.L. PENNEY, "Territorial and Social Behaviour in the Adélie Penguin," the "Antarctic Research Series," vol. 12, *Antarctic Bird Studies,* pp. 83–131 (1968), reviews many studies of the behaviour of this species. JEAN PREVOST, *Écologie du Manchot empereur, Aptenodytes forsteri Gray* (1961), is a detailed study, in French, of the largest penguin species. Also of interest is L.E. RICHDALE, *Sexual Behavior in Penguins* (1951). G.G. SIMPSON, "Fossil Penguins," *Bull. Am. Mus. Nat. Hist.,* 87:1–99 (1946), is a basic work on the evolution of penguins.

Pelecaniformes. R.S. PALMER (ed.), *Handbook of North American Birds,* vol. 1 (1962), detailed accounts of the biology of all species of North American pelecaniforms; R.C. MURPHY, *Oceanic Birds of South America,* 2 vol. (1936), a classic work that includes excellent accounts of the guano birds of the Peru Current; D. LACK, *Ecological Adaptations for Breeding in Birds* (1968), an analysis that includes a useful discussion of pelecaniforms; G.F. VAN TETS, "A Comparative Study of Some Social Communication Patterns in the Pelecaniformes," *Amr. Orn. Union, Orn. Monogr. No. 2* (1965), a general discussion of behaviour and relationships of the different groups; B. NELSON, *Galapagos: Islands of Birds* (1968), readable and authoritative accounts of the ecology and behaviour of tropical pelecaniforms, especially boobies and frigatebirds; P. BRODKORB, "Catalogue of Fossil Birds: Part 1 (Archaeopterygiformes through Ardeiformes)," *Fla. St. Mus. Bull.* 7, pp. 179–293 (1963), a list of the fossil pelecaniform birds.

Anseriformes. G.L. ATKINSON-WILLES (ed.), *Wildfowl in Great Britain* (1963), a regional study of distribution and populations; K.M. BAUER and U.N. GLUTZ VON BLOTZHEIM, *Handbuch der Vögel Mitteleuropas,* vol. 2 and 3, *Anseriformes* (1968–69), much wider coverage than the name implies, the most complete source book on the biology of Holarctic waterfowl; H.J. BOYD, G.V.T. MATTHEWS, and M.A. OGILVIE (eds.), *Wildfowl,* formerly *Annual Reports of the Wildfowl Trust* (1950–73), 24 volumes, containing articles on all aspects of the biology of wildfowl; J. DELACOUR, *The Waterfowl of the World,* 4 vol. (1954–64), monographic treatment of all species with coloured plates by Peter Scott; H.J. FRITH, *Waterfowl in Australia* (1967), the only book devoted to waterfowl of the Southern Hemisphere; H.A. HOCHBAUM, *The Canvasback on a Prairie Marsh,* 2nd ed. (1959), a classic species monograph, *Travels and Traditions of Waterfowl* (1955), a review of waterfowl migration and orientation; P.A. JOHNSGARD, *Handbook of Waterfowl Behaviour* (1965), an inventory of behaviour patterns, especially social and sexual, *Waterfowl: Their Biology and Natural History* (1968), contains photographs, many coloured, of nearly every species; F.H. KORTRIGHT, *The Ducks, Geese and Swans of North America* (1942), a thorough treatment, with excellent illustrations; J.P. LINDUSKA (ed.), *Waterfowl Tomorrow* (1964), authoritative articles on all aspects of waterfowl conservation, management, and research; J.G. MILLAIS, *The Natural History of the British Surface-feeding Ducks* (1902), an early classic, still of value, *British Diving Ducks* (1913), two-volume work with much useful information; J.C. PHILLIPS, *The Natural History of the Ducks,* 4 vol. (1922–26), a classic monograph covering many aspects of waterfowl biology; P. SCOTT, *A Coloured Key to the Wildfowl of the World,* rev. ed. (1972), contains coloured plates of all species of the Anatidae, with details of distribution and aids to identification.

Ciconiiformes. R.P. ALLEN, *The Flamingos: Their Life History and Survival* (1956), a survey of the family; W.J. BOCK, "A Generic Review of the Family Ardeidae (Aves)," *Am. Mus. Novit.,* no. 1779 (1956), a discussion of the taxonomy of the herons; L.H. BROWN, *Mystery of the Flamingos* (1959), a description of the natural history of the East African species; F.A. LOWE, *The Heron* (1954), a discussion of the natural history of the European grey heron (*Ardea cinerea*); A.J. MEYERRIECKS, *Comparative Breeding Behaviour of Four Species of North American Herons* (1960), a valuable contribution to knowledge of behaviour in the group; R.S. PALMER (ed.), *Handbook of North American Birds,* vol. 1 (1962), detailed accounts of 22 species of the order; A.L. THOMSON (ed.), *A New Dictionary of Birds* (1964), short articles on individual ciconiiforms.

Falconiformes. R. AUSTING, *The World of the Red-Tailed Hawk* (1964), a photographic essay on the daily life of this common North American buteo; A.C. BENT, "Life Histories of North American Birds of Prey," *Bull. U.S. Natn. Mus.*, vol. 167, pt. 1 (1937), and vol. 170, pt. 2 (1938), a review by species of the natural history of all of the falconiforms and strigiforms (owls) found in North America; L.H. BROWN, *Eagles* (1955; shortened version, 1970), an account of the biology of these impressive birds, written for the layman, and with D. AMADON, *Hawks, Eagles and Falcons of the World* (1969), extensive information on the natural history of every species of the falconiforms; L.H. BROWN, *African Birds of Prey* (1971), an ecological study of falconiforms and strigiforms on the African continent; P.E. BROWN and G. WATERSTON, *The Return of the Osprey* (1962), a detailed account of the natural history of the osprey; J.J. and F.C. CRAIGHEAD, *Hawks, Owls and Wildlife* (1956), a detailed study of the food ecology of raptorial birds and their effect on prey populations; M.L. GROSSMAN and J. HAMLET, *Birds of Prey of the World* (1964), a heavily illustrated work dealing with both falconiforms and owls; J.J. HICKEY (ed.), *Peregrine Falcon Populations* (1969), a report of a symposium to determine the cause of the decline of the falconiform populations, especially that of the peregrine; H.K. SWANN, *Monograph of the Birds of Prey (Order Accipitres),* vol. 1 (1930), vol. 2 (1945), a classic work on the biology of the falconiforms of the world, with many fine colour plates.

Galliformes (works arranged by family). *Megapodiidae:* H.J. FRITH, *The Mallee-Fowl: The Bird That Builds An Incubator* (1962), is an extensive study of the breeding habits of *Leipoa ocellata.*

Cracidae: A.F. SKUTCH, "Habits of the Chestnut-winged Chachalaca," *Wilson Bull.*, 75:262–269 (1963), presents information on the breeding habits of *Ortalis garrula.* C. VAURIE, "Taxonomy of the Cracidae (Aves)," *Bull. Am. Mus. Nat. Hist.*, 138:133–259 (1968); and F. VUILLEUMIER, "Relationships and Evolution Within the Cracidae (Aves, Galliformes)," *Bull. Mus. Comp. Zool. Harv.*, 134:1–27 (1965), are two analyses of the taxonomic relationships within this family.

Tetraonidae: A.W. BOBACK, *Das Auerhuhn* (1952), is a short monograph on the capercaille; and A.W. BOBACK and D.W. MULLER-SCHWARZE, *Das Birkhuhn* (1968), is a study of the black grouse. G.L. GIRARD, "Life History, Habits, and Food of the Sage Grouse, *Centrocercus urophasianus* Bonaparte," *Univ. Wyo. Publs.*, 3:1–56 (1937), provides insight into the natural history of this grassland species. G. BUMP *et al., The Ruffed Grouse: Life History, Propagation, Management* (1947), is a classic study of this woodland grouse.

Phasianidae: C.W. BEEBE, *A Monograph of the Pheasants,* 4 vol. (1918–22), is a classic work on the pheasants, magnificently illustrated with colour plates. A revised, less technical edition was published in two volumes under the title *Pheasants: Their Lives and Homes* (1926) and later in one volume (1936). J.T. DELACOUR, *The Pheasants of the World* (1951), is a fully illustrated treatment of the group, leaning heavily toward aviculture. H.L. STODDARD, *The Bobwhite Quail: Its Habits, Preservation and Increase* (1931), is an important book on this game species. P. WAYRE, *A Guide to the Pheasants of the World* (1969), is an extensively illustrated work with emphasis on conservation and on breeding in captivity.

Numididae: A.R. LEE, "The Guineafowl," *Fmrs' Bull. U.S. Dep. Agric. 1391* (1924), presents information on the guinea fowl, from an avicultural standpoint.

Meleagrididae: H.S. MOSBY and C.O. HANDLEY, *The Wild Turkey in Virginia* (1943), is a broad study of the natural history of *Meleagris gallopavo.* A.W. SCHORGER, *The Wild Turkey: Its History and Domestication* (1966), is primarily a historical treatise.

Opisthocomidae: C.W. BEEBE, "A Contribution to the Ecology of the Adult Hoatzin," *Zoologica,* 1:45–66 (1909); and *Tropical Wildlife in British Guiana,* pp. 155–182 (1917), present information from the author's field observations of the hoatzin.

Gruiformes. A.C. BENT, "Life Histories of North American Marsh Birds," *Bull. U.S. Natn. Mus.* no. 135 (1926), contains long and comprehensive accounts of North American cranes and rails and the limpkin; H.F. WITHERBY *et al.* (eds.), *The Handbook of British Birds,* vol. 4 and 5 (1940–41), provides excellent accounts of European cranes, rails, and bustards, with coloured plates; R.P. ALLEN, *The Whooping Crane* (1952), is the classic monograph on this endangered species, with a brief descriptive and distributional treatment of the cranes of the world; L.H. WALKINSHAW, "The Sandhill Cranes," *Bull. Cranbrook Inst. Sci.* no. 29 (1949), contains detailed information on this species; H.E. HOWARD, *A Waterhen's Worlds* (1940), is a monograph of the common gallinule or moorhen, with emphasis on behaviour, one of the early classics in ethology; S. KEITH, C.W. BENSON, and M.P. STUART IRWIN, "The Genus *Sarothrura* (Aves, Rallidae)," *Bull. Am. Mus. Nat. Hist.*, vol. 143, art. 1 (1970), is a study of this genus of African rails, with colour plates of the birds, diagrams of vocalizations, and a general treatment of rail voices; H.T. HENDRICKSON, "A Comparative Study of the Egg White Proteins of Some Species of the Avian Order Gruiformes," *Ibis,* 3:80–91 (1969), contains an exhaustive listing of the taxonomic characters for the order.

Charadriiformes. General works include C.G. LOW, *The Literature of the Charadriiformes from 1894–1928,* 2nd rev. and enl. ed. (1931); and H. SEEBOHM, *The Geographical Distribution of the Family Charadriidae* (1888), a classical, well-illustrated monograph that includes the Scolopacidae. Form and function are treated in J. BEDARD, "Adaptive Radiation in Alcidae," *Ibis,* 111:189–198 (1969), on feeding adaptations; F.A. HARTMAN, "Locomotor Mechanisms of Birds," *Smithson. Misc. Collns.*, vol. 143, no. 1 (1961); R. MEINERTZHAGEN, "The Speed and Altitude of Bird Flight," *Ibis,* 97:81–117 (1955); and R.W. STORER, "Evolution in the Diving Birds," *Proc. XII Int. Orn. Congr.*, pp. 694–707 (1960), on locomotor adaptations; R.L. ZUSI, "Structural Adaptations of the Head and Neck in the Black Skimmer (*Rynchops nigra* Linnaeus)," *Publs. Nuttall Orn. Club,* no. 3 (1962), a technical discussion of feeding behaviour and adaptations.

Many short accounts of the natural history occur in regional books. A.C. BENT has written on the life histories of the North American diving birds, gulls and terns, and shorebirds, published in the *Bull. U.S. Natn. Mus.*, no. 107, 113, 142, and 146 (1919, 1921, 1927, and 1929). R.H. DRENT, "Breeding Biology of the Pigeon Guillemot, *Cepphus columba,*" *Ardea,* 53:99–160 (1965); R.C. MURPHY, *Oceanic Birds of South America,* vol. 2 (1936), a readable discussion of many southern species; D. NETHERSOLE-THOMPSON, *The Greenshank* (1951), a very complete life history account; R.S. PALMER, "A Behavior Study of the Common Tern (*Sterna hirundo hirundo* L.)," *Proc. Boston Soc. Nat. Hist.*, 42:1–119 (1941); N. TINBERGEN, *The Herring Gull's World* (1953), an exceptionally clearly written behavioral study; G.D. STOUT (ed.), *The Shorebirds of North America* (1967), excellent illustrations and detailed species accounts.

The major sources of general information on charadriiform fossils are P. BRODKORB, "Catalogue of Fossil Birds: Part 3 (Ralliformes, Ichthyornithiformes, Charadriiformes)," *Bull. Fla. St. Mus. Biol. Sci.*, 2:99–220 (1967), and K. LAMBRECHT, *Handbuch der Palaeornithologie,* 8 vol. (1933).

Taxonomic works include W.J. BOCK, "A Generic Review of the Plovers (Charadriinae, Aves)," *Bull. Mus. Comp. Zool. Harv.* vol. 118, no. 2 (1958), on the function and value of traditional taxonomic characters; J.R. JEHL, JR., "Relationships in the Charadrii (Shorebirds): A Taxonomic Study Based on Color Patterns of the Downy Young," *Mem. S. Diego Soc. Nat. Hist. 3* (1968), a discussion of a taxonomic character not previously stressed; P.R. LOWE, "An Anatomical Review of the 'Waders' (Telmatomorphae) with Special Reference to the Families, Subfamilies and Genera Within the Suborders Limicolae, Grui-Limicolae, and Lari-Limicolae," *Ibis,* 13th ser., 1:712–771 (1931), an important classification based mainly on anatomy; M. MOYNIHAN, "A Revision of the Family Laridae (Aves)," *Am. Mus. Novit.*, no. 1928 (1959), the basis for many classifications of gulls and terns; J.L. PETERS, *Check-list of Birds of the World,* vol. 2 (1934), the distribution of all species; R. RIDGWAY, "The Birds of North and Middle America," *Bull. U.S. Natn. Mus.*, no. 50, pt. 8 (1919), taxonomic characters of the order, families, genera, and species.

Columbiformes. For accounts of the natural history of columbiform birds, the reader should consult D. GOODWIN, *Pigeons and Doves of the World* (1967); for the biology of an abundant European species, R.K. MURTON, *The Wood Pigeon* (1965); for Australian species, H.J. FRITH, "Notes on the Pigeons of the Richmond River, N.S.W.," *Emu,* 52:89–99 (1952); for North American pigeons, A.C. BENT, "Life Histories of North American Gallinaceous Birds," *Bull. U.S. Natn. Mus. 162,* pp. 353–477 (1932); and for neotropical species, A.F. SKUTCH, "Life Histories of Central American Pigeons," *Wilson Bull.*, 76:211–247 (1964). W.M. LEVI, *The Pigeon,* rev. ed. (1957), provides a complete discussion of the care and breeding of domestic pigeons. A.W. SCHORGER, *The Passenger Pigeon* (1955), is an exceptionally thorough account of the natural history, economics, and demise of this once abundant North American pigeon. In addition to Goodwin's book, the taxonomy of pigeons is discussed in R.F. JOHNSTON, "Taxonomy of Pigeons," *Condor,* 64:69–74 (1962); D. GOODWIN "Taxonomy of the Genus *Columba,*" *Bull. Br. Mus. Nat. Hist. (Zool.)*, no. 6, pp. 1–23 (1959); and E.W. GIFFORD, "Taxonomy and Habits of Pigeons." *Auk,* 58:239–245 (1941).

Psittaciformes. Popular works on parrots and related birds include J.M. FORSHAW, *Australian Parrots* (1969); and W.R. EASTMAN, JR. and A.C. HUNT, *Parrots of Australia* (1966), both large, lavish books describing and depicting in colour all Australian parrots. H. BATES and R. BUSENBARK, *Parrots and*

Related Birds (1959); and the DUKE OF BEDFORD, *Parrots and Parrot-like Birds* (1954), treat all of the parrots, with particular reference to aviculture. H.S. ZIM, *Parakeets* (1953), is devoted to the aviculture of the budgerigar. W.C. DILGER, "The Behavior of Lovebirds," *Scient. Am.*, 206:88–98 (1962), is an excellent summary of the author's research into the behaviour and evolution of *Agapornis*.

Among the more technical works: H. VON BOETTICHER, *Papageien* (1959), is a 116-page booklet, in German, containing 10 pages of introductory information, followed by a new classification based on external morphology, especially of the cere, with all species described briefly. A. NEWTON, *A Dictionary of Birds* (1893–96), contains a seven-page summary of parrot biology, as known at the end of the last century. J.L. PETERS, *Check-List of Birds of the World*, vol. 3 (1937), presents a classification of all parrots down to subspecies, with information on geographic ranges and scientific names. A. REICHENOW, *Vogelbilder aus fernen Zonen-Papageien*, 2nd ed. (1955), includes colour paintings and brief descriptions, in German, of almost all parrots.

Cuculiformes. E. BALDAMUS, *Das Leben der europäischen Kuckucke* (1892); and W. VON CAPEK, "Beiträge zur Fortpflanzungsgeschichte des Kuckucks," *Orn. Jb.*, 7:42–72, 102–117, 146–157, 165–183 (1896), are two classic works, in German, about the common cuckoo. E.P. CHANCE, *The Cuckoo's Secret* (1922), is an important and highly readable book about the common cuckoo. D.E. DAVIS, "Social Nesting Habits of the Smooth-Billed Ani," *Auk*, 57:179–218 (1940), presents the results of extensive field work on anis. H. FRIEDMANN, *The Parasitic Cuckoos of Africa* (1948); "Evolutionary Trends in the Avian Genus *Clamator*," *Smithson. Misc. Collns.*, 146:1–127 (1964), and "The Evolutionary History of the Avian Genus *Chrysococcyx*," *Bull. U.S. Natn. Mus. 265* (1968), are technical papers on Old World tropical cuckoos. A.C. BENT, "Life Histories of North American Cuckoos, Goatsuckers, Hummingbirds and Their Allies," *ibid. 176* (1940), provides readable accounts of the natural history of North American cuckoos and of some Asiatic *Cuculus* species. R.E. MOREAU, "A Contribution to the Biology of the Musophagiformes, the So-Called Plantain-Eaters," *Ibis*, 2: 639–671 (1938), is one of the few detailed studies of musophagids.

Strigiformes. O.L. AUSTIN, *Birds of the World*, ed. by H.S. ZIM (1961), presents an excellent general account of owls, with fine colour illustrations that include some rarely seen species. A.C. BENT, "Life Histories of North American Birds of Prey, Part II," *Bull. U.S. Natn. Mus. 170* (1938; reissued in 1961 as vol. 2 of series of same title), contains complete accounts of the natural history of North American owls. J.J and F.C. CRAIGHEAD, *Hawks, Owls and Wildlife* (1956, reissued in pa. 1969), is a classic in the ecology of raptorial birds. M.L. GROSSMAN and J. HAMLET, *Birds of Prey of the World* (1964), provides range maps for each species, good photographs, and a reading list by geographical region and by genus. G.P. DEMENTIEV *et al.*, *Birds of the Soviet Union*, vol. 1 (Eng. trans. 1966; orig. pub. in Russian, 1951), contains an extensive and well-illustrated section on Eurasian owls. E.C.S. BAKER, *Fauna of British India (Birds)*, vol. 4 (1927), includes an excellent discussion of the anatomical traits used in the classification of owls. Of a more specialized nature: R.S. PAYNE and W.H. DRURY, JR., "Marksman of the Darkness," *Nat. Hist.*, vol. 67, pp. 316–323 (June 1958), describes the discovery of the hearing ability of the barn owl. D.J. LIGON, "The Biology of the Elf Owl, *Micrathene Whitneyi*," *Misc. Publs. Mus. Zool. Univ. Mich. No. 136* (Feb. 1968), is a detailed study of the life history of the smallest owl, compared with other owls. A. ROSS, "Ecological Aspects of the Food Habits of Insectivorous Screech-owls," *Proc. West. Fdn. Vertebr. Zool.* vol. 1, no. 6, pp. 301–344 (1969), is a definitive correlation between body size and prey size, one of the few such papers in which stomach contents are correctly identified. L.W. WALKER, "Nocturnal Observations of Elf Owls," *Condor*, vol. 45, no. 5, pp. 165–167 (Sept.-Oct. 1943), with excellent photography and concise scientific writing. B.E. SMYTHIES, *The Birds of Burma*, 2nd ed. rev. (1953), and *The Birds of Borneo* (1960), provide the best and most reliable information on the habits and calls of Asian owls.

Caprimulgiformes. The natural history of North American nightjars is extensively discussed by A.C. BENT, "Life Histories of North American Cuckoos, Goatsuckers, Hummingbirds and Their Allies," *Bull. U.S. Natn. Mus. 176* (1940); that of European nightjars in D.A. BANNERMAN and G.E. LODGE, *The Birds of the British Isles*, vol. 4 (1955). F. HAVERSCHMIDT, *The Birds of Surinam* (1968), includes much information on the South American caprimulgiforms. J.P. CHAPIN, "Birds of the Belgian Congo, Part II," *Bull. Am. Mus. Nat. Hist.*, vol. 75 (1939), contains readable accounts of the natural history of several tropical nightjars. D.W. SNOW, "The Natural History of the Oilbird, *Steatornis caripensis*, in Trinidad, W.I.," *Zoologica*, vol. 46, pp. 27–48 (1961) and vol. 47, pp. 199–222 (1962), provides an excellent and readable account of the natural history of that species. The information on nightjar hibernation is scattered among a number of short journal articles, but the reader will find interesting summaries in E.C. JAEGER, "Further Observations on the Hibernation of the Poorwill," *Condor*, vol. 51, no. 3, pp. 105–109 (1949); and J.T. MARSHALL, JR., "Hibernation in Captive Goatsuckers," *Condor*, vol. 57, no. 3, pp. 129–134 (1955). A review of the later work in this field is presented by G.T. AUSTIN and W.G. BRADLEY, "Additional Responses of the Poorwill to Low Temperatures," *Auk*, vol. 86, no. 4, pp. 717–725 (1969).

Apodiformes. Two notable works on swifts are RICHARD B. FISCHER, *The Breeding Biology of the Chimney Swift "Chaetura pelagica" (Linnaeus)* (1958), a thorough (excellently illustrated) single-species study of a New World swift; and DAVID L. LACK, *Swifts in a Tower* (1956), a popular summary based on numerous scattered scientific papers on *Apus apus*.

CRAWFORD H. GREENEWALT, *Hummingbirds* (1960), is a beautifully illustrated popular book, with emphasis on the physics of plumage iridescence and of hummingbird flight; EUGENE L. SIMON, *Histoire naturelle des "Trochilidae" (Synopsis et catalogue)* (1921), is the basis of a standard classification of hummingbirds, with detailed descriptions, keys, and nomenclatorial synonymies.

Coraciiformes. A. NEWTON, *A Dictionary of Birds*, 4 pt. (1893–96), a most important historical review of the classification and natural history of birds, with data on roller-like birds arranged alphabetically; E. STRESEMANN, "The Status of Avian Systematics and Its Unsolved Problems," *Auk*, 76: 269–280 (1959), an important essay with bibliography; R.E. MOREAU, "The Comparative Breeding Biology of the African Hornbills (*Bucerotidae*)," *Proc. Zool. Soc. Lond.*, 107A:331–346 (1937); "The Nesting of African Birds in Association with Other Living Things," *Ibis*. 6:240–263 (1942), includes insect scavengers found in nests occupied by hornbills; H. FRIEDMANN, "The Honey-Guides," *Bull U.S. Natn. Mus. 208* (1955), includes a section on host relationships of honey-guides, birds that victimize kingfishers, bee-eaters, hoopoes, and wood hoopoes.

Piciformes. A.F. SKUTCH, "Life-History of the Blackchinned Jacamar," *Auk*, 54:135–146 (1937), is the only relatively complete study of a species of jacamar; "Life History Notes on Puff-Birds," *Wilson Bull.*, 60:81–97 (1948), although not complete on any species, contains most of the information known about the habits of puffbirds. S.D. RIPLEY, "The Barbets," *Auk*, 62:542–563 (1945), is chiefly a taxonomic, technical treatment, but summarizes the habits and characteristics of various groups; A.F. SKUTCH, "The Life-History of the Prong-Billed Barbet," *Auk*, 61:61–88 (1944), presents a fairly complete account of the habits of a barbet, one of few detailed accounts existing. H. FRIEDMANN, *The Honey-Guides* (1955), is a technical but readable account of the habits and relationships of honey guides. J. VAN TYNE, *The Life History of the Toucan* Ramphastos brevicarinatus (1929), provides a good, though technical, account of the habits of a large toucan; H.O. WAGNER, "Notes on the Life History of the Emerald Toucanet," *Wilson Bull.*, 56:65–76 (1944), is a general account of the habits of a small toucan; and A.F. SKUTCH, "Life History of the Blue-Throated Toucanet," *Wilson Bull.*, 56:133–151 (1944), a very readable study of another small toucan; "Life History of the Olivaceous Piculet and Related Forms," *Ibis*, 90:433–449 (1948), presents an interesting account of the habits of these little relatives of the woodpeckers.

D. BLUME, "Uber die Lebensweise einiger Spechtarten (*Dendrocopos major, Picus viridis, Dryocopus martius*)," *J. Orn., Lpz.*, vol. 102 (supplement), in German, with English summary (1961), is the classic modern behavioral treatment of woodpeckers, covering three common European species (fairly technical). H. SIELMANN, *Das Jahr mit den Spechten* (1958; Eng. trans., *My Year with the Woodpeckers*, 1959) is a readable, accurate account of the habits of European woodpeckers. L. DE K. LAWRENCE, *A Comparative Life-History Study of Four Species of Woodpeckers* (1966), presents an accurate, not overly technical treatment of the habits of some North American species. A.C. BENT, *Life Histories of North American Woodpeckers* (1939), summarizes, at times anthropomorphically, the knowledge, through about 1938, of the habits of all North American woodpeckers. J.T. TANNER, *The Ivory-Billed Woodpecker* (1942), is an account of the habits and history of one of the largest woodpeckers, now nearly extinct on the North American continent.

Passeriformes. General works, written in a popular style, include O.L. AUSTIN, JR., *Birds of the World* (1961) and *Families of Birds* (1971); JAMES FISHER and R.T. PETERSON, *The World of Birds* (1964); and E.T. GILLIARD, *Living Birds of the World* (1958). General works, somewhat more technical in nature are ALFRED NEWTON, *A Dictionary of Birds* (1896); A.L. THOMSON (ed.), *A New Dictionary of Birds* (1964); JOSSELYN VAN TYNE and A.J. BERGER, *Fundamentals of Ornithology* (1959). Specialized works and technical review articles include P.L. AMES, "The

Morphology of the Syrinx in Passerine Birds," *Bull. Peabody Mus. Nat. Hist. 37* (1971); C.G. SIBLEY, "A Comparative Study of the Egg-White Proteins of Passerine Birds," *ibid. 32* (1970); K.E.L. SIMMONS, "Anting and the Problem of Self-Stimulation," *J. Zool.*, 149: 145–162 (1966); E.F. POTTER, "Anting in Wild Birds. Its Frequency and Probable Purpose," *Auk*, 87:692–713 (1970); P. BRODKORB, "Origin and Evolution of Birds," in D.S. FARNER and J.R. KING (eds.), vol. 1, *Avian Biology* (1971).

Regional works: For the Eurasian region, see D.A. BANNERMAN, *The Birds of the British Isles*, vol. 6–12 (1957–63); CHARLES VAURIE, *The Birds of the Palearctic Fauna: A Systematic Reference, Order Passeriformes* (1959); H.F. WITHERBY *et al.*, *The Handbook of British Birds*, 5 vol. (1938–41). For tropical Asia, see E.C. STUART BAKER, *The Fauna of British India, Including Ceylon and Burma*, vol. 1–4 (1922–27); SALIM ALI and S.D. RIPLEY, *Handbook of the Birds of India and Pakistan, Together with Those of Nepal, Sikkim, Bhutan and Ceylon*, vol. 4 ff. (1970–); A.L. RAND and E.T. GILLIARD, *Handbook of New Guinea Birds* (1968); B.E. SMYTHIES, *The Birds of Burma* (1940) and *The Birds of Borneo* (1960). For Australasia, see G.M. MATHEWS, *The Birds of Australia*, 12 vol. (1910–26); D.L. SERVENTY and H.M. WHITTELL, *Birds of Western Australia*, 3rd ed. (1962); W.R.B. OLIVER, *New Zealand Birds*, 2nd ed. rev. (1955); ERNST MAYR, *Birds of the Southwest Pacific* (1945); J.E. DU PONT, *Philippine Birds* (1972). For Africa, see D.A. BANNERMAN, *The Birds of Tropical West Africa*, 8 vol. (1930–51) and *The Birds of West and Equatorial Africa*, 2 vol. (1953); J.P. CHAPIN, "The Birds of the Belgian Congo," *Bull. Am. Mus. Nat. Hist.*, *65, 75*, 4 pt. (1932–54); C.W. MACKWORTH-PRAED and C.H.B. GRANT, *Birds of Eastern and North-eastern Africa* (1955) and *Birds of the Southern Third of Africa* (1963). For the birds of North America, see A.C. BENT, "Life Histories of North American Birds . . . ," 8 *Bulletins* of the United States National Museum (1942–68); E.H. FORBUSH, *Birds of Massachusetts and Other New England States*, vol. 2–3 (1927–29); I.N. GABRIELSON and F.C. LINCOLN, *The Birds of Alaska* (1959); W.E. GODFREY, *The Birds of Canada* (1966); and volumes on birds of individual states. For the birds of the Caribbean region and Central and South America, see ALEXANDER WETMORE and B.H. SWALES, "The Birds of Haiti and the Dominican Republic," *Bull. U.S. Natn. Mus. 155* (1931); JAMES BOND, *Birds of the West Indies*, 2nd ed. (1971); R. MEYER DE SCHAUENSEE, *The Birds of Colombia, and Adjacent Areas of South and Central America*, 2nd ed. (1971), *The Species of Birds of South America and Their Distribution* (1966), and *A Guide to the Birds of South America* (1970); ALEXANDER WETMORE, "Observations on the Birds of Argentina, Paraguay, Uruguay, and Chile," *Bull. U.S. Natn. Mus. 133* (1926); A.F. SKUTCH, *Life Histories of Central American Birds*, vol. 2–3 (Pacific Coast Avifauna, no. 34-35; 1960–69); *Life Histories of Central American Highland Birds* (1967); and *Studies of Tropical American Birds* (1972).

Taxonomic works: D. AMADON, "Remarks on the Classification of the Perching Birds," *Proc. Zool. Soc., Calcutta, Mookerjee Mem. Vol.*, pp.2599–268 (1957); J. DELACOUR and CHARLES VAURIE, "A Classification of the Oscines (Aves)," *Contr. Sci.*, no. 16, pp. 1–6 (1957); ERNST MAYR and D. AMADON, "A Classification of Recent Birds," *Am. Mus. Novit. 1496* (1951); ERNST MAYR and J.C. GREENWAY, JR., "Sequence of Passerine Families," *Breviora 58* (1956); J.L. PETERS, *Check-list of Birds of the World*, vol. 7–15, ed. by R.A. PAYNTER, JR., ERNST MAYR, and J.C. GREENWAY, JR. (1951–); R.W. STORER, "Classification of Birds," in D.S. FARNER and J.B. KING (eds.), vol. 1, *Avian Biology* (1971); ALEXANDER WETMORE, "A Classification for the Birds of the World," *Smithson. Misc. Collns.*, vol. 139, no. 11 (1960).

Birth Control

The term birth control refers to the volitional control of the number and spacing of children in a family. It encompasses the wide range of rational and irrational methods that have been used in the attempt to regulate human fertility, as well as the response of individuals and of groups within society to the choices offered by such methods. Birth control has been and remains controversial. The U.S. reformer Margaret Sanger coined the phrase in 1914–15 and, like the social movement she founded, the term has been caught up in a quest for acceptance, generating many synonyms: family planning, planned parenthood, responsible parenthood, voluntary parenthood, contraception, fertility regulation, and fertility control.

Human reproduction involves a range of activities and events, from sexual intercourse through birth, and depends as well on a series of physiological interactions, such as the timing of ovulation within the menstrual cycle. The visible events are central to the transmission of life and have been subject to social and religious control. The invisible factors in human reproduction gave rise early on to speculation and in modern times have become the topic of scientific investigation and manipulation. New knowledge relevant to birth control has diffused at different rates through various social groups and has not always been available to those with the greatest need. Hence, the conflicts and controversies surrounding birth control have been complex and impassioned. The disagreement over birth control arises in part from the debate over what is natural and what is artificial (and, to some, unacceptable). For information on human reproduction in general see REPRODUCTION AND REPRODUCTIVE SYSTEMS: *The human reproductive system* and *Human reproduction from conception to birth.*

This article is divided into the following sections:

NATURAL FERTILITY

At first glance the species *Homo sapiens* appears to have low potential for reproduction. Puberty begins late, pregnancy is long, normally only one baby is delivered at a time, and lactation can continue for several years. Yet on the global level the human race now experiences 1,000,000 more births than deaths every five days, and a large percentage of the world's population lives in urban areas, often at extremely high population densities. In experiments, when mammals are placed in crowded conditions the age of sexual maturity rises, the interval between pregnancies increases, and infant mortality jumps, leading to slower growth in the population. Among human beings in analogous crowded conditions, however, in the absence of artificial birth control the opposite situation arises.

In many cases ovulation does not take place in the first several cycles after the onset of menstruation (the menarche). Once a woman is fertile, social factors determine whether she is exposed to the opportunity to become pregnant. In preindustrial Britain, couples were expected to form their own nuclear group upon marriage, and many a first-time bride was in her later 20s. By contrast, in contemporary Third World societies that encourage extended families, girls often marry in the early teens.

Lactation's control over fertility

In all mammals whose reproduction is not tied to seasonal changes, physiological mechanisms ensure the optimum spacing of pregnancies. In *Homo sapiens,* as in other primates, breast-feeding provides the basis for nature's own method of birth control. In the few remaining societies of hunters and gatherers, whose way of life may represent the conditions under which most of human evolution took place, women nurse their babies frequently and ovulation and menstruation are suppressed for two to three years after birth. Nomadic women of the *!Kung,* a group of the San people of southern Africa, use no contraceptives but have a mean interval between births of 44 months and an average of four or five deliveries in a fertile lifetime. Modern methods of birth control substitute for the control over fertility once provided by lactation and permit a degree of control over human reproduction not previously available.

The combination of high infant mortality with relatively low fertility associated with traditional patterns of breast-feeding kept population growth in preagricultural human societies virtually static. Ten thousand years ago the world's population may have stood at 10,000,000. Since that time natural restraints on human reproduction have broken down at an accelerating pace. By the beginning of the Christian Era the world's population was perhaps 300,000,000. In the mid-1980s it passed the 5,000,000,000 mark. Since the Industrial Revolution, and with intensely increasing pressure in the past century, both individuals and societies have had to make important decisions about the use of birth control.

HISTORY OF BIRTH CONTROL

Methods. Written records of birth control methods survive from ancient times. Methods are mentioned among the various formulas and remedies recorded in the Ebers papyrus, a compilation of Egyptian medical texts dating from 1550 BC. Classical writers, including Pliny the Elder, Pedanius Dioscorides (*De materia medica, c.* AD 77), and Soranus of Ephesus (*On Midwifery and the Diseases of Women, c.* AD 100), refer to contraception and abortion. Several authors from the flowering of Arabic medicine in the 10th century mention contraception, notably ar-Rāzī (Rhazes; *Quintessence of Experience*), Ali ibn Abbas (*The Royal Book*), and Avicenna (Ibn Sīnā; *The Canon of Medicine*). The methods recommended by these early commentators fall into three groups: the reasonable but probably ineffective, such as wiping out the vagina after intercourse (Soranus); the reasonable and perhaps effective, such as using honey, alum, or lactic acid as spermicidal barriers (Ebers papyrus, Dioscorides, and Soranus); and the mystical and manifestly ineffective, for example suggesting that the woman jump backward seven times immediately after coitus (Soranus).

Ancient records of birth control methods

By 1900 all the methods of birth control now in use, with the exception of oral contraceptives, were understood and available in Europe and North America. The first to be developed was the condom. Folklore attributes the invention to a Dr. Condom, said to have been alarmed by the number of illegitimate offspring of Charles II of England. It is more likely, however, that the name derives from the Latin

Invention of the condom

condus, for receptacle. The earliest published description is by the Italian anatomist Gabriel Fallopius in 1564. The first condoms were made from animal intestines and for the most part were used to prevent sexual transmission of disease. When Charles Goodyear discovered the process for vulcanization of rubber in 1839 he initiated a revolution in contraception, as well as transport, and condoms have been a popular choice for birth control since the second half of the 19th century. The use of vaginal barriers (diaphragms and caps, which are commonly used with spermicides) was recorded by the German physician F.A. Wilde in 1823. The medical forerunner of the intrauterine device was the stem pessary, first described and illustrated in 1868. By 1909, Richard Richter, a practitioner from near Breslau (Wrocław in present-day Poland), had described most of the advantages and disadvantages of this method of birth control. Vasectomy, or male sterilization, was practiced in the 19th century, and the first female sterilization by surgical occlusion of the fallopian tubes was performed by a U.S. surgeon in Ohio in 1881. The surgical techniques of induced abortion in use today were also known in the 19th century. In the 1860s an Edinburgh gynecologist, James Young Simpson, described a procedure for "dry cupping" the uterus. The procedure adumbrated vacuum aspiration, a method commonly used today for performing legal abortion.

Ovulation and the menstrual cycle

The fact that conception was more likely to take place during certain phases of the menstrual cycle than others was suspected by classical authors. Adam Raciborski, a Paris physician, noted in 1843 that brides married soon after their menstruation often conceived in that cycle, while if the wedding occurred later in the cycle they commonly had another period before pregnancy occurred. Hermann Knaus in Austria (1929) and Kyūsaku Ogino in Japan (1930) independently and correctly concluded that ovulation occurs 14 days prior to the next menstruation. In 1964 an Australian medical team, John and Evelyn Billings, showed how women could monitor changes in their cervical mucus and learn to predict when ovulation would occur.

"The greatest invention some benefactor can give mankind," wrote Sigmund Freud in the early years of the 20th century, "is a form of contraception which does not induce neurosis." Many of the elements to meet the goal of a new, more acceptable form of contraception were present about the time of World War I, yet two generations were to reach maturity before those elements were exploited. The role of hormones from the ovary was understood early in the 20th century by Walter Heape and John Marshall. The first extract of estrogen was produced in 1913, and the pure compound was isolated by the Americans Willard Allen and Alan Doisy in 1923. At this time an Austrian physiologist, Ludwig Haberlandt, was carrying out experiments on rabbits to apply the new-found knowledge of hormones for contraceptive ends. By 1927 he was able to write, "It needs no amplification, of all methods available, hormonal sterilization based on biologic principles, if it can be applied unobjectionably in the human, is an ideal method for practical medicine and its future task of birth control." Hostile public attitudes made research on birth control virtually impossible, however, and Haberlandt's ideal was not realized until the 1960s.

Onanism

Users. In the Old Testament story of Onan (Genesis 38:8–10), Judah ordered his son Onan to sleep with Onan's recently widowed sister-in-law, but Onan refused on the ground that "the descendants would not be his own, so whenever he had relations with his brother's wife, he let [the seed] be lost on the ground." As a punishment God killed him, although it is unclear whether the punishment was for his practice of coitus interruptus or for filial disobedience. Perhaps the earliest first-person account of contraception comes from the verbatim records of the Inquisition. During a trial of Albigensian heretics from the village of Montaillou in France in the early 14th century, Beatrice, the mistress of one of the accused, berates her lover, asking "What shall I do if I become pregnant by you?" He replies, "I have a certain herb. If a man wears it when he mingles his body with that of a woman he cannot engender, nor she conceive." The method was almost certainly mystical and inefficacious. James Boswell in his *London Journal, 1762–63* records a more practical experience (for May 10, 1763) when he picked "up a strong young jolly damsel, led her to Westminster Bridge and there, in armour complete, did I enjoy her upon this noble edifice." It is notable that, prior to the Industrial Revolution, most accounts of the use of contraceptives relate to illicit sex.

The 17th-century European upper classes, many of whom had their infants wet-nursed, felt the pressure of excess births within marriage, both physically and emotionally. A French aristocrat writing in 1671 to her daughter, who had borne three children by age 22, recommends, "Continue the nice custom of sleeping separately and restore yourself . . . I kiss your husband. I like him even better in his apartment than in yours." Queen Victoria later expressed a similar sentiment: "Men never think, at least seldom think, what a hard task it is for us women to go through [childbirth] *very often.*"

Decline in birth rates as a result of birth control

In the 19th century better diet, more stable political conditions, and improvements in water supply and hygiene and other simple advances in public health began to bring down the death rate. For the first and probably the last time in the history of industrialized nations a large family became the rule. Eighteenth-century France had seen an overall decline in the birth rate, probably brought about by increasing use of coitus interruptus, and most of western Europe followed suit in the 19th century. In 1860 a quarter of all marriages in England and Wales had eight or more children, but by 1925, 50 percent had only one or two children and one in six was childless. In the United States a similar decline in fertility began slightly later: in 1830 the crude birth rate for white Americans was 50 per 1,000, but by 1930 it was only 18 per 1,000.

Among English couples married before 1910 only 15 percent used a method of birth control, while among those married in the years 1935–39, 66 percent used a method. In 1982 in the United States 67.9 percent of married couples aged 15 to 44 used a contraceptive method and another 14 percent were seeking to be pregnant, were pregnant, or had just delivered. There was little variation by religion or race (61 percent of black couples and 69.6 percent of white couples using a method). The commonest method was female sterilization (one-quarter of all users), followed by the contraceptive pill (one-fifth). About 15 percent of couples used condoms, and another 15 percent relied on male sterilization. Fewer than one in 20 couples used periodic abstinence.

In developing countries where family planning services have been emphasized by the government or private organizations, prevalence of contraception usually rises rapidly. In Thailand, for example, use jumped from 15 percent in 1970 to nearly 60 percent in 1981. In Mexico it rose from 30 percent in 1976 to more than 40 percent in the 1980s and in Bangladesh from 8 percent in 1975 to more than 20 percent in 1984. There has been less success, however, in countries with weak birth control services.

SOCIAL AND POLITICAL ASPECTS OF BIRTH CONTROL

Thomas Malthus

Early advocates. In 1798 Thomas Malthus wrote *An Essay on the Principle of Population.* It posed the conundrum of geometrical population growth's outstripping arithmetic expansion in resources. Malthus, who was an Anglican clergyman, recommended late marriage and sexual abstinence as methods of birth control. A small group of early 19th-century freethinkers, including Jeremy Bentham, Francis Place (himself the father of 15 children), and John Stuart Mill, suggested more pragmatic birth control methods such as coitus interruptus, vaginal barriers, and postcoital douching. Robert Dale Owen, the son of a Scottish social reformer, helped spread these revolutionary ideas in North America, and in 1832 a Massachusetts physician and freethinker, Charles Knowlton, wrote a slim book called *The Fruits of Philosophy: or The Private Companion of Young Married People.* Although Knowlton's first edition was published anonymously, he was fined and imprisoned. The book appeared in England two years later and continued to be read for the next 50 years. In 1876 a Bristol publisher was prosecuted for selling *The Fruits* *of Philosophy.* Incensed, Charles Bradlaugh, the leader of Britain's National Secular Society and subsequently a member of Parliament, and Annie Besant reissued the pamphlet and notified the police. They were charged and tried, the public prosecutor claiming "this is a dirty, filthy book," but the conviction was quashed on grounds of a faulty indictment. The trial received wide publicity and, through the national press, brought birth control onto the breakfast table of the English middle classes at a time when, for economic reasons, they were eager to control their fertility. The Malthusian League, founded some years earlier by George Drysdale, began to attract wide public support. Similar leagues began in France, Germany, and The Netherlands, the latter opening the world's first family planning services, under Dr. Aletta Jacobs, in 1882.

Margaret Sanger and Marie Stopes

But it was two women, Margaret Sanger in the United States and Marie Stopes in Britain, who were to make birth control the object of a national, and ultimately global, social movement. Both used the controversy that surrounded birth control as a ready way of attracting attention. Sanger, a trained nurse, encountered miserable conditions in her work among the poor. She was inspired to take up her crusade when she attended a woman who was dying from a criminally induced abortion. In 1914 she started a magazine, *The Woman Rebel,* to challenge laws restricting the distribution of information on birth control. She was indicted and fled to Europe, but when she returned to stand trial in 1916 the charges against her were dropped. Later that year she opened a family planning clinic in Brownsville, Brooklyn, New York, but the police immediately closed it, and Sanger was arrested and convicted on charges of "maintaining a public nuisance." After many vicissitudes, a compromise was struck and family planning clinics were allowed in the United States on the condition that physicians be involved in prescribing contraceptives. In 1936 a New York court, in a case known as *United States* v. *One Package of Japanese Pessaries,* ruled that contraceptives could be sent through the post if they were to be intelligently employed by conscientious physicians for the purpose of saving life or promoting the well-being of their patients.

The movement for birth control was led in Britain by Marie Stopes, the daughter of a middle-class Edinburgh family. She was one of the first women to obtain a doctorate in botany (from the University of Munich in 1904). In 1918 she published an appeal for sexual equality and fulfillment within marriage, *Married Love,* which at the time was considered to be a radical text. Margaret Sanger met Marie Stopes and persuaded her to add a chapter on birth control. While Sanger's advocacy emphasized the alleviation of poverty and overpopulation, Stopes sought as well to relieve women of the physical strain and risks of excessive childbearing. Her *Married Love* was followed by *Wise Parenthood* (1918), and in 1922 Stopes founded the Society for Constructive Birth Control and Racial Progress.

The population explosion. In 1790 a Venetian monk, Gianmaria Ortis, concluded that human population growth could not continue indefinitely. Malthus' work a few years later stimulated more discussion and also provided the intellectual clue that inspired Charles Darwin's theory of biological evolution through the survival of the fittest. The debate about human numbers remained academic, however, until the 1950s, when a surge in population occurred as a result of the comparative peace and prosperity following World War II.

In Malthus' time world population was under 1,000,000,000, and when Sanger and Stopes opened the first birth control clinics population was still less than 2,000,000,000. In 1960 global population surpassed 3,000,000,000, and the next 1,000,000,000 was added in a mere 15 years. In the 19th century the population of industrialized nations rarely grew by more than 1 percent per annum, but in the 1960s and '70s many developing countries exploded at a rate of 2 to 3 percent per year.

Rapid population growth has several economic consequences. It requires heavier investment in education, health, and transport merely to maintain these services at their previous level; yet, the working population has a higher burden of dependence to support, making both individual and national saving more difficult. Although population growth is not the only problem dividing rich and poor countries, it is one important variable that has widened the gap in growth in per capita income between developed and developing nations. Advocates of birth control see it as a means to prevent the personal and social pressures that result from rapid population growth.

BIRTH CONTROL AND HEALTH

Risk to the mother and infant

There is a marked relationship between patterns of reproduction and the risk of death to the mother and her child. Maternal deaths and infant mortality are up to 60 percent higher among girls under 15 than among women who have a child in their early 20s. The risk of death to the mother and her child rises again in the second half of the 30s. Maternal and infant mortality is lowest for the second and third deliveries. The risk of certain congenital abnormalities, such as Down's syndrome (mongolism), is also greater in older women. Therefore, patterns of sexual abstinence and birth control, which concentrate childbearing in the age group 20–35 and limit family size to two or three children, have a direct impact on public health.

At the same time, it must be recognized that patterns of human reproduction have been finely tuned over millions of years of evolution and the postponement of childbearing until the later 20s or 30s also increases the risk of certain diseases. In particular, cancer of the breast is more common in women who postpone the first birth until the later 20s or older. In the Western world, the risk of death to women in childbirth is approximately one in 10,000, but in developing countries, where half the children born are delivered by traditional birth attendants, it is often 10 times as high. As the number of births worldwide rises, a greater number of women are likely to die having children. Simple access to birth control may be expected to reduce high death rates.

METHODS OF BIRTH CONTROL

Nonmedical methods. *Abstinence.* Abstinence is important in many societies. In the West, most individuals abstain from regular sexual intercourse for many years between puberty and marriage. Raising the age of marriage has been an important element in the decline of the birth rate in China, Korea, and Sri Lanka. Abstinence among couples with grown children is important in some traditional societies, such as certain Hindu groups.

Breast-feeding. The role of breast-feeding in the regulation of human fertility can be illustrated by the following calculation: in Pakistan breast-feeding is virtually universal, and many women breast-feed for two years or more. Fewer than one in 10 women use a modern method of contraception; but if breast-feeding were to decline to levels now found in Central America, four out of 10 women would have to use an artificial method of birth control just to prevent the fertility rate from rising.

Although the information is important to demography, there is no simple way to predict when an individual breast-feeding woman will become fertile again. If she seeks security against pregnancy, a woman may in fact have an overlap of several months between the time she adopts an artificial method and the end of her natural protection.

Coitus interruptus and coitus reservatus

Coital techniques. Coitus interruptus, the practice by which the male withdraws the penis prior to ejaculation, has been an important method of birth control in the West and was used by more than half of all British couples until well after World War II. It is most common among Roman Catholic and Islāmic groups but is less used in the Orient, where coitus reservatus (intercourse without ejaculation) may be more common. The failure rate for coitus interruptus (five to 20 pregnancies per 100 women-years of exposure) overlaps with that of barrier methods of birth control. Although frequently condemned by those promoting other methods of family planning, there is no evidence that coitus interruptus causes any physical or emotional harm. There may be preferable ways of controlling fertility, but for many couples coitus interruptus is better than no method.

The belief that conception cannot take place unless the woman has an orgasm is widespread but untrue. Postcoital douching is not an effective method of birth control.

Barrier methods. Modern high-quality condoms have the advantage of simplicity of use and anonymity of distribution. They are sold in pharmacies, in supermarkets, through the mail, and even in barber shops and at news stands and have been used by more than half of British and American men at one time or another. Use is most extensive in Japan. The acceptance of condoms has been increased in recent decades by advances in packaging and lubrication and, more recently, by the addition of a spermicide. When used carefully, condoms can have a failure rate as low as some intrauterine devices (two to five per 100 women-years of exposure).

Many chemicals act as spermicides; one of the most widely used is a detergent, nonoxynol-9, found in most foams, pessaries, and dissolving vaginal tablets. Spermicides are either used alone, when they have a moderate failure rate, or in combination with a barrier method such as a diaphragm or a disposable sponge.

Periodic abstinence. Although a couple may make a private choice to use periodic abstinence, just as they might buy condoms, most modern methods of periodic abstinence require careful training by a trained counsellor. Awareness of human fertility can be valuable when a couple is attempting to conceive a child. The method makes considerable demands on the partners, but if well taught it may also enhance the marital relationship.

Several types of periodic abstinence, also known as the rhythm method or natural family planning, are practiced. The time of ovulation can be estimated from a calendar record of previous menstruation, but this method has low effectiveness. More reliable methods include keeping a daily record of body temperature or recording physical changes in the cervix (the neck of the womb) and cervical mucus (the mucous method, also called the Billings method). These methods may also be combined (sympothermic method). As with several methods of birth control, a wide range of failure rates has been recorded for the various types of periodic abstinence, extending from one pregnancy per 100 women-years of exposure to more than 20 per 100.

Medical methods. *Hormonal contraceptives.* Hormonal contraceptives use artificially synthesized derivatives of the natural steroid hormones estrogen and progesterone. Estrogen is responsible for the growth of the lining of the womb (endometrium), which occurs early in the menstrual cycle. Progesterone is produced in the second half of the cycle and in great quantities in pregnancy. It makes the mucus in the lower part of the reproductive tract resistant to the ascent of sperm and also alters the lining of the womb. Both hormones cause changes in the breasts and elsewhere in the body. They act on the base of the brain and the associated pituitary gland. This gland, in turn, secretes hormones (gonadotrophins) that regulate the production of estrogens and progesterone by the ovaries.

Oral contraceptives

Most oral contraceptives contain a combination of estrogen and progesterone. The combination, like the hormone balance of normal pregnancy, prevents the release of eggs from the ovaries. A minority of pills contain only a progestogen (a progestational steroid) and act mainly by causing changes in the mucus that prevent the ascent of sperm. In different doses, combination pills and certain other hormonal preparations can be used after coitus. They prevent pregnancy up to two or three days after the fertilizing intercourse, primarily by rendering the lining of the womb unsuitable for the attachment (implantation) of a fertilized egg.

More than 100,000,000 women currently use oral contraceptives or have used them in the past. In many countries pills are widely distributed by community workers and through pharmacies, without direct medical supervision. Injectable contraceptives are registered for use in more than 80 countries, including most of the Third World, the United Kingdom, Sweden, and New Zealand. The injectable preparation Depo-Provera has had a particularly controversial history, having been referred for further study by the U.S. Food and Drug Administration in 1974, 1978, and 1984. Research has been undertaken on subdermal implants and intravaginal rings (which slowly release hormones for absorption through the vaginal wall). In China a once-a-month pill is available.

Hormonal contraceptives belong to the 20th century. Slow to be developed, sometimes misunderstood by physicians, and often the centre of the news media's attention, they have been alternately oversold and overcriticized. Nevertheless they have wrought a medical and social revolution. They are remarkably effective, cheap to manufacture, and relatively simple to use. But as methods that imitate, albeit imperfectly, the menstrual cycle and some of the changes normally occurring in pregnancy, they are responsible for a wide range of good and bad changes in the body.

Risks and benefits of oral contraceptives

As noted, the principle of hormonal contraception was understood in the 1920s, but it was 30 years before the drive of Margaret Sanger (then more than 70 years old) and the philanthropy of Mrs. Page McCormick were to draw the first oral contraceptive preparations from somewhat reluctant scientists and physicians. The first clinical report of the use of oral steroid hormones to suppress ovulation was published by Gregory Pincus and John Rock from Boston in 1956. The approval of the U.S. Food and Drug Administration was granted in 1960, and marketing of the preparations in Britain began two years later. When oral contraceptives are used correctly, fewer than one woman in 100 per year of use will conceive an unintended pregnancy. A woman's menstrual cycle is more regular when she uses the pill, and users tend to be less anemic than nonusers. Immediate adverse side effects can include nausea, breast tenderness, headaches, and weight gain. But it was only after the first few million women had used the method for some years that important but rare side effects began to be reliably documented and accurately measured. Predictably adverse conditions leading to death or serious disease were discovered before a number of beneficial, and even lifesaving, effects were demonstrated. The order of these discoveries, together with the perceived social impact of the method, probably accounts for much of the controversy that has surrounded and continues to surround oral contraceptives.

Large-scale epidemiological research involving tens of thousands of women has now demonstrated that users of the pill are more likely than nonusers to suffer from heart attacks, strokes, and blood clots in the veins. These effects are extremely rare in younger women, but occurrence is multiplied several times in all age groups among users who smoke. Users of oral contraceptives are less likely than nonusers to develop cancer of the ovary or uterus. Use reduces the chance of benign breast disease but neither protects against nor causes breast cancer. The risk of pelvic infection is approximately halved among users. Fertility returns rapidly after discontinuing use, and, while some artificial steroids in high doses can damage the fetus, there is no consistent evidence that oral contraceptives cause congenital abnormalities.

It is difficult to balance the list of the oral contraceptive's risks and benefits, some of which (such as the small risk of heart disease) appear when use begins while others (such as protection against certain forms of cancer) only develop after several years of use but persist even after use has stopped. Overall, taking all known risks and benefits into account, the average woman in a Western nation actually increases her life expectancy by a small but calculable amount if she uses oral contraceptives, while the older woman, especially if she smokes, is at a small but measurably higher risk of death. In Western nations women over 40 and those over 35 who smoke are usually advised to use another method of birth control. Among women in Third World countries the risks of death from childbirth remain many times greater, and, although the pill has not been as closely studied in such settings, the advantages of its use are almost certainly correspondingly greater.

Male contraception. In normal circumstances a man can produce several million sperm per day and is almost continually fertile. A woman's menstrual cycle, with predictable time of ovulation, is medically much simpler to control. Research on a male pill has been disappointing. Sperm production has been controlled under experimental conditions, and in China a substance called gossypol, derived from the cottonseed, has been used as an oral contraceptive for males. Most substances used in the control of male fertility, however, either have proved toxic or have depressed sexual drive as well as sperm count.

Intrauterine devices. Almost any foreign body placed in the uterus will prevent pregnancy. While intrauterine devices (IUD's) were invented in the 19th century, they only came into widespread use in the late 1950s, when flexible plastic devices were developed by Jack Lippes and others. The IUD, made in a variety of shapes, is placed in the uterus by passing it through the cervix under sterile conditions. Like oral contraceptives, IUD's probably act in several complementary ways. When the IUD is in place an abnormally high number of white blood cells pass into the uterine cavity, and the egg, even if fertilized, is destroyed by the white blood cells before implantation. Nevertheless, one to three out of every 100 users per year will get pregnant with the IUD in place.

An intrauterine device can be inserted on any day of the menstrual period and immediately after a birth or abortion. The advantage of an IUD lies in its long-term protection and relative ease of use. The disadvantages include heavier menstrual flow and an increased risk of uterine infection. Approximately 60 million women use IUD's worldwide. The largest use is recorded in China. IUD's are most satisfactory when used by older women who have had children and are recommended less frequently for young women, primarily because of the risk of pelvic infection.

In 1970 Jaime Zipper, a physician from Chile, added copper to plastic devices, thereby permitting designs that caused less bleeding and increased effectiveness. IUD's that slowly release progesterone derivatives have also been developed.

Voluntary sterilization. More than 100,000,000 couples worldwide have selected sterilization, and the method prevents more pregnancies each year than any other method of birth control. Voluntary sterilization has proved popular in both rich and poor countries, and the number of operations performed is likely to continue to rise. Wherever sterilization of the female (tubal sterilization) has been offered it has proved popular. Fewer male sterilizations (vasectomies) than female sterilizations have been performed worldwide but demand grows consistently wherever a reliable service is offered.

Tubal sterilization and vasectomy

Vasectomy is a quick, simple operation normally carried out under local anesthesia. The vas deferens, the tube carrying the sperm from the testicles to the penis, is blocked, and a number of ejaculations must be made after the operation to remove all the sperm capable of fertilization. Local bleeding and infection can occur after the operation, but no long-term adverse effects have been demonstrated in men. In some animals, however, disease of the blood vessels has been reported to be more common after experimental vasectomy.

The fallopian tubes, which carry the egg from the ovary to the uterus, lie buried deep in the female pelvis. To perform sterilization a surgeon must either open the abdomen, in a procedure called laparotomy, and close the tubes under direct vision, or insert an optical instrument (laparoscope) to view the tubes so that a clip, ring, or electrocautery can be applied. The only proved side effects of female sterilization are those associated with any surgery and local or general anesthesia.

An individual seeking sterilization must accept the operation as irreversible while at the same time understanding that in rare cases, in either sex, the operation can fail even when properly carried out. In cases of extreme need, reversal of both female and male sterilization has been attempted, with more than 50 percent of patients later conceiving children. Surgical reversal is easier for male sterilization.

Abortion. Abortion is the termination of pregnancy less than 28 weeks after the last menstrual period. Until the eighth week of pregnancy the conceptus is called an embryo, and after that time a fetus. Abortion may be spontaneous (miscarriage) or induced, and induced abortions are legal in some circumstances in some countries and illegal in others. An incomplete abortion is one after which part of the conceptus remains in the uterus. It is associated with bleeding and the risk of infection.

Human reproduction is an imperfect process. Only one sperm is necessary for fertilization, yet the male's ejaculate contains millions of sperm. As many as half of the eggs fertilized die within 10 days of fertilization without the woman even knowing she has conceived. As many as one-fifth of recognized pregnancies miscarry. Much of this massive wastage is associated with chromosomal and other abnormalities in the embryo.

Induced abortion

Induced abortion has occurred throughout history and is known in almost all contemporary societies. A variety of herbs and potions have been used over the ages, and physical violence as a cause of abortion is mentioned in the Bible (Exodus 21:22). In the contemporary world tens of millions of abortions are performed annually. Some are deemed legal—*i.e.,* carried out by qualified persons with proper supervision—and others illegal. Massage abortion is common in Southeast Asia. It is usually conducted by a traditional birth attendant who pounds the pregnant abdomen until uterine bleeding commences or pain stops the procedure. In the rest of the world a common method is to pass an object through the neck of the womb to dislodge the placenta. Abortions performed by unqualified persons can endanger the woman's life. In Latin America, for example, approximately 1,000,000 women a year are admitted to hospitals suffering from incomplete abortions, mostly the result of illegal abortion.

Abortion and contraception have a complex relationship during the process of demographic change. A decline in the birth rate may reflect a rise in the number of abortions and the use of contraception. As the rate declines further, abortions peak (as in Japan in the 1950s and 1960s), but, if contraceptive services are readily available, then the number of abortions falls as the number of conceptions falls. If, however, contraceptive services are not readily available (as in the Soviet Union), then the number of abortions remains high.

The commonest technique of inducing legal abortion is vacuum aspiration of the uterine cavity. When completed before the 12th week of pregnancy the procedure is brief and can be done without general anesthesia. It has proved to be remarkably safe for the woman, with a death rate of less than one in 100,000 operations. Scraping (curettage) of the uterus is an older surgical procedure. It is less satisfactory than vacuum aspiration early in pregnancy but can be more easily used after 12 weeks. Late abortions can also be performed by chemical means (the introduction of prostaglandins) or by the injection of urea or salt into the space around the embryo.

FAMILY PLANNING SERVICES

National family planning movements have emphasized the right of the individual to determine family size as well as the contribution family planning can make to national and global population problems. Some methods of birth control, such as coitus interruptus and, in extreme cases, abortion, may involve no person other than the individual or couple. But most methods require manufacture, distribution, promotion, counselling, and in some cases financial subsidy.

The retail trade in contraceptives has been a major element in the spread of contraception and remains important in the developing world. In particular, social marketing programs, which adjust prices to people's needs, have allowed governments to make contraceptives available to large numbers of people quickly and at affordable cost. Private doctors may advise patients about the use of birth control on a confidential basis and may charge a fee.

National and international movements

The first altruistic attempts to offer direct family planning services began with private, pioneering groups and often aroused strong opposition. The work of Sanger and Stopes reached only a small fraction of the millions of couples who in the 1920s and '30s lived in a world irrevocably altered by World War I, crushed by economic depression, and striving for the then lowest birth rates in history. In 1921 Sanger founded the American Birth Control League, which in 1942 became the Planned Parenthood Federation of America. In Britain the Society for the Provision of

Birth Control Clinics was to evolve into the Family Planning Association. As early as 1881 the British Malthusian League had brought together individuals from 40 nations to discuss birth control, and five genuinely international meetings had taken place by 1930. A conference was held in Sweden in 1946. The first birth control clinic in India opened in 1930, and in 1952 in Bombay, Margaret Sanger took the first steps toward creating what became the International Planned Parenthood Federation (IPPF).

The modern era in international family planning opened in the second half of the 1960s when governments, beginning with Sweden, gave money to support the worldwide work of the IPPF. William Draper lobbied with particular effectiveness in the United States to build up the IPPF and to put together the United Nations Fund for Population Activities (UNFPA), established in 1969. For several years the U.S. Agency for International Development helped to support the IPPF and the UNFPA. The United Nations held international conferences on population in Bucharest in 1974 and Mexico City in 1984.

THE LEGALITY OF BIRTH CONTROL

The Comstock Act

In the 19th century the law was used as an assertion of existing morality. In the United States Anthony Comstock lobbied to pass an Act for the Suppression of Trade in, and the Circulation of, Obscene Literature and Articles of Immoral Use. When asked why he classified contraception with pornography, Comstock answered, "If you open the door to anything, the filth will pour in." Anti-contraceptive and anti-sterilization clauses were added to the Napoleonic Code applying to France and French colonies. In Britain, however, the law never specifically condemned contraception or sterilization, and Bradlaugh and Besant were accused under the Obscene Publications Act.

The 20th century has seen statute laws used as a vehicle of social change and as a battleground of conflicting philosophies. The Nazi Third Reich invaded the bedrooms of its citizens before it moved its troops into the Sudetenland and Czechoslovakia. It forbade the display of contraceptives, which it condemned as the "by-product of the asphalt civilization." By contrast, the Proclamation of Teheran in 1968 (paragraph 16) provided "Parents have a basic human right to determine freely and responsibly the number and spacing of their children." This concept was written into Yugoslavia's constitution, and China officially made family planning an obligation for each citizen. U.S. courts interpreted the constitutional right of privacy to include birth control choices when the Comstock Act was finally overthrown in the cases of *Griswold* v. *Connecticut* (1965) and *Eisenstadt* v. *Baird* (1972). In Ireland the case of Mary McGee (1973) reversed an Irish anti-contraceptive law of 1935, and in the Luigi deMarchi case in 1971 the Italian Supreme Court struck down the Fascist laws limiting the availability of contraception. At the other extreme, Singapore has passed legislation removing certain tax credits from couples with three or more children.

Laws prohibiting abortion

By the end of the 19th century almost every nation in the world had passed antiabortion legislation. In the United States restrictive laws were propelled not so much by moral considerations as by the desire of the medical profession to regulate the practices of unqualified doctors.

The 20th century has seen the pendulum swing in the opposite direction, and 70 percent of the world's population now lives in countries where abortion is legally available. The Soviet Union (1920) became the first country in the 20th century to permit legal abortion, and the Scandinavian and most Eastern European countries had liberal abortion laws by the late 1960s. In Britain the Offenses Against the Person Act of 1861 was reversed by the 1967 Abortion Law, and by 1970 Canada and several U.S. states (including New York State) had passed abortion reform legislation. Arguments usually centred on hard cases, such as that of a woman carrying an abnormal fetus or living in extreme poverty. On January 22, 1973, the U.S. Supreme Court struck down as unconstitutional all antiabortion laws remaining in the United States. The Court argued "that the right of personal privacy includes the abortion decision." India, China, Australia, Italy, France, The Netherlands, and many other countries decided to permit abortion under statute law or following individual case precedents. It has always been difficult to harmonize statute law with biological processes, and several new therapies, such as the use of drugs to induce delayed menstruation, and even the use of IUD's, have not been clearly defined as falling under the category of either contraception legislation or abortion legislation.

In this most controversial aspect of birth control, legal positions have oscillated, depending on circumstance and on government. In 1935 Joseph Stalin reversed Lenin's liberal abortion law in the Soviet Union, and the Nazis declared abortions to be "acts of sabotage against Germany's racial future." In 1942 a woman was guillotined in Nazi-dominated France as a punishment for abortion, and in 1943 the government of the Third Reich introduced the death penalty for abortionists who "continually impaired the vitality of the German people." After the defeat of the U.S. antiabortion laws in 1973, a strong drive was undertaken by antiabortionists in the United States to limit the interpretation of the Supreme Court ruling and, if possible, to reverse that ruling by congressional action, constitutional amendment, or the appointment to the Supreme Court of justices who were against abortion.

The law, by defining marriage age, regulating medical practice, and controlling advertising and such factors as the employment of women, also affects many other variables that determine the size of a family. For example, Section 4(5) of the 1954 British Television Act prohibits the advertising of matrimonial agencies, fortune-tellers, and contraceptives.

ETHICS AND THE INFLUENCE OF RELIGIOUS SYSTEMS

The ethics of birth control has always been a topic of debate. All of the world's major religions endorse responsible parenthood, but when it comes to methods the consensus often dissolves. Hindu and Buddhist teachings are linked by a belief in reincarnation, but this has not been extended to an obligation to achieve maximum fertility. The Buddhist religion requires abstinence from any form of killing, and strict Buddhist groups have interpreted this requirement as support for opposition to contraception. At the same time, Buddhist scripture contains the phrase "Many children make you poor," and the few prevailing constraints against birth control have been interpreted as affecting individuals, not state policy.

In the Muslim religion, the Prophet Muḥammad endorsed the use of *al-azl* (coitus interruptus) for socioeconomic reasons and to safeguard the health of women. The Qu'rān instructs, "Mothers shall give suck to their offspring for two whole years if they desire to complete their term" (II,233). In general, modern methods of family planning have been accepted by Islāmic religious leaders, although sterilization is resisted as mutilation. Some fundamentalist Islāmic groups, most notably in Iran in the 1980s, have opposed family planning in general.

The Judeo-Christian tradition has been more divided in its approach to birth control; and Europe and North America have had a disproportionate role in medical research and practice. Until the Industrial Revolution in the West, artificial methods of birth control seemed irrelevant or even antagonistic to reproduction and to the spiritual goals of marriage. Christendom was very slow to recognize new medical knowledge and new social needs, thereby retarding the development of birth control methods and diffusion of services. For example, in part because of religious objections, the U.S. National Institutes of Health were explicitly barred from research on contraception until 1961.

Historically, Jewish doctrines on marriage and procreation were related to the national struggle for survival and the traditions of a close-knit monotheistic community in which the individual was perpetuated through family. Judaism imposes an obligation to have children, although love and companionship are deemed an equally important goal of marriage. Orthodox sections of Judaism permit women to use certain methods of birth control, especially when necessary to protect the mother's health. Reformed and Conservative branches urge proper education in all methods of birth control as enhancing the spiritual life of the couple and the welfare of mankind. Many Jewish physicians and leaders, such as Alan Guttmacher, have joined in the advocating of birth control.

Augustine's views

The early Christian Church reacted against the hedonism of the later Roman Empire and, believing that the Second Coming of Christ preempted the need for procreation, held celibacy superior to marriage. Early Christians opposed the Gnostic movement that viewed the world as the creation of evil and procreation as the perpetuation of that evil. Instead they supported the Stoic argument that sexual passions distracted man from the contemplation of the One, the True, the Good, and the Beautiful. It was a short step for the 2nd-century theologian Clement of Alexandria to associate sexual intercourse with guilt and argue that it could only be justified by the obvious need to reproduce. Clement even argued that the human soul fled the body during a sexual climax. Augustine (AD 354–430), in his writings, especially in *Marriage and Concupiscence* (AD 418), laid the intellectual foundation for more than 1,000 years of Christian teaching on birth control. He concluded that the male semen both contained the new life and transmitted Adam's original sin from generation to generation.

Among the practices Augustine condemned were not only coitus interruptus (onanism) but also what today would be called natural family planning. Not surprisingly the explicit justification of periodic abstinence by the modern church continues to come into conflict with remnants of Augustine's more pessimistic identification of sex with sin.

An important challenge to traditional Roman Catholic teaching arose in 1853 when the church's Sacred Penitentiary ruled that couples using periodic abstinence were "not to be disturbed." Among all Christian denominations, however, change was halting. In 1920 the Anglican Lambeth Conference condemned "any deliberate cultivation of sexual activity as an end in itself," although by 1930 the Conference had taken some steps toward the moral justification of birth control. By 1958 its members concluded that "implicit within the bond of husband and wife is the relationship of love with its sacramental expression in physical union."

The Roman Catholic viewpoint developed even more slowly. The conservative theologian Arthur Vermeersch drafted much of Pope Pius XI's encyclical *Casti Connubii* (1930), condemning all methods of birth control except periodic abstinence as "grave sin." This teaching was reaffirmed by Pius XII in 1951. The Second Vatican Council (1962–65), however, described marriage as a "community of love" and the council's Constitution on the Church and the Modern World (*Gaudium et Spes*) exhorts parents to "thoughtfully take into account both their own welfare and that of their children, those already born and those which may be foreseen." Once the dual purposes of sexual relations to procreate and to express love had been accepted by the Second Vatican Council, however, some theologians and a great many Roman Catholic couples examined their own consciences and found it increasingly difficult to distinguish between intercourse during intervals of infertility brought about by the use of hormonal contraceptives and intercourse during the infertile intervals of the menstrual cycle. John Rock, who helped to develop the contraceptive pill and was himself a Roman Catholic, argued for just such a reassessment in his book *The Time Has Come* (1963). Gathering pressure led to the establishment of the Commission for the Study of Population and Family Life. It submitted its report to Pope Paul in 1966. Among the commission's members, the medical experts recommended by a vote of 60 to four, and the cardinals by nine to six, to liberalize Roman Catholic teaching on birth control.

The *Humanae Vitae*

In 1968, however, Pope Paul restated the traditional teaching of *Casti Connubii* in his landmark encyclical *Humanae Vitae*, using papal authority to assert that "every conjugal act [has] to be open to the transmission of life." *Humanae Vitae* came as a surprise to most church leaders and left many of the laity in a painful conflict between obedience and conscience. Six hundred Roman Catholic scholars signed a statement challenging *Humanae Vitae*, many episcopates attempted to soften the harsher aspects of the encyclical, a flood of priests left the church, and the number of U.S. Catholics attending mass weekly fell from 70 percent before the issuing of the encyclical to 44 percent a few years afterward. The total marital fertility (the number of children in a completed family) of U.S. Catholics (2.27 in 1975) became virtually the same as that of non-Catholics (2.17). At the same time a new movement began within the Roman Catholic Church, taking strength and inspiration from *Humanae Vitae*. Among lay organizations, the International Federation for Family Life Promotion was founded in 1974 and the Family of the Americas Foundation (formerly World Organization of the Ovulation Method—Billings; WOOMB) was founded in 1977.

The Eastern Orthodox Church maintains that parenthood is a duty. While it considers the use of contraception to be a failure in spiritual focus, the church has not sought to hinder the distribution of birth control information or services.

Misuse of birth control

Birth control, like other technologies, can be misused. In the 19th century vasectomy was used for men judged to be compulsive masturbators, and a century later, during the state of emergency declared in India in 1975, the Indian government supported forcible sterilization of low-caste men as part of a population control program. In the not too distant past unmarried women in the Western world who became pregnant faced such hostility from society in general that the majority felt they had no choice but illegal abortion, while in China today women are subject to intense social pressure to legally abort a second or subsequent pregnancy inside marriage. In contemporary Western society conventional restraints on sexual experience prior to marriage are in turmoil. Vigorous debate centres on the question of whether the availability of birth control to young people encourages premarital sexual relations or avoids unplanned pregnancies that otherwise might occur. Certainly, similar patterns of availability of contraceptives may be observed in markedly different social settings with high and low incidence of premarital sex (for example, the United States and China, respectively). There is no evidence that the availability of birth control either encourages or discourages particular patterns of sexual behaviour.

Personal opinions on abortion

The debate over the ethics of induced abortion can arouse deep divisions even in otherwise homogeneous groups. At one extreme abortion is considered to be the moral equivalent of murder and the life of the fetus is held to take precedence over that of the pregnant woman. At the other extreme it is argued that a woman has an absolute right over the pregnancy within her body. Surveys of opinion show that most people find abortion to be a sad and complex topic. The majority would prefer not to experience abortion but nevertheless feels that abortion is justified in certain cases, such as when tests show evidence of congenital abnormality, when pregnancy results from sexual crimes, or when the parents live in extreme poverty. The embryological discoveries of the past century cannot solve the metaphysical questions posed in the past. The U.S. Supreme Court decision on abortion in 1973 concluded "We need not resolve the difficult question of when life begins. When those trained in the respective disciplines of medicine, philosophy, and theology are unable to arrive at any consensus, the judiciary, at this point in the development of man's knowledge, is not in a position to speculate as to the answer." In short, the definition individuals give to the beginning of life determines their judgment about the acceptability or licitness of abortion, and those definitions remain in the sphere of wholly human judgment.

CONCLUSIONS

Modern mankind can never return to the way of life that characterized most of human evolution. Settled agriculture and, to an even greater extent, urban living have irrevocably altered natural, finely tuned patterns of human reproduction. New social and artificial restraints on fertility must replace high infant mortalities and the invisible but important physiological controls that once limited family size. The variables that encourage small families are still not fully understood, but they include urbanization, educational and employment opportunities for women, and easy access to family planning services. In a traditional agricultural society children bring hope of economic rewards to their parents at an early stage by sharing in the work that is necessary to support the family, whereas in modern industrial societies the care and educating of children represent long years of heavy expenditure by the parents. This switch in the cost of children may be the most important factor determining the adoption of family planning.

Western societies took more than a century to reach zero population growth and adjust to the rapid expansion of population that accompanied their industrialization. Most of the changes that occurred in patterns of family planning took place before public family services were established and at considerable emotional and physical costs to many couples. By contrast, the majority of the governments of contemporary Third World countries have established national family planning policies and actively encourage the use of public family services. The World Fertility Survey shows that more couples in developing countries desire small families than actually achieve their goals.

The significance of the choices facing policymakers and individual families can be illustrated by reference to trends in family planning in the People's Republic of China. For a generation after the Revolution of 1949 national leaders maintained that a Communist economy could accommodate any rate of population growth, and family planning services, while available, were not emphasized. As a result of the rapid population growth in the 1950s and '60s, however, the number of marriages in China exceeds by 10,000,000 each year the number of fertile partnerships broken by death or by the onset of the woman's menopause. In order to try to stabilize the population, the Chinese government has recommended that 50 percent of rural couples and 80 percent of urban couples have only one child. The application of this type of policy can have an ironic effect on individual women: older women belong to a generation that could not always obtain birth control services, and younger women may be encouraged or, in some cases, even forced to abort pregnancies they would like to keep.

Although consensus has not been reached on the range of birth control methods society should offer to individual members, the right of couples to determine the number and spacing of their children is almost universally endorsed, while the possibility of coercive family planning is almost as widely condemned. Throughout the world, awareness of the advantages and disadvantages of specific methods of birth control, thoughtful judgments about ethics, and further evolution in medical and scientific knowledge will continue to be important to the welfare of the family, of individual nations, and of the entire globe.

Bismarck

Otto von Bismarck—or Otto Eduard Leopold, Prince von Bismarck, Count von Bismarck-Schönhausen, Duke von Lauenburg—was a Prussian statesman who in 1871 founded the German Empire and served as its first chancellor for 19 years. Once the empire was established, he actively and skillfully pursued pacific policies in foreign affairs, succeeding in preserving the peace in Europe for about two decades. But in domestic policies his patrimony was less benign, for he failed to rise above the authoritarian proclivities of the landed squirearchy to which he was born.

Archiv fur Kunst und Geschichte

Bismarck, 1880.

LIFE

Early years. Bismarck was born on April 1, 1815, at Schönhausen, near Magdeburg, in the northeastern provinces of Prussia. His father, Ferdinand von Bismarck-Schönhausen, was a Junker squire descended from a Swabian family that had ultimately settled as estate owners in Pomerania. Ferdinand was a typical member of the Prussian landowning elite. The family's economic circumstances were modest—Ferdinand's farming skills being perhaps less than average—and Bismarck was not to know real wealth until the rewards flowed in after the achievement of German unification. His mother, Whilhelmine Mencken, came from an educated bourgeois family that had produced a number of higher civil servants and academics. She had been married to Ferdinand von Bismarck at age 16 and found provincial life confining. When her son Otto was seven, she enrolled him in the progressive Plamann Institute in Berlin and moved to the capital to be near him. The young Bismarck resented exchanging an easy life in the country for a more circumscribed life in a large city, where in school he was pitted against the sons of Berlin's best-educated families. He spent five years at the school and went on to the Frederick William gymnasium for three years. He took his university entrance examination (*Abitur*) in 1832.

Education

With his mother's encouragement, he took up the study of law at the University of Göttingen in the kingdom of Hanover. Evidently Bismarck was a mediocre student who spent much of his time drinking with his comrades in an aristocratic fraternity. After a brief stint at the university in Berlin, he entered the Prussian civil service, where he was plagued by boredom and an inability to adhere to the hierarchical principles of the bureaucracy. His mother's death in 1839 gave him the opportunity of resigning in order to come to the assistance of his father, who was experiencing financial difficulties in the management of his estate. From 1839 to 1847 Bismarck lived the ordinary life of a Prussian country squire. Subsequently he was to romanticize these years on the land and wonder why he had abandoned an idyllic existence for the insecurities of a life in politics. This frequently expressed nostalgia may have been more guise than reality.

During this period he met and married Johanna von Puttkamer, the daughter of a conservative aristocratic family famed for its devout pietism. While courting Johanna, Bismarck experienced a religious conversion that was to give him inner strength and security. A subsequent critic was to remark that Bismarck believed in a God who invariably agreed with him on all issues. There is no question that the marriage was a very happy one. Bismarck's last words before dying in 1898 expressed the wish that he would see Johanna, who had died some years earlier, once again.

His politics during the 1840s did not diverge substantially from those of a typical country squire; if anything, they were more conservative. He believed in a Christian state that received its sanction ultimately from the deity. The existing social and political order was to be defended in order to prevent a Hobbesian chaos of all against all. Given his views, Bismarck was welcomed as a member of the religious conservative circle around the brothers von Gerlach, who were stout defenders of the noble estate against the encroachments of bureaucratic centralization. Bismarck had nothing but sarcasm for aristocratic liberals who viewed England as a model for Prussia. In 1847 he attended the Prussian United Diet, where his speeches against Jewish emancipation and contemporary liberalism gained him the reputation of a backwoods conservative, out of touch with the dynamic forces of his age.

Bismarck's response to the liberal revolution that swept through Europe in 1848 confirmed his image as a reactionary. He opposed any concessions to the liberals and expressed contempt for the king's willingness to bargain with the revolutionaries. He even considered marching his peasants to Berlin to free Frederick William IV from the baneful influence of the rebels. With other archconservatives, including Ernst Ludwig von Gerlach, he began contributing to the *Kreuzzeitung* newspaper (1848) as an organ of antirevolutionary sentiment.

Response to the revolution of 1848

For Bismarck's future role, it is important to understand his analysis of the revolution. Like his contemporary Karl Marx, he identified the forces of change as confined solely to the educated and propertied middle class. The vast majority of Prussians, however, were peasants and artisans, who, in Bismarck's view, were loyal monarchists. The task of the forces of order was to confirm the loyalty of these two groups by means of material concessions. The economic policies of the urban middle-class radicals were rooted in pure self-interest, he maintained. The radicals would spur industrial growth at the expense of the lower middle class and the farm population. Ultimately, even the middle class itself might be won over by tactical concessions and success in foreign policy. This strategic and opportunist thinking distanced Bismarck from the ideological conservatives, who were wedded to traditional concepts of authority. His vision of a manipulative state that sustained its power by rewarding obedient groups remained with him throughout his political career.

Early career. In 1849 he was elected to the Prussian Chamber of Deputies (the lower chamber of the Prussian Diet) and moved his family to Berlin. At this stage he was far from a German nationalist. He told one of his fellow conservatives, "We are Prussians, and Prussians we shall remain. . . . We do not wish to see the Kingdom of Prussia obliterated in the putrid brew of cosy south German sentimentality." In 1851 Frederick William IV appointed Bismarck as the Prussian representative to the federal Diet in Frankfurt, a clear reward for his loyalty to the monarchy.

With the defeat of the revolution in central Europe, Austria had reasserted its supremacy in the German Confederation, and Bismarck, being an archconservative, was assumed to support the status quo, which included Austrian hegemony. He lived in Frankfurt for eight years, where he experienced a commercial and cultural environment quite different from that of a Prussian estate.

It was in Frankfurt that Bismarck began to reassess his view of German nationalism and the goals of Prussian foreign policy. Not only did he find the constant deference to the Austrians in Frankfurt demeaning, but he also realized that the status quo meant acceptance of Prussia as a second-rate power in central Europe. In 1854 he opposed close cooperation with Austria, arguing that it entailed "binding our spruce and seaworthy frigate to the wormy old warship of Austria." Gradually he began to consider the options that would make Prussia the undisputed power in Germany. A vision of a Prussian-dominated northern Europe and a redirection of Austrian power to the Slavic areas in the south took shape in his mind. If necessary, a war with Austria to destroy its hegemony was not to be excluded. Implementation of such a policy would be anything but conservative because it would entail radical changes in the map of Europe as it had been drawn by the conservative powers at Versailles in 1815.

Experience in foreign affairs

Prime minister. In 1859 Bismarck was sent to Russia as Prussian ambassador, and not long thereafter (May 1862) he moved to Paris as ambassador to the court of Napoleon III. Thus he had 11 years of experience in foreign affairs before he became prime minister and foreign minster of Prussia in September 1862. He had come to know personally the architects of French, Russian, and Austrian foreign policy. Ironically, Bismarck was called back by King William I (1861–88) to the reigns of power at a critical juncture in Prussia's internal development.

For more than two years William had been locked in a battle with the Chamber of Deputies over military reform. Having been in the army much of his adult life, the monarch (similar to earlier Prussian kings) considered it entirely within his prerogative to increase the size of the military and the years of service. When the liberal majority did not approve the revenue for these reforms, William refused to negotiate or compromise with liberal politicians over the fundamental issue of sovereignty. He prorogued Parliament twice, and each time the liberal majority increased.

The appointment of Bismarck was the monarch's last desperate effort to avoid parliamentary sovereignty over the military. The Chamber of Deputies interpreted it as an act of defiance—a throwing down of the gauntlet. But the Bismarck who returned to Berlin from Paris was not the backwoods conservative of 1848. Having lived in Frankfurt and Paris, he had come to appreciate the growing importance of the propertied and educated middle class. And in France he had experienced the Bonapartist regime of Napoleon III, which relied on the combination of success in foreign policy and plebiscites at home to shore up the emperor's authoritarian regime. Bismarck had changed to such a degree that he actually returned with the idea of seeking a compromise over the military issue. But William I rejected a sensible proposal offered by Bismarck, leaving him no alternative but a policy of confrontation. Bismarck then announced that there was a "hole" in the constitution. If the king and the members of the Upper Chamber and the Chamber of Deputies, who together were responsible for the budget, failed to come to an agreement, the government in the interim had to proceed without it. Taxes were to be collected (and spent) on the basis of the old budget because civil servants had to be paid and the government had to continue functioning. This tactic, applied from 1863 to 1866, allowed him to implement the military reforms without the sanction of Parliament. Bismarck did, indeed, appear to be the reactionary, confrontational aristocrat out of tune with his time.

But there were hints that this was more appearance than reality. Bismarck said that "Prussia must collect and keep its strength for the right moment, which has been missed several times already; Prussia's frontiers as laid down by the Vienna treaties are not conducive to a healthy national life; it is not by means of speeches and majority resolutions that the great issues of the day will be decided—that was the great mistake of 1848 and 1849—but by blood and iron." He was giving the opposition evidence that he intended to use Prussia's military might not for internal suppression but for the liberal goal of achieving national unification. The liberal opposition, however, chose to ignore these hints, and on May 22, 1863, by a vote of 239 to 61, they informed William I that they would not deal with his prime minister any further. After eight months in office, Bismarck had failed to achieve any agreement with the parliamentary opposition.

Bismarck now turned to foreign policy in the hope that success on this front would weaken the electorate's clear desire for political reform. Trouble had been brewing since 1848 between the Danes and the German population of the duchies of Schleswig and Holstein. (Both duchies were in union with Denmark; Schleswig, however, had a large German population, and Holstein was a member of the German Confederation.) When the Danish king acted rashly, Bismarck made sure that it was Prussia and Austria rather than the German Confederation which represented German interests. Liberal leaders like Rudolf Virchow still saw Bismarck as an unrepentant reactionary who was "no longer the man who joined us with feeling that he was going to accomplish something with an energetic foreign policy."

Convention of Gastein

A quick successful war against Denmark left the fate of Schleswig and Holstein up to Bismarck and the Austrians. After much haggling, the Convention of Gastein was signed on Aug. 20, 1865; it provided for Schleswig to be administered by Prussia and Holstein by Austria. Liberals remained unappeased by Prussian military prowess and once again defeated the army bill in January 1865.

In 1866 Bismarck nonetheless continued his efforts to divert liberal interest from the budget conflict and toward the success of Prussian arms. He repeatedly told the Austrians that their future lay in the south and that they would be wise to yield dominance in Germany. But in both cases his words fell on deaf ears. Bismarck had clearly decided to play the German national card in order to achieve a Prussian-dominated Germany. After making sure that Russia would not intervene and after gaining an alliance with Italy, he set about fostering conflict with the Austrians. He stirred up Hungarian nationalism against Austria—a policy that showed how radical means could be used in the service of his own conservative ends. On June 9, 1866, Prussian troops invaded Holstein, and a few days later Austria, supported by the smaller states of Saxony, Hesse-Kassel, and Hanover, went to war. Within six weeks Prussia had inflicted a major defeat on the Austrians at Königgrätz (Sadowa). Bismarck then counseled moderation so that Austria would not be humiliated. Against a king and generals who wanted to march to Vienna, he urged a quick cessation of hostilities, recognizing that other powers might intervene if the war continued. Europe was stunned: in a few weeks Prussia had transformed the distribution of power in central Europe. Austria, the major power in Germany for centuries, was now relegated to secondary status.

Bismarck now showed both ruthlessness and moderation. The Peace of Nikolsburg scarcely demanded anything from Austria. But Hanover, Hesse-Kassel, Nassau, and Frankfurt, all of which had fought against Prussia, were annexed, to the shock of conservatives. The king of Hanover was removed from power, as was the ruling house in Hesse. While conservatives were appalled at the German civil war between the two powers who had been opposed to revolution, the liberal middle class flocked to support Bismarck. Their goal of German unification seemed close at hand. Bismarck, moreover, now apologized for his high-handedness over the issue of the military budget and offered an olive branch of peace to the liberals. The party divided over Bismarck's offer. He had achieved one of his major goals—gaining a large part of the middle class to see the Prussian monarchy as their ally.

The North German Confederation was established in 1867 with Prussia as its matrix. Its constitution, on the

The North German Confederation

surface, appeared progressive. To begin with, it established universal manhood suffrage with a secret ballot. But this was a result of Bismarck's belief that the vast majority of Prussians, if enfranchised, would vote conservative. From this perspective, a restricted ballot aided the liberals. (Of course, in 1867 neither the socialists nor the Catholic Centre had established political parties.) Moreover, whereas in theory the lower house (Reichstag) seemed an important reservoir of power given its ability to reject any bill, in practice its powers were circumscribed in the areas of military and foreign policy. Ministers were chosen by and responsible to the king and not the legislature. Nevertheless, the constitution provided a basis for evolution in a democratic direction.

Although Bismarck voiced doubts whether unification would occur in his lifetime, he actually set about tying the southern states to the north almost immediately. An all-German customs parliament was proposed, joint military training was negotiated, and a plan was advanced which entailed that the southern states recognize William as German emperor. All these efforts failed because of popular opposition in the south. Bismarck then sought to propel history a bit faster by seeking conflict with France. If he could not bring the south into a united German nation by reason, he would rely on the passions aroused by war. Ever the master tactician, he worked behind the scenes to be certain that neither Russia nor Austria would intervene in such a war. Nor did he have to work hard to produce a conflict, because the French emperor, Napoleon III, was indignant at the sudden emergence of Prussia, especially since he did not receive the compensation he sought—the annexation of Luxembourg.

When in 1869 the Spanish throne was offered to the king's cousin, Prince Leopold of Hohenzollern-Sigmaringen, Napoleon III perceived this as an effort to encircle France. He twice sent his ambassador, Vincent Benedetti, to the Prussian king at Bad Ems, once to demand that acceptance of the offer be withdrawn (which it was on July 12) and a second time to demand that under no circumstances should a member of the Hohenzollern family accept the Spanish throne in the future. The king politely refused the second request. Bismarck received a telegram from Bad Ems (the Ems telegram) giving a detailed account of the interview between William I and the French ambassador, which he proceeded to edit and abridge for the press in such a way that the French appeared to seek a humiliation of the Prussian monarch, and the monarch's rejection of Napoleon's demands seemed insultingly brusque to the French. The French responded by declaring war on Prussia on July 19, 1870. When the French were decisively defeated at Sedan in September, it appeared as though Bismarck would be able to score a third rapid victory in seven years. But guerrilla warfare broke out, and Paris held out despite the capture of the emperor. Bismarck, however, stirred anti-French passions to such a fever pitch that in January 1871 the four southern states joined the North German Confederation to create the German Empire. The lesser German solution, with seven million German-speaking Austrians excluded, was the result of Bismarck's three wars. He was showered with honours and hailed as a national hero.

The German Empire

Imperial chancellor. It is important to note that the Germany Bismarck created was not the result of strong popular currents of nationalist sentiment but of cabinet diplomacy and war. Not all German-speaking areas of Europe were included but only as many as Prussia could unite while retaining hegemony. The new constitution was a revision of the Prussian constitution from 1867; it included the position of chancellor, designed with Bismarck specifically in mind. Bismarck also remained prime minister of Prussia until 1890, apart from a brief period in 1872–73.

The peace treaty with France was harsh. Alsace and Lorraine, two French provinces with sizable German-speaking populations, were annexed. Also, a five-billion-franc indemnity was exacted. While Austria and Denmark quickly forgot their defeats, France did not. Regardless of whether Bismarck annexed the provinces in response to German public opinion or for other reasons, French hostility was to haunt the German Empire until the provinces were returned to France in 1918.

Foreign policy. Until his resignation in 1890, Bismarck had a relatively free hand in the conduct of foreign policy. After three successful wars, he saw his task as promoting peace and gaining time so that the powerful German Empire would come to be accepted as natural. Bismarck's two areas of concern were the Balkans, where the disintegration of the Turkish empire could easily lead to conflict between the Habsburg monarchy and Russia, and France, where the desire to avenge the defeat at Sedan was strong. In each area a general European conflagration could flare up and involve Germany. In 1873 he embraced a pacific foreign policy when he negotiated the Dreikaiserbund (Three Emperors' League) with Russia and Austria-Hungary. But the alliance did not survive the Russo-Turkish War of 1877. When the Austrians and British threatened war over a Carthaginian peace imposed on Turkey by the Russian victors, Bismarck called for a peace congress in Berlin. The German chancellor succeeded in getting the Russians to moderate their gains, and peace was preserved.

But a European conflagration had barely been averted. Soon after the conference, Bismarck negotiated a defensive alliance with Austria-Hungary, which remained in effect through World War I. Although in the mid-1860s he had rejected such an alliance as harmful, he now considered it advantageous. Because he feared that the dissolution of the Habsburg monarchy would lead to Russian expansion into central Europe, he sought the alliance to gain leverage in Vienna. He steadfastly used it to prevent a war in the Balkans. In addition, he did not want seven million Austro-German Catholics seeking admission to the empire.

Dreikaiserbund

Having a solid ally, Bismarck demonstrated his virtuosity by negotiating a revived Dreikaiserbund in 1881. He now had influence in St. Petersburg as well as in Vienna to prevent a Balkan war. In 1882, Italy, fearing French hostility, joined the Dual Alliance, making it into the Triple Alliance. On the surface Bismarck had triumphed. France had no allies for a war of revenge, and, for the moment, a Balkan war seemed unlikely.

But the ephemeral nature of all these alliances soon became apparent. A crisis in Bulgaria inflamed Russo-Austrian relations, leading to a breakup of the revived league. Once again a war was avoided with Bismarck's intervention, but his efforts could not reconstitute the league. He then negotiated a separate secret treaty with Russia, while maintaining the 1879 accord with Austria-Hungary.

Between 1870 and 1890 Bismarck earned the respect of European leaders for his earnest efforts in behalf of peace. Apart from a few colonial acquisitions in the mid-1880s, Germany had acted as a satiate power. All of Bismarck's considerable tactical skills had been successful in creating a powerful German Empire in his first decade in power. For the next two decades these same skills maintained the peace.

Domestic policy. From the defeat of Austria in 1866 until 1878 Bismarck was allied primarily with the National Liberals. Together they created a civil and criminal code for the new empire and accomplished Germany's adoption of the gold standard and move toward free trade. Just as they had earlier written off Bismarck as an archconservative, liberals now viewed him as a comrade—a man who had rejected his conservative roots. Many conservative leaders agreed with this assessment. Bismarck had cashiered kings, gone to war against conservative regimes, and adopted policies that promoted rapid industrialization. Their fears were further enhanced when he joined liberals in a campaign against political Catholicism (Kulturkampf) in 1873.

Bismarck had not counted on the emergence of new parties such as the Catholic Centre or the Social Democrats, both of whom began participating in imperial and Prussian elections in the early 1870s. Along with the left liberal Progressive Party, he labeled them all enemies of the empire (*Reichsfeinde*). Each in its own way rejected his vision of a united Germany. The Progressives found the empire too conservative and its elite essentially feudal; the socialists questioned its capitalist character; and for the Centre the empire was Protestant and too centralized.

Bismarck's aim was clearly to destroy the Catholic Centre Party. He and the liberals feared the appeal of a clerical party to the one-third of Germans who professed Roman Catholicism. In Prussia the minister of public worship and education, Adalbert Falk, with Bismarck's blessing, introduced a series of bills establishing civil marriage, limiting the movement of the clergy, and dissolving religious orders. All church appointments were to be approved by the state. Clerical civil servants were purged from the Prussian administration. Hundreds of parishes and several bishoprics were left without incumbents.

The Kulturkampf failed to achieve its goals and, if anything, convinced the Catholic minority that their fear of persecution was real. Bismarck gradually relented in his campaign, especially after the death of the activist pope, Pius IX, in 1878. But he never relented in his hatred for the Centre leader, Ludwig Windthorst, a Hanoverian who had earlier experienced Bismarck's methods in the annexation of his kingdom. Bismarck's speeches continued to be barbed with anticlericalism until his fall in 1890.

Change in economic policy

In 1878–79 Bismarck initiated a significant change in economic policy, which coincided with his new alliance with the conservative parties at the expense of the liberals. Tariffs were introduced on iron as well as on major grains. The new policy was a result of the "great depression" that had swept Europe and the United States in the mid-1870s. Bismarck's shift had serious political implications: it signified his opposition to any further evolution in the direction of political democracy. The liberal ministers Falk and Rudolph von Delbrück resigned, and Robert von Puttkamer became minister of public worship and education in 1879 and minister of interior in 1881. The grain tariffs provided the Junker estate owners of Prussia, who constituted the main opposition to political reform, subventions that isolated them somewhat from the world market. From 1879 onward, the landed elite, major industrialists, the military, and higher civil servants formed an alliance to forestall the rise of social democracy.

Ever since the Commune of Paris of 1871, Bismarck had developed an uncompromising hatred for socialists and anarchists. His attacks on them were egregious. At one point he wrote, "They are this country's rats and should be exterminated." Another time he called them "a host of enemies bent on pillage and murder." He thus introduced a crude and unsavory discourse into everyday German politics that was to be long-lived. Although only two socialists sat in the Reichstag in 1871, their number and support grew with each election, until they had 35 seats in 1890. As early as 1876 Bismarck had sought legislation to outlaw the party but failed to get a majority. After two assassination attempts against William I he prorogued Parliament and ran a campaign in which the socialists (quite unjustly) were blamed for the failed efforts to kill the emperor. The conservative parties triumphed and the Social Democratic Party was banned in 1878. The ban was renewed until 1890.

The second part of Bismarck's strategy to destroy social democracy was the introduction of social legislation to woo the workers away from political radicalism. During the 1880s, accident and old-age insurance as well as a form of socialized medicine were introduced and implemented by the government. But Bismarck's two-pronged strategy to win the workers for the conservative regime did not succeed. Support for the Social Democrats increased with each election.

Resignation

The election of 1890 was a disaster for Bismarck. The Centre, the Social Democrats, and the Progressives, the parties that he had termed enemies of the empire, gained more than half of the seats in the new Reichstag. The new young emperor William II (b. 1859; emperor and king of Prussia from 1888 to 1918) did not want to begin his reign with a bloodbath or a coup d'état by the state. Seventy-five years old in 1890, Bismarck resigned with a sense of having failed. The antisocialist law was not revived, and the new government set out to win the workers to the regime. Bismarck retired to his estate an embittered man. That he was now a prince and extremely wealthy did not ease his retirement. For the next eight years (he died on July 30, 1898) he issued sharp critiques of his successors. Elected to the Reichstag, he chose not to take his seat. He wrote his memoirs, which became best-sellers. To some extent he orchestrated the Bismarck legend that was to dominate German historical writing for the next half century.

ASSESSMENT

Bismarck was a towering figure who put his stamp on his age, as Luther and Metternich had done earlier. When Bismarck became prime minister of Prussia in 1862, the kingdom was universally considered the weakest of the five European powers. Less than nine years later Prussia had been victorious in three wars, and a unified German Empire had emerged in the heart of Europe, arousing envy and fear among its rivals. When Bismarck left office in 1890, after 28 years as prime minister of Prussia and 19 as chancellor of the German Empire, the map of Europe had been changed beyond measure. The European centre, characterized by a weak conglomeration of small and medium-sized states for centuries, was now home to the foremost military and industrial power on the Continent.

Bismarck's legacy to the next generation, however, was a mixed one. In foreign affairs his skill had led to 20 years of peace in Europe, which had gained him a deserved reputation for moderation and a sense of limits. Bismarck's greatest achievement, the German Empire, only survived him by 20 years. Although he had united Germany in one sense, he had failed to create an internally unified people. In domestic affairs—as in foreign policy—he sought to freeze the status quo after 1871. His empire was designed to be conservative. Thus he opposed the Catholic Centre in the 1870s and the socialists in the 1880s because both constituted unforeseen threats to his authoritarian creation. He also introduced a vicious rhetoric into German politics that forestalled a sense of common destiny. While German industry developed rapidly during his decades in power, he would allow no evolution in the political system toward greater participation. In this sense, Bismarck was a last representative of the world of the ancien régime and cabinet diplomacy.

BIBLIOGRAPHY. Studies of Bismarck's life include ALAN PALMER, *Bismarck* (1976); GEORGE O. KENT, *Bismarck and His Times* (1978); FRITZ STERN, *Gold and Iron: Bismarck, Bleichröder, and the Building of the German Empire* (1977, reissued 1987), a dual biography of Bismarck and his banker, based on archival sources; and LOTHAR GALL, *Bismarck, the White Revolutionary,* 2 vol. (1986; originally published in German, 1980), a somewhat revisionist analysis regarding the author's positive assessment of Bismarck's first two decades of power. OTTO VON BISMARCK, *Reflections and Reminiscences,* ed. by THEODORE S. HAMEROW (1968), is a compilation of translated excerpts from Bismarck's memoirs and is of interest as the highly literary work of a political genius, although its historical accuracy is suspect.

Interpretive histories of 19th-century Germany that provide insights into Bismarck's role in the events of the period include JAMES J. SHEEHAN, *German Liberalism in the Nineteenth Century* (1978, reissued 1982), dealing with two liberal parties and their evolution during the Bismarckian and Wilhelmian periods; OTTO PFLANZE, *Bismarck and the Development of Germany: The Period of Unification, 1815–1871* (1963, reprinted 1971), a thorough study of Bismarckian policies leading to the creation of a united Germany in 1871; MARGARET LAVINIA ANDERSON, *Windthorst: A Political Biography* (1981), an examination of the life of the leader of the Catholic Centre Party and a major opponent of Bismarck; GEORGE F. KENNAN, *The Decline of Bismarck's European Order: Franco-Russian Relations, 1875–1890* (1979), a traditional diplomatic history stressing the stability created by Bismarck's diplomacy; VERNON L. LIDTKE, *The Outlawed Party: Social Democracy in Germany, 1878–1890* (1966), an exploration of the 12 years of the Bismarckian period when the Social Democratic Party was illegal; DAVID BLACKBOURN AND GEOFF ELEY, *The Peculiarities of German History: Bourgeois Society and Politics in Nineteenth-Century Germany* (1984), a neo-Marxist interpretation of late 19th-century Germany, stressing its similarity to other Western nations; and HANS-ULRICH WEHLER, *The German Empire, 1871–1918* (1985; originally published in German, 1973; 5th German ed., 1983), a critical study of the Bismarckian period stressing the shortcomings of his achievement. Blood

Human blood consists of several types of specialized cells suspended in a liquid medium, plasma. The circulatory system provides the mechanism by which the blood transports many substances to and from the organs and tissues. The circulating blood continuously supplies oxygen, nutrient substances, and other materials necessary for the viability and activity of all the cells of the body and carries away cell products, including carbon dioxide and other waste materials. If blood flow ceases, death occurs within minutes because of the effects of an unfavourable environment on highly susceptible cells.

The constancy of the composition of the blood is made possible by the circulation, which conveys blood through the organs that regulate the concentrations of its components. In the lungs blood acquires oxygen and releases carbon dioxide transported from the tissues. The kidneys remove excess water and dissolved waste products. Nutrient substances derived from food reach the bloodstream after absorption by the intestinal tract. Endocrine glands release their secretions into the blood, which transports these hormones to the tissues in which they exert their effects. Many substances are recycled through the blood; for example, iron released during the destruction of old red cells is conveyed by the plasma to sites of new red cell production where it is reused. Each of the numerous components of the blood is kept within appropriate concentration limits by an effective regulatory mechanism. In many instances feedback control systems are operative; thus a declining level of blood sugar leads to accelerated release of sugar into the blood so that a potentially hazardous depletion of blood sugar does not occur.

Unicellular organisms, primitive multicellular animals, and the early embryos of higher forms of life lack a circulatory system, and exchange of substances between cell and environment is accomplished by simple diffusion. In larger and more complex animals transport of adequate amounts of oxygen and other substances requires some type of blood circulation. The diffusion process then occurs between the body cells and the fluid derived from the blood, which by its constant motion maintains the constancy of the internal environment. Some simple animals, including small worms and mollusks, have blood that lacks an oxygen-binding substance analogous to hemoglobin; others are provided with pigments capable of transporting relatively large amounts of oxygen. In many invertebrates the blood pigment is dissolved in the plasma. Hemocyanin, a copper-containing protein chemically unlike hemoglobin, is found in certain crabs and other lower animals. Hemocyanin is blue in colour when oxygenated and colourless when oxygen is removed. Some invertebrates have hemoglobin in solution in the plasma. In almost all vertebrates, including humans, hemoglobin is contained exclusively within the red cells (erythrocytes) of the blood. The red cells of the lower vertebrates (*e.g.,* birds) have a nucleus, whereas mammalian red cells lack a nucleus. Red cells vary markedly in size among mammals; those of the goat are much smaller than those of humans, but the goat compensates by having many more red cells per unit volume of blood. The concentration of hemoglobin inside the red cell varies little between species.

For additional information on blood in general and comparison of the blood and lymph of diverse organisms, see TISSUES AND FLUIDS: *The tissues and fluids of animals: Blood and lymph* and CIRCULATION AND CIRCULATORY SYSTEMS. This article is divided into the following sections:

Characteristics of human blood

PROPERTIES

Blood is an opaque red fluid, freely flowing but denser and more viscous than water. The characteristic colour is imparted by hemoglobin, a unique iron-containing protein. Hemoglobin brightens in colour when saturated with oxygen (oxyhemoglobin) and darkens when oxygen is removed (deoxyhemoglobin). For this reason, the partially deoxygenated blood from a vein is darker than oxygenated blood from an artery. The red cells constitute about 45 percent of the volume of the blood, and the remaining cells (white cells and platelets) less than 1 percent. The fluid portion, plasma, is a clear, slightly sticky, yellowish liquid. After a fatty meal plasma transiently appears turbid. Within the body the blood is permanently fluid, and turbulent flow assures that cells and plasma are fairly homogeneously mixed.

Characteristics of shed blood

When blood is shed, physicochemical changes are initiated that cause the blood to coagulate (see below *Bleeding and blood clotting*). The blood clot consists of microscopic strands of a complex protein, called fibrin, forming a gel in which the erythrocytes and other cells are entrapped. When the clot shrinks, or retracts, it squeezes out an incoagulable yellowish fluid, which is called the serum. An anticoagulant can be added to the shed blood to prevent clot formation, thereby maintaining the blood in a fluid state. When blood treated in this way is undisturbed, the cells gradually settle because they are denser than the plasma; the red cells go to the bottom, the white cells and platelets form a thin white layer (buffy coat) overlying the red cells, and the plasma appears in the upper portion of the container. Rapid segregation of cells and plasma may be accomplished by the use of a centrifuge, a machine in which rapid rotation accelerates sedimentation by increasing gravitational forces.

The total amount of blood varies with age, sex, weight, body build, and other factors, but a rough average figure for adults is about 60 millilitres per kilogram of body weight. An average young male has a plasma volume of about 35 millilitres, and a red cell volume of about 30 millilitres, per kilogram of body weight. There is little variation in the blood volume of a healthy person over long periods, although each component of the blood is in a continuous state of flux. In particular, water rapidly moves in and out of the bloodstream, achieving a balance with the extravascular fluids (those outside the blood vessels) within minutes. The normal volume of blood provides such an adequate reserve that appreciable blood loss is well tolerated. Withdrawal of 500 millilitres (about a pint) of blood from normal blood donors is a harmless procedure. Blood volume is rapidly replaced after blood loss; within hours plasma volume is restored by movement of extravascular fluid into the circulation. Replacement of red cells is completed within several weeks. The vast area of capillary membrane, through which water passes freely, would permit instantaneous loss of the plasma from the circulation were it not for the plasma proteins, in particular, the plasma albumin. Capillary membranes are impermeable to albumin, the smallest in weight and highest in concentration of the plasma proteins. The osmotic effect of the plasma albumin retains fluid within the circulation, opposing the hydrostatic forces that tend to drive the fluid outward into the tissues.

FUNCTIONS

Maintaining homeostasis

Broadly conceived, the function of the blood is to maintain the constancy of the internal environment (homeostasis). The circulating blood makes possible human adaptability to changing conditions of life—the endurance of wide variations of climate and atmospheric pressure; the capacity to alter the amount of physical activity; the tolerance of changing diet and fluid intake; the resistance to physical injury, chemical poisons, and infectious agents. The blood has an exceedingly complex structure, and many components participate in its functional activities. Some of the regulatory mechanisms with which the blood is involved include sensors that detect alterations in temperature, in pH, in oxygen tension, and in concentrations of the constituents of the blood. Effects of these stimuli are in some instances mediated via the nervous system or by the release of hormones (chemical mediators). Some of the major functions of the blood are outlined in the paragraphs that follow.

pH. The pH of blood is kept relatively constant at the slightly alkaline level of about 7.4 (a pH of less than 7 indicates acidity, of more than 7 alkalinity). Venous blood is maintained at a somewhat less alkaline level (7.35) because of the higher carbon dioxide content. A system of efficient buffers in the blood and the selective excretory functions of the lungs and kidneys keep the pH within these narrow limits. Physiological mechanisms stabilize a normal pH in the blood both by regulating the rate and depth of respiration in order to maintain a normal tension of carbon dioxide in the blood and by excreting acid or alkaline urine from the kidneys.

Maintenance of pH

Respiration. In terms of immediate urgency, the respiratory function of the blood is vital. A continuous supply of oxygen is required by living cells, in particular those of the brain since deprivation is followed in minutes by unconsciousness and death. A normal male at rest uses about 250 millilitres of oxygen per minute, a requirement increased manyfold during vigorous exertion. All of this oxygen is transported by the blood, most of it bound to the hemoglobin of the red cells. The minute blood vessels of the lungs bring the blood into close apposition with the pulmonary air spaces (alveoli), where the pressure of oxygen is relatively high. Oxygen diffuses through the plasma and into the red cell, combining with hemoglobin, which is about 95 percent saturated with oxygen on leaving the lungs. One gram of hemoglobin can bind 1.35 millilitres of oxygen, and about 50 times as much oxygen is combined with hemoglobin as is dissolved in the plasma. In tissues where the oxygen tension is relatively low, hemoglobin releases the bound oxygen.

The two main regulators of oxygen uptake and delivery are the pH of tissues and the content of 2,3-diphosphoglycerate (2,3-DPG) in red cells. The effect of pH on the ability of hemoglobin to bind oxygen is called the Bohr effect (Figure 1): when pH is low, hemoglobin binds oxygen less strongly, and when pH is high (as in the lungs), hemoglobin binds more tightly to oxygen. The Bohr effect is due to changes in the shape of the hemoglobin molecule as the pH of its environment changes. The oxygen affinity of hemoglobin is also regulated by 2,3-DPG, a simple molecule produced by the red cell when it metabolizes glucose. The effect of 2,3-DPG is to reduce the oxygen affinity of hemoglobin. When the availability of oxygen to tissues is reduced, the red cell responds by synthesizing more 2,3-DPG, a process that occurs over a period of hours to days. By contrast, tissue pH mediates minute-to-minute changes in oxygen handling.

Elimination of carbon dioxide

Carbon dioxide, a waste product of cellular metabolism, is found in relatively high concentration in the tissues. It diffuses into the blood and is carried to the lungs to be eliminated with the expired air. Carbon dioxide is much more soluble than oxygen and readily diffuses into red cells. It reacts with water to form carbonic acid, a weak

From A.L. Lehninger, *Principles of Biochemistry* (1982), Worth Publishers, Inc., New York City

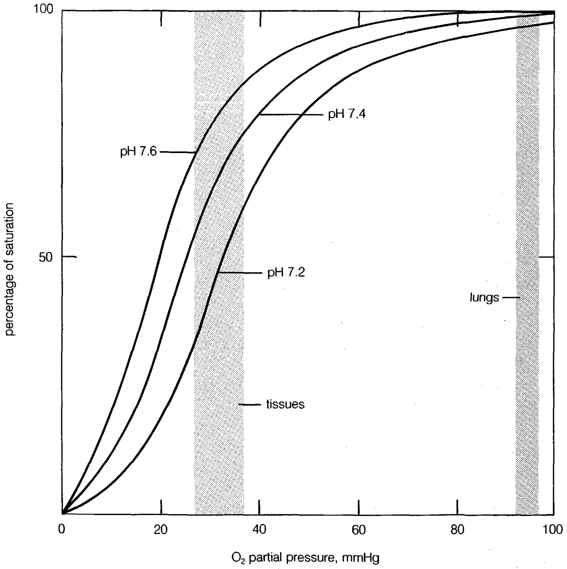

Figure 1: *The Bohr effect.*
The oxygen affinity of hemoglobin weakens with decreasing pH. The body tissue has a lower pH, and the oxygen is released more readily. In the lungs, the pH is higher and oxygen is more easily bound to the hemoglobin molecule.

acid that at the alkaline pH of the blood appears principally as bicarbonate.

The tension of carbon dioxide in the arterial blood is regulated with extraordinary precision through a sensing mechanism in the brain that controls the respiratory movements. Carbon dioxide is an acidic substance, and an increase in its concentration tends to lower the pH of the blood (*i.e.,* becoming more acidic). This may be averted by the stimulus that causes increased depth and rate of breathing, a response that accelerates the loss of carbon dioxide. It is the tension of carbon dioxide, and not of oxygen, in the arterial blood that normally controls breathing. Inability to hold one's breath for more than a minute or so is the result of the rising tension of carbon dioxide, which produces the irresistible stimulus to breathe. Respiratory movements that ventilate the lungs sufficiently to maintain a normal tension of carbon dioxide are, under normal conditions, adequate to keep the blood fully oxygenated. Control of respiration is effective, therefore, in regulating the uptake of oxygen and disposal of carbon dioxide and in maintaining the constancy of blood pH.

Nutrition. Each substance required for the nutrition of every cell in the body is transported by the blood: the precursors of carbohydrates, proteins, and fats; minerals and salts; vitamins and other accessory food factors. These substances must all pass through the plasma on the way to the tissues in which they are used. The materials may enter the bloodstream from the gastrointestinal tract, or they may be released from stores within the body or become available from the breakdown of tissue.

Regulators of nutrients

The concentrations of many plasma constituents, including glucose and calcium, are carefully regulated, and deviations from the normal may have adverse effects. One of the regulators of the blood sugar is insulin, a hormone released into the blood from glandular cells in the pancreas. Ingestion of a carbohydrate meal is followed by increased production of insulin, which tends to keep the blood sugar from rising excessively as the carbohydrates are broken down into their constituent sugar molecules. But an excess of insulin may severely reduce the blood sugar, causing a reaction that, if sufficiently severe, may include coma and even death. Glucose is transported in simple solution, but some substances require specific binding proteins (proteins with which the substances form temporary unions) to convey them through the plasma. Iron and copper, essential minerals, have special and necessary transport proteins. Nutrient substances may be taken up selectively by the tissues that require them. Growing bones use large amounts of calcium, and bone marrow removes iron from plasma for hemoglobin synthesis.

Excretion. The blood carries the waste products of cellular metabolism to the excretory organs. The removal of carbon dioxide via the lungs has been described above. Water produced by the oxidation of foods or available from other sources in excess of needs is excreted by the kidneys as the solvent of the urine. Water derived from the blood also is lost from the body by evaporation from the skin and lungs and in small amounts from the gastrointestinal tract. The water content of the blood and of the body as a whole remains within a narrow range because of effective regulatory mechanisms, hormonal and other, that determine the urinary volume. The concentrations of physiologically important ions of the plasma, notably sodium, potassium, and chloride, are precisely controlled by their retention or selective removal as blood flows through the kidneys. Of special significance is the renal (kidney) control of acidity of the urine, a major factor in the maintenance of the normal pH of the blood. Urea, creatinine, and uric acid are nitrogen-containing products of metabolism that are transported by the blood and rapidly eliminated by the kidneys. The kidneys clear the blood of many other substances, including numerous drugs and chemicals that are taken into the body. In performing their excretory function, the kidneys have a major responsibility for maintaining the constancy of the composition of the blood. (See also EXCRETION AND EXCRETORY SYSTEMS.) The liver is in part an excretory organ. Bilirubin (bile pigment) produced by the destruction of hemoglobin is conveyed by the plasma to the liver and is excreted through the biliary ducts into the intestinal tract. Other substances, including certain drugs, also are removed from the plasma by the liver.

Immune and inflammatory responses

Defense mechanisms. Cells of the blood and constituents of the plasma interact in complex ways to confer immunity to infectious agents, to resist or destroy invading organisms, to produce the inflammatory response, and to destroy and remove foreign materials and dead cells. The leukocytes (white blood cells, discussed later in this section) have a primary role in these reactions: granulocytes and monocytes phagocytize (ingest) bacteria and other organisms, migrate to sites of infection or inflammation and to areas containing dead tissue, and participate in the enzymatic breakdown and removal of cellular debris; lymphocytes are concerned with the development of immunity. Acquired resistance to specific microorganisms is in part attributable to antibodies, proteins that are formed in response to the entry into the body of a foreign substance (antigen). Antibodies that have been induced by microorganisms not only participate in eliminating the microbes but also prevent reinfection by the same organism. Cells and antibodies may cooperate in the destruction of invading bacteria; the antibody may attach to the organism, thereby rendering it susceptible to phagocytosis. Involved in some of these reactions is complement, a group of protein components of plasma that participates in certain immunologic reactions. When certain classes of antibodies bind to microorganisms and other cells, they trigger the attachment of components of the complement system to the outer membrane of the target cell. As they assemble on the cell membrane, the complement components acquire enzymatic properties. The activated complement system is thus able to injure the cell by digesting (lysing) portions of the cell's protective membrane.

Hemostasis. The blood is contained under pressure in a vascular system that includes vast areas of thin and delicate capillary membranes. Even the bumps and knocks of everyday life are sufficient to disrupt some of these fragile vessels, and serious injury can be much more damaging. Loss of blood would be a constant threat to survival if it were not for protective mechanisms to prevent and to control bleeding. The platelets contribute to the resistance of capillaries, possibly because they actually fill chinks in vessel walls. In the absence of platelets capillaries become more fragile, permitting spontaneous loss of blood and increasing the tendency to form bruises after minor injury. Platelets immediately aggregate at the site of injury of a blood vessel, tending to seal the aperture. A blood clot, forming in the vessel around the clump of adherent platelets, further occludes the bleeding point. The coagulation mechanism involves a series of chemical reactions in which specific proteins and other constituents of the blood, including the platelets, play a part. Plasma also is provided with a mechanism for dissolving clots after they have been formed. Plasmin is a proteolytic enzyme—a substance that causes breakdown of proteins—derived from an inert plasma precursor known as plasminogen. When clots are formed within blood vessels, activation of plasminogen to plasmin may lead to their removal. (For additional information about the mechanics and significance of hemostasis, see below *Bleeding and blood clotting.*)

Mechanisms to prevent blood loss

Temperature regulation. Heat is produced in large amounts by physiological oxidative reactions, and the blood is essential for its distributing and disposing of this heat. The circulation assures relative uniformity of temperature throughout the body and also carries the warm blood to the surface, where heat is lost to the external environment. A heat-regulating centre in the hypothalamus of the brain functions much like a thermostat. It is sensitive to changes in temperature of the blood flowing through it and, in response to the changes, gives off nerve impulses that control the calibre of the blood vessels in the skin and thus determine blood flow and skin temperature. A rise in skin temperature increases heat loss from the body surface. Heat is continuously lost by evaporation of water from the lungs and skin, but this loss can be greatly increased when more water is made available from the sweat glands. The activity of the sweat glands is controlled by the nervous system under direction of the temperature-regulating cen-

The hypothalamus

tre. Constancy of body temperature is achieved by control of the rate of heat loss by these mechanisms.

PLASMA

The liquid portion of the blood, the plasma, is a complex solution containing more than 90 percent water. The water of the plasma is freely exchangeable with that of body cells and other extracellular fluids and is available to maintain the normal state of hydration of all tissues. Water, the single largest constituent of the body, is essential to the existence of every living cell. The major solute of plasma is a heterogeneous group of proteins constituting about 7 percent of the plasma by weight. The principle difference between the plasma and the extracellular fluid of the tissues is the high protein content of the plasma. Plasma protein exerts an osmotic effect by which water tends to move from other extracellular fluid to the plasma. Fatty substances (lipids) are present in plasma in suspension and in solution. Other plasma constituents include salts, glucose, amino acids, vitamins, hormones, and waste products of metabolism.

Proteins. Proteins are large molecules formed of chains of amino acids, organic acids that contain both an acidic and a nitrogenous basic (amino) group. Chains (polypeptides) are formed by linkage of the acid group of one amino acid to the amino group of the next (peptide bond). The characteristics of a protein are determined by the number and types of amino acids and the sequence in which they are arranged.

Albumin

When dietary protein is digested in the gastrointestinal tract, individual amino acids are released from the chains and are absorbed. The amino acids are transported through the plasma to all parts of the body, where they are taken up by cells and are assembled in specific ways to form proteins of many types. These plasma proteins are released into the blood from the cells in which they were synthesized. Much of the protein of plasma is produced in the liver. The major plasma protein is albumin, a relatively small molecule, the principal function of which is to retain water in the bloodstream by its osmotic effect. The amount of albumin in the blood is a determinant of the total volume of plasma. Depletion of albumin permits fluid to leave the circulation and to accumulate and cause swelling of soft tissues (edema). Albumin binds certain other substances that are transported in plasma and thus serves as a nonspecific carrier protein. Bilirubin, for example, is bound to albumin during its passage through the blood.

Albumin has physical properties that permit its separation from other plasma proteins, which as a group are called globulins. In fact, the globulins are a heterogeneous array of proteins of widely varying structure and function, only a few of which will be mentioned here. The immunoglobulins, or antibodies, are produced in response to a specific antigen. For example, administration of poliomyelitis vaccine is followed by the appearance in the plasma of antibodies that react with poliovirus and effectively prevent that infection. Antibodies may be induced by many foreign substances in addition to microorganisms; immunoglobulins are involved in some hypersensitivity and allergic reactions. Other plasma proteins are concerned with the coagulation of the blood (see below *Bleeding and blood clotting*).

Transport proteins

Many proteins are involved in highly specific ways with the transport function of the blood. Blood lipids are incorporated into protein molecules as lipoproteins, substances important in lipid transport. Iron and copper are transported in plasma by unique metal-binding proteins (transferrin and ceruloplasmin, respectively). Vitamin B_{12}, an essential nutrient, is bound to a specific carrier protein. Although hemoglobin is not normally released into the plasma, a hemoglobin-binding protein (haptoglobin) is available to transport hemoglobin should hemolysis (breakdown) of red cells occur.

Lipids. The concentration of lipids in plasma varies, particularly in relation to meals, but ordinarily does not exceed one gram per 100 millilitres. The largest fraction consists of phospholipids, complex molecules containing phosphoric acid and a nitrogen base in addition to fatty acids and glycerol. Triglycerides, or simple fats, are molecules composed only of fatty acids and glycerol. Free fatty acids, lower in concentration than triglycerides, are responsible for a much larger transport of fat. Other lipids include cholesterol, a major fraction of the total plasma lipids. These substances exist in plasma combined with proteins of several types as lipoproteins. The largest lipid particles in the blood are known as chylomicrons and consist largely of triglycerides; after absorption from the intestine they pass through lymphatic channels and enter the bloodstream through the thoracic lymph duct. The other plasma lipids are derived from food or enter the plasma from tissue sites.

Other plasma components. Some plasma constituents occur in plasma in low concentration but have a high turnover rate and great physiological importance. Among these is glucose, the blood sugar. Glucose is absorbed from the gastrointestinal tract or may be released into the circulation from the liver. It provides a source of energy for tissue cells and is the only source for some, including the red cells. Glucose is conserved and used and not excreted. Amino acids also are so rapidly transported that the plasma level remains low, although they are required for all protein synthesis throughout the body. Urea, an end product of protein metabolism, is rapidly excreted by the kidneys. Other nitrogenous waste products—uric acid and creatinine—are similarly removed.

Sodium, potassium, and other metals

Several inorganic materials are essential constituents of plasma, and each has special functional attributes. The predominant cation (positively charged ion) of the plasma is sodium, an ion that occurs within cells at a much lower concentration. Because of the effect of sodium on osmotic pressure and fluid movements, the amount of sodium in the body is an influential determinant of the total volume of extracellular fluid. The amount of sodium in plasma is controlled by the kidneys under the influence of a hormone (aldosterone) of the adrenal gland. If dietary sodium exceeds requirements, the excess is excreted by the kidneys. Potassium, the principal intracellular cation, occurs in plasma at a much lower concentration than sodium. The renal excretion of potassium is influenced by aldosterone, which causes retention of sodium and loss of potassium. Calcium in plasma is in part bound to protein and in part ionized. Its concentration is under the control of two hormones: parathyroid hormone, which causes the level to rise, and calcitonin, which causes it to fall. Magnesium, like potassium, is a predominantly intracellular cation and occurs in plasma in low concentration. Variations in the concentrations of these cations may have profound effects on the nervous system, the muscles, and the heart, effects normally prevented by precise regulatory mechanisms. Iron, copper, and zinc are required in trace amounts for synthesis of essential enzymes; much more iron is needed in addition for production of hemoglobin and myoglobin, the oxygen-binding pigment of muscles. These metals occur in plasma in low concentrations. The principal anion (negatively charged ion) of plasma is chloride; sodium chloride is its major salt. Bicarbonate participates in the transport of carbon dioxide and in the regulation of pH. Phosphate also has a buffering effect on the pH of the blood and is vital for chemical reactions of cells and for the metabolism of calcium. Iodide is transported through plasma in trace amounts; it is avidly taken up by the thyroid gland, which incorporates it into thyroid hormone.

The hormones of all the endocrine glands are secreted into the plasma and transported to their target organs, the organs in which they exert their effect. The plasma levels of these agents often reflect the functional activity of the glands that secrete them; in some instances measurements are possible though concentrations are extremely low. Among the many other constituents of plasma are numerous enzymes. Some of these appear simply to have escaped from tissue cells and have no functional significance in the blood.

BLOOD CELLS

There are four major types of blood cells: red blood cells, platelets, lymphocytes, and phagocytic cells. Collectively, Functions of the blood cells

the lymphocytes and phagocytic cells constitute the white blood cells. Each type of blood cell has a specialized function: red cells take up oxygen from the lungs and deliver it to the tissues; platelets participate in forming blood clots; lymphocytes are involved with immunity; and phagocytic cells occur in two varieties—granulocytes and monocytes—and ingest and break down microorganisms and foreign particles. The circulating blood functions as a conduit, bringing the various kinds of cells to the regions of the body in which they are needed: red cells to tissues requiring oxygen, platelets to seal over points of injury, lymphocytes to areas of infection, and phagocytic cells to sites of microbial invasion and inflammation. Each type of blood cell is described in detail below.

The process of blood cell formation (hematopoiesis) takes place in hematopoietic tissue. In the developing embryo, blood cell formation occurs in the liver, but, as the fetus develops, hematopoiesis shifts to the bone marrow, a dark red, gelatinous tissue in the central cavities of the bones. In young children, hematopoietic bone marrow fills most of the skeleton, whereas in adults the marrow is located mainly in the central bones (ribs, sternum, vertebrae, and pelvic bones). Bone marrow is a rich mixture of developing and mature blood cells, as well as fat cells and other cells that provide nutrition and an architectural framework upon which the blood-forming elements arrange themselves. The weight of the marrow of a normal adult is 1,600 to 3,700 grams and contains over 1,000,000,000,000 hematopoietic cells (18×10^9 cells per kilogram). Nourishment of this large mass of cells comes from the blood itself. Arteries pierce the outer walls of the bones, enter the marrow, and divide into fine branches, which ultimately coalesce into large venous sacs (sinusoids) through which blood flows sluggishly. In the surrounding hematopoietic tissue, newly formed blood cells enter the general circulation by penetrating the walls of the sinusoids.

Colony-stimulating factors

All blood cells arise from primordial cells called multipotent hematopoietic stem cells. By dividing and differentiating, these precursor cells give rise to the four major blood cell lineages: red cells, phagocytic cells, megakaryocytes, and lymphocytes. The cells of the marrow are under complex controls that regulate their formation and adjust their production to the changing demands of the body. When marrow stem cells are cultured outside the body they form tiny clusters of cells (colonies), which correspond to red cells, phagocytic cells, and megakaryocytes. The formation of these individual colonies depends on hormonal sugar-containing proteins (glycoproteins), referred to collectively as colony-stimulating factors (CSFs). These factors are produced throughout the body. Even in minute amounts, CSFs can stimulate the division and differentiation of precursor cells into mature blood cells and thus exert powerful regulatory influences over the production of blood cells. A master colony-stimulating factor (multi-CSF), also called interleukin-3, stimulates the most ancestral hematopoietic stem cell. Further differentiation of this stem cell into specialized descendants requires particular kinds of colony-stimulating factors; for example, the CSF erythropoietin is needed for the maturation of red cells, and granulocyte colony-stimulating factor controls the production of granulocytes. These glycoproteins, as well as other colony-stimulating factors, serve as signals from the tissues to the marrow. For instance, a decrease in the oxygen content of the blood stimulates the kidney to increase its production of erythropoietin, thus ultimately raising the number of oxygen-carrying red cells in the blood. Certain bacterial components accelerate the formation of granulocyte colony-stimulating factor, thereby leading to an increased production of phagocytic granulocytes by the bone marrow during infection.

Hematocrit

Red blood cells (erythrocytes). The red blood cells are highly specialized, well adapted for their primary function of transporting oxygen from the lungs to all of the body tissues. Red cells are approximately 7.8 micrometres in diameter and have the form of biconcave disks, a shape that provides a large surface-to-volume ratio. When blood is centrifuged to cause the cells to settle, the volume of packed red cells (hematocrit value) ranges between 42 and 54 percent of total volume in men and between 37 and 47 percent in women; values are somewhat lower in children. Normal red blood cells are fairly uniform in volume, so that the hematocrit value is determined largely by the number of red cells per unit of blood. The normal red cell count ranges between 4,000,000 and 6,000,000 per cubic millimetre. Hemoglobin constitutes about one-third of the weight of each red cell. The amount of hemoglobin in blood is related to the hematocrit value and to the red cell count, and in normal adults ranges between 14 and 18 grams per 100 millilitres. When fresh blood is examined with the microscope, red cells appear to be yellow-green disks with pale centres containing no visible internal structures.

The red cell is enclosed in a thin membrane that is composed of chemically complex lipids, proteins, and carbohydrates in a highly organized structure. Extraordinary distortion of the red cell occurs in its passage through minute blood vessels, many of which have a diameter less than that of the red cell. When the deforming stress is removed, the cell springs back to its original shape. The red cell readily tolerates bending and folding, but, if appreciable stretching of the membrane occurs, the cell is damaged or destroyed. The membrane is freely permeable to water, oxygen, carbon dioxide, glucose, urea, and certain other substances, but it is impermeable to hemoglobin. Within the cell the major cation is potassium; in contrast, in plasma and extracellular fluids the major cation is predominantly sodium. A pumping mechanism, driven by enzymes within the red cell, maintains its sodium and potassium concentrations. Red cells are subject to osmotic effects. When they are suspended in very dilute (hypotonic) solutions of sodium chloride, red cells take in water, which causes them to increase in volume and to become more spheroid; in concentrated salt solutions they lose water and shrink. In distilled water red cells continue to swell until they become spherical, whereupon they disrupt, releasing the dissolved hemoglobin into the surrounding fluid (hemolysis).

Breakdown of red cells

Hemolysis. When red cell membranes are damaged, hemoglobin and other dissolved contents may escape from the cells, leaving the membranous structures as "ghosts." This process, called hemolysis, is produced not only by the osmotic effects of water but by numerous other mechanisms. These include physical damage to red cells, as when blood is heated, is forced under great pressure through a small needle, or is subjected to freezing and thawing; chemical damage to red cells by agents such as bile salts, detergents, and certain snake venoms; and damage caused by immunologic reactions that may occur when antibodies attach to red cells in the presence of complement. When such destruction proceeds at a greater than normal rate, hemolytic anemia results (see below *Blood diseases*).

Blood groups. The membrane of the red cell has on its surface a group of molecules that confer blood group specificity (*i.e.,* that differentiate blood cells into groups). Most blood group substances are composed of carbohydrate linked to protein, and it is usually the chemical structure of the carbohydrate portion that determines the specific blood type. Blood group substances are antigens capable of inducing the production of antibodies when injected into persons or animals lacking the antigen. Detection and recognition of the blood group antigens are accomplished by the use of serum containing these antibodies. The large number of different red cell antigens makes it extremely unlikely that persons other than identical twins will have the same array of blood group substances. (For a full treatment of the subject, see below *Blood groups.*)

Interaction of hemoglobin and oxygen

Hemoglobin. About 95 percent of the dry weight of the red cell consists of hemoglobin, the substance necessary for oxygen transport. Hemoglobin is a protein; a molecule contains four polypeptide chains (a tetramer), each chain consisting of more than 140 amino acids (Figure 2). To each chain is attached a chemical structure known as a heme group. Heme is composed of a ringlike organic compound known as a porphyrin to which an iron atom is attached. It is the iron atom that reversibly binds oxygen as the blood travels between the lungs and the tissues. There are four iron atoms in each molecule of hemoglobin, which, accordingly, can bind four atoms of oxygen. The complex porphyrin and protein structure may be considered to provide just the proper environment for the iron atom so that it binds and releases oxygen appropriately under physiological conditions. The affinity of hemoglobin for oxygen is so great that at the oxygen pressure in the lungs about 95 percent of the hemoglobin is saturated with oxygen. As the oxygen tension falls, as it does in the tissues, oxygen dissociates from hemoglobin and is available to move by diffusion through the red cell membrane and the plasma to sites where it is used. The proportion of hemoglobin saturated with oxygen is not directly proportional to the oxygen pressure. As the oxygen pressure declines, hemoglobin gives up its oxygen with disproportionate rapidity, so that the major fraction of the oxygen can be released with a relatively small drop in oxygen tension. The affinity of hemoglobin for oxygen is primarily determined by the structure of hemoglobin, but it is also influenced by other conditions within the red cell, in particular the pH and certain organic phosphate compounds produced during the chemical breakdown of glucose, especially 2,3-diphosphoglycerate (see above *Functions*).

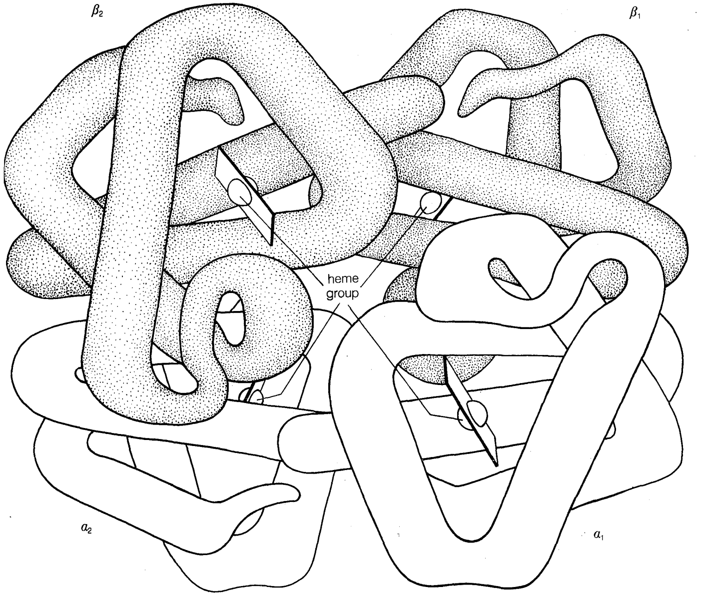

Figure 2: *The hemoglobin tetramer.*
Two $\alpha\beta$ dimers combine to form the complete hemoglobin molecule. Each heme group contains a central iron atom, which is available to bind a molecule of oxygen. The $\alpha_1\beta_2$ region is the area where the α_1 subunit interacts with the β_2 subunit.

Hemoglobin has a much higher affinity for carbon monoxide than for oxygen. Carbon monoxide produces its lethal effects by binding to hemoglobin and preventing oxygen transport. The oxygen-carrying function of hemoglobin can be disturbed in other ways. The iron of hemoglobin is normally in the reduced or ferrous state, both in oxyhemoglobin and deoxyhemoglobin. If the iron itself becomes oxidized to the ferric state, hemoglobin is changed to methemoglobin, a brown pigment incapable of transporting oxygen. The red cells contain enzymes capable of maintaining the iron in its normal state, but under abnormal conditions large amounts of methemoglobin may appear in the blood.

Sickle-cell anemia

Discovery of the cause of sickle-cell anemia has led to major advances in understanding of genetics, molecular biology, and the mechanisms of disease. Sickle-cell anemia is a serious and often fatal disease characterized by an inherited abnormality of the hemoglobin. Persons who have sickle-cell anemia are predominantly blacks. The disease is caused by the mutation of a single gene that determines the structure of the hemoglobin molecule. Sickle hemoglobin differs from normal hemoglobin in that a single amino acid (glutamic acid) in one pair of the polypeptide chains has been replaced by another (valine). This single intramolecular change so alters the properties of the hemoglobin molecule that anemia and other effects are produced. The entire structure of the hemoglobin molecule is known, and many other genetically determined abnormalities have been identified. Some of these also produce diseases of several types. Study of the effects of altered structure of hemoglobin on its properties has greatly broadened knowledge of the structure-function relationships of the hemoglobin molecule. (For more information about sickle-cell anemia, see below *Blood diseases.*)

Red cell metabolism. Survival of the red cell in the circulation depends upon the continuous utilization of glucose for the production of energy. Two chemical pathways are employed, and both are essential for the normal life of the red cell. An extraordinary number of enzyme systems participate in these reactions and direct the energy evolved into appropriate uses. Red cells contain neither a nucleus nor RNA (ribonucleic acid, necessary for protein synthesis), so that cell division and production of new protein are impossible. Energy is not necessary for oxygen and carbon dioxide transport, which depends principally on the properties of hemoglobin. Energy, however, is needed for another operation. There is a tendency for the extracellular cation, sodium, to leak into the red cell and for potassium to leak out; energy is required to operate a pumping mechanism in the red cell membrane to maintain the normal gradients (differences in concentrations) of these ions. Energy is also required to convert methemoglobin to oxyhemoglobin and to prevent the oxidation of other constituents of the red cell.

Erythropoiesis (production of red cells). Red cells are produced continuously in the marrow of certain bones. As stated above, in adults the principal sites are the marrow spaces of the vertebrae, ribs, breastbone, and pelvis. Within the bone marrow the red cell is derived from a primitive precursor, or erythroblast, a nucleated cell in which there is no hemoglobin. Proliferation occurs as a result of several successive cell divisions. During maturation hemoglobin appears in the cell, and the nucleus becomes progressively smaller. After a few days the cell loses its nucleus and is then introduced into the bloodstream in the vascular channels of the marrow. Almost 1 percent of the red cells are generated each day, and the balance between red cell production and the removal of aging red cells from the circulation is precisely maintained. If blood is lost from the circulation, the erythropoietic activity of marrow increases until the normal number of circulating cells has been restored.

Nutrients needed for red cell production

In a normal adult the red cells of about half a litre (almost one pint) of blood are produced by the bone marrow every week. A number of nutrient substances are required for this process. Some nutrients are the building blocks of which the red cells are composed. For example, amino acids are needed in abundance for the construction of the proteins of the red cell, in particular of hemoglobin. Iron also is a necessary component of hemoglobin. Approximately one-quarter of a gram of iron is needed for the production of a pint of blood. Other substances, required in trace amounts, are needed to catalyze the chemical reactions by which red cells are produced. Important among these are several vitamins, riboflavin, vitamin B_{12}, and folic acid, necessary for the maturation of the developing red cell; and pyridoxine (vitamin B_6), required for the synthesis of hemoglobin. The secretions of several endocrine glands influence red cell production. If there is an inadequate supply of thyroid hormone, erythropoiesis is retarded and anemia appears. The male sex hormone, testosterone, stimulates red cell production; for this reason, red cell counts of men are higher than those of women.

The capacity of the bone marrow to produce red cells is enormous. When stimulated to peak activity and when provided adequately with nutrient substances, the marrow can compensate for the loss of several pints of blood per week. Hemorrhage or accelerated destruction of red cells leads to enhanced marrow activity. The marrow can increase its production of red cells up to eight times the usual rate. After that, if blood loss continues, anemia develops. The rate of erythropoiesis is sensitive to the oxygen tension of the arterial blood. When oxygen tension falls, more red cells are produced and the red cell count rises.

Effects of altitude

For this reason, persons who live at high altitude have higher red cell counts than those who live at sea level. There is a small but significant difference between average red cell counts of persons living in New York City, at sea level pressure, and persons living in Denver, Colo., one mile above sea level, where the atmospheric pressure is lower. Natives of the Andes, living nearly three miles above sea level, have extremely high red cell counts.

The rate of production of erythrocytes is controlled by a hormone (erythropoietin) that is produced largely in the kidneys. When the number of circulating red cells decreases or when the oxygen transported by the blood diminishes, an unidentified sensor detects the change and the production of erythropoietin is increased. This substance is then transported through the plasma to the bone marrow, where it accelerates the production of red cells. The erythropoietin mechanism operates like a thermostat, increasing or decreasing the rate of red cell production in accordance with need. When a person who has lived at high altitude moves to a sea level environment, production of erythropoietin is suppressed, the rate of red cell production declines, and the red cell count falls until the normal sea level value is achieved. With the loss of one pint of blood, the erythropoietin mechanism is activated, red cell production is enhanced, and within a few weeks the number of circulating red cells has been restored to the normal value. The precision of control is extraordinary, so that the number of new red cells produced accurately compensates for the number of cells lost or destroyed. Erythropoietin has been produced in vitro (outside the body) by the technique of genetic engineering (recombinant DNA). The purified, recombinant hormone has promise for persons with chronic renal failure, who develop anemia because of a lack of erythropoietin.

Breakdown and removal

Destruction of red cells. Red cells have an average life span of 120 days. Although they use glucose to produce energy necessary for their survival, they cannot synthesize protein; therefore reparative processes are not possible. As red cells age, wear and tear leads to loss of some of the protein, and the activity of some of the essential enzymes decreases. Chemical reactions necessary for the survival of the cell are consequently impaired. As a result, water passes into the aging red cell, transforming its usual discoid shape into a sphere. These spherocytes are inelastic, and, as they sluggishly move through the circulation, they are engulfed by phagocytes (Figure 3). Phagocytic cells form a part of the lining of blood vessels, particularly in the spleen, liver, and bone marrow. These cells, called macrophages, are constituents of the reticuloendothelial system and are found in the lymph nodes, in the intestinal tract, and as free-wandering and fixed cells. As a group they have the ability to ingest not only other cells but also many other microscopic particles, including certain dyes and colloids. Within the reticuloendothelial cells erythrocytes are rapidly destroyed. Protein, including that of the hemoglobin, is broken down, and the component amino acids are transported through the plasma to be used in the synthesis of new proteins. The iron removed from hemoglobin passes back into the plasma and is transported to the bone marrow, where it may be used in the synthesis of hemoglobin in newly forming red cells. Iron not necessary for this purpose is stored within the reticuloendothelial cells but is available for release and reuse whenever it is required. In the breakdown of red cells there is no loss to the body of either protein or iron, virtually all of which is conserved and reused. In contrast, the porphyrin ring structure of hemoglobin, to which iron was attached, undergoes a chemical change that enables its excretion from the body.

Bilirubin

This reaction converts porphyrin, a red pigment, into bilirubin, a yellow pigment. Bilirubin released from reticuloendothelial cells after the destruction of erythrocytes is conveyed through the plasma to the liver, where it undergoes further changes that prepare it for secretion into the bile. The amount of bilirubin produced and secreted into the bile is determined by the amount of hemoglobin destroyed. When the rate of red cell destruction exceeds the liver's capacity to handle bilirubin, the yellow pigment accumulates in the blood, causing jaundice. Jaundice can also occur if the liver is diseased (*e.g.*, hepatitis) or if the egress of bile is blocked (*e.g.*, by a gallstone).

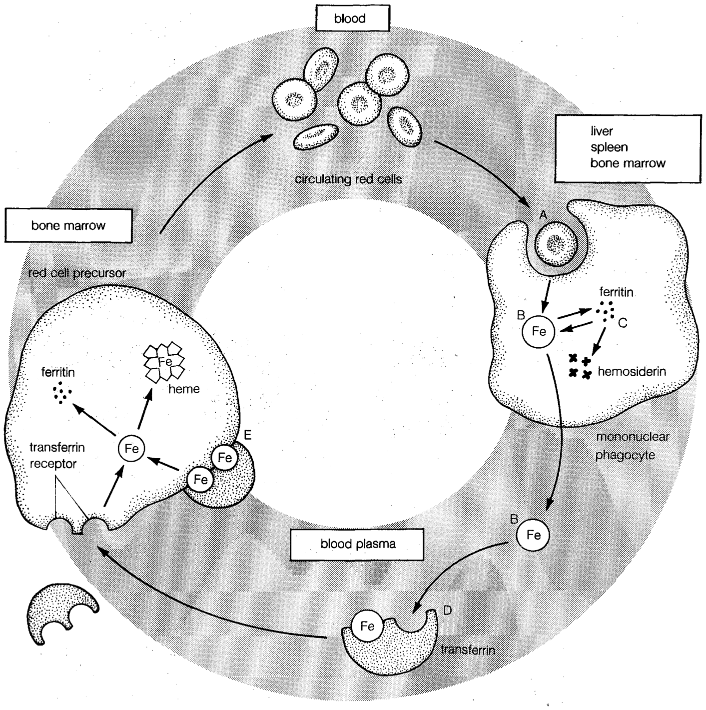

Figure 3: *The iron cycle.*
(A) Aging red cells phagocytized by mononuclear phagocytes in the liver, spleen, or bone marrow. (B) Released iron from degraded hemoglobin. (C) Excess iron stored as ferritin (a quick releaser of iron) or hemosiderin (a slow releaser). (D) The plasma protein transferrin binds iron and transports it to the bone marrow. (E) The transferrin-iron molecule enters the red cell precursor by attaching to a receptor for transferrin. Iron in food is also absorbed from the intestines and carried by transferrin to developing red cells in the bone marrow.

White blood cells (leukocytes). White cells, unlike red cells, are nucleated and independently motile (Figures 4 and 5). Highly differentiated for their specialized functions, they do not undergo mitosis (ordinary cell division) in the bloodstream, but some retain the capability of cell division. As a group they are involved in the body's defense mechanisms and reparative activity. The number of leukocytes in normal blood ranges between 4,500 and 11,000 per cubic millimetre. Fluctuations occur during the day; lower values are obtained during rest and higher values during exercise. Violent physical exertion may cause the count to exceed 20,000 per cubic millimetre. Most of the leukocytes are outside the circulation, and the few in the bloodstream are in transit from one site to another. As living cells, their survival depends on their continuous

production of energy. The chemical pathways utilized are more complex than those of the red cells and are similar to those of other tissue cells. Leukocytes, containing a nucleus and able to produce RNA, can synthesize protein. They comprise three classes of cells, each unique as to structure and function, that are designated granulocytes, monocytes, and lymphocytes.

Granulocytes. Granulocytes, the most numerous of the white cells, are larger than red cells (approximately 12–15 micrometres). They have a multilobed nucleus and contain large numbers of cytoplasmic granules (*i.e.,* granules in the cell substance outside the nucleus). Granulocytes are important mediators of the inflammatory response. There are three types of granulocytes: neutrophils, eosinophils, and basophils. Each type of granulocyte is identified by the colour of the granules when the cells are stained with a compound dye. The granules of the neutrophil are pink, those of the eosinophil are red, and those of the basophil are blue-black. About 50 to 80 percent of the white cells are neutrophils, while the eosinophils and basophils together constitute no more than 3 percent.

Neutrophils

The neutrophils are fairly uniform in size with a diameter between 12 and 15 micrometres. The nucleus consists of two to five lobes joined together by hairlike filaments. Neutrophils move with amoeboid motion. They extend long projections called pseudopods into which their granules flow; this action is followed by contraction of filaments based in the cytoplasm, which draws the nucleus and rear of the cell forward. In this way neutrophils rapidly advance along a surface. The bone marrow of a normal adult produces about 100,000,000,000 neutrophils daily (Figure 6). It takes about one week to form a mature neutrophil from a precursor cell in the marrow, yet once in the blood the mature cells live only a few hours, or perhaps a little longer after migrating to the tissues. To guard against rapid depletion of the short-lived neutrophil (for example, during infection), the bone marrow holds a large number of them in reserve to be mobilized in response to inflammation or infection. Within the body the neutrophils migrate to areas of infection or tissue injury. The force of attraction that determines the direction in which neutrophils will move is known as chemotaxis and is attributed to substances liberated at sites of tissue damage. Of the 100,000,000,000 neutrophils circulating outside the bone marrow, half are in the tissues and half are in the blood vessels; of those in the blood vessels, half are within the mainstream of rapidly circulating blood and the other half move slowly along the inner walls of the blood vessels ("marginal pool"), ready to enter tissues on receiving a chemotactic signal from them.

stage of maturation	percentage of total nucleated bone marrow cells
myeloblast	0.2–1.5
promyelocyte	2–4
myelocyte	8–16
metamyelocyte	10–25
band form	10–15
polymorphonuclear leukocyte	6–12

Figure 6: *Maturation of neutrophils.*
Mitotic and postmitotic stages of the neutrophil, with progressive condensation and segmentation of the nucleus after the myelocyte stage.

Neutrophils are actively phagocytic; they engulf bacteria and other microorganisms and microscopic particles. The granules of the neutrophil are microscopic packets of potent enzymes capable of digesting many types of cellular materials. When a bacterium is engulfed by a neutrophil, it is encased in a vacuole lined by the invaginated membrane. The granules discharge their contents into the vacuole containing the organism. As this occurs, the granules of the neutrophil are depleted (degranulation). A metabolic process within the granules produces hydrogen peroxide and a highly active form of oxygen (superoxide), which destroy the ingested bacteria. Final digestion of the invading organism is accomplished by enzymes.

Eosinophils and basophils

Eosinophils, like other granulocytes, are produced in the bone marrow until they are released into the circulation. Although about the same size as neutrophils, the eosinophil contains larger granules and the chromatin is generally only concentrated in two nonsegmented lobes. Eosinophils leave the circulation within hours of release from the marrow and migrate into the tissues (usually those of the skin, lung, and respiratory tract) through the lymphatic channels. Like neutrophils, eosinophils respond to chemotactic signals released at the site of cell destruction. They are actively motile and phagocytic. Eosinophils are involved in defense against parasites, and they participate in hypersensitivity and inflammatory reactions, primarily by dampening their destructive effects.

Basophils are the least numerous of the granulocytes, and their large granules almost completely obscure the underlying, double-lobed nucleus. Within hours of their release from the bone marrow, basophils migrate from the circulation to the barrier tissues (*e.g.,* the skin and mucosa), where they synthesize and store histamine, a natural modulator of the inflammatory response. When aggravated, basophils release, along with histamine and other substances, leukotrienes, which cause bronchoconstriction during anaphylaxis (a hypersensitivity reaction). Basophils incite immediate hypersensitivity reactions in association with platelets, macrophages, and neutrophils.

The largest blood cell

Monocytes. Monocytes are the largest cells of the blood (averaging 15–18 micrometres), and they make up on the average about 7 percent of the leukocytes. The nucleus is relatively big and tends to be indented or folded rather than multilobed. The cytoplasm contains large numbers of fine granules, which often appear to be more numerous near the cell membrane. Monocytes are actively motile and phagocytic. They are capable of ingesting infectious agents as well as red cells and other large particles, but they cannot replace the function of the neutrophils in the removal and destruction of bacteria. Monocytes usually enter areas of inflamed tissue later than the granulocytes. Often they are found at sites of chronic infections.

In the bone marrow, granulocytes and monocytes arise from a common precursor under the influence of the granulocyte–macrophage colony-stimulating factor (see above *Formation of blood cells*). Monocytes leave the bone marrow and circulate in the blood. After a period of hours the monocytes enter the tissues, where they develop into macrophages, the tissue phagocytes that constitute the reticuloendothelial system (or macrophage system). Macrophages occur in almost all tissues of the body: those in the liver are called Kupffer cells; those in the skin are called Langerhans cells. Apart from their role as scavengers, macrophages play a key role in immunity by ingesting antigens and processing them so that they can be recognized as foreign substances by lymphocytes.

Lymphocytes. Lymphocytes constitute about 28–42 percent of the white cells of the blood, and they are part of the immune response to foreign substances in the body. Most lymphocytes are small, only slightly larger than erythrocytes, with a nucleus that occupies most of the cell. Some are larger and have more abundant cytoplasm that contains a few granules. Lymphocytes are sluggishly motile, and their paths of migration outside of the bloodstream are different from those of granulocytes and monocytes. Lymphocytes are found in large numbers in the lymph nodes, spleen, thymus, tonsils, and lymphoid tissue of the gastrointestinal tract. They enter the circulation through lymphatic channels that drain principally into the thoracic lymph duct, which has a connection with the venous system. Unlike other blood cells, some lymphocytes may leave and reenter the circulation, surviving for about a year or more. The principal paths of recirculating lymphocytes are through the spleen or lymph nodes. Lymphocytes freely leave the blood to enter lymphoid tissue, passing barriers that prevent the passage of other blood cells. When stimulated by antigen and certain other agents, some lymphocytes are activated and become capable of cell division.

Functions and types of lymphocytes

The lymphocytes regulate or participate in the acquired immunity to foreign cells and antigens. They are responsible for immunologic reactions to invading organisms, foreign cells such as those of a transplanted organ and foreign proteins and other antigens not necessarily derived from living cells. The two classes of lymphocytes are not distinguished by the usual microscopic examination but rather by the type of immune response they elicit. The B lymphocytes (or B cells) are involved in what is called humoral immunity. Upon encountering a foreign substance (or antigen), the B lymphocyte differentiates into a plasma cell, which secretes immunoglobulin (antibodies). The second class of lymphocytes, the T lymphocytes (or T cells), are involved in regulating the antibody-forming function of B lymphocytes as well as in directly attacking foreign antigens. T lymphocytes participate in what is called the cell-mediated immune response. T lymphocytes also participate in the rejection of transplanted tissues and in certain types of allergic reactions.

All lymphocytes begin their development in the bone marrow. The B lymphocytes mature partly in the bone marrow until they are released into the circulation. Further differentiation of B lymphocytes occurs in lymphoid tissues (spleen or lymph nodes), most notably on stimulation by a foreign antigen. In humans the precursors of the T lymphocytes migrate from the marrow to the thymus, where they differentiate under the influence of a hormonelike substance. (The thymus is a small organ lying just behind the breastbone in the upper portion of the chest. It is relatively large at birth, begins to regress after puberty, and may be represented only by a fibrous cord in the elderly. The thymus begins to exert its effects on the differentiation of lymphocytes before birth. The removal of the thymus from certain animals at birth prevents the normal development of immunologic responses.) Once they have matured, the T lymphocytes leave the thymus and circulate through the blood to the lymph nodes and the spleen. The two classes of lymphocytes originally derived their names from investigations in birds, in which it was found that differentiation of one class of lymphocyte was influenced by the bursa of Fabricius (an outpouching of the gastrointestinal tract) and thus was called the B lymphocytes, and the other was influenced by the thymus and was called the T lymphocytes.

Major histocompatibility antigens

A primary function of lymphocytes is to protect the body from foreign microbes. This essential task is carried out by both T lymphocytes and B lymphocytes, which often act in concert. The T lymphocytes can only recognize and respond to antigens that appear on cell membranes in association with other molecules termed major histocompatibility complex antigens. The latter are glycoproteins that present the antigen in a form that can be recognized by T lymphocytes. In effect, T lymphocytes are responsible for continuous surveillance of cell surfaces for the presence of foreign antigens. By contrast, the antibodies produced by B lymphocytes are not confined to recognizing antigens on cell membranes; they can bind to soluble antigens in the blood or extravascular fluids. T lymphocytes typically recognize antigens of infectious organisms that must penetrate cells in order to multiply, such as viruses. During their intracellular life cycle, viruses produce antigens that appear on the cell membrane. Two classes of T lymphocytes can be involved in the response to those cell-associated viral antigens: cytotoxic T lymphocytes, which destroy the cells by a lytic mechanism; and helper T lymphocytes, which assist B cells to produce antibodies against the microbial antigens. Helper T lymphocytes exert their influence on B lymphocytes through several hormone-like peptides termed interleukins (IL). Five different T lymphocyte interleukins (IL-2, IL-3, IL-4, IL-5, and IL-6) have been discovered, each with different (and sometimes overlapping) effects on B lymphocytes and other blood cells. Interleukin-1, produced by macrophages, is a peptide that stimulates T lymphocytes and that also acts on the hypothalamus in the brain to produce fever. The ability to develop an immune response (*i.e.,* the T cell-mediated and humoral immune responses) to foreign substances is called immunologic competence (immunocompetence). Immunologic competence, which begins to develop during embryonic life, is incomplete at the time of birth but is fully established soon after birth. If an antigen is introduced into the body before immunologic competence has been established, an immune response will not result upon reinfection, and that person is said to be tolerant to that antigen.

Study of immunologic competence and immune tolerance has been accelerated by interest in organ transplantation. The success rates of organ transplantations have been improved by better knowledge about donor selection and improved techniques for suppressing the immune responses of the recipient. An important element in donor selection is tissue typing: the matching of the donor's histocompatibility antigens (human leukocyte antigens) with those of the prospective recipient. The closer the match, the greater the probability that the graft will be accepted. (See also TRANSPLANTS, ORGAN AND TISSUE.)

Platelets (thrombocytes). The blood platelets are the smallest cells of the blood, averaging about two to four micrometres in diameter. Although much more numerous (150,000 to 400,000 per cubic millimetre) than the white cells, they occupy a much smaller fraction of the volume of the blood because of their relatively minute size. Like the red cells they lack a nucleus and are incapable of cell division, but they have a more complex metabolism and internal structure than have the red cells. When seen in fresh blood they appear spheroid, but they have a tendency to extrude hairlike filaments from their membranes. They adhere to each other but not to red cells and white cells. Tiny granules within platelets contain substances important for the clot-promoting activity of platelets.

Platelet metabolism

The function of the platelets is related to hemostasis, the prevention and control of bleeding. When the endothelial surface (lining) of a blood vessel is injured, platelets in large numbers immediately attach to the injured surface and to each other, forming a tenaciously adherent mass of platelets. The effect of the platelet response is to stop the bleeding and to form the site of the developing blood clot, or thrombus. If platelets are absent, this important defense reaction cannot occur, and protracted bleeding from small wounds (prolonged bleeding time) results. The normal resistance of capillary membranes to leakage of red cells is dependent upon platelets. Severe deficiency of platelets reduces the resistance of the capillary walls, and abnormal bleeding from the capillaries occurs, either spontaneously or as the result of minor injury. Platelets also contribute substances essential for the normal coagulation of the blood, and they cause the shrinking, or retraction, of a clot after it has been formed. (For additional information about the causes, consequences, and treatment of thrombosis, see below *Bleeding and blood clotting.*)

Platelets are formed in the bone marrow by segmentation of the cytoplasm (the cell substance other than the nucleus) of cells known as megakaryocytes, the largest cells of the marrow. Within the marrow the abundant granular cytoplasm of the megakaryocyte divides into many small segments that break off and are released as platelets into the circulating blood. After about 10 days in the circulation, platelets are removed and destroyed. There are no reserve stores of platelets except in the spleen, in which platelets occur in higher concentration than in the peripheral blood. Some platelets are consumed in exerting their hemostatic effects, and others, reaching the end of their life span, are removed by reticuloendothelial cells (any of the tissue phagocytes). The rate of platelet production is controlled but not so precisely as the control of red cell production. A hormonelike substance, thrombopoietin, which has not been identified chemically, is believed to be the chemical mediator that regulates the number of platelets in the blood by stimulating an increase in the number and growth of megakaryocytes, thus controlling the rate of platelet production.

EXAMINATION OF THE BLOOD IN THE LABORATORY

Physicians rely upon laboratory analysis to obtain measurements of many constituents of the blood, information useful or necessary for the detection and recognition of disease. Hemoglobin contains a highly coloured pigment that interferes with the passage of a beam of light. To measure hemoglobin concentration, blood is accurately diluted and the red cells broken down to yield a clear red solution. A photoelectric instrument is used to measure the absorbance of transmitted light, from which hemoglobin concentration can be calculated. Changes in the hemoglobin concentration of the blood are not necessarily directly paralleled by changes in the red cell count and the hematocrit value, because the size and hemoglobin concentration of red cells may change in disease. Therefore, measurements of the red cell count and the hematocrit value may provide useful information as well. These three tests can be carried out rapidly and in large numbers by automated machines. Electronic particle counters for determining red cell, white cell, and platelet counts are widely used. Only a drop of blood is needed for the analyses, which are completed within a minute; results are printed in a laboratory report that is sent to the physician. Although expensive, the equipment increases the output of the laboratory and saves the technician valuable time.

Blood tests

Adequate examination of the blood cells requires that a thin film of blood be spread on a glass slide, stained with a special blood stain (Wright's stain), and examined under the microscope. Individual red cells, white cells, and platelets are examined, and the relative proportions of the several classes of white cells are tabulated. The results may have important diagnostic implications. In iron deficiency anemia, for example, the red cells look paler than normal because they lack the normal amount of hemoglobin; in malaria the diagnosis is established by observing the malarial parasites within the red cells. In pneumonia and many infections the proportion of neutrophilic leukocytes is usually increased, while in others, such as whooping cough and measles, there is an increase in the proportion of lymphocytes.

Chemical analyses

Chemical analyses measure many of the constituents of plasma. Often serum rather than plasma is used, however, since serum can be obtained from clotted blood without the addition of an anticoagulant. Changes in the concentrations of chemical constituents of the blood can indicate the presence of a disease process. For example, quantitative determination of the amount of sugar in the blood is essential for the diagnosis of diabetes, a disease in which the blood sugar tends to be elevated. Nitrogenous waste products, in particular urea, tend to accumulate in patients with diseased kidneys that are unable to excrete these substances at a normal rate. An increase in the concentration of bilirubin in the serum often reflects a disorder of the liver and bile ducts or an increased rate of destruction of hemoglobin. Measurements of these and many other serum constituents are so valuable in medical diagnosis that often multiple tests are performed.

Tests can be performed manually using an individual procedure for each analysis; however, the autoanalyzer, a completely automated machine, increases the number of chemical analyses that can be performed in laboratories. A dozen analyses may be made simultaneously by a single machine employing a small amount of serum. The serum is automatically drawn from a test tube and is propelled through plastic tubing of small diameter. As the serum specimen advances, it is divided; appropriate reagents are added; chemical reactions occur with formation of a product that can be measured with a photoelectric instrument; and the result appears as a written tracing from which serum concentration of various substances can be read directly. The data acquired by the machine may be fed automatically into a computer and the numerical results printed on a form that is submitted to a physician. Many of the available analyses are not performed routinely but are invaluable in special circumstances. In cases of suspected lead poisoning, for example, detection of an elevated level of lead in the blood may be diagnostic. Some analytical procedures have specific diagnostic usefulness. These include assays for certain hormones, including measurement of the thyroid hormone in the serum of patients suspected of having thyroid disease.

Blood typing

Other important laboratory procedures are concerned with immunologic reactions of the blood. Careful determinations of the blood groups of the patient and of the blood donor, and cross matching of the cells of one with the serum of the other to ensure compatibility, are essential for the safe transfusion of blood. The Rh type of a pregnant woman is regularly determined and is necessary for the early detection of fetal–maternal incompatibility and for proper prevention or treatment of hemolytic disease of the newborn. The diagnosis of certain infectious diseases depends upon the demonstration of antibodies in the patient's serum.

Many other kinds of blood examination yield useful results. Enzymes normally present in the muscle of the heart may be released into the blood when the heart is damaged by a coronary occlusion (obstruction of the coronary artery) with consequent tissue necrosis. Measurement of these enzymes in the serum is regularly performed to assist in diagnosis of this type of heart disease. Damage to the liver releases other enzymes, measurement of which aids in evaluation of the nature and severity of liver disease. Inherited abnormalities of proteins are increasingly recognized and identified by use of sophisticated methods. Accurate diagnosis of hemophilia and other bleeding disorders is made possible by investigations of the coagulation mechanism. Measurements of the concentration of folic acid and vitamin B_{12} in the blood provide the basis for diagnosis of deficiencies of those vitamins. The number of potentially useful blood tests is so vast that they must be selected judiciously in the evaluation of the individual patient. (C.L.C./R.S.S.)

Blood groups

Blood groups are classifications of blood based on inherited differences (polymorphisms) in antigens on the surfaces of the red cells. Inherited differences of white cells, platelets, and plasma proteins also constitute blood groups, but they are not included in this discussion.

GENERAL SURVEY OF BLOOD GROUPING

Historical background. William Harvey, the English physician, announced his observations on the circulation of the blood in 1616 and published his famous monograph entitled *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*The Anatomical Exercises Concerning*

The first human transfusions

the Motion of the Heart and Blood in Animals, 1653) in 1628. His discovery, that blood circulates around the body in a closed system, was an essential prerequisite of the concept of transfusing blood from one animal to another of the same or different species. In England experiments on the transfusion of blood were pioneered in dogs in 1665 by Richard Lower, an English physician. A later experiment, in which dogs were also used, is described in the diary of Samuel Pepys in the entry for Nov. 14, 1666. In November 1667 Lower transfused the blood of a lamb into a man; this event also is recorded in Pepys's diary. Meanwhile, in France, Jean-Baptiste Denis had also been transfusing lambs' blood into human subjects and described what is probably the first recorded account of the signs and symptoms of a hemolytic transfusion reaction. After a fatality Denis was arrested, and the procedure of transfusing the blood of other animals into humans was prohibited by an act of the Chamber of Deputies in 1668, unless sanctioned by the Faculty of Medicine of Paris. Ten years later, in 1678, the British Parliament also prohibited transfusions. Little advance was made in the next 150 years.

In 19th-century England interest was reawakened by the activities of James Blundell, whose humanitarian instincts had been aroused by the frequently fatal outcome of hemorrhage occurring after childbirth. He insisted that it was better to use human blood for transfusion in such cases. During the years 1875–1900 another hiatus of interest resulted from the introduction of the treatment of shock by injecting physiological saline solution (salt solution of the same osmotic pressure as the blood).

Discovery of ABO blood groups

In 1875 the German physiologist Leonard Landois published a monograph reviewing 347 transfusions between humans and 129 transfusions between animals. He showed that, if the red blood cells of an animal belonging to one species were mixed with serum taken from an animal of another species, the red cells usually clumped and that sometimes the red cells burst—*i.e.,* hemolyzed. He attributed the appearance of black urine after transfusion of heterologous blood (blood from a different species) to the hemolysis of the incompatible red cells. Thus, the dangers of transfusing blood of another species to humans were established scientifically. Safe transfusion rests primarily on two more advances, the first of which was the discovery of the human ABO blood groups by the Austrian-born American biologist Karl Landsteiner in 1901. Landsteiner found that there were substances in the blood, antigens and antibodies, that induced clumping of red cells when red cells of one type were added to those of a second type. He recognized three groups—A, B, and O—based on their reaction to each other. A fourth group, AB, was identified a year later by another research team. The red cells of an individual contain antigens on their surfaces that correspond to their blood group and antibodies in the serum that identify and combine with the antigen sites on the surfaces of red cells of another type. Red cells of the A group clump with donor blood of the B group; those of the B group with blood of the A group; those of the AB group with those of the A or the B group because AB cells contain both A and B antigens; and those of the O group do not generally clump with any group because they do not contain either A or B antigens. The ABO blood groups and other groups discovered later, such as Kell, Diego, Lutheran, Duffy, and Kidd, are determined in this manner, and it is in this way that blood groups are defined. In 1939–40 the rhesus (Rh) blood group system was discovered as a result of similar techniques.

The second advance involved the use of substances such as sodium citrate that prevent the clotting of blood being used in transfusion. These substances are innocuous when given by infusion to humans. In 1914 Luis Agote demonstrated that small, nontoxic quantities of sodium citrate could prevent the coagulation of blood. The introduction of citrate transformed the hectic, nerve-racking procedure of direct transfusion into a simple, relaxed operation and eventually led to the development of blood storage. In 1943 John Freeman Loutit and Patrick Loudon Mollison acidified the citrate and added dextrose, which allowed storage of red cells at 4° C for 21 days. Minor modifications in the formula and the addition of adenine have further increased storage time of blood in the liquid state. Addition of a cryoprotective agent (glycerol) makes frozen storage of red cells possible. The first blood banks were opened in the United States in 1937.

Definitions of antigen and antibody

The importance of antigens and antibodies. As has been stated previously, blood groups are determined by the presence of antigens on the surfaces of the red cells. An antigen has been defined as a substance that can, in certain circumstances, induce the production of the corresponding antibody. (An antigen that can induce antibody production is also called an immunogen.) An antibody is a substance that is capable of reacting with a specific antigen to counter its effects.

The human red cells carry many antigens. Because the reaction between red cells and corresponding antibodies usually results in clumping—agglutination—of the red cells, the antigens on the surfaces of these red cells are often referred to as agglutinogens. Antibodies are part of the circulating plasma proteins known as immunoglobulins. Immunoglobulins are classified by molecular size and weight and by several other biochemical properties. Most blood group antibodies are found either on immunoglobulin G (IgG) or immunoglobulin M (IgM) molecules, but occasionally the immunoglobulin A (IgA) class may exhibit blood group specificity.

It has been customary to distinguish between naturally occurring antibodies and immune antibodies. So-called naturally occurring antibodies are really the result of immunization by substances in nature that have structures similar to human blood groups. Naturally occurring antibodies are present in an individual despite the fact that there has been no previous exposure to the corresponding red cell antigens—for example, anti-A in the plasma of people of blood group B and anti-B in the plasma of people of blood group A. Immune antibodies—for example, Rh antibodies (see below)—occur only if they are invoked by exposure to the corresponding red cell antigens. Immunization (*i.e.,* the production of antibodies in response to antigen) against blood group antigens in humans can occur as a result of pregnancy (see below *Blood groups and disease*), therapeutic transfusion, or deliberate immunization. The combination of pregnancy and transfusion is a particularly potent stimulus. Individual blood group antigens vary in their antigenic potential; for example, some of the antigens belonging to the Rh and ABO systems are strongly immunogenic (*i.e.,* capable of inducing antibody formation), whereas the antigens of the Kidd and Duffy blood group systems are much weaker immunogens.

The MN, P, and Rh systems

Discovery of the individual blood groups. In Table 1 the well-established human blood group systems are listed in the order of discovery. The discovery of the ABO blood group system in 1901 was the result of a deliberate search for intraspecies differences among humans. The application of knowledge of the ABO system in blood transfusion practice is of enormous importance, since mistakes can have fatal consequences. Twenty-six years after the initial discovery, Landsteiner, with his colleague Philip Levine, discovered the MN (later called MNSs) and P blood group systems because they had the idea of immunizing another species with human blood. The discovery of the Rh sys-

Table 1: Major Human Blood Group Systems

system	date of discovery	main antigens
ABO	1901	A_1, A_2, B, H
MNSs	1927	M, N, S, s
P	1927	P_1, P_2
Rh	1940	D, C, c, E, e
Lutheran	1945	Lu^a, Lu^b
Kell	1946	K, k
Lewis	1946	Le^a, Le^b
Duffy	1950	Fy^a, Fy^b
Kidd	1951	Jk^a, Jk^b
Diego	1955	Di^a, Di^b
Yt	1956	Yt^a, Yt^b
I	1956	I, i
Xg	1962	Xg^a
Dombrock	1965	Do^a

tem by Landsteiner and Alexander S. Wiener in 1940 was made because they tested human red cells with antisera developed in rabbits and guinea pigs by immunization of the animals with the red cells of the rhesus monkey *Macaca mulatta.* A few months elapsed before it was realized that antibodies induced by antigens of the Rh system could be found in human beings as a result of pregnancies or blood transfusions.

The remaining blood group systems were first described after antibodies were identified in patients. Frequently, such discoveries resulted from the search for the explanation of an unexpected unfavourable reaction in a recipient after a transfusion with formerly compatible blood. In such cases the antibodies in the recipient were produced against previously unidentified antigens in the donor's blood. In the case of the Rh system, for example, the presence of antibodies in the maternal serum directed against antigens present on the child's red cells can have serious consequences because of antigen–antibody reactions that produce hemolytic disease of the newborn, or erythroblastosis fetalis. Some of the other blood group systems—for example, the Kell and Kidd systems—were discovered because an infant was found to be suffering from hemolytic disease of the newborn even though mother and child were compatible as far as the Rh system was concerned.

Presence of ABO antigens in tissues

Blood group antigens in tissues. The blood group antigens are inherited characteristics; they are present on the red cells as a property of the cell membrane, although they are not restricted solely to red cells or even to hematopoietic tissues. There is no doubt that the antigens of the ABO system are widely distributed throughout the tissues. These antigens have been unequivocally identified on platelets and white cells (both lymphocytes and polymorphonuclear leukocytes) and in skin, the epithelial (lining) cells of the gastrointestinal tract, the kidney, the urinary tract, and the lining of the blood vessels. Evidence for the presence of the antigens of other blood group systems on cells other than red cells is less well substantiated, and sometimes the opinions of different workers disagree. Among the red cell antigens, only those of the ABO system are regarded as tissue antigens and therefore need to be considered in transplantation.

As they occur on the red cells, the blood group substances are in an alcohol-soluble form. In the ABO and Lewis systems the blood group specific substances also occur in tissue fluids and secretions in a water-soluble form. In the case of the Lewis system the antigens are present primarily in the secretions, and their presence on the red cells is a consequence of passive adsorption onto the cells from the plasma.

Chemistry of the blood group substances. The exact chemical structure of some blood groups has been identified, as have the gene products (*i.e.,* those molecules synthesized as a result of an inherited genetic code on a gene of a chromosome) that assist in synthesizing the antigens on the red cell surface which determine the blood type. Blood group antigens are present on glycolipid and glycoprotein molecules of the red cell membrane. The carbohydrate chains of the membrane glycolipids are oriented toward the external surface of the red cell membrane and carry antigens of the ABO, Hh, Ii, and P systems. Glycoproteins, which traverse the red cell membrane, have a polypeptide backbone to which carbohydrates are attached. An abundant glycoprotein, band 3, contains ABO, Hh, and Ii antigens. Another integral membrane glycoprotein, glycophorin A, contains large numbers of sialic acid molecules and MN blood group structures; another, glycophorin B, contains Ss and U antigens.

Effects of glycosyltransferase

The genes responsible for inheritance of ABH and Lewis antigens are glycosyltransferases (a group of enzymes that catalyzes the addition of specific sugar residues to the core precursor substance). For example, the *H* gene codes for the production of a specific glycosyltransferase that adds L-fucose to a core precursor substance, resulting in the H antigen; the *Le* gene codes for the production of a specific glycosyltransferase that adds L-fucose to the same core precursor substance, but in a different place, forming the Lewis antigen; the *A* gene adds *N*-acetyl-D-galactosamine (H must be present), forming the A antigen; and the *B* gene adds D-galactose (H must be present), forming the B antigen. The P system is analogous to the ABH and Lewis blood groups in the sense that the P antigens are built by the addition of sugars to precursor globoside and paragloboside glycolipids, and the genes responsible for these antigens must produce glycosyltransferase enzymes.

The genes that code for MNSs glycoproteins change two amino acids in the sequence of the glycoprotein to account for different antigen specificities. Additional analysis of red cell membrane glycoproteins have shown that in some cases the absence of blood group antigens is associated with an absence of minor membrane glycoproteins that are present normally in antigen-positive persons.

METHODS OF BLOOD GROUPING

Identification of blood groups. The basic technique in identification of the antigens and antibodies of blood groups is the agglutination test. Agglutination of red cells results from antibody cross-linkages established when different specific combining sites of one antibody react with antigen on two different red cells. By mixing red cells (antigen) and serum (antibody), either the type of antigen or the type of antibody can be determined depending on whether a cell of known antigen composition or a serum with known antibody specificity is used.

In its simplest form, a volume of serum containing antibody is added to a thin suspension (2–5 percent) of the red cells suspended in physiological saline solution in a small tube with a narrow diameter. After incubation for an adequate time, at the appropriate temperature, the red cells will have settled to the bottom of the tube. These sedimented red cells are examined macroscopically (with the naked eye) for agglutination, or they may be spread on a slide and viewed through a low-power microscope.

Complete and incomplete antibody

An antibody that agglutinates red cells when they are suspended in saline solution is called a complete antibody. With powerful complete antibodies, such as anti-A and anti-B, agglutination reactions visible to the naked eye take place when a drop of antibody is placed on a tile together with a drop containing red cells in suspension. After stirring, the tile is rocked, and agglutination is visible in a few moments. It is always necessary in blood grouping to include a positive and negative control for each test that is done.

An antibody that does not clump red cells when they are suspended in saline solution is called incomplete. Such antibodies block the antigenic sites of the red cells so that subsequent addition of complete antibody of the same antigenic specificity does not result in agglutination. Incomplete antibodies will agglutinate red cells carrying the appropriate antigen, however, when the cells are suspended in media containing protein. Albumin from the blood of cattle is a substance that is frequently used for this purpose. Red cells may also be rendered specifically agglutinable by incomplete antibodies after treatment with such protease enzymes as trypsin, papain, ficin, or bromelain.

The Coombs test. When an incomplete antibody reacts with the red cells in saline solution, the antigenic sites become coated with antibody globulin (gamma globulin) and no visible agglutination reaction takes place. The presence of antibody globulin on cells can be detected by a test that is called the Coombs test, after its inventor, the English immunologist Robert Coombs. The Coombs reagent (also called antiglobulin) is made by immunizing rabbits with human immunoglobulin. The rabbits respond by making antihuman globulin (*i.e.,* antibodies against human immunoglobulin and complement) that must be purified before use. The antiglobulin reagent or solution usually contains antibodies against IgG and complement. The Coombs reagent is added to the washed cells, the tube is centrifuged, and if they are coated by antibody globulin or complement, agglutinates will form. Newer antiglobulin reagents (made by immunizing with purified protein) can detect either globulin or complement. Depending on how it is performed, the Coombs test can detect incomplete antibody in the serum or antibody bound to the red cell membrane. In certain diseases, anemia may be caused by the coating of red cells with antibody globulin. This can happen when a mother has made antibodies against the red cells of her newborn child or if a person makes an autoantibody against his own red cells.

Adsorption, elution, and titration. If a serum contains a mixture of antibodies, it is possible to prepare pure samples of each by a technique that is called adsorption. By this technique an unwanted antibody is removed by mixing it with red cells carrying the appropriate antigen. The antigen interacts with the antibody and binds it to the cell surface. These red cells are washed thoroughly and spun down tightly by centrifugation, all the fluid above the cells is removed, and the cells are then said to be packed. The cells are packed to avoid dilution of the antibody being prepared. Adsorption, then, is a method of separating mixtures of antibodies by removing some and leaving others. It is used to identify antibody mixtures and to purify reagents. The purification of the Coombs reagent, mentioned earlier, is done in the same way.

If red cells have adsorbed antibody globulin onto their surfaces, the antibody can sometimes be recovered by a process known as elution. One simple way of eluting (dissociating) antibody from washed red cells is to heat them at 56° C (133° F) in a small volume of saline solution. Other methods include use of acid or ether. This technique is sometimes useful in the identification of antibodies.

Titration technique

The technique used to determine the strength of an antibody is called titration. Doubling dilutions of the antibody are made in a suitable medium in a series of tubes. Cells carrying the appropriate antigen are added, and the agglutination reactions are read and scored for the degree of positivity. The actual titre (concentration) of the antibody is given by the dilution at which some degree of agglutination, however weak, can still be seen. This would not be a safe dilution to use for blood-grouping purposes. If an antiserum can be diluted, the dilution chosen must be such that strong positive reactions occur with selected positive control cells. Titration is helpful when preparing reagents and comparing antibody concentrations at different time intervals.

Inhibition tests. Inhibition tests are used to detect the presence of antigen with blood group specificity in solutions; inhibition of a known antibody–antigen reaction by a fluid indicates a particular blood group specificity. If an active substance is added to antibody, neutralization of the antibody's activity prevents agglutination when red cells carrying the appropriate antigen are subsequently added to the mixture. A, B, Lewis, Chido, Rogers, and P antigens are readily available and can be used to facilitate antibody identification. This technique was used to elucidate the biochemistry of ABH, Ii, and Lewis systems, and it is important in forensic medicine as a means of identifying antigens in blood stains. Chido and Rogers are present in plasma. P substance has been isolated from cyst fluid. ABH and Lewis substances (appropriate to their blood type) are also present in saliva of secretor (*Se*) individuals.

Hemolysis. Laboratory tests in which hemolysis (destruction) of the red cells is the end point are not used frequently in blood grouping. For hemolysis to take place, a particular component of fresh serum called complement must be present. Complement must be added to the mixture of antibody and red cells. It may sometimes be desirable to look for hemolysins that destroy group A red cells in mothers whose group A children are incompatible or in individuals, not belonging to groups A or AB, who have been immunized with tetanus toxoid that contains substances with group A specificity.

Hemolytic reactions may occur in patients who have been given transfusions of blood that either is incompatible or has already hemolyzed. The sera of such patients require special investigations to detect the presence of hemoglobin that has escaped from red cells destroyed within the body and for the breakdown products of other red cell constituents.

Naturally occurring antibodies

Sources of antibodies and antigens. Normal donors are used as the source of supply of the so-called naturally occurring antibodies, such as those of the ABO, P, and Lewis systems. These antibodies work best at temperatures below that of the body (37° C, or 98.6° F); in the case of what are known as cold agglutinins, such as anti-P$_1$, the antibody is most active at 4° C (39° F). Most antibodies used in blood grouping must be searched for in immunized donors.

Antibodies for MN typing are usually raised in rabbits—similarly for the Coombs reagent. Antibodies prepared in this way have to be absorbed free of unwanted components and carefully standardized before use. Additional substances with specific blood group activity have been found in certain plants. Plant agglutinins are called lectins. Some useful reagents extracted from seeds are anti-H from *Ulex europaeus* (common gorse); anti-A$_1$, from another member of the pulse family Fabaceae (Leguminosae), *Dolichos biflorus;* and anti-N from a South American plant, *Vicia graminea.* Agglutinins have also been found in animals; for example, the fluid pressed from the land snail *Octala lactea.* Additional plant lectins and agglutinins from animal fluids have been isolated.

Monoclonal antibodies (structurally identical antibodies produced by hybridomas) to blood groups are replacing some of the human blood grouping reagents. Mouse hybridomas (hybrid cells of a myeloma tumour cell and lymphocyte merging) produce anti-A and anti-B monoclonal antibodies. The antibodies are made by immunizing with either red cells or synthetic carbohydrates. In addition to their use in blood grouping, these monoclonal antibodies can be of use in defining the hereditary background (heterogenicity) and structure of the red cell antigen.

DIFFICULTIES IN BLOOD GROUPING

Effects of disease on cells

Suspensions of cells suitable for blood grouping can be prepared from blood taken with or without an anticoagulant. Serologists have individual preferences. After such infections as pneumonia, red cells may become agglutinable by almost all normal sera because of exposure of a hitherto hidden antigenic site (T), as a result of the action of bacterial enzymes. When the patient recovers, the blood also returns to normal with respect to agglutination. It is unusual for the red cells to reflect antigenicity other than that determined by the individual's genetic makeup. The presence of an acquired B antigen on the red cells has been described occasionally in diseases of the colon, thus allowing the red cell to express an antigenicity other than that genetically determined. Other diseases may alter immunoglobulins; for example, some may induce the production of antibodies directed against the person's own blood groups (autoimmune hemolytic anemia) and thus may interfere with blood grouping. In other diseases, a defect in antibody synthesis may cause the absence of anti-A and anti-B antibody.

Preservation of antibodies. Blood group antibodies are relatively stable and can be stored for extended periods of time. At 4° C the usual shelf life is two years. Frozen storage can extend the shelf life even longer. The reagents must be appropriately standardized and tested with both positive and negative controls when used for blood grouping. Because contaminated or infected sera may give incorrect results, the reagents contain sodium azide to prevent contamination. A minimal amount of protein (approximately 1 percent) may need to be added to the reagent to stabilize the antibody. Other additives and chemical modification of the antibody molecules to enhance agglutination may also be used to improve the reagents.

Identification of antibodies. When an antibody is found that apparently does not correspond to any that are already known, it must first be tested with a large panel of red cells of known antigen makeup, which should include representation from different races. (An antigen common in one population may be rare in a different racial group.) In most cases the reactivity pattern corresponds to the specificity of a known antigen or antigens. In occasional cases, no specificity is detected and the possibility exists that either a new blood group or new antigen within a blood group has been found. Statistical evaluation can then be made to see whether the reactions of the new antibody are independent of all the systems known at the time of testing. Finally, the pattern of inheritance of a new blood group antigen can be established by testing families whose members have been typed for all the known systems. This is the way in which the inheritance patterns of a new system are demonstrated.

USES OF BLOOD GROUPING

Tests of blood donors

Medical uses. *Transfusion.* The blood donated by healthy persons is tested to ensure that the level of hemoglobin is satisfactory and that there is no risk of transmitting certain diseases, such as venereal disease or liver infection. It is then fractionated (split) into its component parts, particularly red cells, plasma, and platelets. Correct matching for the ABO system is vital. Compatible donors on the basis of their possessing A, B, or O blood are shown in Table 2.

Table 2: The ABO and Rh Groups in Transfusion

system	recipient type	donor red cell type	donor plasma type
ABO	A	A* or O	A or AB
ABO	B	B or O	B or AB
ABO	O	O only	O, A, B, or AB
ABO	AB	A*B, A*, B or O	AB
Rh	positive	positive or negative	positive or negative
Rh	negative	negative or positive†, ‡	negative or positive†

*Not if the patient's serum contains anti-A$_1$ (antibody to common type A red cell in subgroup A patients). †Not if the patient is a female less than 45 years old (child-bearing possible), unless life-threatening hemorrhage is present and transfusion of Rh-positive blood is lifesaving. ‡Not if the patient's serum contains anti-D (antibody to positive red cells) except under unusual medical circumstances.

As explained above, the most important blood group systems for transfusion of red cells are ABO and Rh. Persons who have either of the red cell antigens (A and B) have antibody present in their serum of the type that will oppose an antigen of its opposite nature; for example, group A blood contains A antigens on red cell surfaces and anti-B antibodies in the surrounding serum. On the other hand O group individuals lack both the A and the B antigen and thus have both anti-A and anti-B in their serum. If these antibodies combine with the appropriate antigen, the result is hemolytic transfusion reaction, and possibly death. Red cell transfusions must therefore be ABO compatible. The blood groups A and B have various subgroups (called, for example, A$_1$, A$_2$, A$_3$, and B$_1$, B$_2$, and B$_3$, respectively). The only common subgroups that are likely to affect red cell transfusions are the subgroups of A.

Potential donors are also tested for some of the antigens of the Rh system, since it is essential to know whether they are Rh-positive or Rh-negative. Rh-negative indicates the absence of the D (Rh$_0$) antigen. Rh-negative persons transfused with Rh-positive blood will make anti-D antibodies from 50 to 75 percent of the time. Alloantibody (antibody made in response to a foreign red cell antigen) is usually not harmful but does require subsequent transfusions to be antigen-negative. Rh-positive blood should never be given to Rh-negative females before or during the childbearing age unless Rh negative blood is not available and the transfusion is livesaving. If such a woman subsequently became pregnant with an Rh-positive fetus, she might form anti-Rh antibody, even though the pregnancy was the first, and the child might suffer from hemolytic disease of the newborn.

Direct match test

Care must be taken not to give a transfusion unless the cells of the donor have been tested against the recipient's serum. If this compatibility test indicates the presence of antibodies in the recipient's serum for the antigens carried by the donor's cells, the blood is not suitable for transfusion because an unfavourable reaction might occur. The test for compatibility is called the direct match test. It involves testing the recipient's serum with the donor's cells, suspended in saline solution at 20° C and 37° C, in albumin at 37° C, and by the indirect Coombs test at 37° C. These are adequate screening tests for most naturally occurring and immune antibodies.

If, in spite of all the compatibility tests, a reaction does occur after the transfusion is given (the unfavourable reaction often manifests itself in the form of a fever), an even more careful search must be made for any red cell antibody that might be the cause. A reaction after transfusion is not necessarily due to red cell antigen–antibody reactions. It could be caused by the presence of antibodies to the donor's platelets or white cells. Transfusion reactions are a particular hazardfor persons requiring multiple transfusions.

Usefulness of ABO antigens

Organ transplants. The ABO antigens are widely distributed throughout the tissues of the body. Therefore, when organs such as kidneys are transplanted, most surgeons prefer to use organs that are matched to the recipient's with respect to the ABO antigen system, although the occasional survival of a grafted ABO-incompatible kidney has occurred. The remaining red cell antigen systems are not relevant in organ transplantation.

Blood groups and disease. The question of whether the blood groups merely have nuisance value in clinical practice has led to a search for evidence of associations with disease. In some cases an increased incidence of a particular antigen seems to be associated with a certain disease. Cancer of the stomach is more common in people of group A than in those of groups O and B. Duodenal ulceration is more common in nonsecretors of ABH substances than in secretors. For practical purposes, however, these statistical correlations are unimportant. There are other examples that illustrate the importance of blood groups to the normal functions of red cells.

Persons who lack all Rh antigens have been described. In such people red cells of altered shape (stomatocytes) and a mild compensated hemolytic anemia (Rh$_{null}$ disease) are present. The McLeod phenotype (weak Kell antigens and no K$_x$ antigen) is associated with an acanthocytosis and a compensated hemolytic anemia. Blood group antigens or related structures may also serve as receptors. There is evidence that Duffy-negative human red cells are resistant to infection by *Plasmodium knowlesi,* a simian malaria parasite. Other studies indicate that *Plasmodium falciparum* receptors may reside on glycophorin A and may be related to the Wr^b antigen. Blood group incompatibility between mother and child can cause hemolytic disease of the newborn. In this disease IgG blood group antibody molecules cross the placenta, enter the fetal circulation, react with the fetal red cells, and destroy them. Only certain blood group systems cause hemolytic disease of the newborn, and the severity of the disease in the fetus varies greatly. ABO incompatibility usually leads to mild disease. Rh, or D antigen, incompatibility is now largely preventable by treating Rh-negative mothers with Rh immunoglobulin (antibody), which prevents immunization (forming antibodies) to the D antigen. Many other Rh antigens, as well as other red cell group antigens, cause hemolytic disease of the newborn. The baby may be anemic at birth, which can be treated by transfusion with antigen-negative red cells. Even total exchange transfusion may be necessary. In some cases, transfusions may be given while the fetus is still within the uterus, so-called "intrauterine transfusion." Another common problem for the baby is bilirubin, a breakdown product of hemoglobin. Hyperbilirubinemia may lead to neurological deficits. Exchange transfusion eliminates most of the hemolysis by providing red cells, which do not react with the antibody. It also decreases the amount of antibody and allows the child to recover from the disease. Once the antibody disappears, the child's own red cells survive normally.

Medicolegal uses. Although blood group studies cannot be used to prove paternity, they can provide unequivocal evidence that a male is not the father of a particular child. Since the red cell antigens are inherited as dominant traits, a child cannot have a blood group antigen that is not present in one or both parents. For example, if the child

Table 3: Exclusions of Paternity on the ABO System

matings	possible children	impossible children
O×O	O	A, B, AB
O×A	O, A	B, AB
O×B	O, B	A, AB
O×AB	A, B	O, AB
A×A	O, A	B, AB
A×B	O, A, B, AB	
A×AB	A, B, AB	O
B×B	O, B	A, AB
B×AB	A, B, AB	O
AB×AB	A, B, AB	O

Evidence against paternity

in question belongs to group A and both the mother and the putative father are group O, the man is excluded from paternity. Table 3 shows the phenotypes (observed characters) of the offspring that can and cannot be produced in the matings on the ABO system, considering only the three alleles (alternative genes) *A, B,* and *O.* Similar inheritance patterns are seen in all blood group systems. Furthermore, if one parent is genetically homozygous for a particular antigen—that is, has inherited the gene for it from both the grandfather and grandmother of the child—then that antigen must appear in the blood of the child. For example, on the MN system, a father whose phenotype is M and whose genotype is *MM* (in other words, a father who is of blood type M and has inherited the characteristic from both parents) must transmit an *M* allele to all his progeny.

In medicolegal work it is important that the blood samples are properly identified. By using multiple red cell antigen systems and adding additional studies on other blood types (HLA [human leukocyte antigen], red cell enzymes, and plasma proteins), it is possible to state with a high degree of statistical certainty that a particular male is the father.

GENETIC AND EVOLUTIONARY SIGNIFICANCE OF BLOOD GROUPS

Blood groups as genetic markers

Blood groups and genetic linkage. Red cell groups act as markers (inherited characteristics) for genes present on chromosomes which are responsible for their expression. The site of a particular genetic system on a chromosome is called a locus. Each locus may be the site of several alleles (alternative genes). In an ordinary cell of the human body there are 46 chromosomes arranged in 23 pairs, 22 pairs of which are autosomes (chromosomes other than sex chromosomes), with the remaining pair being the sex chromosomes, designated XX in females and XY in males. The loci of the blood group systems are on the autosomes, except for Xg, which is unique among the blood groups in being located on the X chromosome. Genes carried by the X chromosome are said to be sex-linked. Since the blood groups are inherited in a regular fashion, they can be used as genetic markers in family studies to investigate whether any two particular loci are sited on the same chromosome—*i.e.,* are linked. The genes sited at loci on the same chromosome travel together from parent to child, and, if the loci are close together, the genes will rarely be separated.

Loci that are farther apart can be separated by recombination. This happens when material is exchanged between homologous chromosomes (pair of chromosomes) by crossing over during the process of cell division. The reproductive cells contain half the number of chromosomes of the rest of the body; ova carry an X chromosome and spermatozoa an X or a Y. The characteristic number of 46 chromosomes is restored at fertilization. In a classical pedigree linkage study, all the members of a family are examined for a test character and for evidence of the nonindependent segregation of pairs of characters. The results must be assessed statistically to determine linkage. Individual chromosomes are identified by the banding patterns revealed by different staining techniques. Segments of chromosomes or chromosomes that are aberrant in number and morphology may be precisely identified. Other methods for localizing markers on chromosomes include somatic cell hybridization (cell culture with alignment of single strands of RNA and DNA) and use of DNA probes (strands of radiolabeled DNA). These methods are useful in classical linkage studies to locate blood group loci. The loci for many red cell groups have been found on chromosomes and in many cases have been further localized on a particular chromosome. Their chromosome assignments and linkage to genes as well as associated abnormalities are outlined in Table 4.

Table 4: Chromosome Location, Gene Linkage, and Disease Associated with Genes for Blood Group Systems

chromosome	gene	known linkage	associated disease

	Lutheran	DM	myotonic dystrophy
	Lutheran	FHC	familial hypercholesterolemia
	Lutheran	NF	neurofibromatosis
19	H		
X	Xg		hemophilia

Genetic determinations

Genetic pathways. In some of the blood group systems the amount of antigen produced depends on the genetic constitution. The ABO blood group gene codes for a specific carbohydrate transferase enzyme that catalyzes the addition of specific sugars onto a precursor substance. As a new sugar is added, a new antigen is produced. Antigens in the MNSs blood system are the products of genes that control terminal amino acid sequence. The amount of antigen present may depend on the amount of gene product inherited or on the activity of the gene product (*i.e.,* transferase). The red cells of a person whose genotype is *MM* show more M antigen than do *MN* red cells. In the case of ABO, the same mechanism may also play a role in antigen expression, but specific activity of the inherited transferase may be more important.

The amount of antigen produced can also be influenced by the position of the genes. Such effects within a genetic complex can be due to determinants on the same chromosome—they are then said to be in cis—or to determinants on the opposite chromosome of a chromosome pair—in trans.

In the Rh combination cdE/cde, more E antigen is produced than in the combination cDE/cde. This may be due to the suppressor effect of D on E. An example of suppression in the trans situation is that more C antigen is detectable on the red cells from CDe/cde donors than on those of CDe/cDE people. The inheritance of the Rh system probably depends on the existence of operator genes, which turn the activity of closely linked structural genes on or off. The operator genes are themselves controlled by regulator genes. The operator genes are responsible for the quantity of Rh antigens, while the structural genes are responsible for their qualitative characteristics.

The detection of recombination (exchange of material between chromosomes) or mutation in human families is complicated by questions of paternity. In spite of the large number of families that have been studied, it is an extremely rare occurrence. The paucity of examples may indicate that the recombinant and mutation rate for blood group genes is lower than that estimated for other human genes.

Dizygotic and monozygotic twins

Twins and chimeras. Twins may be either dizygotic or monozygotic. Dizygotic twins result from two distinct fertilizations and are therefore as different as two ordinary siblings. Monozygotic twins result from fertilization of one egg by one sperm followed by cleavage of the zygote during early mitotic division. These siblings are genetically identical. It is not possible to prove that they are identical but, just as in paternity studies, a high statistical probability can be ascertained by using red cell groups and other antigen inheritance patterns. Some unexpected discoveries also have been described as the result of blood group analysis. In occasional pairs of dizygotic twins a dual population of red cells with different markers can be found. The phenomenon, first described in cattle, is believed to occur because of vascular anastamosis between twins (exchange of cells and graft tolerance).

Blood groups and anthropology. The human species is

Populations

composed of natural reproductive groups referred to as populations. The blood groups are found in all human populations but vary in frequency. An analysis of populations yields striking differences in the frequency of some blood group genes. Table 5 indicates only the major and characteristic differences. The presence of the Di^a antigen indicates a Mongolian origin; the frequency of the antigen is about 10 percent among the Japanese and Chinese, but it has not been found in Eskimos. The Fy(a−b−) phenotype is characteristic of blacks; Negro origin can also be recognized by the presence of the Js^a antigen, which forms part of the Kell system and the V antigen of the Rh system.

Table 5: Distribution of Blood Groups in Populations

system	blood group	comments on frequency in populations
ABO	A	increased in Scandinavians, Australians, and North American Indians
ABO	B	increased in Central Asians; lowest frequency in Basques
ABO	O	increased in Central and South American Indians and northwest Europeans
ABO	A$_2$	present only in Europeans, Middle Easterners, and East Africans
ABO	Hh	silent varieties, (h) present in people of India
P	P$_1$	increased in black Africans; decreased in Far Easterners
Duffy	Fy(a−b−)	increased in black Africans and blacks
Kell	Js^a	increased in black Africans and blacks
Rh	V	increased in black Africans and blacks
Kidd	JK(a−b−)	increased in Filipinos and Hawaiians
Diego	Di^a	increased in Mongolians
MNSs	M, N, S, s	some rare antigens found only in blacks (S^u and Henshaw genes)

When a population is being investigated, an adequate sample of the people is classified according to the phenotypes. The gene and genotype frequencies can be computed according to the Hardy–Wienberg law, a mathematical model based on the assumptions that genes remain stable, matings take place randomly, and sample size is large.

Distribution of ABO groups

The frequency of the *A* gene is high in western Europe, western Asia, and among Australian Aborigines and certain American Indian tribes in North America. The *O* gene frequency is high in northern and western Europe and southern West Africa. Isolated populations such as the Indians of South and Central America may be entirely of group O. The maximum frequency of the *B* gene occurs in Central Asia and northern India. The *B* gene was probably absent from American Indians and Australian Aborigines before racial admixture occurred with the coming of the white man.

On the Rh system most northern and central European populations differ from each other only slightly and are characterized by a *cde* (*r*) frequency of about 40 percent. The frequencies of the most common Rh combinations of the English population are given in Table 6; they are representative of all Caucasian populations. The peoples of Africa show a preponderance of the complex *cDe* (R^0), and the frequency of *cde* (*r*) is about 20 percent. In eastern Asia, *cde* (*r*) is almost wholly absent, and, since everyone has the D (Rh$_o$) antigen, hemolytic disease of the newborn, due to the presence of maternal anti-D, is unknown in these populations.

Table 6: Frequency of the Most Common Rh Gene Complexes in the English Population

gene complex	frequency‡
*CDe** (R^1)†	41
cde (*r*)	39
cDE (R^2)	14
cDe (R^0)	3
C^wDe (R^{1w})	1
cdE (*r″*)	1
Cde (*r′*)	1
CDE (R^z)	<1

*Fisher–Race notation. †Wiener notation.
‡In percentage.

The uniqueness of the genetic characters of Africans probably results from their long isolation from other humans. The blood group frequencies in small inbred populations reflect the influences of genetic drift. In a small community an allele can be lost from the genetic pool if persons carrying it happen to be infertile, while it can increase in frequency if advantage exists. It has been suggested, for example, that *B* alleles were lost by chance from American Indians and Australian Aborigines when these communities were small. There are pronounced discrepancies in blood group frequencies between the people of eastern Asia and the aboriginal people of America. Other blood group frequencies in different populations show that ancestors might share some common attribute indicating a close resemblance between populations.

The ABO system and primates

Nonhuman primates carry blood group antigens that can be detected with reagents used for typing human beings. The closer their evolutionary relationship to humans, the greater their similarity with respect to antigens. The red cells of the apes, with the exception of the gorilla, have ABO antigens that are indistinguishable from those of human cells. Chimpanzees and orangutans are most frequently group A, but groups O, B, and AB are represented. Gibbons can be of any group except O, and gorillas have a B-like antigen that is not identical in activity with the human one. In both Old and New World monkeys the red cells do not react with anti-A or with anti-B, but, when the secretions are examined, A and B substances and agglutinins are present in the serum. The red cells of the apes have been shown to carry M-like and N-like antigens.

As far as the Rh system is concerned, chimpanzees carry two Rh antigens—D (Rh$_o$) and c (hr′)—but not the others, whereas gibbons have only c (hr′). The red cells of monkeys do not give clear-cut reactions with human anti-Rh sera. The original Rh antibody, anti-D (anti-Rh$_o$), was formed when rabbits and guinea pigs were immunized with the cells of rhesus monkeys, and the specificity appeared to be the same as the antibody formed in patients, which was also called anti-D (anti-Rh$_o$). Later, it became apparent that the antibodies from the two different sources were not developing in response to the same antigen.

By the time this was discovered it was too late to change the name Rh, important in clinical medicine. It was therefore decided that the antigen defined by the nonhuman antibody should be called LW, thus honouring Landsteiner and Wiener, and that Rh would define the blood group. The gene locus for LW is separate from that for Rh, but the two systems are in competition for a precursor substance. Most people have the LW antigen, but a very few do not.

Blood groups and biology. The blood groups are an important means of identifying an individual, and they play a role in linkage studies. Their relevance in medicine lies in the practice of blood transfusion and in the effects of incompatibility between mother and child and the pathogenesis of hemolytic disease of the newborn. The fundamental role of blood groups is related to the more recent elucidation of their presence on specific parts of the red cell membrane. Deletions of membrane proteins (blood groups) have been shown to cause shortened survival of the red cell. Other receptor functions are evident from the studies of chronic granulomatous disease (inherited disorder of a leukocyte function) and invasion of red cells by malaria parasites. The importance of the genetic polymorphisms involved in blood grouping have not been made clear; however, the biologic function of certain blood groups is evident from the diseases that result in persons who lack the red cell membrane protein. (S.La./E.M.B.)

Bleeding and blood clotting

SIGNIFICANCE OF HEMOSTASIS

Components of hemostasis

The evolution of high-pressure blood circulation in vertebrates has brought with it the risk of bleeding after injury to tissues. Mechanisms to prevent bleeding (*i.e.*, hemostatic mechanisms) are essential to maintain the closed blood-circulatory system. Normal hemostasis is the responsibility of a complex system of three individual components: blood cells (platelets), cells that line the blood vessels (endothelial cells), and blood proteins (blood-clotting proteins). The blood platelet is a nonnucleated cell that circulates in the blood in an inactive, resting form. Endothelial cells line the wall of the blood vessel and inhibit blood from clotting on the vessel wall under normal conditions. Blood-clotting proteins circulate in the blood plasma in an inactive form, poised to participate in blood coagulation upon tissue injury. Blood-clotting proteins generate thrombin, an enzyme that converts fibrinogen to fibrin, and a reaction that leads to the formation of a fibrin clot.

The hemostatic mechanism involves three physiologically important reactions: (1) the formation of a blood clot, (2) the formation of a platelet plug, and (3) changes associated with the wall of the blood vessel after injury of its cells. In humans, defects in any of these processes may result in persistent bleeding from slight injuries, or, alternatively, in an overreaction that causes the inappropriate formation of blood clots (thrombosis) in blood vessels. When a blood vessel is injured, blood escapes for as long as the vessel remains open and the pressure within the vessel exceeds that outside. Blood flow can be stopped or diminished by closing the leak or by equalizing the pressure. The leak may be closed by contraction of the blood vessel wall or by the formation of a solid plug. Pressure may be equalized by an increase in external pressure as blood becomes trapped in the tissues (hematoma) or by a decrease in the intravascular pressure (the pressure within the blood vessel) caused by constriction of a supply vessel. The timing and relative importance of these events can vary with the scale of the injury. Bleeding from the smallest vessels can be stopped by platelet plugs; when bleeding is from larger vessels, blood clot formation is required; in still larger vessels the severe drop in pressure associated with shock is the last line of defense.

THE HEMOSTATIC PROCESS

Blood vessels that constitute the circulatory system include arterioles (the smallest arteries) and venules (the smallest veins) connected by capillaries (the smallest of all blood vessels). Blood cells, including red cells and platelets, normally have no tendency to adhere to each other or to the lining (endothelium) of the vessels. An injury too slight to rupture a vessel, however, may still bring about a hemostatic reaction that causes blood cells to adhere to each other. After minor tissue injury there may be partial vessel contraction and platelet adhesion in successive layers at the point of injury. A platelet mass is formed that grows until it blocks, or almost blocks, the vessel. Sometimes this platelet mass breaks down and then reforms, a cycle that repeats perhaps many times. These masses consist of minimally altered platelets. Even these slight injuries cause shedding of some endothelial cells from the vessel and the exposure of deeper layers to which the platelets adhere.

Slight injuries

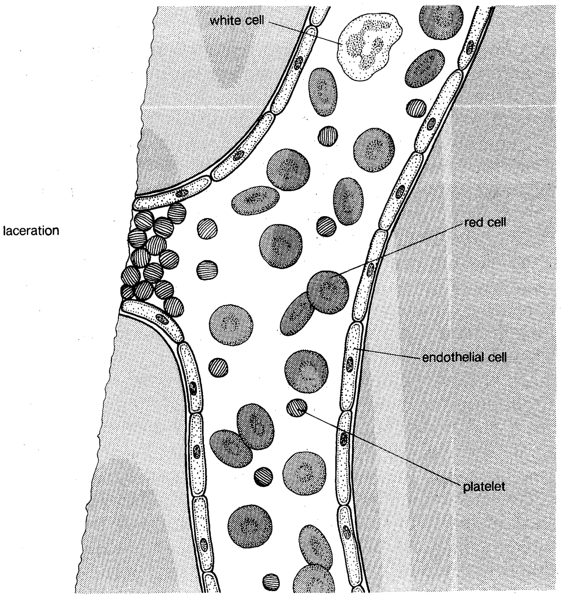

Figure 7: *Formation of the platelet plug.*
With laceration of a small blood vessel, platelets are recruited to the site of tissue injury. The clump of platelets is known as the platelet plug; the endothelial cells line the wall of the vessel.

Massive injuries

If the vessel is cut so that blood escapes, the hemostatic reaction is different. In muscular vessels there may be immediate contraction and narrowing of the vessel, but this usually only minimizes blood loss. A mass of activated platelets adheres to the site of vessel injury (a platelet plug) and normally stops the flow of blood out of the vessel (Figure 7). Unlike the platelets circulating in the blood and those adhering to minor tissue injuries, these platelets have undergone a biochemical and morphological change characteristic of platelet activation, a process that includes the secretion of the contents of platelet granules into the surrounding blood and the extension of pseudopodia. Between the platelets develop bundles of fibrin fibres (coagulation). These changes occur near damaged collagen, the fibrous protein found in connective tissue that underlies the endothelial cell. Later, normal healing of the wound occurs. The platelets subsequently degenerate into an amorphous mass and after several days, the fibrin itself is dissolved (fibrinolysis) by an enzyme, plasmin. The fibrin clot is replaced by a permanent framework of scar tissue that includes collagen, and healing is thus complete.

The normal hemostatic response to damage to the vascular endothelium can be organized into four stages: (1) initial vasoconstriction, (2) aggregation of platelets on and around the lesion and the formation of a platelet plug, (3) activation of the reactions of coagulation, and (4) the activation of fibrinolysis.

Vascular function. The most obvious hemostatic vascular reaction is constriction of the blood vessel after injury. This is important in large arteries because platelet adhesion and clotting are insufficient to arrest bleeding. Delayed surgical aid notwithstanding, the survival of some persons who have lost limbs in accidents is due to constriction of their main arteries. Other vascular reactions to injury have only a subsidiary hemostatic effect.

Platelets and their aggregation. Mammalian platelets are nonnucleate cells produced by large bone marrow cells called megakaryocytes and circulate in the blood in a resting, inactive form for an average of 10 days. The normal platelet count in humans is between 150,000 and 400,000 platelets per cubic millimetre of blood. The inactive platelet contains three types of internal granules: the alpha granules, the dense granules, and the lysosomes. Each of these granules is rich in certain chemicals that have an important role in platelet function. For example, dense granules contain large quantities of calcium ions and adenosine diphosphate (ADP). Upon release from the platelet, ADP stimulates other platelets to activate when it binds to the ADP receptor on the platelet membrane. The alpha granules contain many proteins, including fibrinogen, thrombospondin, fibronectin, and von Willebrand factor. Upon platelet activation, platelets alter their shape from discoid to spherical and extend long footlike projections called pseudopodia. The alpha granules and dense granules move to the surface of the platelet, fuse with the platelet membrane, and release their contents into the blood surrounding the platelet. The lysosomes contain enzymes that digest spent proteins and other metabolites of the cell.

Platelet granules

Activated platelets strongly adhere to surfaces other than the lining of blood vessels, such as collagen, glass, metals, and fabrics. Adherent platelets themselves become adhesive for other activated platelets so that, in a flow system, a platelet plug develops. The propagation of this adhesiveness from one layer to the next is probably due to chemicals, such as ADP and thromboxane A_2, secreted into the blood from the granules of the activated platelets. The ADP released from the dense granules binds to a receptor on the platelet surface, initiating the biochemical and morphological changes associated with platelet activation and secretion. The property of adhesiveness for normal platelets requires a protein on the surface of the platelet membrane, known as glycoprotein Ib, to bind von Willebrand factor, a large multimeric plasma protein released from the alpha granules. Von Willebrand factor,

The platelet plug

when bound to glycoprotein Ib on the platelet surface, facilitates the interaction of platelets with a variety of other surfaces (*e.g.,* the damaged vessel lining).

Platelet aggregation is the property of platelets to clump with each other to form a platelet plug. Two proteins on the platelet membrane play an important role in platelet aggregation: glycoprotein IIb and glycoprotein IIIa. These proteins form a complex in the membrane and expose a receptor site after platelet activation that binds fibrinogen (a bivalent molecule with two symmetrical halves that is found in relatively high concentration in plasma). Fibrinogen can bind simultaneously to two platelets. Thus, fibrinogen links platelets together (aggregation) through the glycoprotein IIb–IIIa complex that serves as the fibrinogen receptor.

Injury to the vessel lining and contact of the blood with tissues outside the vessel stimulates thrombin production by the activation of the clotting system. Thrombin causes platelet aggregation. Platelets exposed to thrombin secrete their granules and release the contents of these granules into the surrounding plasma.

Blood coagulation. Coagulation is the replacement of a relatively unstable platelet plug with a stronger, more resilient blood clot through a series of interdependent, enzyme-mediated reactions that bring about the generation of thrombin and the formation of fibrin from fibrinogen. The intrinsic and the extrinsic pathways of coagulation are involved in regulating coagulation; each is activated by a different trigger, although they share many steps in the course of the generation of thrombin.

Elements of the intrinsic pathway

Intrinsic pathway of blood coagulation. All the components necessary for the clotting process to proceed are found in the blood. As such, the proteins required for such clotting to take place are part of the intrinsic pathway of blood coagulation. This pathway involves a series of proteins, protein cofactors, and enzymes, which interact in reactions that take place on membrane surfaces. These reactions are initiated by tissue injury and result in the formation of a fibrin clot (Figure 8).

The intrinsic pathway is initiated by the activation of factor XII by certain negatively charged surfaces, including glass. High-molecular-weight kininogen and prekallikrein are two proteins that facilitate this activation. The enzyme form of factor XII (factor XIIa) catalyzes the conversion of factor XI to its enzyme form (factor XIa). Factor XIa catalyzes the conversion of factor IX to the activated form, factor IXa, in a reaction that requires calcium ions. Factor IXa assembles on the surface of membranes in complex with factor VIII; the factor IXa–factor VIII complex requires calcium to stabilize certain structures on these proteins associated with their membrane-binding properties. Factor X binds to the factor IXa–factor VIII complex and is activated to factor Xa. Factor Xa forms a complex with factor V on membrane surfaces in a reaction that also requires calcium ions. Prothrombin binds to the factor Xa–factor V complex and is converted to thrombin, a potent enzyme that cleaves fibrinogen to fibrin, a monomer. The monomer fibrin molecules then link together (polymerize) to form long fibres. Later, additional bonding between the units of the polymer is promoted by an enzyme known as factor XIIIa, which stabilizes the newly formed clot by cross-linkages. Although the detailed mechanisms are not known, this cascade, or waterfall, effect offers the possibility for amplification of a small signal associated with tissue injury into a major biologic event—the formation of a fibrin clot. Furthermore, careful regulation of this system is possible with the participation of two protein cofactors, factor VIII and factor V.

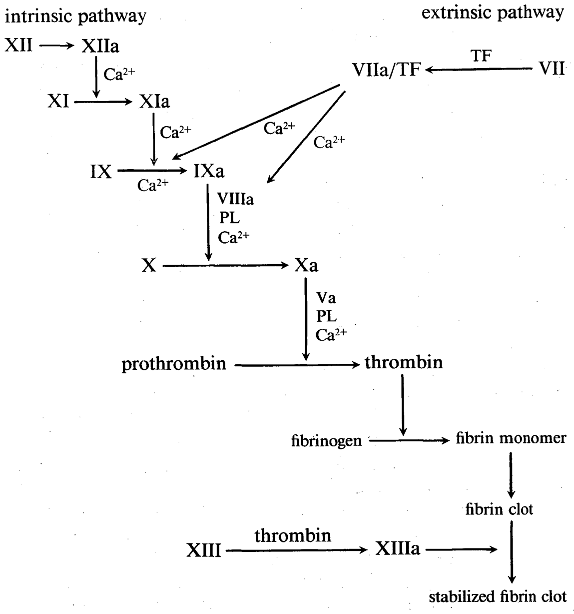

Figure 8: *The blood coagulation cascade.*
Each protein circulates in the blood in an active form. Upon initiation of the clotting system, the pathways for generating fibrin are activated. Many of the clotting proteins are referred to as numbered factors. PL indicates platelet phospholipids and TF indicates tissue factor.

Active and inactive surfaces

Certain negatively charged surfaces, including glass, kaolin, some synthetic plastics, and fabrics, activate factor XII to its enzyme form, factor XIIa. In contrast, certain materials have little tendency to activate factor XII. Inactive surfaces include some oils, waxes, resins, silicones, a few plastics, and endothelial cells, the most inert surface of all. The physicochemical properties that determine activity are not known. The problem is important, for modern surgery requires a perfectly inactive material to make substitutes (prostheses) for heart valves and sections of blood vessels. The formation of clots (thrombi) on these surfaces can lead to serious or even fatal complications. Open-heart surgery requires pumping of blood through equipment that does not activate the blood-clotting process significantly. Similarly, blood filtration of waste products during kidney dialysis must not lead to the generation of fibrin clots. To minimize the activation of blood coagulation when blood flows over foreign surfaces, special drugs (anticoagulants) such as heparin are employed.

The activity of the intrinsic pathway may be assessed in a simple laboratory test called the partial thromboplastin time (PTT), or, more accurately, the activated partial thromboplastin time. Plasma is collected and anticoagulated with citrate buffer; the citrate binds and effectively removes functional calcium ions from the plasma. Under these conditions, a fibrin clot cannot be generated. A negatively charged material, such as the diatomaceous material kaolin, is added to the plasma. Kaolin activates factor XII to its enzyme form, factor XIIa, which then activates factor XI. The process is blocked from further activation because of the lack of calcium ions, which are required for the next reaction, the activation of factor IX. Upon the addition of calcium ions and a phospholipid preparation (which serves as an artificial membrane for the assembly of the blood-clotting protein complexes), the duration of time is recorded until a visible clot is formed. This reaction takes place in a matter of 25 to 50 seconds, depending upon the formulation of chemicals used. In practice, the clotting time of a test plasma is compared to the clotting time of normal plasma. Delayed clotting, measured as a prolonged partial thromboplastin time, may be due to a deficiency in the activity of one or more of the blood-clotting factors or to a chemical inhibitor of blood coagulation.

Tissue factor

The extrinsic pathway of blood coagulation. Upon the introduction of cells, particularly crushed or injured tissue, blood coagulation is activated and a fibrin clot is rapidly formed. The protein on the surface of cells that is responsible for the initiation of blood clotting is known as tissue factor, or tissue thromboplastin. Tissue factor is found in many of the cells of the body but is particularly abundant in those of the brain, lungs, and placenta. The pathway of blood coagulation activated by tissue factor, a protein extrinsic to blood, is known as the extrinsic pathway (Figure 8).

Tissue factor serves as a cofactor with factor VII to facilitate the activation of factor X. Alternatively, factor VII can activate factor IX, which, in turn, can activate factor X. Once activated, factor X proceeds to activate prothrombin to thrombin in a reaction requiring factor V. The thrombin converts fibrinogen to fibrin. With the exception of factor VII, all components of the extrinsic pathway are also components of the intrinsic pathway.

The activity of the extrinsic pathway may be assessed in the laboratory using a simple test known as the prothrombin time. Tissue extract, or tissue thromboplastin, is extracted from animal tissues rich in tissue factor. Plasma, anticoagulated with citrate buffer, is allowed to clot with the simultaneous addition of phospholipid, calcium, and thromboplastin. The duration of time until clot formation, known as the prothrombin time, is usually between 10 and 12 seconds. In practice, the clotting time of a test plasma is compared to the clotting time of normal plasma. Delayed clotting, measured as a prolonged prothrombin time, may be due to a deficiency in the activity of one or more of the blood-clotting factors in the extrinsic pathway or to a chemical inhibitor of blood coagulation that interferes with the extrinsic pathway.

In summary, there are two independent mechanisms for initiating blood coagulation and for activating factor X: (1) negatively charged surfaces that initiate blood clotting through the intrinsic pathway (factors XII, XI, IX, and VIII), and (2) tissue factor on cells outside the blood that participates in the extrinsic pathway (factor VII). The common pathway (factor X, factor V, prothrombin, and fibrinogen) is shared by both systems. Although both pathways provide the opportunity to acquire meaningful information about clotting proteins using the partial thromboplastin time and the prothrombin time, it is most likely that the physiologically important pathway of blood coagulation is the extrinsic pathway initiated by tissue factor.

Zymogens

Biochemical basis of activation. The blood-clotting proteins circulate in the blood in their inactive, proenzyme form. The biochemical term for such proenzymes is zymogen. These zymogens are precursor enzymes that are converted to active enzymes by the cleavage of one or in some instances two peptide bonds. By splitting the protein into specific fragments, the zymogen is turned into an active enzyme that can itself split particular peptide bonds. This process, known generally as limited proteolysis, is equivalent to a molecular switch; by cutting a specific bond that connects two amino acids in the string of amino acids known as a polypeptide, an active enzyme is formed. Thus, the blood contains a system poised to become engaged instantaneously in the formation of blood clots if tissue is injured. Under normal conditions, however, blood clotting does not take place in the absence of tissue injury. The clotting proteins that function as zymogens in the blood include factor XII, factor XI, prekallikrein, factor IX, factor X, factor VII, and prothrombin.

Protein cofactors also play an important role in blood coagulation. Two protein cofactors, factor V and factor VIII, are large proteins that probably regulate blood coagulation. These proteins circulate in the blood as inactive cofactors. By the process of limited proteolysis, in which several cuts in the polypeptide chains of these cofactors are formed by the enzyme thrombin, factors V and VIII are converted to active cofactors. Factor V and factor VIII bind to membrane surfaces and form a focal point for the organization of certain protein complexes.

Antithrombin III

Inhibition of clotting. After the activation of the blood-clotting system, the active enzymes must be turned off and the clotting process contained locally to the area of tissue injury. The details of the regulation of blood coagulation remain obscure, but it is clear that a series of blood proteins play a specialized role in disengaging the activated blood-clotting system. Antithrombin III is a plasma protein that combines with thrombin as well as most of the other activated blood-clotting proteins (*e.g.,* factors Xa and IXa) to form inert complexes. This action is greatly enhanced by the presence of heparin, a substance formed by mast cells of the connective tissue. The hereditary deficiency of antithrombin III is associated with an excessive tendency toward clot formation, and manifestations of this defect are recurrent thrombophlebitis and pulmonary embolism. Heparin cofactor II is another plasma protease inhibitor that specifically forms a complex with thrombin, thus inactivating this enzyme. Protein C, a vitamin K-dependent protein, is a zymogen that requires vitamin K for its activation by thrombin complexed to thrombomodulin, a protein on the endothelial cell membrane. Activated protein C is capable of inactivating the active cofactor forms of factors VIII and V. Its action is enhanced when bound to protein S, a vitamin K-dependent protein that is attached to cell membranes (platelet or possibly endothelial cells). A deficiency in the level of protein C or protein S is associated with an excessive tendency to form clots.

Fibrinolysis

Another anticoagulant effect is the fibrinolytic (fibrin-splitting) action of plasmin, an enzyme that catalyzes the removal of old fibrin at injury sites and any which may be deposited in normal vessels. Plasmin is derived from plasminogen, an inert protein precursor that can be activated by tissue plasminogen activator. Streptokinase, urokinase, and tissue plasminogen activator are drugs that activate plasminogen and lead to the dissolution of clots.

Synthesis of blood-clotting proteins. Most of the blood coagulation proteins are synthesized in the liver. In addition, factor VIII is synthesized in a large number of other tissues. Six proteins involved in blood coagulation require vitamin K for their complete synthesis: factor IX, factor X, prothrombin, factor VII, protein C, and protein S. These proteins are synthesized in precursor form. In a region of the liver cell called the rough endoplasmic reticulum, specific glutamic acid residues in the protein are changed by an enzyme-mediated reaction to form a modified glutamic acid known as γ-carboxyglutamic acid. This enzyme reaction, known as γ-carboxylation, requires vitamin K as a cofactor. γ-Carboxyglutamic acid is a unique amino acid that binds to calcium. In the protein, γ-carboxyglutamic acids form the calcium-binding sites that characterize this form of calcium-binding protein, the vitamin K-dependent proteins. Calcium stabilizes certain structural forms of the vitamin K-dependent proteins, enabling these proteins to bind to cell membranes. In the absence of vitamin K or in the presence of vitamin K antagonists such as warfarin, γ-carboxylation is inhibited and proteins are synthesized that are deficient in γ-carboxyglutamic acid. These proteins have no biologic activity because they do not bind to calcium and do not interact with membrane surfaces. (B.Fu.)

Blood diseases

The hematopoietic system

The blood diseases are abnormal conditions that involve the corpuscular elements of the blood—red cells, white cells, and platelets—and the tissues in which they are formed—the bone marrow, the lymph nodes, the spleen (*i.e.,* the hematopoietic system). This definition, however, needs expansion and modification. In certain types of illness (*e.g.,* pneumonia, appendicitis) the number of leukocytes is increased. This is called leukocytosis and is a physiological response rather than a disease of the blood. In other diseases, as will be mentioned below, a reduction in the number of red cells in the blood (anemia) occurs; such anemia is not usually thought of as representing a "blood disease," but it does represent the response of the hematopoietic system to the underlying disease. Strictly speaking, the term blood disease refers only to those types of anemia and those disorders of leukocytes, of platelets, of coagulation, and of the bone marrow, lymph nodes, and spleen in which the blood-forming organs or coagulation systems are the primary sites involved.

In the following, all varieties of alteration in the three corpuscular elements of the blood will be discussed. For convenience, disorders chiefly affecting the red cells, the leukocytes, the platelets, and the process of blood coagulation will be considered in turn, but, as will become apparent, alterations in disease do not necessarily occur in only one of these groups of blood cells; in its reactions in disease the hematopoietic system may demonstrate multiple changes.

Since the blood circulates throughout the body and carries nutritive substances as well as waste products, examination of it can be important in detecting the presence of disease. Examination of the blood may be considered in two categories; namely, the analysis of the plasma and the study of the corpuscles. Examination of the plasma includes measurement of plasma proteins, blood sugar, salts (which, being in solution and in the ionic state, are referred to as electrolytes), lipids, enzymes, urea, and various hormones. Such measurements are useful in the identification of diseases that are not classified as blood diseases—*e.g.,* diabetes, kidney disease, and thyroid disease. Special studies of plasma or its components can be carried out to determine the status of blood clotting.

Historical background

Long before the nature and composition of blood were known, a variety of complaints were attributed to disordered blood. The red cells were not recognized until the 17th century, and it was another 100 years before one of the forms of the white cells, the lymphocyte, and the clotting of blood were described. In the 19th century other forms of leukocytes were discovered, and a number of diseases of the blood and blood-forming organs were distinguished.

In the 19th century and also in the first quarter of the 20th century much attention was given to descriptions of the morphological changes—the changes in form and structure—that take place in the blood during disease and to the signs and symptoms of the various blood diseases. In the years that followed, a more physiological approach began to develop, concerned with the mechanisms underlying the development of disease and with the ways in which abnormalities might be corrected. Following World War II, progress was greatly accelerated by the strong financial support that medical science received during a particularly productive age of medical research.

The study of a particular instance of disease involves inquiry into the circumstances of its development, the symptoms, and the course of the illness (the history). A thorough physical examination of the affected person and specific laboratory tests are essential.

In the case of the blood, certain features of the physical examination are especially important in diagnosis. These include noting the presence or absence of pallor or, the opposite, an excess of colour; jaundice, red tongue, enlargement of the heart or liver; the presence or absence of small purple spots or larger bruises in the skin; enlargement of lymph glands (nodes); enlargement of the spleen; and tenderness of the bones.

Laboratory studies particularly valuable in diagnosis include (1) determination of the number and characteristics of red cells in the blood; *i.e.,* the existence of anemia or polycythemia, (2) study of the white cells, their number and their proportions as to type, (3) enumeration of the blood platelets and a study of the blood-clotting process, and (4) in many instances a study of the bone marrow. It is sometimes necessary to remove a lymph node for microscopic examination, and X-ray examinations may be necessary for the detection of organ or lymph node enlargement or bone abnormalities. The more unusual cases may require further examinations—*e.g.,* special serological (serum-related) or biochemical procedures or various measurements using radioactive isotopes to outline an organ or quantitate blood volume.

DISORDERS AFFECTING RED CELLS

Normal values for red blood cells

The quantity of red blood cells in normal human beings varies with age and sex as well as with external conditions, primarily atmospheric pressure. At sea level an average normal man has 5,400,000 red blood cells per cubic millimetre of blood. These carry an average of 16 grams of hemoglobin per 100 millilitres of blood. If such blood is centrifuged so that the red cells are packed in a special tube known as the hematocrit, they are found, on the average, to occupy 47 percent of the volume of the blood. In the average woman the normal figures are lower than this (red cell count 4,800,000; hemoglobin 14 grams; volume of packed red cells 42 percent). In the newborn infant these values are higher but decrease in the course of the first several weeks of postnatal life to levels below those of the normal woman; thereafter, they rise gradually. The differences in male and female blood begin to appear at about the time of puberty. It should be emphasized that these figures represent average values; those found in normal persons range approximately 15 percent on either side of this mean.

From the physiological standpoint it is the quantity of hemoglobin in the blood that is important because this iron-containing protein is required for the transport of oxygen from the lungs to the tissues. In disease, as well as in certain situations in which physiological adjustments take place, the quantity of hemoglobin may be reduced below normal levels, a condition known as anemia, or may be increased above normal, leading to erythrocytosis (also called polycythemia).

The anemias. Anemia varies in severity, and the tolerance of different persons for anemia varies greatly, depending in part upon the rate at which it has developed. When anemia has developed gradually, affected persons may endure severe grades of anemia with few or no complaints, whereas rapidly developing anemia causes severe symptoms; if sufficiently severe and rapid in development, anemia can be fatal. In anemia the blood is capable of carrying only a reduced amount of oxygen to tissues, a condition that stimulates the lungs to increase the respiratory rate in order to pick up more oxygen and the heart to increase its rate (pulse) in order to increase the volume of blood delivered to the tissues. Associated complaints include a pounding headache due to the increased blood flow.

Determination of anemia

Anemia is always a sign, either predominant or incidental, of some underlying congenital condition or acquired disease. There are many varieties of anemia. Their clinical manifestations are generally similar, and yet they must be differentiated because their causes differ, and consequently their treatment is not the same. Differentiation is based on the history and physical examination, which may reveal an underlying cause, and on examination of the blood. The latter includes measurement of the degree of anemia and microscopic study of the blood cells. If the number of red cells, the hemoglobin concentration of the blood, and the volume of packed red cells are known, the mean volume and hemoglobin content can be calculated. The mean corpuscular volume (MCV) normally is 82 to 92 cubic micrometres, and about a third of this is hemoglobin (mean corpuscular hemoglobin concentration, MCHC, normally is 32 to 36 percent). If determined accurately, the MCV and the MCHC are useful indexes of the nature of an anemia.

Under the microscope the red cells of humans appear as round biconcave disks of uniform size with an average diameter of approximately 7.8 micrometres, or 0.0078 millimetre (a common pin is about one millimetre thick). Microscopic inspection of films of blood dried on glass slides and stained with aniline dyes allows observation of variations in the size and colour and other abnormalities of individual red cells and also permits examination of the white cells and platelets.

Normal production of red cells

Derangement of function in anemia. Red cells are formed within the marrow cavities of the central bones of the adult human skeleton (skull, spine, ribs, breastbone, pelvic bones). The marrow contains nucleated red cells (normoblasts), as well as white cells of all stages of development and megakaryocytes, the source of blood platelets. The normoblasts are present in various stages of development toward the mature, adult, nonnucleated, hemoglobin-containing red cells that will be released into the circulating blood.

The newly arrived red cells in the circulation remain as reticulocytes, young red cells with a characteristic threadlike network, for two or three days. Each day's output of new red cells survives an average of 120 days before succumbing to old age. The red cells are able to withstand the vicissitudes of the circulation because glucose absorbed from the plasma is metabolized within the cell to supply energy in the form of adenosine triphosphate (ATP) as well as to provide reducing systems that protect against the products of oxidation (oxidation-reduction systems).

Ultimately the aged red cells are broken down by specialized reticuloendothelial cells that are found throughout the body and especially in the spleen and liver. The hemoglobin is digested into its components: iron, a red pigment with a ring-shaped structural formula (porphyrin), and a protein (globin). The iron remains within the body to be used over and over again in the formation of new hemoglobin. The porphyrin ring opens and is changed chemically to become the yellow pigment of the blood plasma, bilirubin. This is then excreted by the liver and gives the bile its characteristic colour. The globin is metabolized. In a healthy person, red cell production (erythropoiesis) is so well adjusted to red cell destruction that the levels of red cells and hemoglobin remain constant.

The circulation is a closed system from which there normally is no loss of blood except that which occurs physiologically in menstruation. Anemia results when (1) the production of red cells and hemoglobin lags behind the normal rate of their destruction, (2) excessive destruction exceeds production, or (3) blood loss occurs. The bone marrow normally is capable of increasing production as much as sixfold to eightfold through an increased rate of development from the primitive precursors. Anemia ensues when the normal fine balance between production, destruction, and physiological loss is upset and erythropoiesis has not been accelerated to a degree sufficient to reestablish normal blood values.

Conditions of anemia

The rate of production of red cells by the bone marrow normally is controlled by a physiological feedback mechanism analogous to the thermostatic control of temperature in a room. The mechanism is triggered by a reduction of oxygen in the tissues (hypoxia) and operates through the action of a hormone, erythropoietin, in the formation of which the kidney plays an important role. Erythropoietin is released and stimulates further erythropoiesis. When oxygen needs are satisfied, erythropoietin production is reduced and red cell production diminishes.

Failure of production of red cells may be caused by deficiency of certain essential materials, such as iron, folic acid, or vitamin B_{12}. It may be due to other causes, such as the presence of certain types of disease—*e.g.,* infection; damage of the bone marrow by ionizing radiation or by drugs or other chemical agents; or anatomical alterations in the bone marrow, as by leukemia or tumour metastases (migration of tumour cells to the marrow from distant sites of origin). Accelerated destruction of red cells may occur for any one of a large variety of causes (see below *Hemolytic anemias*). Finally, blood loss may result from trauma or may be associated with a variety of diseases.

Persons whose anemia is due to increased destruction of red cells have excessive amounts of bilirubin in the plasma. They appear to be slightly jaundiced, and the excess pigments darken the excreta. Certain laboratory tests measure the degree of excessive pigment production. The bone marrow responds to increased destruction of red cells by increasing the rate of their production, thereby increasing the number of reticulocytes in the blood. These cells, in addition to their unique staining characteristics, are larger than fully mature red cells. If their number is increased sufficiently, the mean corpuscular volume of the cells in the circulation is increased. The anemia is then characterized as macrocytic.

Classification of anemia

Macrocytic anemia also is produced when the anemia results from impaired production of red cells, *e.g.,* when vitamin B_{12} or folic acid is lacking. In other circumstances, as for example when there is a deficiency of iron, the circulating red cells are smaller than normal and poorly filled with hemoglobin—this is termed hypochromic microcytic anemia. In still other forms of anemia there is no significant alteration in the size, shape, or coloration of the red cells—normocytic anemias.

Anemias may be classified according to the underlying abnormality in the basic physiological mechanism (decreased production, increased destruction, blood loss) or on morphological grounds (macrocytic, normocytic, or microcytic hypochromic) or according to their cause (*e.g.,* vitamin B_{12} deficiency). In practice it is by a combination of clinical, morphological, and physiological studies that the cause is determined. Accurate diagnosis is essential before treatment is attempted because, just as the causes differ widely, so the treatment of anemia differs from one patient to another. Indiscriminate treatment by the use of hematinics (drugs that stimulate production of red cells or hemoglobin) is wasteful and can be dangerous.

Megaloblastic anemias. Lack of vitamin B_{12} or folic acid leads to the production in the bone marrow of abnormal nucleated red cells known as megaloblasts. Such cells can be identified by their characteristic appearance. When such a vitamin deficiency occurs, bone marrow activity is seriously impaired; marrow cells proliferate but do not mature properly, and erythropoiesis becomes largely ineffective. Anemia develops, the number of reticulocytes is reduced, and even the numbers of granulocytes (leukocytes that contain granules in the cell substance outside the nucleus) and platelets are decreased. The adult red cells that are formed from megaloblasts are larger than normal, resulting in a macrocytic anemia. The impaired and ineffective erythropoiesis is associated with accelerated destruction of the red cells, thereby providing the features of a hemolytic anemia.

Vitamin B_{12} is a red, cobalt-containing vitamin that is found in animal but not in vegetable foods. Unlike other vitamins, it is not formed by higher plants but only by certain bacteria and molds and in the rumina of sheep and cattle, provided that traces of cobalt are present in their fodder. In other species, including humans, vitamin B_{12} must be obtained passively, by eating food of animal source. Furthermore, this vitamin is not absorbed efficiently from the human intestinal tract unless a certain secretion of the stomach, the so-called intrinsic factor (IF), is available to concentrate the vitamin on the intestinal wall.

Pernicious anemia

The most common cause of vitamin B_{12} deficiency is pernicious anemia, a condition usually affecting patients past middle age. In this disorder all stomach secretion of IF fails, perhaps as the result of an immune process consisting of the production of antibodies directed against the stomach lining. The tendency to form such antibodies may be hereditary.

The English physician Thomas Addison first described this condition in 1849. The discovery of vitamin B_{12} came about because of the investigations of the American physician George H. Whipple, who studied the value of various foods in promoting the formation of hemoglobin in dogs made anemic by bleeding. Whipple found liver to be most effective in the treatment of pernicious anemia. The American physicians George R. Minot and William P. Murphy further tested the value of liver. The activity of the foods tested by Whipple was due mainly to their iron content rather than to the presence of vitamin B_{12}. Investigations by William B. Castle, also an American physician and medical scientist, later revealed the defect in pernicious anemia to be a deficiency of a factor secreted by the stomach, which is necessary for the absorption of vitamin B_{12} across the wall of the intestine into the circulation.

The first treatment for pernicious anemia was to prescribe that the patient eat liver each day; later regular amounts of liver extract were given orally or by injection. Today patients are given injections of the equivalent of a millionth of a gram of vitamin B_{12} per day. In practice, the necessary amount of this vitamin can be given once a month or even once in three months. Oral treatment with vitamin B_{12} is possible but inefficient because absorption is poor.

Other forms of vitamin B_{12} deficiency are rare. They are seen in complete vegetarians whose diets lack vitamin B_{12}, in persons whose stomachs have been completely removed and so lack a source of IF, in those who are heavily infested with the fish tapeworm *Diphyllobothrium latum* or have intestinal cul-de-sacs or partial obstructions where competition by the tapeworms or by bacteria for vitamin B_{12} deprives the host, and in persons with primary intestinal diseases that affect the absorptive capacity of the small intestine (ileum). In these conditions, additional nutritional deficiencies, as of folic acid and iron, are also likely to develop.

Effects of folic acid deficiency

Blood changes similar to those occurring in vitamin B_{12} deficiency result from deficiency of folic acid. Folic acid is a vitamin found in leafy vegetables, but it is also synthesized by certain intestinal bacteria. In humans deficiency usually is the result of a highly defective diet or of chronic intestinal malabsorption as mentioned above. Pregnancy greatly increases the need for this vitamin. There is also an increased demand in cases of long-continued accelerated production of red cells. This type of deficiency also has been observed in some patients receiving anticonvulsants, and there is some evidence that absorption of the vitamin may be impaired in these cases. Often several factors affecting supply and demand of the vitamin play a role in producing folic acid deficiency.

Unless folic acid deficiency is complicated by the presence of intestinal or liver disease, its treatment rarely requires more than the institution of a normal diet. In any event the oral administration of folic acid relieves the megaloblastic anemia. Some effect can be demonstrated even in pernicious anemia, but this treatment is not safe because the nervous system is not protected against the effects of vitamin B_{12} deficiency, and serious damage to the nervous system may occur unless vitamin B_{12} is given.

In the above conditions, megaloblastic anemia develops as the result of dietary deficiency of, faulty absorption of, or increased demands for vitamin B_{12} and/or folic acid. In addition to these circumstances, megaloblastic anemia may arise in still other situations. Selective vitamin B_{12} malabsorption may be the consequence of a hereditary defect. Deranged metabolism may play a role in some instances of megaloblastic anemia that accompany pregnancy. Metabolic antagonism is thought to be the mechanism underlying the megaloblastic anemia associated with the therapeutic use of certain anticonvulsant drugs and some drugs employed in the treatment of leukemia and other forms of cancer. In fact, one of the earliest drugs used to treat leukemia was a folic acid antagonist.

Normocytic normochromic anemias. The term normocytic normochromic anemia is applied to those forms of anemia in which the mean size and hemoglobin content of the red cells are within normal limits. Usually microscopic examination of the red cells shows them to be much like normal cells. In other cases there may be marked variations in size and shape, but these are such as to equalize one another, thus resulting in normal mean values. The normocytic anemias are a miscellaneous group, by no means as homogeneous as the megaloblastic anemias.

Blood loss and chronic infections

Anemia caused by the sudden loss of blood is necessarily normocytic at first, since the cells that remain in the circulation are normal. The blood loss stimulates increased production, and the young cells that enter the blood in response are larger than those already present in the blood. If the young cells are present in sufficient number, the anemia temporarily becomes macrocytic (but not megaloblastic).

The many causes of acute blood loss include trauma, peptic ulceration of the stomach or bowel, and ulcerative lesions of other types. Treatment includes replacement, by transfusion, of the blood lost and appropriate steps directed against the cause.

A common form of anemia is that occurring in association with various chronic infections and in a variety of chronic systemic diseases. As a rule the anemia is not severe, although the anemia associated with chronic renal insufficiency (defective functioning of the kidneys) may be extremely so. Most normocytic anemias appear to be the result of impaired production of red cells, and in renal failure there is a deficiency of erythropoietin, the factor in the body that normally stimulates red cell production. In these states, the life span of the red cell in the circulation may be slightly shortened, but the mechanism of production of the anemia is failure of red cell production. The anemia of chronic disorders is characterized by abnormally low levels of iron in the plasma in the face of excessive quantities in the reticuloendothelial cells (cells whose function is ingestion and destruction of other cells and of foreign particles) of the bone marrow. Successful treatment depends on the possibility of eliminating or relieving the underlying disorder.

The mild anemias associated with deficiencies of the anterior pituitary, thyroid, adrenocortical, and testicular hormones usually are normocytic. As in the case of anemia associated with chronic infections or various systemic diseases, the symptoms usually are those of the underlying condition, although sometimes anemia may be the most prominent sign. Unless complicated by deficiencies of vitamin B_{12} or iron, these anemias are abolished by appropriate treatment with the lacking hormone.

Invasion of bone marrow by cancer cells carried by the bloodstream, if sufficiently great, is accompanied by anemia, usually normocytic in type but associated with abnormalities of both red and white cells. It is thought that such anemia is due to impaired production of red cells through mechanical interference. Whether this is true or not, a characteristic sign in the peripheral blood is the appearance of many irregularities in the size and shape of the red cells and of nucleated red cells; these young cells normally never leave the bone marrow but appear when the marrow's structure is distorted by invading cells.

In aplastic anemia the normally red marrow becomes fatty and yellow and fails to form enough of its three cellular products—red cells, white cells, and platelets. Anemia with few or no reticulocytes, reduced levels of the types of leukocytes formed in the bone marrow (granulocytes), and reduced platelets in the blood are characteristic. Manifestations of aplastic anemia are related to these deficiencies and include weakness, increased susceptibility to infections, and bleeding manifestations. In some cases the onset of aplastic anemia has been found to have been preceded by exposure to such organic chemicals as benzol, insecticides, or a variety of drugs, including especially the antibiotic chloramphenicol. While it is well established that certain agents may produce aplastic anemia, most persons exposed to these agents do not develop the disease and most persons with aplastic anemia have no clear history of exposure to such agents. There are other agents that produce aplasia in a predictable way. These include some of the chemotherapeutic agents used in the treatment of cancer, lymphoma, and leukemia, as well as irradiation treatment for these diseases. Because of this fact, blood counts are frequently checked and doses of drugs or irradiation modified in patients being treated. Withdrawal of medication is followed by recovery of the bone marrow in such cases. On the other hand, in those patients who develop aplastic anemia as a result of exposure to other toxic agents, cessation of exposure may not result in recovery of the marrow, or at best the marrow may be indolent and incomplete.

Chemotherapy and aplasia

Treatment of aplastic anemia is a twofold process. First, the patient must be supported through complications of the disease: infection calls for vigorous treatment with antibiotics; symptoms due to anemia call for red cell transfusions; bleeding calls for platelets. Second, efforts should be directed toward inducing bone marrow recovery. Based on the hypothesis that one of the mechanisms of production of the aplasia is autoimmunity, medication to suppress the immune response, such as the administration of antithymocyte globulin, is occasionally successful. An important and effective treatment is transplantation of bone marrow from a normal, compatible donor, usually a sibling. This treatment is limited by the availability of compatible donors and also by the fact that the recipient is increasingly prone to serious complications with advancing age.

Hypochromic microcytic anemias. Hypochromic microcytic anemias, characterized by the presence in the circulating blood of red cells that are smaller than normal and poorly filled with hemoglobin, fall into two main categories. The first is that due to deficiency of iron, and the second is that due to impaired production of hemoglobin (the globin); in either case there is an inadequate amount of the final product in the red cell.

Iron-deficiency anemia

Deficiency of iron is probably the most common cause of anemia throughout the world. Iron is required for hemoglobin formation; if the supply is insufficient to produce normal quantities of hemoglobin, the bone marrow ultimately is forced to produce cells that are smaller than normal and poorly filled with hemoglobin. Iron is derived from the diet and absorbed in the intestinal tract. Once in the body, it is retained and used over and over again, only minimal amounts being lost through shedding of cells from the skin and the exposed membranes and through normal menstruation. In the adult the body content is approximately 3.7 grams of iron, of which more than half is hemoglobin. In the male there is virtually no further need for iron. Deficiency results if the dietary supplies of iron are insufficient to meet the needs; if absorption is faulty, as in malabsorption disorders; or if blood loss is occurring. Common causes of iron deficiency are excessive menstrual loss in women and bleeding peptic ulcer in men. Iron deficiency is common in infancy and childhood because demands are great for the ever-expanding pool of circulating hemoglobin in the growing body and in pregnancy when the fetus must be supplied with iron. Hookworm infestation is a common cause of iron deficiency where conditions for the worm are favourable, because the intestinal blood loss caused by the myriad of worms attached to the wall is great.

Victims of iron-deficiency anemia are pale but not jaundiced. The deficiency of iron-containing enzymes in the tissues, if sufficiently great, results in a smooth tongue; brittle, flattened fingernails; and lustreless hair. Under the name of chlorosis, this type of anemia was mentioned in popular literature and depicted in paintings, especially those of the Dutch masters, until the 20th century. Although it is not necessarily less common now, there is no doubt that it is less severe in Europe and North America than it once was. The only treatment required is oral administration of iron salts in some palatable form, such as ferrous sulfate.

Small red cells poorly filled with hemoglobin are characteristic of a hereditary disorder of hemoglobin formation, thalassemia, that is common among people of Mediterranean stock and is discussed below. With the exception of iron deficiency and thalassemia, hypochromic microcytic anemia is rare. It is seen in anemia responsive to the vitamin pyridoxine, where the anemia probably results from a metabolic fault in the synthesis of the heme portion of hemoglobin. Sideroblastic anemia, characterized by the presence in the bone marrow of nucleated red cells, the nucleus of which is surrounded by a ring of iron granules ("ringed sideroblasts") and by a proportion of small, pale red cells in the blood, is of unknown cause and difficult to treat.

Sideroblastic anemia

Hemolytic anemias. Destruction of red cells at a rate substantially greater than normal, if not compensated for by accelerated red cell production, causes a type of anemia called hemolytic. Increased red cell destruction is recognized by demonstrating increased quantities of the pigmentary products of their destruction, such as bilirubin and urobilinogen, in the blood plasma, urine, and stools andbyevidence of accelerated erythropoiesis, such as an increase in the number of young corpuscles (reticulocytes) in the blood. When blood destruction is extremely rapid or occurs in the blood vessels, free hemoglobin is found in the urine (hemoglobinuria). Treatment varies with the cause of the hemolytic anemia.

There are two principal causes of hemolytic anemia: (1) inherently defective red cells and (2) an environment hostile to red cells. Abnormalities within the red cell are usually congenital and hereditary. They are exemplified by diseases in which the cell membrane is weakened, cell metabolism is defective, or hemoglobin is abnormal.

Hereditary defects

Hereditary spherocytosis is the most common disease involving the red cell membrane. It is characterized by the presence of red cells that appear small, stain densely for hemoglobin, and look nearly spherical. Such cells are mechanically fragile and readily swell up and burst in dilute salt solution. In the body they break up when deprived of free access to plasma glucose. The abnormality is aggravated by a tendency for the cells to remain longer than usual in the spleen because of their spheroidal shape. The corpuscular defect may appear if it is inherited from either parent (it is caused by a dominant gene). The anemia varies in severity. It may be so mild as to pass unnoticed for years, but it may suddenly become severe; *e.g.,* when an incidental respiratory infection briefly suppresses the accelerated production of red cells necessary to meet the constantly increased rate of their destruction. An agent known to cause this transient cessation of erythropoiesis is the parvovirus, and the development of severe anemia under these circumstances is termed aplastic crisis. Removal of the spleen, which always is enlarged, cures the anemia by eliminating the site of sequestration and destruction of the red cells but does not prevent hereditary transmission of the disease.

Red cells metabolize glucose by breaking it down to lactic acid either via an anaerobic (oxygenless) pathway, or by oxidation through a pathway called the pentose shunt. The anaerobic pathway, the main route of metabolism, provides energy in the form of ATP. Deficiencies of enzymes, such as pyruvate kinase, in this pathway shorten red cell survival times because energy-requiring activities within the red cell are curtailed. Deficiencies of enzymes in the anaerobic pathway, also a vital pathway for red cell survival, are generally relevant only when they are homozygous (*i.e.,* when the deficiency is inherited from each parent on an autosomal chromosome and is therefore expressed). Abnormalities also have been discovered in the alternative process of glucose metabolism, known as the phosphogluconate oxidative, or pentose shunt, glycolytic pathway. The pathway provides a reducing factor, NADPH (nicotinamide-adenine dinucleotide phosphate), which is part of a mechanism for returning glutathione to its reduced form following its oxidation by peroxides, a reaction that protects other molecules in the cell from oxidative damage by these peroxides. Deficiency of the first enzyme in the pathway, glucose-6-phosphate dehydrogenase (G6PD), is rather common. This deficiency results in a decreased capacity to detoxify peroxides and leads to oxidative damage to the red cell and hemolysis. If the deficiency is mild, there is hemolysis only when an excessive amount of peroxides is present, as may occur with the administration of some medications. The frequency of G6PD deficiency varies up to 36 percent among different Caucasian population groups and is especially frequent in Mediterranean peoples. Ingestion of fava beans by some of these people may induce severe destruction of red cells. The deficiency rarely is extreme and results in hemolysis without exposure to oxidants, medications, or toxins. Another variety of G6PD deficiency has been found in 10 to 14 percent of American blacks; the defect is harmless unless the person is exposed to certain drugs, such as certain antimalarial compounds (*e.g.,* primaquine) and sulfonamides. The full effect of the deficiency is rarely observed in females because the gene is sex-linked (*i.e.,* carried on the X chromosome), and only rarely do both X chromosomes carry the abnormal gene. Males, on the other hand, have only one X chromosome and thus only one gene available, and therefore the deficiency is fully expressed if it is inherited on the X chromosome from the mother.

Acquired forms of anemia

Hemolytic anemia can also result as the consequence of an environment hostile to the red cell. Certain chemical agents destroy red cells whenever sufficient amounts are given (*e.g.,* phenylhydrazine); others are harmful only to persons whose red cells are sensitive to the action of the agent. A number of the toxic drugs are oxidants or are transformed into oxidizing substances in the body. Injury may be accidental, as with moth ball (naphthalene) ingestion in children, or it may be the undesirable effect of a drug used therapeutically. Individual sensitivity is of several kinds. There is the susceptibility of certain patients to oxidant drugs such as antimalarial compounds mentioned above. This is attributable to a sex-linked, inherited deficiency of the enzyme G6PD. In other instances, sensitivity is on an immunologic basis; *e.g.,* hemolytic anemia caused by penicillin, quinidine, or alpha-methyldopa (a drug used in the treatment of elevated blood pressure). The anemia develops rapidly over a few days and without transfusions may be fatal.

A long recognized type of hemolytic anemia is that associated with the transfusion of incompatible red cells. Antibodies to the substances alpha- and beta-isoagglutinin, which occur naturally in the blood, destroy the donor red cells when incompatible blood is given by transfusion. Besides the best-known blood groups—A, B, and O—there are other groups to which a person may develop antibodies that will cause transfusion reactions. The rhesus (Rh) and Kell groups are examples. In hemolytic disease of the newborn (erythroblastosis fetalis) the destruction of the blood of the fetus by that of the mother may be due to Rh or ABO incompatibility. The events that take place are, first, the passage of incompatible red cells from the fetus into the circulation of the mother through a break in the placental blood vessels, then development of antibodies in the mother, and, finally, passage of these antibodies into the fetus, with consequent hemolysis, anemia, and jaundice.

Autoimmune hemolytic anemia

A form of hemolytic anemia that is relatively common depends on the formation of antibodies within the patient's body against his own red cells (autoimmune hemolytic anemia). This may occur in association with the presence of certain diseases, but it is often seen without other illness. Trapping of the red cells by the spleen is thought to depend on the fact that red cells coated with incomplete (nonhemolytic) antibody, when brought into contact with reticuloendothelial cells, adhere, become spherical, are ingested (phagocytosed), and break down.

Such anemias may be severe but often can be controlled by the administration of adrenocorticosteroids (which interfere with the destructive process) and treatment of the underlying disease, if one is present. In a number of instances, splenectomy—removal of the spleen—is necessary and is usually partially or wholly effective in relieving the anemia. The effectiveness of splenectomy is attributed to the removal of the organ in which red cells, coated with antibody, are selectively trapped and destroyed.

Other varieties of hemolytic anemia include that associated with mechanical trauma, such as that produced by the impact of red cells on artificial heart valves, excessive heat, and infectious agents (*e.g.,* the organism causing malaria).

Alpha and beta chains

Thalassemia and the hemoglobinopathies. Hemoglobin is composed of a porphyrin compound (heme) and globin. Normal adult hemoglobin (Hb A) consists of globin containing two pairs of chains of amino acids, of which the alpha chain consists of 141 amino acids, the beta chain 146. (A chain of amino acids is called a peptide or, alternatively, when many amino acids make up the chain, a polypeptide.) A minor fraction of normal adult hemoglobin consists of hemoglobin A_2, which contains alpha and delta chains. A different hemoglobin (Hb F) is present in fetal life and possesses a pair of the same alpha chains as does Hb A, but the second set is different (gamma chains). In normal hemoglobin the order in which the amino acids follow one another in the chain is always exactly the same. Studies by a number of investigators have now shown that qualitative and quantitative abnormalities in the globin chains can lead to disease.

In thalassemia it is thought that a primary genetic defect results in reduction in the rate at which alpha, beta, or delta chains are manufactured, the chains being otherwise normal. The relative deficiency of one pair of chains and the resultant imbalance of chain pairs results in ineffective production of red cells, deficient hemoglobin production, microcytosis (small cells), and hemolysis. In sickle-cell anemia and in other abnormalities affecting hemoglobin, the substitution of one amino acid for another at a particular site in the chain is the underlying fault. The substitution of valyl for glutamyl in the sixth position of the beta chain, for example, results in the formation of Hb S (the hemoglobin of sickle-cell disease) instead of Hb A. The defect is inherited as a Mendelian recessive. Thus, if only one parent transmits the abnormality, the offspring inherits the trait but is harmed relatively little; the red cells contain more Hb A than Hb S. If the trait is inherited from both parents, the predominant hemoglobin in the red cell is Hb S; the serious and sometimes fatal disease sickle-cell anemia is the consequence.

Since the first characterization of the nature of the abnormality in Hb S by Linus Pauling and his associates (1949), more than 100 abnormal hemoglobins have been identified, and other forms of "molecular disease" have been recognized as well. Fortunately, most abnormal hemoglobins are not sufficiently affected to alter their function, and therefore no observable illness occurs.

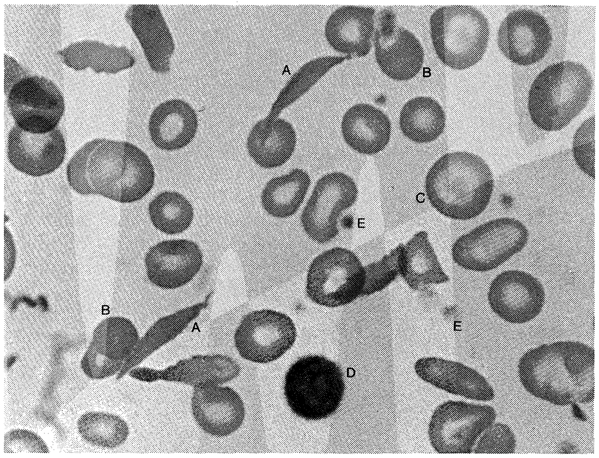

Figure 9: *Blood smear in which the red cells show variation in size and shape typical of sickle-cell anemia.*
(A) Long, thin, deeply stained cells with pointed ends are irreversibly sickled. (B) Small, round, dense cells are hyperchromic because a part of the membrane is lost during sickling. (C) Target cell with a concentration of hemoglobin on its centre. (D) Lymphocyte. (E) Platelets.

Sickle-cell trait and sickle-cell anemia

Sickle-cell anemia (Figure 9) occurs almost exclusively in blacks. In the United States at least 8 percent of blacks carry the sickle-cell trait. The actual disease, sickle-cell anemia, is less common (about 1 in 400 blacks). In this condition most of the red cells of a sample of fresh blood look normally shaped—discoidal—until deprived of oxygen, when the characteristic sickle- or crescent-shaped forms with threadlike extremities appear. Re-exposure to oxygen causes immediate reversion to the discoidal form. Sickle-cell anemia is characterized by severe chronic anemia, punctuated by painful crises, the latter being due to blockage of the capillary beds in various organs by masses of sickled red cells. This gives rise to fever and episodic pains in the chest, abdomen, or joints that are difficult to distinguish from the effects of other diseases. Death results from anemia, from infections, or, ultimately, from heart or kidney failure. While the many complications of the disease can be treated and pain relieved, there is no treatment to reverse or prevent the actual sickling process.

Thalassemia

Thalassemia (Greek: "sea blood") is so called because it was first discovered among peoples around the Mediterranean Sea, among whom its incidence is high. The thalassemias are another group of inherited disorders in which one or more of the hemoglobin subunits are synthesized defectively. This condition, when inherited from one parent, is called thalassemia minor; it causes serious disease only when inherited from both parents (thalassemia major, Cooley's anemia). Thalassemia now is known also to be common in Thailand and elsewhere in the Far East. The red cells in this condition are unusually flat with central staining areas and for this reason have been called target cells. In the mild form of the disease, thalassemia minor, there is usually only slight or no anemia, and life expectancy is normal. Thalassemia major is characterized by severe anemia, great enlargement of the spleen, and body deformities associated with expansion of the bone marrow. The latter presumably represents a response to the need for greatly accelerated red cell production by genetically defective red cell precursors, which are relatively ineffective in producing mature red cells. Anemia is so severe that transfusions are often necessary; however, they are of only temporary value and lead to excessive iron in the tissues once the transfused red cells break down. The enlarged spleen may further aggravate the anemia by pooling and trapping the circulating red cells. Splenectomy may partially relieve the anemia but does not cure the disease.

Causes of thalassemia

The defect in thalassemia may involve the beta chains of globin (beta-thalassemia), the alpha chains (alpha-thalassemia), the delta chains (delta-thalassemia), or both delta- and beta-chain synthesis. In the last (delta–beta-thalassemia), Hb F concentrations usually are considerably elevated since the number of beta chains available to combine with alpha chains is limited and gamma chain synthesis is not impaired. Beta-thalassemia comprises the majority of all thalassemias. A number of genetic mechanisms account for impaired production of beta chains, all of which result in inadequate supplies of messenger RNA available for proper synthesis of the beta polypeptide at the ribosome. In some cases no messenger RNA is produced. Most defects have to do with production and processing of the RNA from the beta gene; in alpha thalassemia, by contrast, the gene itself is deleted. There are normally two pairs of alpha genes, and the severity of the anemia is determined by the number deleted. Since all normal hemoglobins contain alpha chains, there is no increase in F or A$_1$. The extra non-alpha chains may combine into tetramers to form beta$_4$ (hemoglobin H) or gamma$_4$ (hemoglobin Barts). These tetramers are ineffective in delivering oxygen and are unstable. Inheritance of deficiency of a pair of genes from both parents results in intrauterine fetal death or severe disease of the newborn child (hydrops fetalis).

In most forms of hemoglobin abnormality only a single amino acid substitution occurs, but there may be combinations of hemoglobin abnormalities, or a hemoglobin abnormality may be inherited from one parent and thalassemia from the other. Thus, sickle-thalassemia and Hb E-thalassemia are relatively common.

Erythrocythemia

A malfunction of the abnormal hemoglobin may result in erythrocythemia, or overproduction of red cells. In these cases there is increased oxygen affinity, limiting proper delivery of oxygen to tissues and thereby stimulating the bone marrow to increase red cell production. In other cases the iron in heme may exist in the oxidized, or ferric (Fe^{3+}), state and thus cannot combine with oxygen to carry it to tissues. This results in a bluish colour of the skin and mucous membranes (cyanosis). The abnormality in the globin molecule that accounts for this is usually in an area of the molecule called the heme pocket, which normally protects the iron against oxidation, despite the fact that oxygen is being carried at this site.

Erythrocytosis. Erythrocytosis is an increase above normal in the number of red cells in the circulating blood, usually accompanied by an increase in the quantity of hemoglobin and in the volume of packed red cells. The increase may be either an actual rise in the total quantity of red blood cells in the circulation (absolute erythrocytosis), or it may be the result of a loss of blood plasma and thus a relative increase in the concentration of red cells in the circulating blood (relative erythrocytosis). The latter may be the consequence of abnormally lowered fluid intake or of marked loss of body fluid, such as occurs in persistent vomiting, severe diarrhea, or copious sweating or when water is caused to shift from the circulation into the tissue.

Absolute erythrocytosis occurs in response to some known stimulus for the production of red cells. This is in contrast to a disease called polycythemia vera, in which an increased amount of red cells are produced without a known cause. In polycythemia vera there is usually an increase in other blood elements as well.

Common causes

Erythrocytosis is a response by the body to an increased demand for oxygen. It occurs when hemoglobin is not able to pick up large amounts of oxygen from the lungs; *i.e.,* when it is not "saturated." This may result from decreased atmospheric pressure, as at high altitudes, or from impaired pulmonary ventilation. The sustained increase in red cells in persons who reside permanently at high altitudes is a direct result of the diminished oxygen pressure in the environment. Chronic pulmonary disease (*e.g.,* emphysema—abnormal distension of the lungs with air) may produce chronic hypoxemia (reduced oxygen tension in the blood) and lead to erythrocytosis. Extreme obesity also may severely impair pulmonary ventilation and thereby cause erythrocytosis (Pickwickian syndrome).

Congenital heart disorders that permit shunting of blood from its normal path through the pulmonary circuit, thereby preventing adequate aeration of the blood, can also cause erythrocytosis, as can a defect in the circulating hemoglobin. The latter defect may be congenital because of an enzymatic or a hemoglobin abnormality, as mentioned above; or it may be acquired as the result of the excessive use of coal-tar derivatives, such as phenacetin, which convert hemoglobin to pigments incapable of carrying oxygen (methemoglobin, sulfhemoglobin). Lastly, erythrocytosis can develop in the presence of certain types of tumours and as the result of the action of adrenocortical secretions. Treatment of erythrocytosis due to any of these causes involves the correction or alleviation of the primary abnormality.

Polycythemia vera

In polycythemia vera, the numbers of red cells, and often also the numbers of white cells and platelets, are increased and the spleen usually is enlarged. In this disease the stem cell precursor of the bone marrow cells produces excessive progeny. Afflicted persons have an exceptionally ruddy complexion and may complain of headaches, dizziness, a feeling of fullness, and other symptoms. Because of the excessive quantities of red cells, the blood is usually thick, and its flow is retarded; it sometimes clots in the blood vessels (thrombosis) of the heart, the brain, or the extremities with serious consequences. One of the simplest methods of treatment is to remove the blood, one pint at a time, from a vein until the cellular level approaches normal and the symptoms disappear. Occasionally it may be necessary to use drugs or radiation, in the form of radioactive phosphorus, to restrain the overactivity of the marrow cells. These treatments, however, must be avoided when possible because of their potential complications. (M.M.W./Ja.F.D.)

DISEASES RELATED TO WHITE CELLS

Variations in the number of white cells in humans occur normally from hour to hour, the highest counts being recorded in the afternoon and the lowest in the early morning. Temporary increases also normally occur during muscular exercise, menstruation, pregnancy, and childbirth, as well as in certain emotional states. Abnormal changes in the count, appearance, or proportion of the various white cells are indicative of pathological conditions in the body.

Leukocytosis. The condition in which white cells are present in greater numbers than normal is termed leukocytosis. It is usually caused by an increase in the number of granulocytes (especially neutrophils), some of which may be immature (myelocytes). Most often leukocytosis is the result of the presence of an infection, usually caused by pyogenic (pus-producing) organisms such as streptococcus, staphylococcus, gonococcus, pneumococcus, or meningococcus. Leukocyte counts of 12,000 to 20,000 per cubic millimetre during infections are not unusual. As the number of cells increases, the proportion of immature cells usually rises, perhaps because the demands on the leukocyte-producing tissues in the bone marrow have increased to the point at which there is an insufficient number of mature cells for delivery into the circulation. This picture of immaturity is referred to as a "shift to the left." As the infection subsides, the number of younger forms and the total white cell count decrease and ultimately return to normal. During the period of repair following an inflammatory reaction, the monocytes may increase in number, and subsequently the lymphocytes will become more numerous.

Certain types of infection are characterized from the beginning by an increase in the number of small lymphocytes unaccompanied by increases in monocytes or granulocytes. Such lymphocytosis is usually of viral origin. Moderate degrees of lymphocytosis are encountered in certain chronic infections such as tuberculosis and brucellosis.

Infectious mononucleosis

Infectious mononucleosis, caused by the Epstein–Barr virus, is associated with the appearance of unusually large lymphocytes ("atypical" lymphocytes). Those cells represent part of the complex defense mechanism against the virus, and they disappear from the blood when the attack of infectious mononucleosis subsides. Infectious mononucleosis occurs predominantly in persons from 10 to 30 years of age. It is thought to be transmitted by oral contact with exchange of saliva. Discomfort, fever, sore throat, and grippelike symptoms, together with enlargement of lymph nodes and spleen, characterize the condition. The blood serum contains an antibody (sheep cell or heterophil agglutinin) that is characteristic of the disease, but antibodies against the Epstein–Barr virus itself are more specific markers of the infection. The symptoms of this disease vary in severity in different persons, but often they are mild. Recovery takes place, as a rule, within several weeks.

Despite the immune response against the Epstein–Barr virus, the virus is never completely eliminated from the body. A small number of virus particles remain in latent form within B lymphocytes. In a normal person the immune system (the T lymphocytes in particular) keeps the latent viruses in check. If the natural responses of the immune system are suppressed (immunosuppression), however, the Epstein–Barr virus can emerge from its latent form and initiate a new round of infection. The Epstein-Barr virus is a member of the herpesvirus family, which also includes viruses that cause cold sores (herpes simplex type 1), genital ulcers (herpes simplex type 2), and shingles (herpes zoster) and the cytomegalovirus. All of these viruses show the property of latency, and in each case immunosuppression can lead to their activation. The most dramatic example of this can be found in acquired immunodeficiency syndrome (AIDS), which causes a pronounced deficiency of T lymphocytes. Patients with AIDS can develop severe and even fatal herpesvirus infections.

Monocytosis

Monocytosis, an increase in the number of monocytes in the blood, occurs in association with certain infectious processes, especially subacute bacterial endocarditis—inflammation of the lining of the heart—and malaria. Monocytosis also occurs when the bone marrow is recovering from a toxic injury.

Eosinophilia, an increase in the number of eosinophilic leukocytes, is encountered in many allergic reactions and parasitic infections. It is especially characteristic of infestation by trichina larvae, which are ingested when infected and poorly cooked pork or pork products are eaten.

Agranulocytosis

Leukopenia. The term leukopenia refers to leukocyte counts that are abnormally low (below 4,000 per cubic millimetre). Like leukocytosis, which is usually due to an increase of neutrophils (neutrophilia), leukopenia usually is due to a reduction in the number of neutrophils (neutropenia). Of itself, neutropenia causes no symptoms, but persons with neutropenia of any cause may suffer from frequent and severe bacterial infections. The term agranulocytosis refers to an acute disorder characterized by severe sore throat, fever, and marked prostration associated with extreme reduction in the number of neutrophilic granulocytes or even their complete disappearance from the blood.

Neutropenia may be due to a hypersensitivity mechanism in which a drug provokes the formation of antibodies. If the drug happens to bind to the neutrophil, the antibody accidentally destroys the neutrophil when it reacts with the drug. A second important mechanism of neutropenia is toxic damage to the bone marrow. Chemotherapeutic agents used in the treatment of cancer and leukemia often produce leukopenia (and neutropenia) by damaging the bone marrow. Drugs that cause neutropenia include pain relievers, antihistamines, tranquilizers, anticonvulsants, antimicrobial agents, sulfonamide derivatives, antithyroid drugs, and chemotherapeutic agents used for the treatment of cancer and leukemia.

Neutropenia also is associated with certain types of infections (*e.g.,* typhoid, brucellosis, measles) and with certain diseases involving the bone marrow (*e.g.,* aplastic anemia) or the spleen. In addition, sufficiently high doses of radiation will cause neutropenia, as will certain antitumour agents. Treatment includes removal of the cause of the neutropenia and the use of antibiotics appropriate for the existing infection.

Leukemia. *Nature, types, and causes of leukemia.* The term leukemia means "white blood" and arose from the discovery of extremely large numbers of white blood cells in the blood of certain persons; counts as high as 500,000 per cubic millimetre and even 1,000,000 per cubic millimetre may be found in some instances.

Leukemia is a potentially fatal disease of the blood-forming tissues that is encountered at all ages and in both sexes. There are two main varieties of leukemia, myelogenous, or granulocytic, and lymphatic. These terms refer to the types of cell that are involved. Each of these types is further subdivided into acute and chronic categories, and additional, less common varieties are recognized, as will be mentioned below.

Common causes

Filterable viruses have been shown to cause leukemia in mice, rats, cats, and cows. These animal viruses are not infectious for human cells. A human retrovirus, human T-cell lymphotropic virus (HTLV-I), has been suggested to be the cause of a type of leukemia termed T-cell leukemia. Cases of T-cell leukemia associated with HTLV-I have been found in clusters in southern Japan (Kyushu) and in the coastal region of Georgia in the United States, but sporadic cases also have been identified. Other factors, such as ionizing irradiation, contribute to the development of leukemia. Ionizing irradiation is in fact a leukemia-inducing agent in humans. Survivors of the atomic bomb in Hiroshima and Nagasaki, pioneering radiologists who used inadequately shielded apparatus, and certain patients receiving a particular kind of irradiation are known to have developed leukemia with a frequency far exceeding that of the general population. Noteworthy is the fact that almost all radiation-induced leukemia has been of the granulocytic variety. The prolonged administration of radiomimetic drugs used in cancer chemotherapy, termed alkylating agents, is also associated with an increased risk of developing leukemia. Some evidence suggests that certain industrial chemicals, notably benzene, may cause leukemia. Genetic factors may lead to an increased frequency of leukemia in certain selected instances. This is suggested by evidence that shows the higher probability for acute leukemia occurring in both identical twins if one is affected as compared to both fraternal twins under the same conditions, and the frequency of development of acute myeloblastic leukemia in children with Down's syndrome, a condition in which there is a recognized chromosome defect. Evidence for the role of trauma, hormones, infections, and psychological and other influences as factors leading to the development of leukemia is unconvincing.

Genetic studies

Advances in molecular genetics have greatly increased the understanding of leukemia. The disease seems to arise from a genetic change (mutation) in an early progenitor, or stem cell, in the bone marrow. The mutant cell passes the genetic change on to all of its progeny, thus giving rise to a clone of leukemic cells. In many cases of leukemia the mutation is detectable by analysis of the chromosomes of leukemic cells. A well-studied abnormality of this type, the Philadelphia chromosome, occurs in almost all cases of chronic myelogenous leukemia. The chromosomal aberrations affect genes that influence vital aspects of cell growth and function. These genes, the oncogenes, may themselves be mutated or their regulation may be abnormal. The entire process, beginning with the mutation, usually involves many steps that culminate in a cell with the malignant attributes of a leukemic cell. This concept of the mechanism of leukemia has influenced treatment of the disease, which aims to eliminate the mutant clone and all of its progeny by chemotherapy or bone marrow transplantation (see below).

Clinical manifestations. The terms acute and chronic refer to the duration of the untreated disease. Before the advent of modern chemotherapy, patients with acute leukemia usually died within weeks or months of the first manifestations of the disease. The life span of patients with chronic leukemia is now measured in years.

Early signs of leukemia

Leukemia primarily involves the bone marrow, but the lymph nodes and spleen may also be affected. For example, the spleen usually is enlarged in chronic myelogenous leukemia, and in chronic lymphocytic leukemia there often is enlargement of lymph nodes. Changes also take place in the leukocytes, red cells, and platelets, with consequent anemia and bleeding manifestations. The first symptoms may be weakness and an increased tendency to become fatigued because of anemia, or hemorrhages into the skin and nosebleeds, or gum bleeding due to a decrease in the number of platelets. In the acute leukemias these symptoms may be severe, the anemia may progress rapidly, and there may be fever. Chronic leukemia is more insidious in development, and the early manifestations may be overlooked until enlargement of the spleen or lymph nodes is discovered. Leukemia is recognized by examination of the blood, supplemented in most instances by examination of the bone marrow.

Acute leukemia is marked by the presence in the blood of immature cells normally not found there. In acute lymphocytic anemia (also called acute lymphoblastic leukemia), most frequently seen in children, the cells are immature forms of the lymphatic series of cells. In myeloblastic leukemia the predominant cells are the youngest recognizable precursors (myeloblasts) of the neutrophils of the blood. In a third and the least common variety, acute monocytic leukemia, the immature cells appear to be precursors of the monocytes of the blood. Myeloblastic and monocytic leukemia occur more commonly in adults and adolescents than in young children. In general, acute leukemia occurs in young persons, but no age group is exempt.

The total white cell count usually is increased but not uncommonly is normal or lower than normal (leukopenic). In such cases, abnormal immature cells may nevertheless be seen in the blood. In all forms of acute leukemia the typical cells are found in abundance in the bone marrow. "Aleukemic" leukemia refers to those instances of leukemia in which no abnormal cells are found in the blood; in these instances the leukemia is identified by examinations of the bone marrow.

Chronic granulocytic (myelogenous) leukemia is characterized by the appearance in the blood of large numbers of immature white cells of the granulocytic series in the stage following the myeloblast, namely, myelocytes. The spleen becomes enlarged, anemia develops, and the affected person may lose weight. The platelets may be normal or increased in number, abnormally low values being found only in the late stages of the disease or as an unintended result of therapy. The disease is most commonly encountered in persons between the ages of 30 and 60 years. With treatment the leukocyte count falls to normal, anemia is relieved, and the size of the spleen is greatly reduced. When the leukocyte count rises again, treatment is reinstituted. Such cycles of treatment, remission, and beginning relapse with rise of leukocyte count can be repeated many times, but a stage ultimately is reached when treatment no longer is effective. The disease then often terminates in a form resembling acute leukemia ("blastic crisis"). There is considerable variation in the duration of the disease. Although in various series mean life span has been about 3¼ years, many affected persons live in good general condition for five to 10 years and sometimes longer.

Chronic lymphocytic leukemia differs in many ways from other forms of leukemia. It occurs most often in people over 50 years of age, and its course usually is rather benign. It is mainly characterized by an increase in the number of lymphocytes in the blood, often accompanied by more or less generalized enlargement of lymph nodes and the spleen. Affected persons may carry on for many years without treatment and without any other manifestations. There may be no anemia and no loss of weight. Life span in this disease is measured in terms of five, 10, and even 15 years, occasionally even longer. Two events mark a change in the state of relative good health. One is the development of anemia, sometimes hemolytic in type, often accompanied by some decrease in the number of platelets. The other is impairment of immune mechanisms, resulting in great susceptibility to bacterial infections.

Treatment and chances of survival

Treatment differs according to the type of leukemia. Consequently, proper classification of the leukemia is the first step, once the diagnosis of leukemia has been made. Treatment of all types of leukemia reduces illness and, in acute leukemia, prolongs life.

A number of drugs are used for the treatment of leukemia and, now less frequently than before chemotherapy was available, various forms of irradiation. The therapeutic agents are all myelotoxic; *i.e.,* they injure all the cells of the bone marrow, normal cells as well as leukemic cells. Their mode of action is through direct damage to the dividing stem cell (unspecialized cell from which specialized cells develop) or by slowing or cessation of cell division. These effects may be accomplished (1) by antimetabolites, substances that interfere with the synthesis of DNA, a constituent of the chromosomes in the cell nucleus; (2) by blocking DNA strand duplication through the binding of drugs such as the nitrogen mustards with the base groups of DNA; (3) by disruption of the mitotic spindle during cell division; or (4) by interfering with the formation or functioning of RNA, which is manufactured in the cell nucleus and plays an essential role in the production of protein and in other cell functions. Drugs with different modes of action are often combined, especially in the treatment of the acute leukemias.

Much skill and experience are needed in steering the narrow path between maximum possible destruction of the leukemic cells and tolerable injury to the normal cells of the host. In the process of treatment anemia may increase; the body defenses, through the decrease in the number of neutrophils, may be impaired, and the platelets may be greatly reduced in number. Anemia can be treated with blood transfusions, and serious reductions in platelets can be met for a time with platelet transfusions.

Acute lymphoblastic leukemia is more successfully treated than are other forms of acute leukemia; prolonged remissions and even cures can be brought about in children with the disease. Certain drugs are used to bring about remission; if the remission is complete, the patient becomes well, and no signs of the disease are demonstrable in the blood or bone marrow; drugs other than those used to induce remission often are more useful in maintaining the remission than the remission-inducing drugs.

Acute myeloblastic leukemia and acute monocytic leukemia are less effectively treated by available drugs than is acute lymphoblastic leukemia. Nevertheless, new and aggressive forms of chemotherapy can induce lengthy remissions of the disease. Transplantation of normal bone marrow, following total irradiation of the patient to destroy all his normal bone marrow cells as well as the leukemic cells, has shown promise. With the advent of refined techniques of tissue typing, it is no longer necessary that the donor of the bone marrow be an identical twin. Marrow from histocompatible siblings (brother, sister) are effective. Best results have been obtained in patients younger than 35 years of age. When this form of treatment is successful, the patient's marrow is replaced by the donor's marrow. Although the treatment is arduous and complex, cures of acute lymphocytic and acute myelogenous forms of leukemia are now possible with bone marrow transplantation.

Tissue typing

Chronic myelogenous leukemia is treated with a drug, busulfan, in daily doses until the leukocyte count has returned to normal. Treatment then is interrupted until the leukocyte count has risen to about 50,000 cells per cubic millimetre, when treatment is resumed. This can be repeated many times, and thus the affected person is maintained in good health for years. Not infrequently the intervals between treatments are six months in duration or longer. Busulfan, however, like other antileukemic agents, can injure the bone marrow, and other adverse effects may occur. Other drugs and X-ray therapy also have been used but are somewhat less valuable than busulfan. In suitable young patients, bone marrow transplantation has been used successfully in chronic myelogenous leukemia.

In its early stages, chronic lymphocytic leukemia seems best untreated, as long as anemia is not present or glandular enlargement is not too troublesome. None of the current treatments are curative. The high leukocyte counts in themselves are not harmful. When there is severe anemia, however, or when the platelet count is very low and bleeding manifestations are severe, adrenocorticosteroid hormones are often given.

Lymphomas

The lymphomas are malignant tumours of lymphocytes that are usually not associated with a leukemic blood picture. Instead, enlargement of lymph nodes and/or spleen are characteristic. The lymphomas are classified into two main groups: Hodgkin's disease and non-Hodgkin's lymphoma (or lymphocytic lymphoma). Hodgkin's disease usually begins with a painless swelling of a lymph node, and it may involve lymph nodes anywhere in the body. The disease seems to begin in one lymph node and spread from there to others. Exact determination of the extent of the disease ("staging") is important in planning its treatment. Hodgkin's disease is a potentially curable lymphoma, so details of its treatment are crucial. The early stages of the disease can be cured with radiotherapy. More-advanced stages are still curable with chemotherapy, and in some patients a combination of chemotherapy and radiotherapy is used. The staging of the disease entails a thorough medical examination, bone marrow biopsy, and X rays. The latter usually include computerized axial tomography (CAT) scanning to identify enlarged lymph nodes in the interior of the body. In many cases, surgery (laparotomy) is required to obtain for examination lymph nodes from deep within the abdomen. The goal of all these staging procedures is to enable the physician to select the therapy with the maximum curative potential.

The non-Hodgkin's lymphomas constitute a heterogeneous group that arise from either B lymphocytes or T lymphocytes. They may have an indolent course, as in the nodular well-differentiated B lymphocyte lymphomas, or the tumour may be aggressive, as in the diffuse T lymphocyte forms. Unlike Hodgkin's disease, the lymphocytic lymphomas spread through the bloodstream. Therefore, the staging procedure is not as extensive as in Hodgkin's disease. Combination chemotherapy, usually given in cycles over a period of months, is effective in certain types of diffuse lymphocytic lymphomas. Prolonged remissions with eradication of the disease are difficult to achieve in the indolent nodular lymphomas.

Multiple myeloma

Another malignant disease, probably related to the above conditions, is multiple myeloma, which is characterized by a malignant overgrowth of plasma cells within the bone marrow. This severely painful disorder causes defects in the bone of the skull, the ribs, the spine, and the pelvis that ultimately result in fractures. As the bone marrow becomes more involved, anemia develops and hemorrhages occur: the number of leukocytes may be low, and abnormal myeloma or plasma cells are found in the bone marrow. This disorder is associated with a marked overproduction of immunoglobulin by the malignant plasma cell (the normal plasma cell is the source of the antibodies). The plasma cells in multiple myeloma are the progeny of a single malignant clone, and they secrete into the blood a single type of immunoglobulin moleucle—a monoclonal immunoglobulin. In some cases, a component of immunoglobulin, the light chain, may be produced in excess. These light chains appear in the urine, and in multiple myeloma they are called Bence-Jones protein. A type of chronic kidney disease often develops, probably as a result of the high concentration of Bence-Jones protein in the kidney tubules; this frequently is the ultimate cause of death. In some cases the condition remains quiescent for a time, but death is inevitable. Adrenocorticosteroid hormones and chemotherapeutic agents have been used in the treatment of multiple myeloma. (M.M.W./R.S.S.)

DISEASES RELATED TO PLATELETS AND COAGULATION PROTEINS

Bleeding disorders. In humans hemostatic failure may result from inherited or acquired defects of clotting or platelet function. The usual consequence is persistent bleeding from injuries that would normally cause little trouble. Some persons may bleed more easily than normal, perhaps even spontaneously, as a result of an increased fragility of the blood vessels. This fragility is not itself a hemostatic defect but may be associated with one.

Abnormal bleeding. Abnormal bleeding follows a pattern defined by the underlying defect. Platelet abnormalities are associated with spontaneous bleeding from the membranes of the nose, mouth, and gastrointestinal and urogenital tracts. Petechiae, purpuras, and ecchymoses are medical terms denoting different sizes of hemorrhage into the skin. In purpura there is an unexplained and abnormal fragility of the capillaries, resulting in pinpoint hemorrhages in the skin and mucous membranes.

Characteristic features

Defects in clotting. Blood-clotting defects have different clinical manifestations. The most characteristic feature of such defects, as typified by hemophilia, are recurrent, crippling hemorrhages into joints and muscles and bleeding into body cavities.

The diagnosis of hemostatic defects depends on clinical and laboratory data. Investigation of the affected person's family history is important because many of these conditions are inherited. The personal history reveals the type of bleeding and the possible effects of drugs, chemicals, allergy, infection, or dietary abnormalities. Examination reveals visible hemorrhages or vascular lesions and the effects of internal bleeding. Platelets are evaluated by counting them, examining their appearance, and testing functions such as the bleeding time, platelet adhesiveness, and platelet aggregation. Tests of clotting function include such indicators as the prothrombin time and the partial thromboplastin time. These tests allow a deficiency of any of the clotting factors to be identified and a quantitative assessment of activity of individual factors to be made. Most cases of abnormal bleeding can thus be traced to specific defects (Table 7). Precise diagnosis often permits specific and effective treatment.

Table 7: Laboratory Diagnosis of Coagulation Disorders

test	factor evaluated
prothrombin time	extrinsic pathway
partial thromboplastin time	intrinsic pathway
thrombin time	fibrinogen conversion to fibrin
fibrinogen	fibrinogen concentration
fibrin split products	fibrinolysis
bleeding time	ability to generate a platelet plug
platelet adhesiveness	adherence of platelets to glass beads
platelet aggregation	aggregation of platelets with agonists

Vascular causes of bleeding disorders. Vascular defects causing abnormal bleeding are rare. In cases of vitamin C deficiency, capillary integrity is lost, and blood oozes into the tissues. In the inherited condition hemorrhagic telangiectasia, groups of enormously dilated capillaries can be seen in the skin and mucous membranes of the mouth, nose, and gastrointestinal and respiratory tracts. The lesions appear in adult life and tend to bleed on the least provocation. The Ehlers–Danlos syndrome is a disorder of collagen synthesis in which the increased fragility of vessels causes them to be easily ruptured. Cortisone, prednisone, and other corticosteroid drugs are associated with increased capillary fragility and purpura.

Disorders of platelet number. Reduction in the number of blood platelets (thrombocytopenia) may be the result of impaired production or increased destruction of platelets. Normal platelet counts are between 150,000 and 400,000 per cubic millimetre. When the platelet count drops to 50,000 to 75,000, and particularly to 10,000 to 20,000, spontaneous bleeding may occur.

Thrombocytopenia

Thrombocytopenia is associated with such blood diseases as aplastic anemia and leukemia and is attributed to impaired production of platelets. Similarly, excessive irradiation, exposure to certain chemicals (such as benzene), or medications used in cancer chemotherapy decrease the production of platelets. In sensitive persons drugs such as quinidine provoke platelet antibodies and platelet destruction, resulting in thrombocytopenia. Thrombocytopenia also may accompany certain infections such as measles and autoimmune disorders such as systemic lupus erythematosus and idiopathic thrombocytopenic purpura.

Thrombocytopenia, if sufficiently severe, is accompanied by spontaneous bleeding from the capillaries. This causes the appearance of tiny purplish spots (petechiae) or larger black and blue areas (ecchymoses) in the skin. Bleeding occurs commonly from the nose and gums and occasionally from sites such as the urinary tract and the intestines; hemorrhage in the brain can have serious consequences.

Disorders of platelet function. Some bleeding disorders are due to abnormalities of platelet function rather than to a defect in platelet number. Glanzmann's thrombasthenia, an inherited disorder associated with a mild bleeding tendency, is due to a deficiency of glycoprotein IIb–IIIa. Bernard-Soulier syndrome, an inherited disorder associated with a pronounced bleeding tendency, is due to a deficiency of glycoprotein Ib on the platelet membrane. These platelets are unusually large and morphologically bizarre. In the gray platelet syndrome, the alpha granules are missing. Many other platelet defects exist, but they have not been fully characterized at a biochemical level.

Aspirin and platelet disorders

The most common acquired disorder of platelet function is associated with aspirin, or acetylsalicylic acid. Aspirin reacts with platelets, even when the drug is taken at low doses. This reaction impairs the ability of platelets to produce a group of chemicals known as prostaglandins. The inhibition of prostaglandin biosynthesis and the decrease in the production of thromboxane A_2 can be associated with a bleeding disorder. Other drugs have a similar effect, but aspirin is especially important because of its wide use and the sensitivity of certain persons to its action.

Coagulation disorders. Deficiencies in any of the protein factors involved in coagulation can result in hemorrhages following minor injuries. In some of these disorders, a specific deficiency is due to an inherited defect (*e.g.,* hemophilia). In others, an acquired pathological condition may be responsible for the deficiency (*e.g.,* conditions interfering with absorption of vitamin K and severe infection).

Hemophilia

Hereditary coagulation disorders. Coagulation disorders include a number of disorders that are related to defects in the clotting of blood. The best known is hemophilia, which is due to an inherited defect transmitted by the female but manifested almost exclusively in the male. The most common form of hemophilia, hemophilia A, is caused by the absence of the coagulation protein factor VIII. Of patients with hemophilia, approximately 85 percent have factor VIII deficiency. The next most common form of hemophilia, hemophilia B, is due to factor IX deficiency. Both factor VIII deficiency and factor IX deficiency have signs and symptoms that are indistinguishable. Spontaneous bleeding into joints, giving rise to severe chronic arthritis, is a common problem among patients with severe hemophilia; in addition, there is bleeding into the brain and the abdominal cavity, as well as marked bruising. In general, the greater the deficiency in either factor VIII or factor IX, the more severe the manifestations of disease. Treatment of bleeding episodes emphasizes the replacement of the missing plasma protein. In a patient with hemophilia A, factor VIII can be replaced by the infusion into a vein of plasma derived from a normal donor, the cryoprecipitate fraction of normal plasma, or a partially purified preparation of factor VIII derived from normal plasma. The peptide DDAVP (1-deamino-8-D-arginine vasopressin) is useful in treating milder forms of hemophilia A. Similarly, in a patient with hemophilia B, factor IX can be replaced by the infusion into the vein of plasma derived from a normal donor or a partially purified preparation of factor IX derived from normal plasma. Because donor plasma may be contaminated with virus particles, a number of viral diseases including hepatitis and AIDS can be transmitted by plasma protein. New methods of preparing factor VIII and factor IX, using genetic engineering techniques, should lead to the introduction of safer factor VIII and factor IX generated by recombinant DNA methods. With the current methods of medical care, hemophiliacs can live nearly normal, productive lives. Major surgery, if needed, can be accomplished by the administration of the missing protein. The life expectancy of a hemophiliac with access to quality medical care is normal.

Inherited deficiencies of other clotting proteins are also associated with clotting disorders, but these disorders are not common (Table 8).

Table 8: Common Hereditary and Acquired Coagulation Disorders

- Hereditary
  - Hemophilia A (factor VIII deficiency)
  - Hemophilia B (factor IX deficiency)
  - Hemophilia C (factor XI deficiency)
  - Von Willebrand's disease (von Willebrand factor deficiency)
- Acquired
  - Vitamin K deficiency
  - Circulating anticoagulants
  - Disseminated intravascular coagulation
  - Liver disease
  - Medications

Vitamin K deficiency

Vitamin K deficiency leads to a deficiency of the proteins that require vitamin K for their synthesis: prothrombin, factor X, factor IX, factor VII, protein C, and protein S. Vitamin K deficiency is associated with obstructive jaundice, in which the flow of bile into the bowel is interrupted. Bile is necessary for the absorption of vitamin K. Similar changes may take place when absorption of vitamin K is impaired by conditions such as chronic diarrhea or with the administration of certain antibiotics. Vitamin K deficiency also occurs in the newborn infant as hemorrhagic disease of the newborn. This form of prothrombin deficiency can be prevented by administration of vitamin K to the baby during delivery. Accidental consumption or overdoses of the medication warfarin can lead to a deficiency of the vitamin K-dependent blood-clotting proteins and a serious bleeding tendency.

Severe liver diseases such as cirrhosis and hepatitis can be associated with significant bleeding problems. The liver is the site of synthesis of the clotting proteins. When the liver tissue is diseased or replaced by other cancerous tissues, the synthesis of the clotting proteins is impaired. Often, thrombocytopenia complicates severe liver disease and adds to the bleeding tendency.

Afibrinogenemia, or hypofibrinogenemia, refers to a reduction in the amount of the clotting factor fibrinogen in the blood. This problem is seen in rare instances as an inherited disorder, but more commonly it is found as part of the syndrome of disseminated intravascular coagulation.

Von Willebrand's disease

Von Willebrand's disease is due to the lack of von Willebrand factor, a plasma protein that binds to factor VIII and promotes the interaction of platelets with the blood vessel. This disorder is transmitted as an autosomal dominant trait, and its symptoms consist mainly of bleeding through the skin and mucous membranes. Treatment involves the infusion of plasma, the cryoprecipitate fraction of plasma, or the peptide DDAVP.

Disseminated intravascular coagulation is an acquired disorder in which the blood coagulation system is activated inappropriately, and the normal regulatory mechanisms are overwhelmed. Numerous primary problems can be responsible for this activation: bacteria and bacterial products, dead or injured cells as a result of tissue injury or surgery, cells from the placenta or a dead fetus, certain forms of cancer, and venom from snake bites. Treatment involves the removal of the inciting cause of the activation of the blood coagulation system. In this disorder, platelets and blood-clotting components are consumed until a severe deficiency exists, resulting in a bleeding disorder. In addition, the fibrinolytic system—the system that dissolves clots—is also activated, leading to the destruction of fibrinogen and fibrin clots.

General treatment of bleeding disorders consists mainly of temporary replacement therapy by transfusion. In thrombocytopenia (deficiency of platelets) or thrombocytopathy (malfunctioning platelets) transfusions of normal donor platelets can be given. The clotting deficiencies are treated with plasma or plasma proteins containing the missing factor. These agents can restore hemostatic function to normal for hours or days and, with continued treatment, allow injuries to heal or complicated surgery to be performed.

Underlying cause

Thrombosis. Thrombosis, the formation of a blood clot (thrombus) that tends to plug functionally normal blood vessels, is one of the major causes of death in Western societies. In this condition, the normal tendency of platelets to form a clot at the site of a vascular injury is a contributing factor. While the process of thrombosis is not completely understood, the chief underlying cause is believed to be a lesion that destroys the normal endothelial surface of the blood vessel. Platelets tend to adhere to such lesions and eventually form masses that, when reinforced by fibrin, may completely obstruct the blood flow. This obstruction may have disastrous consequences in arteries such as the coronary or cerebral blood vessels or a major artery of a limb or organ. In veins, the local results are less apparent or perhaps not even detected; however, behind the original thrombus, the whole blood content of the vein may clot to form a large mass. This occurs most frequently in the leg veins and may be due to slowing of the blood flow during prolonged surgical operations or confinement to bed. The danger is that the thrombus may become detached (an embolus) and be swept into the pulmonary artery, causing circulatory obstruction in the lung.

Disorders of the regulation of blood coagulation may be either inherited or acquired. The hereditary deficiency of antithrombin III, protein C, protein S, and plasminogen can be associated with a thrombotic tendency; *i.e.,* the inappropriate formation of clots in vessels. The most common of the thrombotic disorders include pulmonary embolism (clots in the lung) and deep vein thrombosis (clots in the leg veins). Other predisposing causes of thrombosis are an increase in platelet numbers in the blood and the formation of functionally abnormal platelets in diseases of the bone marrow. Birth control pills, pregnancy, and many disorders may be associated with a thrombotic tendency, but the reasons for this association are not understood.

Prevention and treatment

The prevention and treatment of thrombosis aims at balancing the overactive clotting tendency and a bleeding tendency. The formation of clots may be prevented by the administration of anticoagulant drugs. Sodium warfarin inhibits the action of vitamin K and renders the blood less able to clot. Heparin facilitates the inhibition of activated clotting enzymes with the inhibitor, antithrombin III. These commonly used medications prevent the formation of clots or the enlargement of already existing clots. Streptokinase, urokinase, and tissue plasminogen activator are enzymes that dissolve clots. As agents that cause the lysis of fibrin clots, they are known collectively as fibrinolytic agents. Their administration, although attended by the possibility of bleeding complications, can restore blood flow through a vessel blocked by a clot. (B.Fu.)

Bohr

One of the foremost scientists of the 20th century, Niels Henrik David Bohr was the first to apply the quantum theory, which restricts the energy of a system to certain discrete values, to the problem of atomic and molecular structure. He was a guiding spirit and major contributor to the development of quantum physics.

Family and home

Early life. Bohr was born in Copenhagen on Oct. 7, 1885. His father, Christian Bohr, professor of physiology at the University of Copenhagen, was known for his work on the physical and chemical aspects of respiration. His mother, Ellen Adler Bohr, came from a wealthy Jewish family prominent in Danish banking and parliamentary circles. Bohr's scientific interests and abilities were evident early, and they were encouraged and fostered in a warm, intellectual family atmosphere. Niels's younger brother, Harald, became a brilliant mathematician.

Bohr distinguished himself at the University of Copenhagen, winning a gold medal from the Royal Danish Academy of Sciences and Letters for his theoretical analysis of and precise experiments on the vibrations of water jets as a way of determining surface tension. In 1911 he received his doctorate for a thesis on the electron theory of metals that stressed the inadequacies of classical physics for treating the behaviour of matter at the atomic level. He then went to England, intending to continue this work with Sir J.J. Thomson at Cambridge. Thomson never showed much interest in Bohr's ideas on electrons in metals, however, although he had worked on this subject in earlier years. Bohr moved to Manchester in March 1912 and joined Ernest Rutherford's group studying the structure of the atom.

At Manchester Bohr worked on the theoretical implications of the nuclear model of the atom recently proposed by Rutherford. Bohr was among the first to see the importance of the atomic number, which indicates the position of an element in the periodic table and is equal to the number of natural units of electric charge on the nuclei of its atoms. He recognized that the various physical and chemical properties of the elements depend on the electrons moving around the nuclei of their atoms and that only the atomic weight and possible radioactive behaviour are determined by the small but massive nucleus itself. Rutherford's nuclear atom was both mechanically and electromagnetically unstable, but Bohr imposed stability on it by introducing the new and not yet clarified ideas of the quantum theory being developed by Max Planck, Albert Einstein, and other physicists. Departing radically from classical physics, Bohr postulated that any atom could exist only in a discrete set of stable or stationary states, each characterized by a definite value of its energy.

By courtesy of the Nobelstiftelsen, Stockholm

Bohr.

The most impressive result of Bohr's essay at a quantum theory of the atom was the way it accounted for the series of lines observed in the spectrum of light emitted by atomic hydrogen. He was able to determine the frequencies of these spectral lines to considerable accuracy from his theory, expressing them in terms of the charge and mass of the electron and Planck's constant (the quantum of action, designated by the symbol h). To do this, Bohr also postulated that an atom would not emit radiation while it was in one of its stable states but rather only when it made a transition between states. The frequency of the radiation so emitted would be equal to the difference in energy between those states divided by Planck's constant. This meant that the atom could neither absorb nor emit radiation continuously but only in finite steps or quantum jumps. It also meant that the various frequencies of the radiation emitted by an atom were not equal to the frequencies with which the electrons moved within the atom, a bold idea that some of Bohr's contemporaries found particularly difficult to accept. The consequences of Bohr's theory, however, were confirmed by new spectroscopic measurements and other experiments.

Bohr returned to Copenhagen from Manchester during the summer of 1912, married Margrethe Nørlund, and continued to develop his new approach to the physics of the atom. The work was completed in 1913 in Copenhagen but was first published in England. In 1916, after serving as a lecturer in Copenhagen and then in Manchester, Bohr was appointed to a professorship in his native city. The university created for Bohr a new Institute of Theoretical Physics, which opened its doors in 1921; he served as director for the rest of his life.

The correspondence principle

Through the early 1920s, Bohr concentrated his efforts on two interrelated sets of problems. He tried to develop a consistent quantum theory that would replace classical mechanics and electrodynamics at the atomic level and be adequate for treating all aspects of the atomic world. He also tried to explain the structure and properties of the atoms of all the chemical elements, particularly the regularities expressed in the periodic table and the complex patterns observed in the spectra emitted by atoms. In this period of uncertain foundations, tentative theories, and doubtful models, Bohr's work was often guided by his correspondence principle. According to this principle, every transition process between stationary states as given by the quantum postulate can be "coordinated" with a corresponding harmonic component (of a single frequency) in the motion of the electrons as described by classical mechanics. As Bohr put it in 1923, "notwithstanding the fundamental departure from the ideas of the classical theories of mechanics and electrodynamics involved in these postulates, it has been possible to trace a connection between the radiation emitted by the atom and the motion of the particles which exhibits a far-reaching analogy to that claimed by the classical ideas of the origin of radiation." Indeed, in a suitable limit the frequencies calculated by the two very different methods would agree exactly.

Bohr's institute in Copenhagen soon became an international centre for work on atomic physics and the quantum theory. Even during the early years of its existence, Bohr had a series of coworkers from many lands, including H.A. Kramers from The Netherlands, George Charles de Hevesy from Hungary, Oskar Klein from Sweden, Werner Heisenberg from Germany, and John Slater from the United States. Bohr himself began to travel more widely, lecturing in many European countries and in Canada and the United States. His work on atomic theory was recognized by the Nobel Prize for Physics in 1922.

At this time, more than any of his contemporaries, Bohr stressed the tentative and symbolic nature of the atomic models that were being used, since he was convinced that even more radical changes in physics were still to come. In 1924 he was ready to consider the possibility that the conservation laws for energy and momentum did not hold exactly on the atomic level but were only valid as statistical averages. This exteme measure for avoiding the apparently paradoxical particle-like properties of light soon proved to be untenable and also unnecessary. During the next few years, a genuine quantum mechanics was created, the new synthesis that Bohr had been expecting. The new quantum mechanics required more than just a mathematical structure of calculating; it required a physical interpretation. That physical interpretation came out of the intense discussions between Bohr and the steady stream of visitors to his world capital of atomic physics, discussions on how the new mathematical description of nature was to be linked with the procedures and the results of experimental physics.

Principle of complementarity

Bohr expressed the characteristic feature of quantum physics in his principle of complementarity, which "implies the impossibility of any sharp separation between the behaviour of atomic objects and the interaction with the measuring instruments which serve to define the conditions under which the phenomena appear." As a result, "evidence obtained under different experimental conditions cannot be comprehended within a single picture, but must be regarded as complementary in the sense that only the totality of the phenomena exhausts the possible information about the objects." This interpretation of the meaning of quantum physics, which implied an altered view of the meaning of physical explanation, was gradually accepted by most physicists. The most famous and most outspoken dissenter, however, was Einstein.

Einstein greatly admired Bohr's early work, referring to it as "the highest form of musicality in the sphere of thought," but he never accepted Bohr's claim that quantum mechanics was the "rational generalization of classical physics" demanded for the understanding of atomic phenomena. Einstein and Bohr discussed the fundamental questions of physics on a number of occasions, sometimes brought together by a close mutual friend, Paul Ehrenfest, professor of theoretical physics at the University of Leiden, Neth., but they never came to basic agreement. In his account of these discussions, however, Bohr emphasized how important Einstein's challenging objections had been to the evolution of his own ideas and what a deep and lasting impression they had made on him.

During the 1930s Bohr continued to work on the epistemological problems raised by the quantum theory and also contributed to the new field of nuclear physics. His concept of the atomic nucleus, which he likened to a liquid droplet, was a key step in the understanding of many nuclear processes. In particular, it played an essential part in 1939 in the understanding of nuclear fission (the splitting of a heavy nucleus into two parts, almost equal in mass, with the release of a tremendous amount of energy).

Bohr's institute continued to be a focal point for theoretical physicists until the outbreak of World War II. The annual conferences on nuclear physics as well as formal and informal visits of varied duration brought virtually everyone concerned with quantum physics to Copenhagen at one time or another. Many of Bohr's collaborators in those years have written lovingly about the extraordinary spirit of the institute, where young scientists from many countries worked together and played together in a lighthearted mood that concealed both their absolutely serious concern with physics and the darkening world outside. "Even Bohr," wrote H.B.G. Casimir, one of the liveliest of the group, "who concentrated more intensely and had more staying power than any of us, looked for relaxation in crossword puzzles, in sports, and in facetious discussions."

Role under German occupation

Later life. When Denmark was overrun and occupied by the Germans in 1940, Bohr did what he could to maintain the work of his institute and to preserve the integrity of Danish culture against Nazi influences. In 1943, under threat of immediate arrest because of his Jewish ancestry and the anti-Nazi views he made no effort to conceal, Bohr, with his wife and some other family members, was transported to Sweden by fishing boat in the dead of night by the Danish resistance movement. A few days later the British government sent an unarmed Mosquito bomber to Sweden, and Bohr was flown to England in a dramatic flight that almost cost him his life. During the next two years, Bohr and one of his sons, Aage (who later followed his father's career as a theoretical physicist, director of the institute, and Nobel Prize winner in physics), took part in the projects for making a nuclear fission bomb. They worked in England for several months and then moved to Los Alamos, N.M., U.S., with a British research team.

Bohr's concern about the terrifying prospects for humanity posed by such atomic weapons was evident as early as 1944, when he tried to persuade British prime minister Winston Churchill and U.S. president Franklin D. Roosevelt of the need for international cooperation in dealing with these problems. Although this appeal did not succeed, Bohr continued to argue for rational, peaceful policies, advocating an "open world" in a public letter to the United Nations in 1950. Bohr was convinced that free exchange of people and ideas was necessary to achieve control of nuclear weapons. He led in promoting such efforts as the First International Conference on the Peaceful Uses of Atomic Energy, held in Geneva (1955), and in helping to create the European Council for Nuclear Research (CERN). Among his many honours, Bohr received the first U.S. Atoms for Peace Award in 1957.

In his last years Bohr tried to point out ways in which the idea of complementarity could throw light on many aspects of human life and thought. He had a major influence on several generations of physicists, deepening their approach to their science and to their lives. Bohr himself was always ready to learn, even from his youngest collaborators. He drew strength from his close personal ties with his coworkers and with his sons, his wife, and his brother. Profoundly international in spirit, Bohr was just as profoundly Danish, firmly rooted in his own culture. This was symbolized by his many public roles, particularly as president of the Royal Danish Academy from 1939 until the end of his life. Bohr died in Copenhagen on Nov. 18, 1962.

BIBLIOGRAPHY. There is no definitive biography of Bohr, but STEFAN ROZENTAL (ed.), *Niels Bohr: His Life and Work As Seen by His Friends and Colleagues* (1967; originally published in Danish, 1964), contains much biographical material. See also the article on Bohr by LÉON ROSENFELD in the *Dictionary of Scientific Biography,* vol. 2, pp. 239–254 (1970), which is an authoritative account of Bohr's life and work, with a helpful bibliography. RUTH MOORE, *Niels Bohr: The Man, His Science and the World They Changed* (1966; also published as *Niels Bohr: The Man and the Scientist,* 1967), is a popular biography. Bohr's own works include *The Theory of Spectra and Atomic Constitution* (1922), *Atomic Theory and the Description of Nature* (1934), *Atomic Physics and Human Knowledge* (1958), and *Essays, 1958–1962: On Atomic Physics and Human Knowledge* (1963). The last two contain, respectively, his wonderful accounts of his relationships with Einstein and with Rutherford. Bohr's published papers and a selection of unpublished material, including drafts, notes, and correspondence, are being published as his *Collected Works,* ed. by LÉON ROSENFELD (1972–), eight volumes having appeared by 1989. Among the books discussing Bohr and his work are WERNER HEISENBERG, *Physics and Beyond: Encounters and Conversations* (1971; originally published in German, 1969); HENDRIK B.G. CASIMIR, *Haphazard Reality: Half a Century of Science* (1983); and WOLFGANG PAULI (ed.), *Niels Bohr and the Development of Physics* (1955). The institutional setting of Bohr's work is discussed in PETER ROBERTSON, *The Early Years: The Niels Bohr Institute, 1921–1930* (1979). For Bohr's work during World War II, see especially MARGARET GOWING, *Britain and Atomic Energy: 1939–1945* (1964), pp. 245–250 and 346–366. Bohr's "Open Letter to the United Nations" is printed in full in Rozental's book cited above. Detailed historical studies of Bohr's work on atomic theory are JOHN L. HEILBRON and THOMAS S. KUHN, "The Genesis of the Bohr Atom," in *Historical Studies in the Physical Sciences,* vol. 1, pp. 211–290 (1969); ULRICH HOYER, *Die Geschichte der Bohrschen Atomtheorie* (1974); and K.M. MEYER-ABICH, *Korrespondenz, Individualität, und Komplementarität* (1965). (M.J.K./Ed.)

Bolivia

The Republic of Bolivia (República de Bolivia) is a landlocked republic in central South America with an area of 424,164 square miles (1,098,581 square kilometres). The country has been landlocked since it lost its Pacific coast territory to Chile in the War of the Pacific (1879–84). Extending a maximum of 950 miles (1,503 kilometres) north–south and 800 miles east–west, Bolivia is bordered to the north and east by Brazil, to the southeast by Paraguay, to the south by Argentina, and to the southwest and west by Chile and Peru. Lake Titicaca, the second largest lake in South America and the world's highest commercially navigable lake, is shared with Peru. Although the constitutional capital is the city of Sucre, where the Supreme Court is established, the de facto capital is the city of La Paz, where the executive and legislative branches of government function.

Although only about one-third of Bolivia lies in the Andes Mountains, it is widely regarded as a highland country because the most developed and densely populated part of its territory is situated in or near the Andean system. The country itself has a rich history: it was once a part of the ancient Inca Empire and later became part of the Spanish viceroyalty of Peru, providing the mother country with immense wealth in silver. Spanish and the Indian languages Aymara and Quechua are official languages, and the overwhelming majority of the people are Roman Catholic. Bolivia, although rich in mineral resources, remains an underdeveloped country whose economic life is based principally upon agriculture and the production of raw materials, notably natural gas and tin.

(J.V.F./V.A.U.)

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Bolivia's mountainous western region, which is one of the highest inhabited areas in the world, constitutes the country's heartland. The Andes there attain their greatest breadth and complexity. The system in Bolivia is dominated by two great parallel ranges. To the west along the border with Chile is the Cordillera Occidental, which contains numerous active volcanoes and is crowned by the republic's highest peak, Mount Sajama, at an altitude of more than 21,400 feet (6,523 metres). To the east is the Cordillera Oriental, whose spectacular northern section near La Paz is called Cordillera Real ("Royal Range"). An impressive line of snowcapped peaks, some exceeding 20,000 feet, characterize this northern section, which maintains an average elevation of more than 18,000 feet for over 200 miles. Between these ranges lies the monotonous, bleak Altiplano ("High Plateau"). The plateau is a relatively flat-floored depression about 500 miles long and 80 miles wide, lying at elevations between 12,000 and 12,500 feet (3,600 and 3,800 metres). The surface of this great plateau, composed mostly of water- and wind-borne deposits from the bordering mountains, slopes gently southward, its evenness broken by occasional hills and ridges. The margins of the Altiplano are characterized by numerous spurs and interlocking alluvial fans (accumulations of silt, gravel, and other debris that were brought down from the mountains and that have spread out in the shape of a fan), which have built up an almost continuous plain of fairly gentle grade lying at the foot of the mountains.

The Altiplano

From the high, snowcapped slopes of the Cordillera Real the descent to the eastern plains is extremely precipitous, plunging through a rainy and heavily forested belt of rugged terrain (deep valleys and gorges separated by high ridges) called the Yungas—an Aymara word roughly translated as "Warm Lands." The Yungas forms the southern end of an unbroken region that extends along the eastern Andes of Colombia, Ecuador, and Peru and continues as far south as Santa Cruz in Bolivia. South of the Yungas the Andes become much wider and are formed by a high, tilted block called the Puna, with west-facing escarpments and more gentle eastward slopes down to the plains. The region is characterized by a system of valleys and mountain basins called the Valles; these are generally larger and less confined than those in the Yungas. Lying mostly at elevations of 6,000 to 9,500 feet, they contain the so-called garden cities of Cochabamba, Sucre, and Tarija. The area is noted for its fertile valleys and rich, varied agriculture.

The Oriente

Beyond the Andes to the north and east is the Oriente region, which covers more than two-thirds of Bolivia. The vast area of the Oriente is composed of low alluvial plains (llanos), great swamps, flooded bottomlands, open savannas, and tropical forests. In the extreme south is the Bolivian Chaco, which forms part of the Gran Chaco; it is a level area that varies strikingly with the seasons. During the rainy season the Bolivian Chaco becomes a veritable swamp, but it is a hot semidesert during the remaining seven or eight months of the year. Northward from the

Chaco the relief of the Santa Cruz area is somewhat more varied, exhibiting a gentle downward slope to the north. The Oriente includes the northern departments of Beni and Pando, where the low plains are covered by savanna and, in the far north, by expanses of tropical rain forest. Much of the Beni department suffers from extensive flooding beginning in March or April, toward the end of the summer rainy season.

Drainage. The rivers of Bolivia belong to three distinct systems—the Amazon system in the northeast, the Río de la Plata system in the extreme southeast, and the Lake Titicaca system in the Altiplano. The eastern lowlands of Bolivia have many lakes, most of them little known except through observation from aircraft.

The great swampy plains along the Beni and Mamoré rivers, which are headwaters of the Amazon, contain several lakes and lagoons, some of them large, such as Lake Rogoaguado. The Amazon headwaters cut deeply into the Andes; even La Paz in the far west is in the Amazon drainage basin.

In the vicinity of the Paraguay River (which runs parallel to Bolivia's far eastern border and is part of the La Plata Basin) there are several shallow lakes (partly produced by obstructed outlets such as the Bahía Negra), the largest being Cáceres, Mandioré, Gaiba, and Uberaba. North of these are the great Xarayes swamps. This region, like that in the northeast, is subject to widespread flooding during summer.

The third drainage system is that of the Altiplano, which constitutes the largest region of inland drainage in South America. One of the most elevated of all inland basins, it consists of Lake Titicaca near the north end; the Desaguadero River, Titicaca's outlet to the southeast; Lake Poopó, into which the Desaguadero flows; the Lacajahuira River, which drains westward into the Coipasa Salt Flat; and the great Uyuni Salt Flat, independent of the rest of the system but receiving the waters of an extensive though generally arid area at the south end. Into this system enter many short streams from the neighbouring heights. Having no outlet to the sea, the water of the Altiplano system is wholly absorbed by the dry soil and by excessive evaporation.

Lakes Titicaca and Poopó

Lake Titicaca itself covers 3,200 square miles (8,300 square kilometres) and is South America's largest inland lake. Situated on the Bolivian-Peruvian border at an elevation of 12,500 feet (3,810 metres), it is about 120 miles long and a maximum of 50 miles wide (190 by 80 kilometres); it reaches a maximum depth of more than 900 feet. Many islands dot the lake's surface. The basin's drainage system maintains Titicaca as a largely freshwater lake despite its high evaporation rate. Lake Poopó, which is very salty, is quite different in character from Lake Titicaca. Occupying a very shallow depression in the plateau, only a few feet below the general level of the surrounding land, Lake Poopó is rarely more than 10 feet deep at its normal level. When its waters are low, it covers an area of about 1,000 square miles; the surrounding land is so flat, however, that at high water the lake reaches sometimes almost to Oruro to the north, fully 30 miles from the low-water shore. The Lacajahuira River, the only visible outlet of Lake Poopó, disappears underground for part of its course and empties into the Coipasa Salt Flat, which at high water covers about the same area that Lake Poopó does at low water; it usually consists, however, only of wide, marshy, salt-encrusted wastes, with a small permanent body of water in the lowest part. There is no outlet. The Uyuni Salt Flat, which lies to the south of the Coipasa Salt Flat, is similar, but it is much larger. Covering about 4,000 square miles, it consists of a great windswept expanse that is totally arid.

Soils. The thin soils of the Altiplano—mainly clays, sands, and gravels—are dry and loosely consolidated; slopes that are exposed to strong winds or storm water are severely eroded. Soils to the south of the plateau are highly saline, but, in the north, rich lake silts border Titicaca, where the waters have receded over the centuries to expose the old lake floor. It is thought that Tiahuanaco, the important pre-Inca site that is now about 10 miles from the southern shore of Lake Titicaca, was once a lakeside port. In the Yungas the soils on the steep valley sides erode rapidly wherever forest is cleared and the slopes are not carefully terraced. The wider, sunnier basins in the Valles region, particularly around Cochabamba, contain deeper, more fertile soils that respond well to irrigation. East of the Andes, the soils over much of the Oriente are poor, lacking in nutrients, and alternately parched or waterlogged.

Climate. In spite of the fact that Bolivia lies wholly within the tropics, it possesses every gradation of temperature from that of the equatorial lowlands to arctic cold. In the Andes, contrasts in temperature and rainfall depend more on altitude than on distance from the Equator. Cold winds sweep the Altiplano with little variation between summer and winter, and rainfall is slight, coming mostly in the form of summer thunderstorms during December and January. Average temperatures range between 45°

and 52° F (7° and 11° C), but winter temperatures fall below freezing, and nights are cold throughout the year. In the north, however, Lake Titicaca has an important moderating influence, and in bright sunshine winter temperatures may reach as high as 70° F (21° C). Cloudless skies and astonishingly clear air bring distant peaks sharply into focus, providing hauntingly beautiful vistas across the Altiplano.

The cloud-filled Yungas valleys

In stark contrast, clouds of moist air from Amazonia to the northeast fill the valleys of the Yungas throughout the year, leaving the humid atmosphere rich with the smell of vegetation. The mean annual temperatures vary between 60° and 68° F (16° and 19° C); precipitation ranges up to 53 inches (1,350 millimetres) annually, occurring throughout the year but heaviest between December and February. The Valles have brighter conditions and less precipitation than the Yungas, as well as somewhat warmer temperatures.

On the low plains of the Oriente the climate is hot, averaging 73° to 77° F (23° to 25° C) in the south and up to 80° F (27° C) in the north. Occasional cold winds called *surazos* blow from the south; laden with sand and dust, they last for a few days, lowering temperatures abruptly. Annual rainfall ranges from about 40 inches in the south to 70 inches or more in the far north, with a pronounced summer maximum. (G.McC.McB./J.V.F.)

Plant life. Huge expanses of the southern Altiplano are saline and barren, but coarse bunchgrass (ichu; Spanish: *paja brava*) is common in the north, where it is grazed by llamas. Tola, a tough wind-resistant shrub, and mosslike cushions of yareta, both widely used for fuel, are well distributed, along with cactus scrub. Totora rushes, which grow on the shores of Lake Titicaca, are used for thatching and for making the Indian boats called balsas. The Altiplano is devoid of native trees, but around Lake Titicaca and in sheltered valleys the eucalyptus has been successfully introduced.

The Yungas is clad in luxuriant mountain jungle that includes an enormous variety of tropical hardwoods, dyewoods, medicinal and aromatic plants, and fruit trees. Characteristic trees include the green pine; aliso, a shrub-like tree; laurel; cedar; *tarco,* a shade tree producing masses of yellow-white flowers; and *saúco,* which yields fruit used to make medicinal syrups. The cinchona, or quina tree, from which quinine is made, and the coca shrub, the source of cocaine, are also indigenous to this region. In the Valles region to the south there is a general covering of drought-resistant grasses, shrubs, and small trees. In the southern foothill zone a strip of deciduous forest includes such tree species as the walnut and quebracho, the latter being a source of tannin and timber. At lower elevations in the Oriente, vegetation is strongly controlled by the degree of waterlogging that occurs and by the length of the dry season. In the south the Chaco is scrub-covered, with scattered stands of quebracho giving way northward to a transitional region of semideciduous tropical forest. Farther north in the Oriente, grass, palm, and swamp savannas extend into Beni. There, strips of tropical forest line the riverbanks, while more continuous forest appears along the Andean foothills and in eastern Bolivia. True Amazonian rain forest (selva) occurs only in the far north, in the department of Pando and adjacent areas. Among the thousands of different tree species are rubber, Brazil nuts, and mahogany.

Animal life. Bolivian highland animal life is distinguished by the presence of members of the camel family—the llama, alpaca, guanaco, and vicuña—all native to the Andes. The llama and alpaca are domesticated varieties of the wild guanaco, which survives in the mountains. The llama, the largest animal on the Altiplano and seldom seen below heights of 7,500 feet, is the traditional beast of burden and is a source of meat, wool, leather, tallow, and fuel (in the form of dried dung). The smaller alpaca is reared for its soft wool, although the wild, now rare vicuña produces an even silkier type of wool. Highland rodents include the chinchilla, the viscacha (a burrower), the mara (a long-legged, long-eared rodent), and the cavy (a guinea pig that is bred for its meat and often kept as a pet). The Andean condor (a New World vulture and the largest flying bird in the Americas) roosts and breeds at heights between 10,000 and 16,000 feet but descends to sea level in search of food on the west side of the Andes. Many smaller birds and waterfowl, including grebes, coots, cormorants, ducks, geese, and gulls, live around Lake Titicaca, while large flocks of flamingos appear farther south around Lake Poopó.

The llama and other highland animals

The rivers of the eastern plains, most of which belong to the Amazon system, have an abundance of fish, and there are numerous frogs, toads, and lizards, along with myriad forms of insect life. The armadillo, the anteater, the peccary (wild pig), the puma, and the marsh deer all inhabit the plains, as does the capybara, the largest rodent in the world, and the rhea, a flightless bird that bears a remarkable resemblance to the ostrich, although it is much smaller.

The rich animal life of the northern forests includes such mammals as the jaguar (the largest of the American cats), the sloth, the monkey, and the tapir; the largest of the numerous reptiles is the caiman, a member of the alligator family, and among the many fish species is the dreaded caribe (piranha). Varieties of snakes include constrictors and venomous species such as the fer-de-lance and the bushmaster. Many brightly coloured birds, such as parrots and toucans, inhabit the forests, seldom descending to the forest floor, and high in the sky above them may be seen the king vulture and the black vulture, gliding in search of carrion.

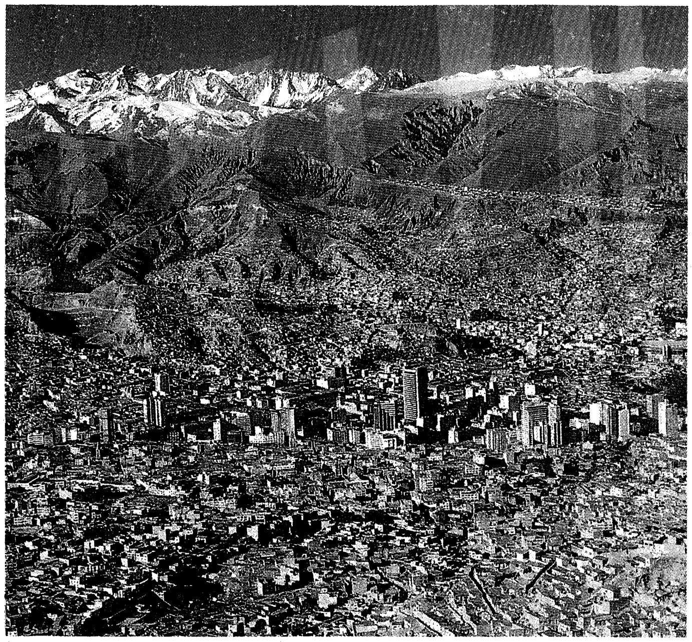
Settlement patterns. The three principal regions of settlement are the Altiplano, the Valles, and the Santa Cruz region of the Oriente.

The Altiplano, which constitutes nearly one-tenth of the total land area of Bolivia, is high, windswept, and cold. The Incas, however, found that this portion of the tropics could be cultivated and that it was healthier and more invigorating than the hot, wet plains. The northern Altiplano has remained Bolivia's most densely populated region; the cities of La Paz and Oruro are located there, as are many small towns and villages.

Much farming is still of the subsistence type, but there have been dramatic changes since the National Revolution of 1952. Until the early 1950s the land was held primarily in the form of large estates, most of which dated to the days of the Spanish conquistadores, although some land was held communally by the Indians. Following the 1953 Agrarian Reform Act, the large estates were broken up and plots of land given to the Indians, who are now called campesinos (peasants) rather than *indios,* a term which has derogatory implications. Despite initial confusion caused by the sheer speed of the reform, the reduced agricultural production, and the disruption to marketing, there has been an infusion of fresh spirit and purpose among Bolivia's new peasant landowners since the 1950s. One development has been the growth of new roadside market towns on the northern Altiplano, where peasants sell their farm surpluses and a wide range of other goods. These are carried to market on foot, by bicycle, or by truck from the valleys of the Yungas. Other campesinos bring wares from La Paz. The National Revolution also introduced a new domestic colonization program that was designed to increase food production and encourage the campesinos to leave the most densely populated parts of the Altiplano and the Valles. Three areas were selected for new settlement: the Yungas northeast of La Paz, the Chaparé foothills below Cochabamba, and the plains of the Oriente around Santa Cruz. For the last of these regions, the opening in 1954 of the paved Cochabamba–Santa Cruz highway was of crucial importance because it relieved centuries of isolation between the Andes and the plains. Within 25 years about 65,000 families had settled in these pioneer zones. The domestic colonization program, however, failed to relieve significantly the population pressure in the Andean highlands, where in the same period the population increase was nearly 10 times that of the number of eastern settlers.

Cities

The city of La Paz is the largest and most important in Bolivia. It lies in a large, spectacular canyon cut below the surface of the Altiplano, a sheltered location selected by the Spaniards in 1548 on the main silver route to the



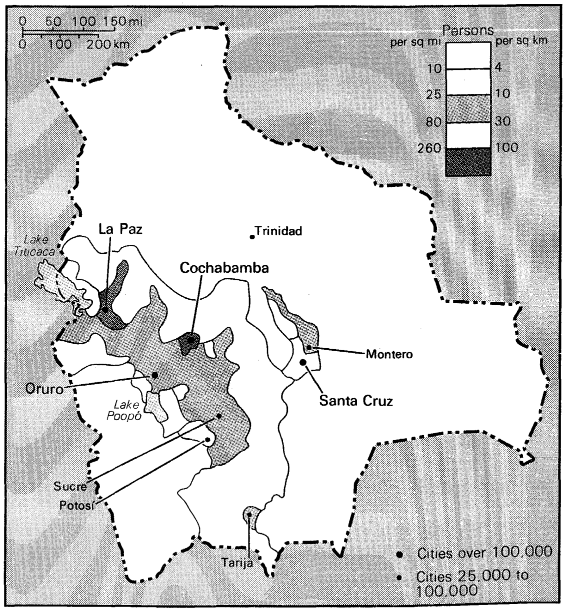
La Paz with the Cordillera Real of the Andes in the background.

Robert Frerck—Odyssey Productions

Pacific coast. Little colonial architecture survives there. La Paz grew rapidly in the late 19th and early 20th centuries as the railway centre and de facto capital of the country. The industrial and lower-income areas of the city are located high up on the valley sides, the commercial district is at the middle level, while the middle-class residential areas are at the lower levels.

The other cities of the Altiplano—Oruro, Uyuni, and Tupiza—are also railway towns and are connected with the mining industry. Potosí, east of the Altiplano, merits special attention. It was established in 1545 on the slopes of the mountain of Potosí (Cerro Rico), which was the richest source of silver found by the Spaniards. Potosí had about 160,000 inhabitants in the mid-17th century, when it was the largest city in the Americas. Even now, at more than 13,000 feet, Potosí is the highest city of its size in the world. It is one of the few cities in Bolivia to retain its architectural personality through the years.

The most important cities in the Valles were founded in the 16th century and include Cochabamba, Sucre, and Tarija. All three are surrounded by farms, fruit orchards, and dairying land. Cochabamba is the largest, busiest, and most accessible of the cities; Tarija is the most isolated—its mountain roads are tortuous, and the city has never been linked to Bolivia's rail system. Unlike conditions on the Altiplano, the climate is mild, and the lower elevations are more agreeable.



Population density of Bolivia.

The Oriente is the largest and most sparsely populated region. Santa Cruz, the only major city, lies close to the Andean foothills but is very much a city of the plains. Since the mid-1950s it has been the fastest-growing centre of agricultural colonization in Bolivia and the centre of oil and natural gas production. By the 1970s Santa Cruz had overtaken Cochabamba to become Bolivia's second largest city—a unique example of a long-isolated town in the Oriente overtaking a major Andean centre. Trinidad is the main town in the heart of the remote, sprawling, cattle-ranching region of the Beni, while farther north in the Oriente a few small towns survive along the riverbanks of the rain forest.

THE PEOPLE

Ethnic and linguistic groups. The population of Bolivia consists of three groups—the Indians, the mestizos (of mixed Indian and Spanish descent), and the descendants of the Spaniards. After four centuries of intermixing it is, however, virtually impossible to measure accurately the percentage of each, although Indians still form some 60 to 70 percent of the total, the largest group being the Quechua.

The Indians

The Indians are mainly composed of two distinct groups—those living on the northern Altiplano, who speak the guttural Aymara language, and those who speak Quechua, the language of the Incas. The Quechua are more widely distributed through the Andes, especially in the Valles. Remnants of plains and forest Indians survive in the Oriente. The great majority of the Indians are farmers, miners, and factory or construction workers. Aymara and Quechua have been added to Spanish as the official languages of Bolivia, but increasing numbers of Indians, particularly in the cities, market towns, and new colonies, speak or understand Spanish.

The mestizos

The mestizos are well represented in the offices, trades, and small businesses in the cities. The traditional minority—those of Spanish descent—have long formed the local aristocracy in small towns and rural areas. Their influence remains, although it has diminished since the National Revolution of 1952.

Few foreigners have emigrated to, or reside in, Bolivia. Small numbers of Germans arrived in the late 19th and early 20th centuries, however, and established themselves with notable success as business agents and entrepreneurs, shopkeepers, and accountants. Japanese and Okinawan farmers have been among the most successful colonists in the Santa Cruz region. Arriving in the late 1950s and 1960s as a relatively small but skilled group of pioneers, they have made an important contribution to the economy.

Religious groups. The Roman Catholic religion has the adherence of nearly 95 percent of the population. At the head of the church hierarchy in Bolivia is a primate cardinalship, located in Sucre. The churches and cathedrals, most of which were built during colonial times, constitute a national architectural treasure. They are generally in the extravagantly ornamented baroque style, although some are in Renaissance (*e.g.,* the cathedral of La Paz) or in later styles. Since the 1940s the Roman Catholic Church has ventured from an almost exclusively ceremonial role into the fields of social aid and education.

Pre-Columbian religious survival

In the Indian communities of the Altiplano, some of the characteristics of pantheistic pre-Columbian religion have survived. Its deities included the Sun God, legendary creator of the first Inca emperor Manco Capac and his sister-wife Mama Ocllo on the Island of the Sun in Lake Titicaca. The Roman Catholic religion has through the centuries accepted some aspects of the Indian religions by assimilating them into the religious life of these communities. There are also various Protestant denominations, as well as a small Jewish community. Freedom of religion is guaranteed by the Constitution.

Demography. At the beginning of the 20th century the population of Bolivia was about 1,800,000, and after 25 years of slow population growth the number had increased to only about 2,300,000. Between 1925 and 1950 the population grew at a slightly accelerated rate (despite the losses of the Chaco War), increasing by about 750,000. The 1950 population of more than 3,000,000 increased dramatically by more than 2,250,000 during the next 25 years, owing primarily to reductions in the death rate and a consistently high birth rate. By the late 20th century the 1950 population had more than doubled.

Urbanization in Bolivia parallels the pattern of population growth. At the beginning of the 20th century the urban population of Bolivia was less than one-tenth of the total, but by 1950 the urban population had more than doubled. By the late 20th century the urban population had grown to about one-half of the total population.

THE ECONOMY

Bolivia is well endowed with natural resources, but high costs of production, lack of investment, inadequate internal transport, and a landlocked location have limited its development. Average income is low, and Bolivia remains one of the poorest nations in South America.

Agrarian reform

The revolutionary program of 1952–53 included immediate agrarian reform, based upon the breakup of the large estates, and nationalization of the mines. This resulted in an initial decrease in agricultural production, a disastrous drop in mineral output, and wage increases. In a period of political turmoil, government attempts to satisfy the new labour unions delayed urgently needed reduction of the numbers employed in the mines and the promotion of greater efficiency in many other sectors of the economy. Thus, despite the long-overdue political and social reforms embodied in the revolution, the rate of national economic growth, at best, remained extremely low. The wildly fluctuating economy declined severely in the late 20th century mainly as a result of falling world prices for tin, bad harvests, debt repayments, and soaring inflation. Although Bolivia has received emergency foreign aid, technical assistance, and World Bank loans over the years, daunting problems that have no quick or easy solutions continue to face the government.

Tin

Resources. Bolivia's mineral deposits are its most valuable natural resource. The country is a major producer of tin; it has reserves of zinc, antimony, tungsten (wolfram), silver, lead, and copper, and there are small quantities of gold. Although tin dominates metal production, Bolivia is a high-cost producer compared with Southeast Asia and is thus exceptionally vulnerable to changes in world demand. The state mining corporation, Comibol, reported heavy losses and declining production in the 1980s when, faced with a world surplus, more than two-thirds of the mining work force became unemployed.

The oil and natural-gas industry

Development of Bolivia's petroleum resources dates from 1920, when the Standard Oil Company of New Jersey acquired a concession to explore and exploit the Andean foothill zone in southeastern Bolivia. A series of small oil fields was discovered there, but Standard Oil's operation was expropriated in 1937 to form the nationalized Yacimientos Petrolíferos Fiscales Bolivianos (YPFB). In the mid-1950s U.S. companies were again encouraged to resume operations, and in 1956 the Bolivian Gulf Oil Company (a branch of Gulf Oil Corporation) began a decade of successful oil and natural gas strikes in the Santa Cruz region. In 1966 Gulf began exporting oil to southern California, via the YPFB pipeline to the Pacific port of Arica (Chile), as well as boosting the Bolivian state company's sales to the domestic market and to Argentina. Political uncertainties have disrupted this industry, however, and in 1969 Bolivia nationalized Gulf Oil. Although Bolivia once again encouraged foreign oil companies in 1972, production continued to fall through lack of investment and failure to replace depleted wells. Soaring domestic consumption forced some oil importation in the late 20th century and led to a new wave of combined Bolivian and foreign oil exploration.

Natural gas production has been more successful, and with falling world markets for tin in the late 20th century, natural gas became Bolivia's most important legal export in value by the mid-1980s, accounting for more than half of official total earnings, Argentina being the principal destination. Gas fields are concentrated in the Santa Cruz region, with good reserves. Bolivia is rich in other natural resources, particularly hydroelectric potential, but exploitation has been minimal.

Agriculture. About half of the working population is engaged in agriculture (including small numbers in hunting, forestry, and fishing), but farming accounts for only about 27 percent of the gross domestic product. Although peasant markets have grown in the northern cities and roadside towns on the Altiplano and around Cochabamba, subsistence farming remains widespread in the Andes.

Highland farming

Potatoes and oca (also an edible tuber) are indigenous staple crops on the northern Altiplano, where they are eaten mainly in the dehydrated forms known as *chuño* or *tunta*. The two important grains that ripen at this altitude, both highly nutritious, are *quinoa* and *cañahu*. Llamas and alpacas are raised in the Andean region and serve a variety of agricultural functions, although the use of the llama as a pack animal has decreased with the growth of truck transport. (See above *Animal life*.)

In the Yungas excellent coffee, cacao, citrus fruits, bananas, avocados, pineapples, mangoes, papayas, melons, chili peppers, sweet potatoes (yams), and cassava (manioc) are among the astonishing variety of crops produced. Development is restricted, however, by poor roads and limited markets. Only coca (see below *Trade*) has a strong international market and a high return on production. In the warm, agreeable climate of the Valles, corn (maize), wheat, barley, alfalfa, grapes, peaches, and vegetables are grown, and sheep and dairy cattle are raised; the area, which is characterized as the garden of Bolivia, is a fertile region that has the potential, with more systematic irrigation, for greatly extended cultivation and increased yields.

In the Oriente around Santa Cruz, sugarcane, rice (dry and paddy), cotton, and beef cattle are significant products, raised mostly for the domestic market. There are also large cattle ranches in the Beni. Tropical hardwoods grow in the quebracho forests of the Chaco and among the tree species of the northern rain forest, but the great distance to market, and competition from more accessible locations outside Bolivia, limit exploitation.

Industry. The manufacturing sector has grown since the 1950s but remains small, despite some stimulus from Bolivia's membership in the Andean Group, a regional trade organization. Historically, mineral processing (including oil refining) and the preparation of agricultural products have dominated Bolivian industry. In the 1970s manufacturing employed about 10 percent of the working population, but this proportion declined somewhat in the 1980s.

Tin mining

Bolivian tin is extracted mostly by shaft mining, which is often very deep and is carried on in difficult, remote sections of the eastern cordilleras at great altitude. The ores are low-grade, often varied in content, and difficult to refine. By the late 20th century, ores with as little as 1 percent tin, or less, were being worked. Bolivian smelters under normal economic conditions produce concentrate for export, the more complex ores being smelted overseas. Food industries include flour milling, dairying, sugar refining, brewing, and alcohol distilling. Other manufactures consist of machinery, textiles, shoes, furniture, glass, bricks, cement, paper, and a wide range of small goods designed to meet the needs of a limited home market with little purchasing power. About two-thirds of Bolivia's manufacturing industry is found in or near La Paz; much of the remainder is located in the department of Cochabamba. There is severe competition from imported Brazilian, Argentine, and Peruvian manufactures, as well as from smuggled goods—the latter being mostly consumer items from neighbouring countries and the United States that can be sold cheaply because they avoid duty.

Bolivia has abundant sources of energy, particularly hydroelectric potential, but per capita consumption remains low. The National Electric Company (Empresa Nacional de Electricidad) mainly supplies the major towns and cities and the mines. Hydroelectric power stations serve La Paz, Cochabamba, and Oruro, the largest single plant being at Corani in the department of Cochabamba. Santa Cruz, Sucre, Tarija, and Trinidad are provided with thermal electric power from oil. Small generators, public and private, supply the more isolated centres in the Oriente.

Tourism does not yet contribute greatly to the economy, but encouraging efforts have been made to develop its potential in selected areas and to improve hotel accommodations, especially in La Paz. By the late 20th century Bolivia had been added to an increasingly popular grand tour of South America—a package tour of continental highlights that attracts visitors from the United States, Europe, and Japan. The main interest focuses on Lake Titicaca and its surroundings: Inca ruins on the Island of the Sun, pre-Inca ruins at Tiahuanaco, lake fishermen, Indian life on the Altiplano, and the city of La Paz itself. A side trip by road over the Cordillera Real and down into the Yungas jungles closest to La Paz is thrilling and popular, providing within a few hours some of the most dramatic scenic and climatic contrasts in the Andes.

Exports

Trade. The export of metals (mostly tin but also including zinc, silver, and tungsten) has traditionally dominated Bolivia's trade. With the collapse of the world market in tin in the 1980s, natural gas became the leading export; together, minerals and natural gas account for more than 80 percent of Bolivia's legitimate export trade. Agricultural exports include coffee, sugar, and timber, together with small quantities of wild rubber, Brazil nuts, hides, and skins. Manufactured products constitute the largest segment of total imports; machinery and equipment for industry and transport are among the main items. Raw materials, consumer goods, and food products are other major import categories. The largest overall trading partners are Argentina and the United States, but considerable trade is also carried on with other South American countries, the United Kingdom, West Germany, and Japan.

Illegal trade in cocaine

Illegal trade in cocaine has become a significant element in the Bolivian economy. The leaves of the indigenous coca shrub have been chewed by the Andean Indians for centuries as a relief against cold and fatigue. Small quantities of coca (from the Quechua *kúka*) have also been legally exported for many years for medicinal purposes. The unprecedented expansion of coca cultivation in the Yungas, and especially in the Chaparé region northeast of Cochabamba, began in the 1960s with the sudden growth in the illegal international market for cocaine. As demand soared in North America and Europe in the 1970s and 1980s, Bolivian peasant farmers soon found that no other crop could compete with coca for profitability. It became the ideal cash crop—easy to grow, valuable, non-perishable, and easy to transport, whether in dried leaf form or as a concentrate ready to be smuggled out of the country from airstrips scattered across the Oriente. By the late 20th century it was estimated that one-third of the world's coca was grown in Bolivia, one-fourth in the Chaparé region alone. Attempts by the government to introduce crop substitution or a voluntary reduction by the peasants of their coca acreage had met with little success. Indeed, the area under coca continued to increase. By the 1980s an estimated $5,000,000,000 worth of cocaine was leaving Bolivia annually from centres around Cochabamba and from remote parts of the Oriente. Despite its illegal nature the drug trafficking has provided a huge addition to the country's gross national product. Bringing needed revenue to both the government and the farmer and untold riches to the illegal dealers, the cocaine trade has become almost impossible to suppress.

Transportation. Bolivia has been hindered in its growth both by its landlocked location and by a difficult internal geography of steep mountains and seasonally flooded plains. The main rail system, in the west, was built mostly between the 1890s and the 1920s and links the major Andean cities and mines with the Pacific ports of Antofagasta and Arica (Chile) and Matarani (Peru), the latter line being connected by Lake Titicaca steamers. Isolated from this network, Santa Cruz, forming the nucleus of an eastern system, was linked by rail to Corumbá in Brazil and to Argentina via Yacuiba during the 1950s; neither line carries much traffic, however.

Road transport has developed dramatically in highland Bolivia and around Santa Cruz since the mid-1950s, and there are connecting paved highways for La Paz–Oruro, Cochabamba–Santa Cruz, Santa Cruz–Montero, and other major colonization centres in the Santa Cruz region. The Pan-American Highway cuts across highland Bolivia between Peru and Argentina, and bus and truck services on unpaved roads connect numerous Andean towns. Journeys are slow and often hazardous. Trails are used in parts of the Oriente after the floods subside; there is no road network. The immense river system sweeps in great loops over the plains, but local traffic is limited. Only in the northern rain forests are small riverboats important in regional transportation.

Air transport

Air transport is the only fast link between Bolivia's major cities and the primary means by which the isolated settlements in the Oriente are connected to the rest of the country. The national airline—Lloyd Aéreo Boliviano (LAB)—was founded by a small group of German businessmen in 1925, and in the second half of the 20th century it has played an indispensable political role in helping to identify the plains and the eastern border regions as Bolivian territory. Newspapers and information are quickly distributed by air services, keeping far-flung clusters of population informed of national affairs. LAB flies international routes to South American capitals, as well as to other cities such as São Paulo, Rio de Janeiro and Manaus (Brazil), Panama City, and Miami, Fla.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Bolivia was declared independent in 1825 and adopted its first constitution in 1826. Despite revisions and numerous coups d'état, the state has retained a unitary system of government, whether elected or under military dictatorship, the latter having held sway for much of Bolivia's history. Under the conditions of the 1947 constitution, executive power is vested in a president, who is directly elected by popular vote for a term of four years. If no candidate receives an absolute majority of votes, the National Congress must select the president from among the three leading contenders. The president cannot be immediately reelected. The bicameral legislature consists of a Senate and a Chamber of Deputies, whose members are directly elected for four-year terms. The judicial system is headed by a Supreme Court of 12 members, who are appointed by Congress for 10-year terms.

The electoral system

The country is divided into nine departments, each of which is headed by a prefect appointed by the Bolivian president. Departments are subdivided into provinces administered by subprefects, and provinces are subdivided into cantons administered by corregidors.

Following the National Revolution of 1952, universal suffrage was introduced, and all men and women became eligible to vote for the first time in Bolivia's history. Previously, though open to both sexes, the franchise had literacy and property requirements and was thus restricted to a tiny proportion of the population. The nation's political system is highly fractionalized by numerous political parties that range from far-right conservatism to left-wing radicalism.

Education, health, and welfare. Primary education from six to 14 years of age is free and officially compulsory, although the latter is difficult to enforce in some areas. Secondary education, lasting up to four years, is not compulsory. In the late 20th century about four-fifths of the primary-age children were attending school, but only about one-fourth of those of secondary age did so. Most education is state-supported, but private institutions are permitted. Roman Catholic, Protestant, and Jewish organizations are active in primary and secondary education. Adult literacy rates have improved dramatically since the 1950s. In the 1960s about three-fourths of the population was illiterate or semiliterate, but by the 1980s the figure had dropped to about one-third. Higher education takes place in the nation's eight state universities (located in each of the departmental capitals except Pando). There are also technical universities and a Roman Catholic university. The largest university is the University of San Andrés, located in La Paz. The university's library and the National Library of Congress house significant collections.

Health services

There are three kinds of health services—those supported by the state through the Ministry of Public Health and Social Security, those provided by the social security system for its affiliates, and private clinics. In general, the medical services and the hospitals in the cities are adequate. This is not so in rural areas, however, where doctors and nurses are in short supply. Traveling health workers provide primary health care and give advice on hygiene and nutrition in colonization zones. Some major problems persist, however. Communicable diseases such as malaria and the deadly Chagas' disease are still prevalent in the Oriente, and respiratory diseases are widespread. Malnutrition is a problem in some areas.

CULTURAL LIFE

Traditional culture. Bolivian culture consists of a mixture of Indian culture with the Mediterranean culture brought by the Spaniards. On religious feast days, for example, pagan pre-Columbian rites are still practiced, and the Indians express themselves through dances and songs that blend the two cultures. In such festivities, some symbolic dress presents the Indian interpretation of European attitudes: the dance of the *palla-palla* or *loco palla-palla* caricatures the European invaders, the dance of the *waka-tokoris* satirizes bullfights, and the *morenada* mocks white men, who are represented leading imported African slaves. Indian musical instruments are used to accompany these dances. In the music itself, the mixture of cultures is also evident, since many of the tunes are based on Spanish dances. The more commonly used instruments are the sicu or zampoña (panpipes) and the *kena, tarka,* and *pinkillo* (vertical flutes). Percussion instruments of various sizes are used, including skin drums, bronze gongs, and copper bells. The costumes, highly embroidered and colourful, imitate the dress of the pre-Columbian Indian or the dress of 16th-century Spaniards. Spain's influence is clearly seen in the charango, a stringed instrument peculiar to Bolivia. It has five double strings and is similar in shape to the guitar, although much smaller. Its sound box is made from the shell of an armadillo.

Traditional dress

The daily dress of highland Indian women in both the urban and rural regions remains traditional: very full skirts (polleras) and colourful shawls. The latter are usually stuffed with goods being taken to market for sale, as well as with fresh purchases, extra clothing, and a baby, all in a carefully balanced bundle on the back, leaving both hands free. Hats always complete the outfit, their shapes varying with the different regions of Bolivia.

Since the 1940s, Indian culture has blossomed. Previously, Indians had attempted to imitate Europeans, in custom as well as in dress. By the early 1970s, however, Indian values had been reestablished; Indian music rose to a higher standard, painters abandoned the imitation of European fashions, and some of the characteristics of Indian culture reemerged in the general life-style. The Academy of the Aymara Language in La Paz is dedicated to the preservation of the purity of the Aymara language.

The arts. The National Academy of Fine Arts in La Paz offers courses in music, painting, sculpture, and ceramics. There are two galleries of pictorial arts and permanent collections in the National Museum of Art and the National Museum of Archaeology (Museo Tiahuanaco). Jewelry in silver and gold, with pre-Columbian decorations and styles, has been made since colonial times. The local markets offer a profusion of colourful handicrafts and fine wood carvings.

In the city of Potosí the impressive Royal Mint (Casa Real de Moneda), founded in the 16th century and rebuilt in the 18th century, has been restored, and its great halls are used to house a collection of fine colonial paintings. Various old temples have also been restored. In La Paz is the National Symphony Orchestra, and at the University of San Andrés a choral group specializes in Indian musical themes.

Recreation. Folk festivals are held periodically, the most important one of which is held in Oruro during the carnival holidays. Many Indian music and dance groups compete, providing a magnificent display of costumes and decorations. Football (soccer) is the national sport, and Bolivian national teams compete in international matches. A number of other spectator sports common to the West may be seen in the large cities. There are occasional bullfights.

Press and broadcasting. Bolivia has an active and constitutionally free press, which has been subject to periodic censorship during dictatorial regimes. Each of the departmental capitals (except Cobija, Pando) has at least one daily newspaper. *El Diario* (the oldest), *Presencia* (Roman Catholic), *Hoy,* and *Ultima Hora,* all in La Paz, have the largest national circulations. Sucre's daily, *Correo del Sud,* was established only late in the 20th century. Radio stations, many of them commercial, are widespread in Bolivia, broadcasting in Spanish, Aymara, and Quechua. The state-owned National Television Company (Empresa Nacional de Televisión), covering national and world events, sports, the arts, documentaries, and general entertainment, operates stations in most of the major cities. The University Television Service (Televisión Universitaria) also presents educational programs. By the 1980s, however, most Bolivians still did not own a television set. The percentage of viewers in the urban areas is, of course, much higher than in rural districts, with television being found not only in homes but in public and commercial establishments as well.

Newspapers

For statistical data on the land and people of Bolivia, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL. (J.V.F./V.A.U.)

History

EARLY PERIOD

Pre-Columbian civilizations

Bolivian society traces its origins to the advanced pre-Columbian civilizations of South America. The high Bolivian plateau known as the Altiplano was already densely populated several centuries before the Spanish conquest in the 16th century.

From the 7th century the Tiahuanaco Empire, the first of the great Andean empires to extend over both the Peruvian coast and highlands, had its centre in the Altiplano region. By the 11th century it had reached its apogee and was replaced by simpler regional states.

In the centuries that followed the collapse of Tiahuanaco, the Bolivian highland region maintained its dense populations and technological civilizations with irrigation agriculture. By the 15th century the region was mostly controlled by some 12 nations of Aymara-speaking Indians. Competitors to the Quechua-speaking nation at Cuzco, in what is now Peru, these Aymara tribes fought with the latter for control of the central Andean highland region. Though the Aymara nations were eventually dominated by Cuzco, they nevertheless remained the most important non-Quechuan group within the expanding Inca Empire; because of their importance they were the only conquered coastal or highland peoples able to retain their language and cultural identity to such an extent that their Aymara language survived the Spanish conquest. But the Aymara were forced to accept a large body of Quechua-speaking immigrants within their midst as part of a deliberate Incan policy of colonization. It was this early pattern of colonization and nonassimilation that gave Bolivia its current linguistic and cultural identity (the two major Indian languages in Bolivia today are Quechua and Aymara).

Part of the Spanish Empire

The southern Andean valleys and central plateau of Bolivia, with their dense Indian populations, became a core population area within the Spanish Empire after the conquest. To the wealth represented by Indian labour there was added the mineral wealth from newly discovered (1545) silver deposits of Potosí—the largest silver mines then known in the Western world. The arid, high-altitude mines of Potosí, along with others discovered near the town of Oruro (founded in 1606), were supplied with food and other basic necessities by such supportive towns as Chuquisaca (founded in 1538), La Paz (1548), and Cochabamba (1571). From the 16th to well into the 18th centuries, this southern Andean area, known then as Charcas, or Upper Peru, was one of the wealthiest and most densely populated centres of Spain's American empire. Its mines were supplied with forced drafts (mitas) of Indian labourers from throughout the Andes; and by the middle of the 17th century its central mining city of Potosí was the largest city in the Americas, with a population estimated at 150,000. By the last quarter of the 18th century this famous mining zone was in decay. The exhaustion of the richest and most accessible veins, the poverty of the miners and their ignorance of advanced technology, and the absorption of colonial capital into the thriving international commerce of the late 18th century all contributed to its decline. Although Potosí continued to be Upper Peru's most important economic centre, the intellectual and political focus of the area was Chuquisaca (also known in the colonial period as Charcas and La Plata and, since independence, as Sucre). With its academies and university, Chuquisaca was the major educational centre for the entire Río de la Plata region; it also served as the seat of Upper Peru's government, which was known from its foundation in 1559 as the Audiencia of Charcas. The Audiencia was first placed under the Viceroyalty of Peru at Lima, but in 1776 it was finally shifted to a new viceroyalty established at Buenos Aires.

In the late 1770s and early 1780s abuses by petty officials instigated Indian uprisings that were carried out in the hope of reestablishing the old Inca Empire. Severe disorders were widespread in the highlands and produced many casualties; La Paz was besieged twice for several months. Eventually the Indian leaders were defeated and executed.

Independence movement

In 1809 Chuquisaca and La Paz became two of the earliest cities in Spanish America to rebel against the Spanish authorities appointed by the new Napoleonic ruler of Spain. Authorities often considered this action to be the beginning of the Wars of Independence in Latin America. Although viceregal authorities in Lima were able to put down the rebellions, similar uprisings were successful in the viceregal capital of Buenos Aires. From that city several revolutionary armies were dispatched without success to liberate Upper Peru. However, the guerrilla armies that formed in the rugged countryside after the events of 1809 kept the revolutionary movements alive in Upper Peru for some 16 years. In 1825 the Bolivian army from the north, under the leadership of Marshal Antonio José de Sucre, liberated Upper Peru. The military victory was facilitated by the continual defections of Upper Peruvian royalists. Mostly a native elite, the defectors convinced Simón Bolívar and Sucre to allow Upper Peru to become independent rather than be joined to either Peru or Argentina. On Aug. 6, 1825, an Upper Peruvian congress declared Bolivia independent. Few of the guerrilla commanders, representing a more humble constituency, were able to become part of the new order, controlled by the elite.

BOLIVIA FROM 1825 TO C. 1930

In recognition of Bolívar's support, the leaders of the congress named the new republic Bolivia after the liberator and invited Sucre, his chief aide, to be the first president.

Foundation and early national period. But the new republic was not as viable as its leaders fervently hoped it would be. It was economically retarded, despite the legendary colonial wealth and prominence of the region. The late 18th-century mining decline had given way to severe depression as a result of the Wars of Independence. Between 1803 and 1825 silver production at Potosí declined by more than 80 percent; and by the time of the first national census in 1846, the republic listed more than 10,000 abandoned mines.

Incapable of exporting its silver at the levels of colonial production, Bolivia rapidly lost its previously advanced economic standing within Spanish America. Already by the end of the colonial period, such marginal areas as the Río de la Plata and Chile were forging ahead on the basis of meat and cereal production. Bolivia, on the other hand, was a net importer of basic foods, even those exclusively consumed by its Indian population. And none of its mineral resources was of sufficient value to overcome the high transportation costs involved in getting the minerals to the coast. The Bolivian republic, with little trade to tax and with few resources to export beyond its very modest precious metals production, was forced to rely on direct taxation of its Indian peasant masses, who made up more than two-thirds of the estimated 1,100,000 population in 1825. Until well into the last quarter of the 19th century, this regressive Indian taxation was a large source of national government revenue. With the more progressive South American states relying almost exclusively on import and export taxes of a constantly expanding international commerce, the Bolivian state rapidly lost its prominent position within the continent and became known as one of the most backward of the new republics.

Economic decline and political stagnation

This economic decline was mirrored by political stagnation. Bolivia emerged initially with a series of military strongmen (caudillos), among whom was Marshal Andrés de Santa Cruz, president from 1829 to 1839. Temporarily reorganizing the war-torn Bolivian economy and state finances, Santa Cruz in the 1830s was able to unite Bolivia with Peru, through the successful overthrow of the Lima regime of General Agustín Gamarra, into a government known as the Confederation (1836–39). But Chilean military intervention destroyed the Confederation attempt; Bolivia quickly turned in upon itself and thenceforth abandoned all attempts at international expansion.

Bolivia's efforts for the next half-century were primarily to integrate its far-flung regions into a coherent relationship between the core of the republic, the Altiplano, and the eastern Andean valleys. This attempt was doomed to failure, however, because Bolivia lacked the population and resources to exploit either its Amazonian or its Pacific frontiers. Despite the enormous wealth in nitrates and guano available on the Bolivian Pacific coast, the nation was incapable of exploiting them even with the help of foreign capital. What little capital was available within Bolivia's upper class was committed to Altiplano mining. It was Peruvians, Chileans, North Americans, and Englishmen who exploited these resources. Between the Chilean War of the Confederation (1838–39) and the outbreak of the War of the Pacific (1879), Chile successfully expanded its claims, both by diplomatic pressure and, finally, by war, against Bolivian sovereignty in the enormous Bolivian Pacific coastal territories.

War with Chile

Loss of the coastal region. The War of the Pacific (1879–84) had its origins in heavy Anglo-Chilean investments in Bolivia, beginning in the 1840s with those in the guano deposits in Bolivia's Atacama coastal province. With the discovery of nitrate deposits in the 1860s, Chilean aggressive expansion along the coast increased even further. By a series of treaties Chile expanded its territorial claims and obtained commercial concessions within Bolivian territory. As a response to this pressure, Bolivia signed an alliance treaty with Peru in 1873; but this did not intimidate the Chileans. When the Bolivian government attempted to increase taxation on Chilean nitrate companies working in Bolivia, Chile unilaterally invaded Bolivian territory in 1879 and forced a war with both Bolivia and Peru. In May 1880, at the Battle of Tacna, Chile defeated a combined Bolivian-Peruvian army, ending effective Bolivian resistance. Rather than attack the Andean core of Bolivia, the Chileans ignored Bolivia for the rest of the war and proceeded on a massive invasion of Peru, which resulted in their eventual capture of Lima.

The fall of the Pacific littoral to Chile may, in many ways, have been a blessing for Bolivia. The War of the Pacific marked a major turning point in national history. From the fall of the Confederation to the War of the Pacific, Bolivia had gone through one of the worst periods of caudillo rule in all Latin America during the 19th century. The decades of the 1860s and '70s, however, were those in which Andean silver mining had revived under the impact of new capital inputs from Chile and Great Britain. By the time of the War of the Pacific, international market conditions for silver and the introduction of new technology and capital had greatly revived the national mining industry. The War of the Pacific enabled the new mining entrepreneurs to capture political control of the nation and to break the hold of the by-then discredited barracks officers on national political life.

Era of civilian government

Formation of Liberal and Conservative parties. Starting in 1880, under the presidency (1880–84) of Narciso Campero, Bolivia moved into an era of civilian government with the national upper class dividing into Liberal and Conservative parties, which then proceeded to share power. This intraclass political party system finally brought Bolivia the stability it needed for economic development. Though the parties split on personality and anticlerical issues, they were identical in their desire to promote economic growth. From 1880 to 1899 the nation was ruled by the Conservatives, whose principal function was to encourage the mining industry through the development of an international rail network.

It was thus an economically expanding nation that the Liberals inherited when they seized power from the Conservatives in the so-called Federal Revolution of 1899. This revolt, although supposedly fought over the permanent placing of national institutions in the city of Sucre or La Paz, was primarily a power struggle between the Conservative and Liberal parties. Unfortunately for the Conservatives, their strength was too closely tied to the traditional Chuquisaca elite, much of which was coterminous with the silver-mining class. The Liberals, however, had the bulk of their strength in La Paz, which by this period was three times the size of Sucre and had the largest urban concentration (some 72,000 persons) in the national population, estimated at 1,700,000 persons in 1900.

Increase in tin mining. The Liberal victory was also closely associated with a basic shift in the mining economy. As the world silver market began to collapse in the 1880s and early 1890s, a major shift to tin mining began on the Bolivian Altiplano. Found in association with silver, tin did not become an important product until the end of the 19th century, when demand suddenly soared in all the major industrialized countries. Thus by 1900 tin had completely superseded silver as Bolivia's primary export, accounting for more than 50 percent of national exports.

The tin-mining elite

The shift to tin mining not only occurred at the same time as the Liberal revolt and was closely associated with the new party but it also brought about a basic change within the capitalist class in Bolivia. Whereas the silver-mining elite had been almost exclusively Bolivian, the new tin miners were far more cosmopolitan, including, in the early years, foreigners of all nationalities as well as some new Bolivian entrepreneurs. Tin mining itself absorbed far more capital and produced far more wealth than had the old silver-mining industry, and the new companies that emerged became complex international ventures directed by professional managers.

Given this new economic complexity and the political stability already achieved by the Conservatives and perpetuated by the Liberals, the tin-mining elite found it profitable to withdraw from direct involvement in national political life. Whereas Bolivian presidents under Conservative rule in the 19th century had either been silver magnates themselves (Gregorio Pacheco, 1884–88; Aniceto Arce, 1888–92) or closely associated with such magnates as partners or representatives (Mariano Baptista, 1892–96; Severo Fernández Alonso, 1896–99), the Liberals and subsequent 20th-century presidents were largely outside the mining elite. No tin magnate actively participated in leadership positions within the political system. Rather, they came to rely on a more effective system of pressure group politics.

Liberal rule, 1899–1920. The primary task of the Liberal politicians, who ruled Bolivia from 1899 to 1920 under the leadership of Ismael Montes (twice president: in 1904–08 and 1913–17), was to settle Bolivia's chronic border problems and to continue and expand the communications network initiated by the Conservatives. A definitive peace treaty was signed with Chile (1904), accepting the loss of all Bolivia's former coastal territories. Also, the Acre problem was resolved: this involved an unsuccessful attempt by the central government to crush an autonomist rebellion (1889–1903) in the rubber-boom territory of Acre on the Brazilian border. Brazil's covert support of the rebels and the defeat of Bolivian forces finally convinced the Liberals to sell the territory to Brazil in the Treaty of Petrópolis (1903). As a result of the financial indemnities provided by both treaties, Bolivia was able to finance a great railroad construction era—by 1920 most of the major cities were linked by rail, and La Paz was connected to the two Chilean Pacific ports of Antofagasta and Arica; new lines had been begun or completed to Lake Titicaca and thus the Peruvian border, and to Tarija and the Argentine frontier.

Railroad-building era

The period of Liberal rule was also the most calm in Bolivian political history. Dominated by the figure of Montes, the Liberal Party easily destroyed the federalists, who had supported the party during the revolution, and Liberal success led to the total collapse of the Conservative Party. Not until 1914 was an effective two-party system again established, when many of the political "outs," along with a large number of new and younger elements, finally organized the Republican Party. Like its predecessors, the Republican Party was a white, upper- and middle-class grouping, with a fundamental belief in liberal and positivist ideologies.

The Republican Party. The abrasive quality of the strong-willed Montes and the disintegration of the ruling Liberal Party finally permitted the Republicans to stage a successful coup d'état, in 1920, and become the ruling party. Upon achieving political power, however, the new party immediately split into two warring sections based on a conflict of personalities and led by two Montes-style politicians—Juan Bautista Saavedra, a La Paz lawyer who captured control of the Republican Party and was national president from 1930 to 1934, and Daniel Salamanca, a Cochabamba landowner who took his following into a separate party, the so-called Genuine Republican Party (Partido Republicano Genuino). The rivalry between these two men became the dominant theme in Bolivian politics for the next decade, until the Salamanca forces captured the presidency.

Below the surface of this political battle of personalities, the national economy in the 1920s was undergoing serious change. The early years of the decade had witnessed a brilliant post-World War I recovery of the Bolivian tin-mining industry, which led to the achievement by 1929 of its highest production figures. This enormous output occurred, however, in a period of steady price decline (a trend that continued long after the Great Depression of the 1930s). By 1930 the international tin market was in a serious crisis, and Bolivian production suffered. The year 1930 marked the end of major new capital investment in tin mining; thereafter the industry in Bolivia would become an ever higher-cost producer of lower-grade ores for the international market.

BOLIVIA SINCE 1930

The installation of Salamanca in the presidency after the revolt of 1930 seemingly involved little change in traditional Bolivian government. But the Great Depression cut brutally into national income and forced the closing of a large part of the vital mining industry. Salamanca was thus forced to take new measures. Attempting a policy of inflation and money manipulation, he ran into bitter hostility from the Liberal Party, his key partner in the 1930 overthrow of the regular Republican Party. The opposition of these two forces in the central government led to a tense political climate, the result of which was to force Salamanca to accept a Liberal veto over internal economic decisions. He refused, however, to permit the Liberals to join his cabinet; rather, he sought to overcome Liberal congressional control and to destroy growing strike movements by turning national attention to other themes. Salamanca had the traditional recourse to patriotism and foreign war open to him in a long-standing border conflict with Paraguay.

Conflict with Paraguay

Already in the mid-1920s, Bolivia and Paraguay both had begun a major program of fort construction in the largely uninhabited and poorly demarcated Chaco Boreal territory, on the southeastern Bolivian frontier. At the height of the Depression, Salamanca had advocated an even heavier armament and fortification program and had contracted for major European loans. In June 1932 a border incident developed between the two states, and Salamanca deliberately provoked a full-scale Bolivian reprisal, which inevitably led to open war between the two nations.

The Chaco War. The Chaco War was a long and costly disaster for Bolivia. In the three years of bitter fighting on its southeastern frontiers, Bolivia lost 100,000 men dead, wounded, deserted, or captured; it also lost far more territory than Paraguay had claimed even in its most extreme prewar demands. The fact that Bolivia had entered the war with a better equipped and supposedly far better trained army only aggravated the sense of frustration among the younger literate veterans—the so-called Chaco generation—at the total failure of Bolivian arms. Charging that the traditional politicians and the international oil companies had led Bolivia into its disastrous war, the returning veterans set up rival Socialist and radical parties and challenged the traditional political system.

Return to military rule. The initial result of this challenge was the overthrow of the civilian government and the first advent of military rule in Bolivia since 1880. In 1936 the younger army officers seized the government, and under two leaders, Colonel David Toro in 1936–37 and Major Germán Busch in 1937–39, they tried to reform Bolivian society. Little was accomplished during this so-called era of military socialism except for the confiscation of the Standard Oil Company holdings, the creation of an important labour code, and the writing in 1938 of an advanced, socially oriented constitution.

Political chaos

Rise of new political groups. Beginning in the 1940s, civilian dissident groups finally began to organize themselves into powerful national opposition parties. The two most important of these were the middle-class and initially fascist-oriented Nationalist Revolutionary Movement (Movimiento Nacionalista Revolucionario; MNR) and the Marxist and largely pro-Soviet Party of the Revolutionary Left (Partido de la Izquierda Revolucionaria; PIR). Both groups established important factions in the national congress of 1940–44. In 1943 the civilian president General Enrique Peñaranda was overthrown by a secret military group, Reason for the Fatherland (Razón de Patria; Radepa), which allied itself with the MNR and tried to create a new-style government. Under Colonel Gualberto Villaroel (1943–46) little was accomplished, except for an initial political mobilization of the Indian peasants by the MNR. Opposed as fascist-oriented by the right and left, the Villaroel government was overthrown in 1946, in a bloody revolution in which Villaroel was hanged before the presidential palace by revolutionary crowds.

During the next six years, the PIR tried to rule in alliance with many of the older parties but failed. It was eventually dissolved and replaced in early 1950 by the more radical Bolivian Communist Party. The Conservative parties proved unable to control the situation; and, after the MNR won a plurality victory in the presidential elections of 1951, the military intervened directly and formed a military junta government. As for the MNR, its disaster under Villaroel led it to disassociate itself from its fascist wing and to seek an alliance with a small Trotskyite party, which had important mine-union support. The resulting alliance brought the labour leader Juan Lechín into the MNR. After several unsuccessful revolts, each more violent than the preceding one, the MNR, in several days of fighting, finally overthrew the military regime in April 1952. During this struggle, workers, civilians, and peasants were armed and the army was almost totally destroyed.

The Bolivian National Revolution (1952). Thus in April 1952 began the so-called Bolivian National Revolution, which became one of Latin America's most important social revolutions. The MNR and its mine-worker and peasant supporters were pledged to a fundamental attack on the tin-mining industry and its allied political supporters. In October 1952 the three largest tin-mine companies were nationalized. In August 1953 came one of the most far-reaching land-reform decrees ever enacted in the Western Hemisphere. Universal suffrage was granted with the abolition of literacy requirements. Not only were Indians granted land, freed from servile labour obligations, and given the vote, but they were also given large supplies of arms. From that point on, the Indian peasants of Bolivia became a powerful, if largely passive, political force upon which all subsequent governments based their strength.

Social reforms

Post-1952 regimes. The most important leader of the MNR, Víctor Paz Estenssoro, was president of Bolivia in 1952–56 and instituted the most revolutionary part of the party's program. In 1956 he was replaced by the more conservative Hernando Siles Zuazo, whose primary concern was to stop an inflation that had followed the 1952 revolution. That inflation had in many ways completed the revolutionary process by virtually destroying the older middle-class supporters of the MNR. With massive financial support from the United States, the inflation was stopped; but most of the advanced social programs of the revolution were suspended as well. The government ended worker co-administration of the nationalized mine companies and cut back on expanded social services. It also invited U.S. petroleum companies back into Bolivia for the first time since 1937, when Standard Oil of Bolivia had been confiscated by the Toro government.

With the return of Paz Estenssoro to the presidency in 1960, the consolidation achieved by Siles Zuazo was further developed, with the power of the army being revived under U.S. support. The attempt of Paz Estenssoro to renew his presidential term for another four years, in 1964, led to the splintering and temporary destruction of the MNR and to the overthrow of his government by the military.

The Barrientos regime

With the support of many conservative elements and the peasant masses, the vice president, General René Barrientos, seized the government and proceeded to dissolve most of the organized labour opposition, marking the beginning of a reign of military leaders. From 1964 until his death in 1969, Barrientos continued with the process of conservative economic reform and political retrenchment and attempted to demobilize all popular groups except the peasants, who had risen to some power as a result of the National Revolution. A poorly organized antigovernment campaign, led by the Argentinian-born revolutionary Ernesto (Che) Guevara, was destroyed in 1967, largely because of its failure to mobilize the peasants.

The death of Barrientos brought the vice president, Luis Adolfo Siles Salinas, into office; he was forcibly replaced in mid-1969 by General Alfredo Ovando Candía, who in turn was forced out of office, after he had nationalized Gulf Oil Company holdings, by the more radical General Juan José Torres in October 1970. Of the several military regimes that governed between 1964 and 1979, that led by Torres was the most radical; for a time the Torres government replaced Congress with a workers' soviet. In 1971 Torres was replaced by Colonel Hugo Banzer Suárez, and the most repressive regime of the period came to power. During the next seven years the labour movement was suppressed, the mines were occupied by troops, all civil rights were suspended, and the peasant syndicates were prohibited. Nevertheless, this was also an era of unprecedented growth in the Bolivian economy, fueled by the sudden increase in world mineral prices and the completion of some of the basic changes in the social and economic infrastructure begun with the National Revolution of 1952. These long-term economic changes involved the relative decline of the importance of tin and the emergence of commercial agricultural exports for the first time in Bolivian republican history. It was also a period of extraordinarily rapid increase in the national population, which between 1950 and 1976 achieved an annual net growth rate of 2.1 percent. Finally, the Banzer regime was unique in contemporary Bolivian affairs because it provided the new commercial agricultural interests of the Santa Cruz region with national representation.

In 1978 the old MNR reemerged, and a complex set of new political parties and movements developed. In the national elections of 1978 and 1979, these new groups gained wide support, and the electorate showed an even balance between conservative and radical positions. Moreover, peasants for the first time no longer voted in block but were as equally divided as the urban populace.

These democratic changes were fragile, however. The results of the elections of July 9, 1978, were voided in the wake of charges of fraud. Banzer resigned later that month under threat of a coup. The unstable state of government went on unabated over the next several years as the country's leadership continued to change hands rapidly. In November 1979 Lidia Gueiler Tejada was chosen by military, political, and union leaders to serve as interim president, the first woman to hold the country's highest office. She served until elections were held in June of the following year. None of the presidential candidates in those elections received a majority vote, however, and, instead of an orderly return to democratic government, the army staged another coup, established a military junta, and declared a state of siege. The new regime immediately lost credibility in the international community because of its repressive measures and because U.S. officials implicated some of its leaders in illegal cocaine trafficking.

Upheaval under military governments

The cycle of coups and overthrows continued. Economic conditions worsened, fueled by the mismanagement of successive military regimes. In September 1982 the military reinstated the Congress that had been elected in 1980. They installed as president Siles Zuazo, who had been the victor in the 1980 elections. Siles Zuazo managed to stay in office until the next elections, held in July 1985, despite massive inflation, crippling strikes to protest his strict economic controls, and disastrous crop failures caused by El Niño, the warm ocean current that sometimes brings climatic upheavals to western South America. As the new elections approached, Bolivia was a country in chaos. Its devastating inflation rate, the world's highest, had gone into quintuple digits; its major source of foreign exchange was derived from cocaine dealing, which the government was reluctant to curtail because of the hardships it would impose on the farmers who grew the coca plant; and strikes and violent demonstrations were frequent occurrences.

The 1985 elections once again brought Paz Estenssoro back to the presidency; it was the first orderly transfer of power in some 25 years. He was chosen by the Congress to lead despite the fact that another candidate, former president Banzer, had a larger plurality. Paz Estenssoro, who once had brought liberal reforms to the country, exacted extreme austerity measures that were greeted with renewed protests and strikes. The new president, however, rather than bending to public pressure, held to his plan, and after several months Bolivia witnessed a turn in the economy, characterized chiefly by a reduction of its ruinous hyperinflation rate. Although this was an encouraging step, Bolivia still faced numerous debilitating problems, particularly that of unemployment, which had been exacerbated by the collapse of world tin prices, causing tens of thousands of miners to lose their jobs. The difficult fight against the large underground cocaine economy was somewhat strengthened, partly as a result of pressure from the United States. Actions taken included the eradication of illegal crops and processing laboratories, done with the aid of U.S. troops and helicopters, and implementation of a program of crop diversification.

Crackdown on illegal cocaine activity

The presidential elections of May 1989 were peaceful, but, because none of the three candidates received a majority as required by the constitution, the choice fell to Congress. Aided by the support of the second-place finisher and former president, Banzer Suárez, third-place finisher Jaime Paz Zamora of the Movement of the Revolutionary Left (Movimiento de la Izquierda Revolucionaria) became the new president on August 6. In most respects, Paz Zamora's policies were a continuation of his predecessor's (a distant relative), except for a new emphasis on national production of food and raw materials. Under the threat of the loss of U.S. aid, Paz Zamora vowed that Bolivia would continue to help fight the drug trade and seek alternative livelihoods for its thousands of coca farmers.

A highly praised reconstruction is NATHAN WACHTEL, *The Vision of the Vanquished: The Spanish Conquest of Peru Through Indian Eyes, 1530–1570* (1977; originally published in French, 1971), also available in a Spanish translation, *Los vencidos: los indios del Perú frente a la conquista española (1530–1570)* (1976). GUSTAVO ADOLFE OTERO, *Life in the Spanish Colonies, with Particular Reference to Upper Peru, Now Bolivia* (1955; originally published in Spanish, 1942), provides information on the influence of Spanish colonization. Negative and positive approaches to Bolivia's history are represented, respectively, by ALCIDES ARGUEDAS, *Obras completas,* vol. 2, *Historia* (1959), a complete history of Bolivia; and CARLOS MONTENEGRO, *Nacionalismo y coloniaje,* 6th ed. (1982). The complex reasons for the emergence of a separate independent Bolivia are given in detail by CHARLES ARNADE, *The Emergence of the Republic of Bolivia* (1957, reissued 1970). A political geography that explains Bolivia's land loss is J. VALERIE FIFER, *Bolivia: Land, Location, and Politics Since 1825* (1972). HERBERT S. KLEIN, *Parties and Political Change in Bolivia, 1880–1952* (1969), is a good political history. AUGUSTO CÉSPEDES, *El dictador suicida: 40 años de historia de Bolivia,* 2nd ed. (1968), provides coverage of the first half of the 1900s. Histories of the Chaco War include DAVID H. ZOOK, JR., *The Conduct of the Chaco War* (1960); and ROBERTO QUEREJAZU CALVO, *Masamaclay,* 4th ed. (1981).

A basic introduction to the Bolivian National Revolution is ROBERT J. ALEXANDER, *The Bolivian National Revolution* (1958, reprinted 1974); while JAMES DUNKERLEY, *Rebellion in the Veins: Political Struggle in Bolivia, 1952–82* (1984), is more detailed. JAMES M. MALLOY, *Bolivia: The Uncompleted Revolution* (1970); and JAMES M. MALLOY and EDUARDO GAMARRA, *Revolution and Reaction: Bolivia, 1964–1985* (1987), are penetrating analyses. A history and negative evaluation of the populist rule of the MNR is offered in CHRISTOPHER MITCHELL, *The Legacy of Populism in Bolivia: From the MNR to Military Rule* (1977). The consequences of the revolution are studied by JONATHAN KELLEY and HERBERT S. KLEIN, *Revolution and the Rebirth of Inequality* (1981); and JERRY R. LADMAN (ed.), *Modern-Day Bolivia: Legacy of the Revolution and Prospects for the Future* (1982). FREDERICK B. PIKE, *The United States and the Andean Republics: Peru, Bolivia, and Ecuador* (1977), treats diplomatic relations. (J.V.F./C.W.A.)

Bombay

Bombay (Mumbai in the Marāṭhī language), the capital of Mahārāshtra state, on the west coast of India, is the country's financial and commercial centre and the principal port on the Arabian Sea. It is one of the largest and most densely populated cities in the world. Bombay is located on a site of ancient settlement and took its name from the local goddess Mumba—a form of Pārvatī, the consort of Śiva (Shiva), one of the principal gods of Hinduism—whose temple once stood in what is now the southeastern section of the city.

Bombay has long been the centre of India's cotton-textile industry, but its other manufacturing industries are now well-diversified and its commercial and financial institutions strong and vigorous. It suffers, however, from the chronic ills of most large, expanding industrial cities—air and water pollution, slums, and overcrowding. Expansion of Bombay is confined by its island location, and the city, which has one of the highest population densities in the world, seems ready to burst at its seams.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. The city of Bombay occupies a peninsular site originally composed of seven islets lying off the Konkan Coast of western India. Since the 17th century, drainage and reclamation projects, as well as the construction of causeways and breakwaters, have joined the islets to form a larger body known as Bombay Island. East of the island are the sheltered waters of Bombay Harbour. Bombay Island consists of a low-lying plain, one-fourth of which lies below sea level; the plain is flanked on the east and west by two parallel ridges of low hills. Colāba Point, the headland formed on the extreme south by the longer of these ridges, protects Bombay Harbour from the open sea. The western ridge terminates at Malabār Hill, 180 feet (55 metres) above sea level, which is one of the highest points in Bombay. Between the two ridges lies the shallow expanse of Back Bay. On a slightly raised strip of land between the head of Back Bay and the harbour is the fort, the original nucleus around which the city grew; it is now chiefly occupied by public and commercial offices. From Back Bay, land slopes northward to the central plain. The extreme north of Bombay Island is occupied by a large salt marsh.

The old city covered about 26 square miles from Colāba in the south to Māhīm and Sion in the north. In 1950 Bombay expanded northward with the inclusion of the large island of Salsette, which was joined to Bombay Island by a causeway. By 1957 a number of suburban municipal boroughs and some neighbouring villages were incorporated into Greater Bombay. The Bombay metropolitan region has continued to expand, and by the mid-1980s the Bombay metropolitan region comprised an area of 233 square miles (603 square kilometres). During the early 1970s, in an effort to relieve congestion, Salsette Island was linked with the mainland by a bridge across Thāna Creek, the headwaters of Bombay Harbour.

Bombay Harbour

The natural beauty of Bombay is unsurpassed by that of any city in the region. The entrance into Bombay Harbour from the sea discloses a magnificent panorama framed by the Western Ghāts (mountains) on the mainland. The wide harbour, studded with islands and dotted with the white sails of innumerable small craft, affords secure shelter to ships, particularly when storms lash the coast. The largest of the harbour's islands is Elephanta, which is famous for its 8th- and 9th-century cave temples.

Typical trees in the city include coconut palms, mango trees, and tamarinds, as well as banyan trees. Salsette Island was once the haunt of wild animals, such as tigers, leopards, jackals, and deer, but these are no longer found on the island. Animal life now consists of cows, oxen, sheep, goats, and other domestic species. Birdlife includes vultures, pigeons, cranes, and ducks.

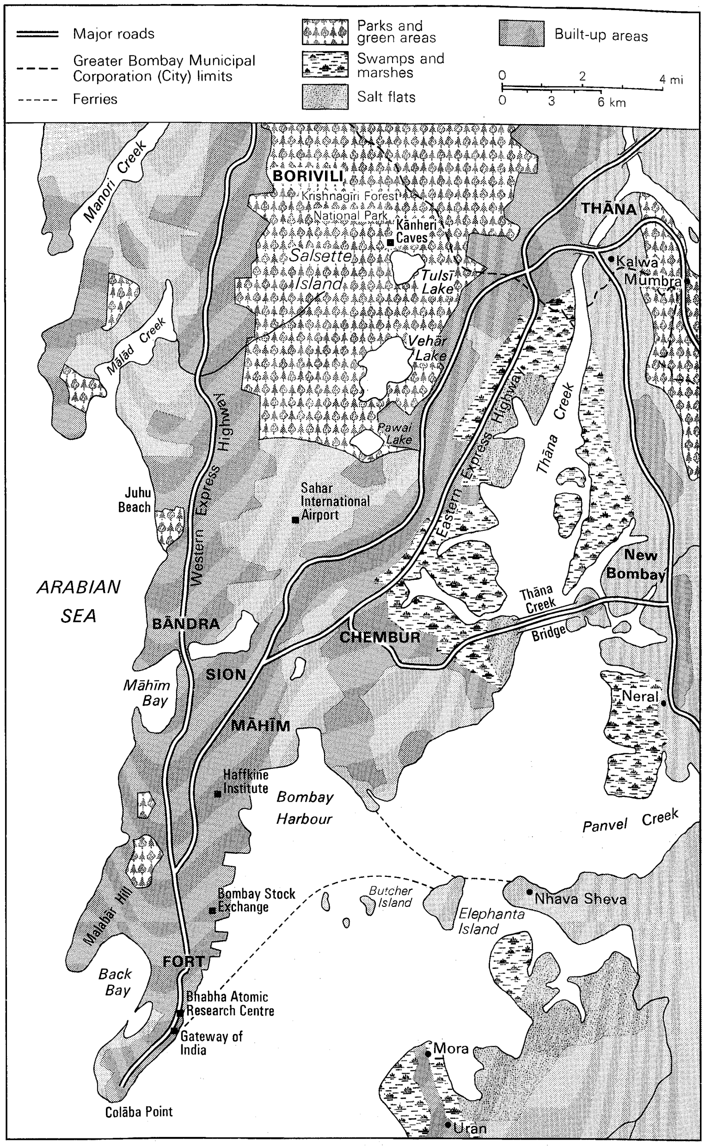
Climate. The climate of Bombay is hot and humid. There are four seasons. Cold weather prevails from December to February, and hot weather from March to May. The rainy season, brought by monsoon winds from the southwest, lasts from June to September and is followed by the post-monsoon season, lasting through October and November, when the weather is again hot. Mean monthly temperatures vary from 91° F (33° C) in May to 67° F (19° C) in January. Annual rainfall is 71 inches (1,800 millimetres), with an average of 24 inches falling in July alone.

The city layout. The older part of Bombay is much built up, but more affluent areas, such as Malabār Hill, contain some greenery; there are also a number of open playgrounds and parks. Bombay's history of burgeoning urbanization has created slums in sections of the city. An alarming rate of air and water pollution has been caused by the many factories still crowding the city, the growing volume of motor-vehicle traffic, and the nearby oil refineries.

The financial district is located in the southern part of the city (around old Fort Bombay). Farther south (around Colāba) and to the west along Netaji Subhas Road (Marine Drive) and on Malabār Hill are residential neighbourhoods. To the north of the fort area is the principal business district, which gradually merges into a commercial-residential area. Most of the older factories are located in this area. Still farther north are residential areas, and beyond them are recently developed industrial areas as well as some shantytown districts.

Housing

Housing is largely privately owned, though there is some public housing built by the government through publicly funded corporations or by private cooperatives with public funds. But Bombay is very crowded, and housing is scarce for anyone who is not very rich. For this reason, commercial and industrial enterprises find it increasingly difficult to attract middle-level professional, technical, or managerial staff. There is continuous immigration of unskilled labour from the hinterland, and the number of indigent and homeless people is increasing. City planners



Bombay and surrounding area.

have sought to stop this movement and to persuade enterprises to locate across Bombay Harbour in the developing "twin city" of New Bombay by banning the development of new industrial units and the expansion of existing ones inside the city. But the ban has been largely breached in practice whenever entrepreneurs threaten to relocate their businesses to some other part of the country.

Bombay's architecture is a mixture of florid Gothic styles, characteristic of the 18th and 19th centuries, and contemporary designs. The older administrative and commercial buildings are intermingled with skyscrapers and multistoried concrete-block buildings.

THE PEOPLE

Bombay's growth since the 1940s has been steady if not phenomenal. At the turn of the 20th century its population was 850,000; in 1941 it had doubled to 1,695,000; and by 1981 it had grown to more than 8,200,000. The city's birth rate is much lower than that of the nation because of family-planning programs, and the high overall growth rate is largely attributable to the influx of people in search of employment.

Low birth rate

Bombay has one of the highest population densities in the world. In 1981 Greater Bombay had an average of more than 35,000 persons per square mile, and in much of the city's older section at least three times that was recorded, though such areas as Girgaum, Bhendi Bazaar, and Bhuleswar, all near Back Bay, had lower population densities. Some parts of the inner city have nearly one million persons per square mile, perhaps the world's highest density.

The city is truly cosmopolitan, and representatives of almost every religion and region of the world can be found in Bombay. Almost half of the population is Hindu; but the city also encompasses important communities of Muslims, Christians, Buddhists, Jains, Sikhs, Zoroastrians, and Jews.

Almost every Indian language and many foreign languages are spoken. Marāṭhī, the state language, is the dominant Indian language, followed by Gujarati and Hindi. Others include Bengali, Pashto, Arabic, Chinese, English, and Urdu.

THE ECONOMY

Bombay is the economic hub and commercial and financial centre of India. Its economic composition in some respects demonstrates India's peculiar fusion of the nuclear and cow-dung ages. The city contains the Indian Atomic Energy Commission's establishment, which includes nuclear reactors and plutonium separators. In many areas of the city, however, traditional biogenic sources of fuel and energy are still in use.

Industry. The cotton-textile industry, through which the city prospered in the 19th century, is still important but is in relative decline. New growth industries—metals, chemicals, automobiles, electronics, engineering, and a host of ancillary enterprises—as well as urban industries such as food processing, papermaking, printing, and publishing have been at the core of expansion of manufacturing employment.

Commerce and finance. The Reserve Bank of India, the country's Central Bank, a number of other commercial banks, and the Life Insurance Corporation of India—a nationalized enterprise and the country's largest investor in government bonds and private stocks—as well as other major long-term investment financial institutions, are located in Bombay. These, in turn, have attracted a number of financial and business services to the city.

The Bombay Stock Exchange

The Bombay Stock Exchange is the country's leading stock and share market. Though a number of the economic hubs that have sprung up around the country since independence have reduced the exchange's pre-independence stature, it remains the preeminent centre in volume of financial and other business transacted and serves as a barometer of the country's economy.

Transportation. Bombay is connected by a network of roads to the north, east, and south of India. It is the railhead for the Western and Central railways, and trains from the city carry goods and passengers to all parts of India. The Sahar International Airport, on Salsette Island, is an important point of entry for many foreign airlines, and nearby Santa Cruz Airport serves domestic flights. Bombay handles about 60 percent of the international and nearly 40 percent of the domestic air traffic in India. The facilities provided by Bombay Harbour make the city India's major western port. Though other major ports have sprung up on the west coast—Kandla to the north and Goa and Cochin to the south—Bombay still handles more than 40 percent of India's maritime trade.

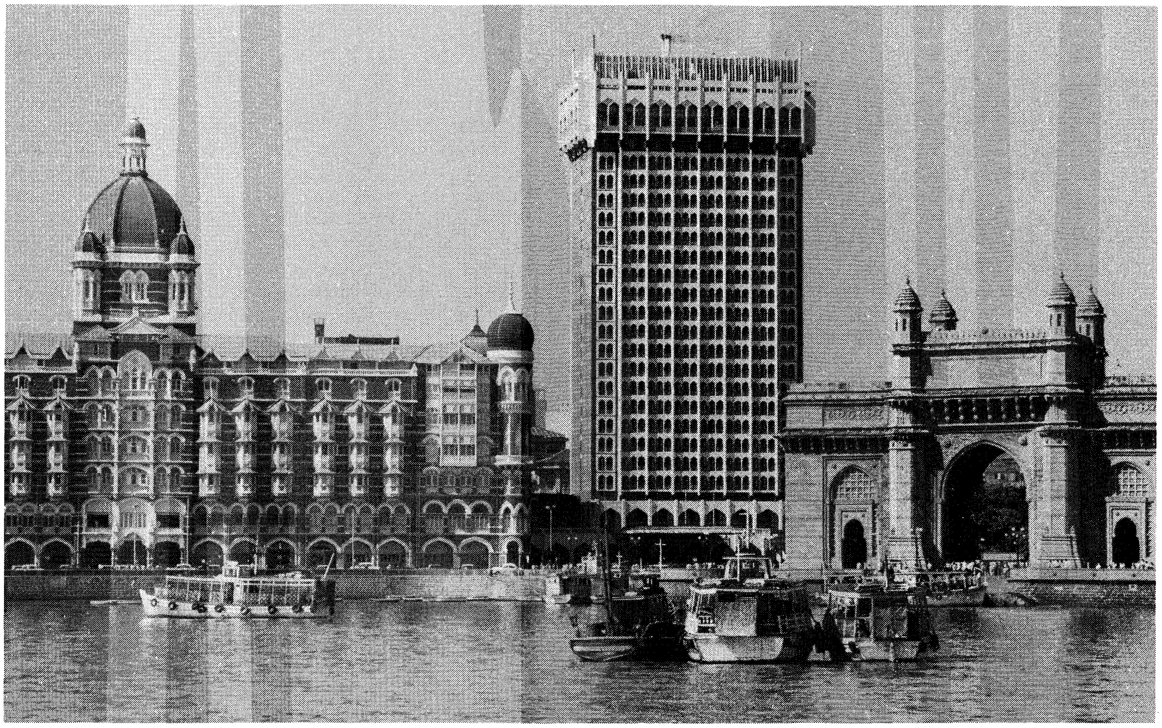
Two suburban electric train systems provide the main public transportation and daily convey hundreds of thousands of commuters from outside the city. There is also a municipally owned bus fleet.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. As the capital of Mahārāshtra state, the city is an integral political division of the state government, the headquarters of which are called the Mantrālaya. The state administers the police force and has administrative control over certain city departments. The central government controls communications such as the post and telegraph system, the railways, the port, and the airport. Bombay is also the headquarters of India's western naval fleet and the base for the Indian flagship.

The Municipal Corporation

The government of the city is vested in the fully autonomous Municipal Corporation of Greater Bombay. Its legislative body is elected on adult franchise every four years and functions through its various standing commit-



Bombay Harbour. The Gateway of India is on the right, and at left and centre are the old and new buildings of the Taj Mahal Hotel.

© Robert Frerck—Odyssey Productions

tees. The chief executive, who is appointed every three years by the state government, is the municipal commissioner. The mayor is annually elected by the Municipal Corporation; the mayor presides over corporation meetings and enjoys the highest honour in the city but has no real power.

Public utilities. The manifold functions of the corporation include the provision or maintenance of medical services, education, water supply, fire services, garbage disposal, markets, gardens, and engineering projects such as drainage development and the improvement of roads and street lighting.

The Municipal Corporation operates the transport system inside the city and the supply of electricity as public utilities. Electric energy is obtained from a grid system supplied by government and privately owned agencies and is then distributed throughout the city. The water supply, also maintained by the municipality, comes mainly from Tāusa Lake in adjoining Thāna district and from Tulsī and Vehār lakes on Salsette Island. Pawai Lake, originally harnessed for water supply, has proved unsatisfactory because its water is not potable.

Health. The city has more than 100 hospitals, including those run by federal, state, or corporation authorities, and a number of specialized institutions treating tuberculosis, cancer, and heart disease. There are also a number of leading private hospitals. The Haffkine Institute, a leading bacteriologic research centre specializing in tropical diseases, is located there.

Security. The police force is headed by the commissioner of police, who is responsible for law and order in Greater Bombay and is answerable administratively to the home secretary of the state.

Education. Bombay's literacy rate is much higher than that of the nation as a whole. Primary education is free and compulsory; it is the responsibility of the Municipal Corporation. Secondary education is provided by public and private schools supervised by the state government. There are also public and private polytechnic institutes and institutions offering students a variety of degree and diploma courses in mechanical, electrical, and chemical engineering. The Indian Institute of Technology, operated by the central government, is also located in the city. The University of Bombay, established in 1857, has some 130 constituent colleges and more than two dozen teaching departments. Several colleges in Goa are also affiliated with the university.

CULTURAL LIFE

Bombay's cultural life reflects its polyglot population. The city has a number of museums, libraries, literary and other cultural institutions, art galleries, and theatres. Perhaps no other city in India can boast of such a high degree of variety and quality in its cultural and entertainment facilities. Bombay is the stronghold of the Indian film industry and has an open-air theatre. Throughout the year Western and Indian music concerts and festivals and Indian dance shows are performed. The Prince of Wales Museum of Western India, housed in a building of Indo-Saracenic architecture, contains three main sections of art, archaeology, and natural history. Nearby is the Jehangir Art Gallery, Bombay's first permanent art gallery and centre of cultural and educational activities.

Publishing and broadcasting

Bombay is an important centre for the Indian printing industry and has a vigorous press. Newspapers are printed in English, Marāṭhī, Hindi, Gujarati, Sindhi, and Urdu. Several monthlies, biweeklies, and weeklies are also published in the city. The regional station of All-India Radio is centred in Bombay, and television services for the city began in 1972.

Krishnagīri Forest, a national park in the north of Greater Bombay, is a pleasant vacation resort located near the Kānheri Caves, site of an ancient Buddhist university; the more than 100 caves contain gigantic Buddhist sculptures dating from the 2nd to 9th century AD. There are several public gardens, including the Jijāmātā Garden, which houses Bombay's zoo in the city proper; the Baptista Garden, located on a water reservoir in Mazagaon; and the Pherozshah Mehta Gardens, the Kamala Nehru Park, and the Sloping Park—all on Malabār Hill.

Cricket matches, which are popular throughout India, are played at Brabourne and Wankhede stadiums. Athletic and cycling track events are held at the Vallabhbhai Patel Stadium. Juhu Beach is the most fashionable area for bathing and swimming.

History

The Kolis, an aboriginal tribe of fishermen, were the earliest known inhabitants, though Paleolithic stone implements found at Kandivli, in Greater Bombay, indicate human occupation during the Stone Age. The area was known as Heptanesia to the ancient Greek astronomer and geographer Ptolemy and was a centre of maritime trade with Persia and Egypt in 1000 BC. It was part of Aśoka's empire in the 3rd century BC and was ruled in the 6th to 8th century AD by the Cālukyas, who left their mark on Elephanta Island (Ghārāpuri). The Walkeswar Temple at Malabār Point was probably built during the rule of Śilāhāra chiefs from the Konkan Coast (9th–13th century). Under the Yādavas of Devagiri (1187–1318) the settlement of Mahikavati (Māhīm) on Bombay Island was founded in response to raids by the Khaljī dynasty of Hindustān in 1294. Descendants of these settlers are found in contemporary Bombay, and most of the place-names on the island date from this era. In 1348 Bombay was conquered by invading Muslim forces and became part of the kingdom of Gujarāt.

A Portuguese attempt to conquer Māhīm failed in 1507, but in 1534 Sultan Bahādur Shāh, the ruler of Gujarāt, ceded the island to the Portuguese. In 1661 it came under British control as part of the marriage settlement between King Charles II and Catherine of Braganza, sister of the king of Portugal. The crown ceded it to the East India Company in 1668.

Urban expansion

In the beginning, compared to Calcutta and Madras, Bombay was not a great asset to the company but merely helped it keep a toehold on the west coast. On the mainland the Mughals, the Marāṭhās, and the territorial princes in Gujarāt were more powerful. Even British naval power was no match for the Mughals, Marāṭhās, Portuguese, and Dutch. By the turn of the 19th century, external events helped stimulate the growth of the city. The decay of Mughal power in Delhi, the Mughal–Marāṭhā rivalries, and the instability in Gujarāt drove artisans and merchants to the islands for refuge, and Bombay began to grow. With the destruction of Marāṭhā power, trade and communications to the mainland were established and those to Europe were extended; Bombay's prosperity had begun. In 1857 the first spinning and weaving mill was established, and by 1860 Bombay had become the largest cotton market in India. The American Civil War (1861–65) and the resulting cutoff of cotton supplies to Britain caused a great trade boom in Bombay. But, with the end of the Civil War, cotton prices crashed and the bubble burst. By that time, however, the hinterland had been opened, and Bombay had become a strong centre of import trade.

With the opening of the Suez Canal in 1869, Bombay prospered, though slums and unsanitary conditions steadily multiplied with its increasing population. Plague broke out in 1896, and a City Improvement Trust was established to open new localities for settlement and to erect dwellings for the artisan classes. An ambitious scheme for the construction of a seawall to enclose an area of 1,300 acres (525 hectares) was proposed in 1918 but not finished until the completion of what is now Netaji Subhas Road from Nariman Point to Malabār Point—the first two-way highway of its kind in India—after World War II. In the postwar years the development of residential quarters in suburban areas was begun, and the administration of Bombay city through a municipal corporation was extended to the suburbs of Greater Bombay. The city had served as the former capital of Bombay presidency and Bombay state, and it was made the capital of Mahārāshtra state in 1960.

Centre of political activity

During the late 19th and early 20th centuries, Bombay was a centre of both Indian nationalist and regional Marāṭhā political activity. In 1885 the first session of the Indian National Congress (a focus of both pro-Indian and anti-British sentiment until independence) was held in the city, where subsequently, at its 1942 session, the Congress passed the "Quit India" resolution, which demanded complete independence for India. From 1956 until 1960 Bombay was the scene of intense Marāṭhā protests against the two-language (Marāṭhī–Gujarati) makeup of Bombay state, a legacy of British imperialism, which led to the state's partition into the modern states of Gujarāt and Mahārāshtra.

Boston

Boston, the capital of the Commonwealth of Massachusetts in the northeastern United States, lies on Massachusetts Bay, an arm of the Atlantic Ocean. The city proper—including part of the Charles River, Boston Harbor, and a portion of the Atlantic Ocean—has an unusually small area for a major city, only 46 square miles (119 square kilometres), more than one-fourth of it water.

The area, the people, and the institutions within its political boundaries can only begin to define the essence of Boston. As a city and as a name, Boston is a symbol of much that has gone into the development of the American consciousness, and its presence reaches far beyond its immediate environs. As the spiritual capital of the New England states, as the nation's closest link to its European heritage, as the progenitor of the American Revolution and the nation, and as the earliest centre of American culture, Boston has influenced the country for nearly three centuries. Though Boston, like New England in general, has played a lessening role in national life during much of the 20th century, it remains the focal point of what may be the most diversified and dynamic combination of educational, cultural, and medical and scientific activities in the United States.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Boston and its sheltered deepwater harbour are ringed by modest hills, from the Middlesex Fells on the north to the Blue Hills on the south.

Original topography

The area of the colonial town. The hilly Shawmut Peninsula, upon which Boston was settled, originally was almost completely surrounded by water. It was connected with mainland Roxbury on the south by a narrow neck of land along the line of present-day Washington Street. To the west of the neck were great reaches of mud flats and salt marshes, which were covered by tides at high water and known collectively as the Back Bay. Beyond this, the Charles River flowed down to the peninsula, further dividing it from the mainland on the north and west as it approached Boston Harbor. On the east the peninsula fronted on the harbour, and Town Cove, jutting in from the harbour, divided Boston into the North End and the South End. The centre of the colonial town was at the present Old State House (1711–47), where the only road from the mainland intersected with the principal approach from the harbour.

Although this original centre and the colonial South End have long been given over to banks, offices, and retail and wholesale trade, a few 18th-century buildings remain: Faneuil Hall (1742–1805), the Old Corner Book Store (1711), the Old South Meeting House (1729), and King's Chapel (1750). The North End is the only part of the early town that has been continuously lived in since the 1630 settlement. Colonial survivals such as the Paul Revere House (*c.* 1680) and Christ Church (1723)—the Old North Church from which lanterns revealed the route of the British march to Lexington in 1775—coexist with the teeming life of a seemingly Mediterranean community.

The considerable extent of shoreline, only a few minutes' walk from any part of the peninsula, provided ample space for wharves and shipyards. From the beginning of the settlement, the shoreline constantly encroached on the harbour as wharves were built and marshy coves were filled. Beyond the original settlement lay Boston Common, a tract of 45 acres (18 hectares) that has remained public open space since its purchase by the town in 1634. Above the Common rose the Trimountain, a three-peaked hill of which Beacon Hill is the only surviving, though greatly reduced, remnant. The other hills became landfill that added to the city's area in the 19th century.

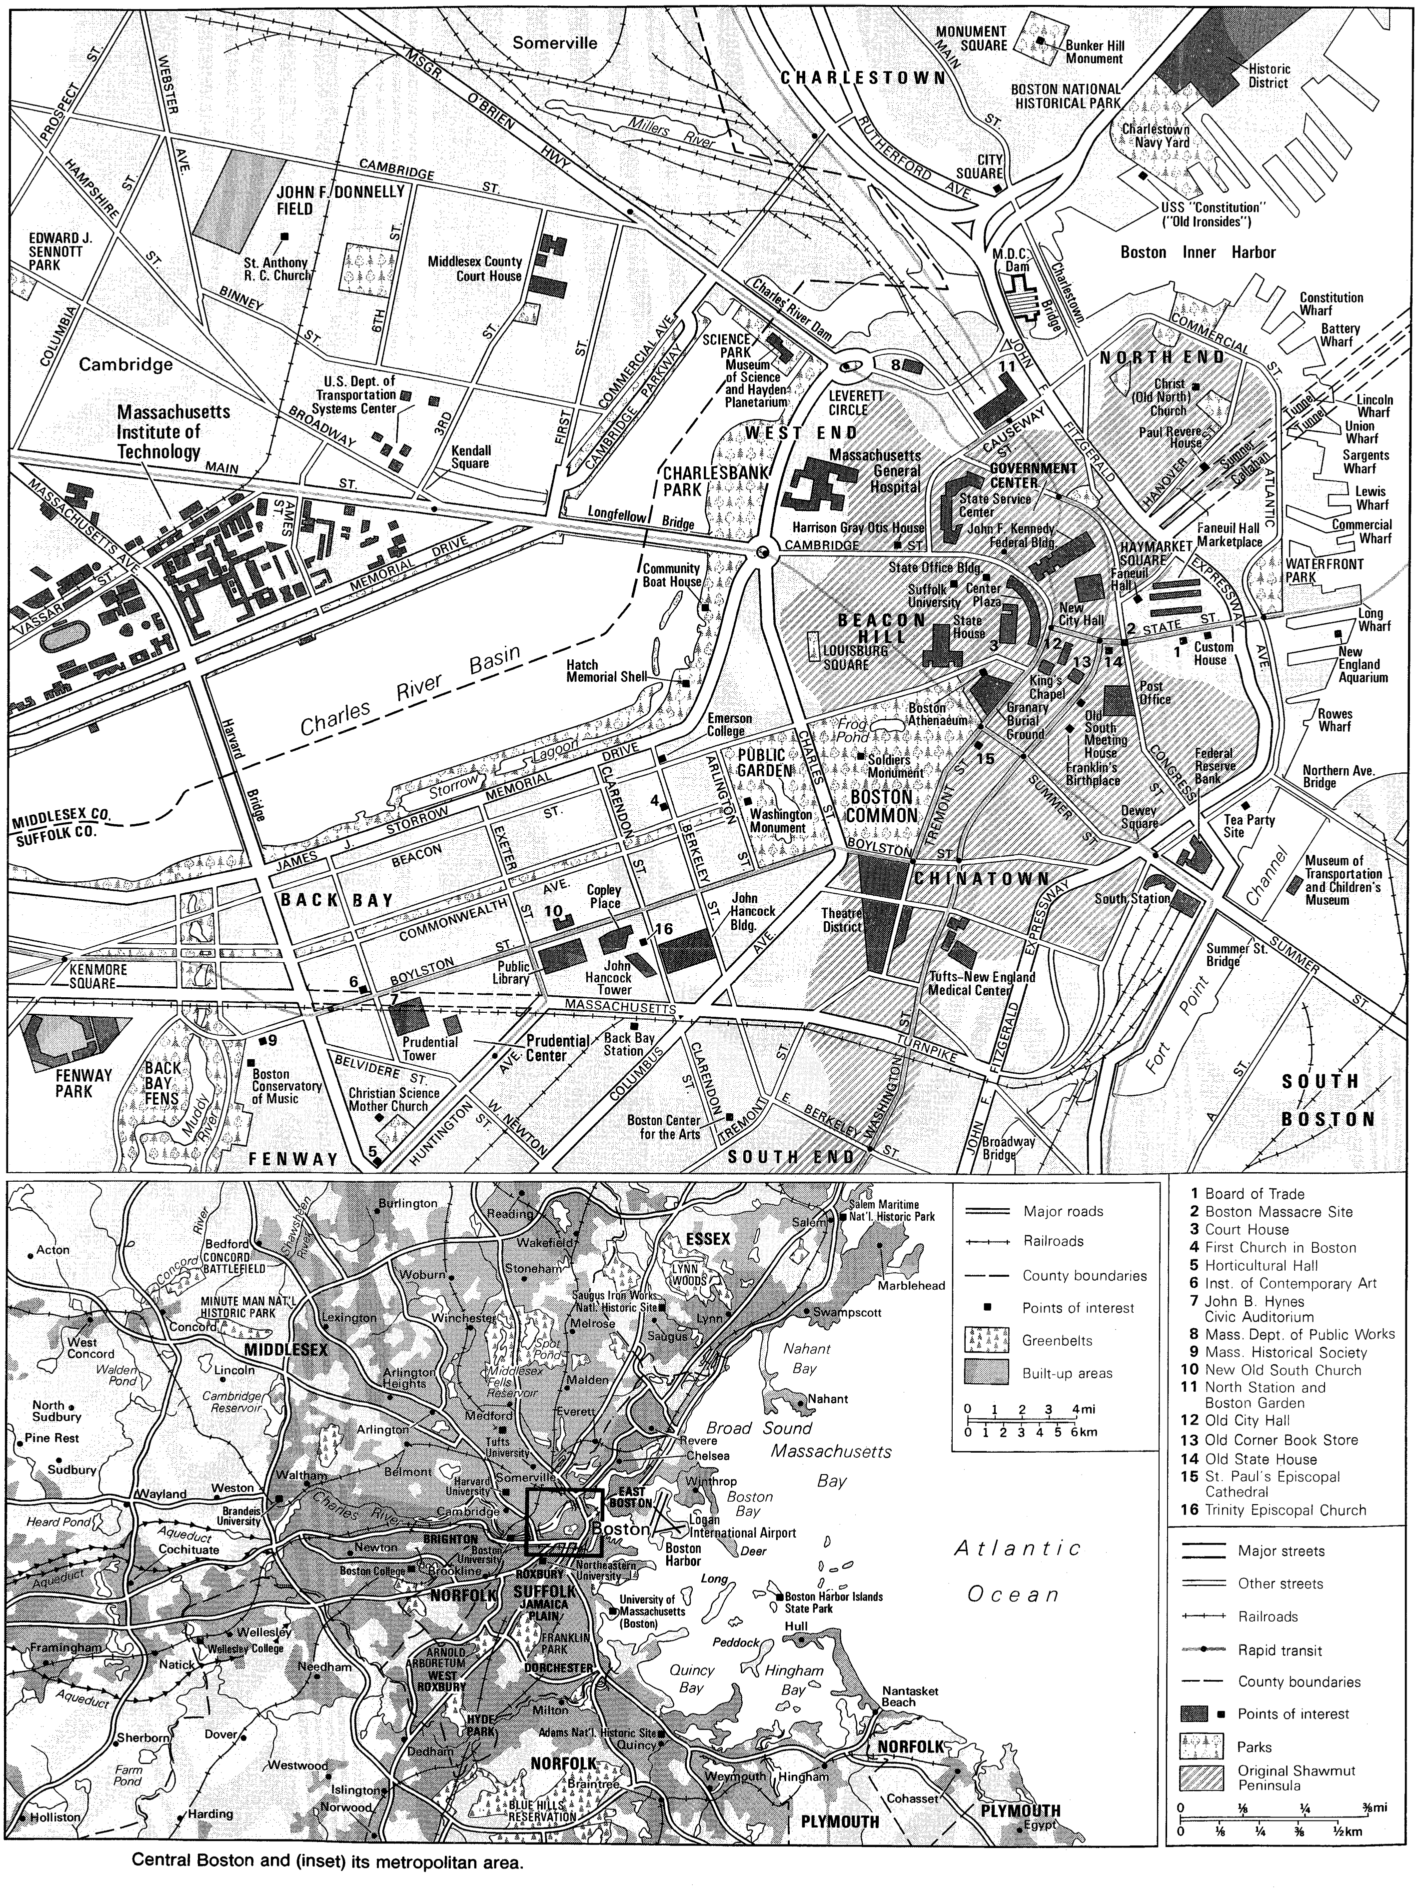
19th-century architecture

Bulfinch's designs. In the last years of the 18th century, when space became scarce, a series of major changes began to alter radically the physical lineaments of the area. In this period of expansion, the architect Charles Bulfinch (1763–1844), who for more than a quarter of a century was also the head of the town government, skillfully transformed an 18th-century English town into a 19th-century American city. Although many of Bulfinch's finest works have been destroyed, the central portion of the present State House (1795–98), above the Common on Beacon Hill, is his work. The construction of the State House on this site led to the conversion of the upland pastures of Beacon Hill into a handsome residential district that has survived with relatively little change. Between the State House and Charles Street are several streets, including famous Louisburg Square, filled with many houses by Bulfinch and other leading 19th-century architects. The area is protected by historic district legislation, and has been designated as the Beacon Hill Historic District.

As pressures of population in the 19th century caused a demand for more and more land, hills were cut down to fill in the coves. So much new land was created that the once water-ringed peninsula has become an indistinguishable part of the mainland. Fill on both sides of the narrow neck that connected the peninsula with the mainland created a new South End, a region that before the end of the century had lapsed into a slum. The waterfront was greatly extended, and the Back Bay was dammed (1818–21) to create tidal power for new mill sites. A causeway along the dam extended west from the Common to Sewell's Point, the present Kenmore Square in the Back Bay area, thus furnishing more direct communication with the mainland. The filling of Back Bay flats just west of Boston Common created land that in the 1830s was laid out as the Public Garden. This became a splendidly planted area with an artificial pond that is spanned by a miniature suspension bridge and traversed by swan-shaped excursion boats in the summer.

Fashioning of the Back Bay

The Back Bay mill basins never developed as their promoters had envisioned, partly because the introduction of railway lines through them in the 1830s hindered the



Central Boston and (inset) its metropolitan area.

flow of water. The area became a stinking nuisance, and the Massachusetts legislature in 1857 authorized its filling, thus creating a substantial amount of new land. The plan adopted provided for four new streets parallel to the Mill Dam (Beacon Street), to be intersected by cross streets. Commonwealth Avenue, which ran west from the Public Garden, was 200 feet (60 metres) wide with a park between its roadways, creating the atmosphere of a Parisian boulevard. Since there were no hills left to cut down, gravel had to be brought in by train from pits some miles away in Needham. By the end of the 19th century the Back Bay was completely filled and built up with houses that were subject to uniform height limits and setbacks. The region today presents a picture of American architecture that is as consistent for the second half of that century as Beacon Hill is for the first. Although many Back Bay houses have been converted to apartments, offices, schools, or other adaptive uses, the region has retained a good deal of its original character, and further changes are subject to architectural control.

Continuous park system. When the Back Bay was nearing completion during the 1880s, the American landscape architect Frederick Law Olmsted (1822–1903) developed an imaginative and large-scale design for the city's parks. It linked the Common, Public Garden, and Commonwealth Avenue with Franklin Park in West Roxbury by way of an open park known as the Fenway, which followed the Muddy River off to Brookline and Jamaica Plain. Included in this coordinated system was the Arnold Arboretum, a botanical outpost of Harvard University in Jamaica Plain. This led around the turn of the 20th century to a considerable western movement of institutions such as the Boston Symphony Orchestra, the New England Conservatory of Music, the Museum of Fine Arts, and the Harvard Medical School and hospitals. The completion in 1910 of a dam that kept the harbour tides out of the Charles River created a body of fresh water north of the Back Bay. The Charles River Basin, patterned after the Alster Basin in Hamburg, West Germany, remains one of the most handsome, distinctive, and popular features of Boston.

Suburbanization and annexations. The introduction, in the 1850s, of horsecar lines (later electrified) made it possible for many workers to move out of the confines of the city. Suddenly the adjacent towns were inundated. Roxbury, West Roxbury, Dorchester, Brighton, and Charlestown—once pleasant, independent communities—were absorbed into the city between 1855 and 1873. Everywhere, the line of demarcation between city and country was lost in a rapid and chaotic orgy of expansion and building.

Except for Hyde Park in 1912, no other towns have been brought into the city government of Boston in the 20th century. Although the city of Cambridge and the town of Brookline are independently governed, a casual visitor would hardly guess where Boston stops and they begin. The Charles River divides Boston from Cambridge, but both riverbanks appear to be part of one metropolis. Some regional cooperation is assured, however, through the Metropolitan District Commission, created in 1919 through the consolidation of the sewer and water districts and the park commission established earlier by the Massachusetts legislature.

Modern architecture. Until the mid-20th century, the low skyline of Boston was punctuated only by church steeples and by the tower of the Custom House, which as a federal building was not bound by the 125-foot height restriction that prevailed generally in the city. Modification of the building code, coincidental with a construction boom, brought about great changes in the 1960s, of which the first conspicuous example was the Prudential Center, with a 52-story tower on the site of train yards. The first major effort in urban renewal in Boston, initiated early in 1958, led to the wholesale demolition of the West End, the displacement of people, and the disruption of neighbourhoods to make way for the apartment towers of Charles River Park. Unfavourable reaction to such total and large-scale demolition of large areas without regard for the feelings of people led the mayor in 1960 to put an experienced lawyer at the head of the Boston Redevelopment Authority. During the next seven years the authority emphasized renewal rather than wholesale demolition and rebuilding. It endeavoured to enhance the traditional character of the city by bringing the best contemporary architecture and imaginative civic design to new projects. The Government Center, containing the new City Hall completed in 1968, in addition to federal, state, and private office buildings, thereby became a harmonious neighbour to Faneuil Hall and to other adjacent historic buildings. The creation of the Government Center stimulated considerable private construction in the vicinity in the 1960s. The John Hancock Mutual Life Insurance Company completed construction in 1976 of a tower that overtopped the Prudential Tower, while the Christian Science Church sponsored the reconstruction of large blocks of property near The Mother Church. Downtown waterfront renewal during the 1960s and 1970s along Atlantic Avenue and later developments on the site of the former Boston Naval Shipyard to the north have helped to open up the waterfront for commercial, residential, and recreational use and to preserve buildings of historical or architectural value. As seen from a distance, the profile of Boston is no longer low but is dominated by a series of towers from the waterfront to well inland.

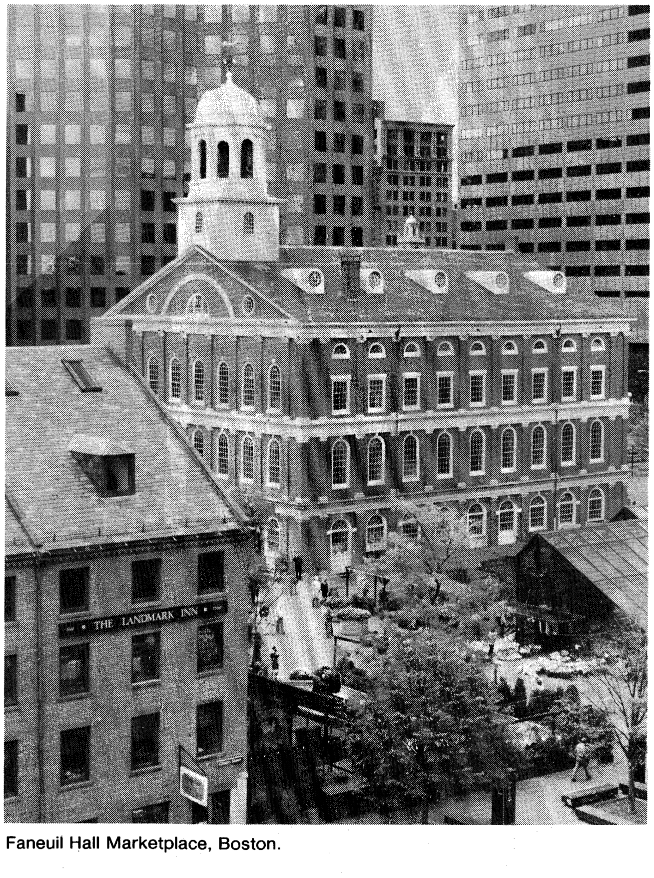
Controls on urban renewal

The narrow and crowded streets of the central city are better suited for walking than driving, for Bostonians are incorrigible jaywalkers. The street markets around Faneuil Hall and in the North End are as essential a part of the city as ever, yet the terraced square of the Government Center provides a handsome setting for the modern City Hall that is a welcome great open space. The second-empire exterior of the old City Hall has been preserved by adapting its interior for revenue-producing use by offices, a bank, and a restaurant.

THE PEOPLE

Between 1800 and 1900 Boston changed from a relatively simple and homogeneous seaport of some 24,000 inhabitants, mainly of English extraction, to a polyglot city of more than 560,000, of whom about one-half were Irish and one-fifth were from the Canadian Maritime Provinces. After counting smaller groups of immigrants from Russia,

© Steve Solum—Bruce Coleman Inc.



Faneuil Hall Marketplace, Boston.

Italy, Germany, and other European countries, as well as American-born blacks, less than 11 percent of the city's population was of traditional New England origin. The burgeoning of Boston's population in the 19th century was due to seemingly endless waves of immigrants that increased the total by at least one-fourth in each decade from 1810 to 1900; during five decades the increase was more than 40 percent. The greatest increases were 52 percent in the 1830s and 47 percent in the 1840s. Many of the new arrivals, who brought with them experience in trades and crafts, though disembarking at Boston, rapidly moved westward to the expanding frontier, where their skills were in demand. Those with only unskilled labour to offer remained in Boston, crowded into urban slums. As earlier arrivals prospered and moved elsewhere, often outside the city limits, their places were taken by more unskilled immigrants. By the middle of the 19th century, Irish immigrants had taken over the North End, but in the last third of the century it became the centre of the first exclusively eastern European Jewish community in Boston. The residents are now predominantly of Italian descent. Similar changes have occurred in many parts of the city.

Inundation by immigration

In the 20th century the greatly reduced immigration has helped to slow the population increase. Through migration from the South, the black population of Boston has risen, the majority crowded into the decaying Roxbury section.

THE ECONOMY

Finance. Banking, insurance, investment management, and other financial and business-service activities are the chief elements in the economic life of the city. The Federal Reserve Bank of the New England district is located in Boston.

Industry. The chief industries are food processing, clothing manufacturing, printing and publishing, and the fabrication of machinery, transport equipment, and instruments. The greater part of the research-and-development activity that burgeoned after World War II is based in the metropolitan area outside the city limits.

Although Boston continues as a centre of retail trade, much wholesale activity has moved outside the city. The great number of universities and hospitals make higher education and health a significant element in the economic life of Boston. Although only one-fifth of the people in the metropolitan area live in Boston, the city produces almost half of the metropolitan area's goods. A large share of the jobs in Boston are filled by commuters from the suburban area.

Transportation. Public transportation is maintained by the Massachusetts Bay Transportation Authority through a network of subway, elevated, and surface lines. The subway system, begun in 1897, was the first in the country, and, though it has been designated as a historic place, it still works to a useful purpose.

Railroad passenger service to the metropolitan area, once excellent, has badly deteriorated through competition from private automobiles and buses. Such vehicles increasingly choke the city, especially the narrow and winding downtown streets laid out in colonial times. Logan International Airport in East Boston is a busy centre for European as well as domestic flights.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. Boston is governed by a mayor, who is elected for a four-year term, and by a city council of nine members. The government of the Commonwealth of Massachusetts is centred in the State House at the top of Beacon Hill and in other buildings adjacent to the Government Center.

Other federal offices occupy an earlier federal building and the Custom House. Boston is the headquarters of the 1st Naval District, but the Boston Naval Shipyard was closed in 1974.

Education and health. Universities, colleges, and schools of every kind fill several pages in the classified section of the Boston telephone directory. Boston University (founded 1869), Northeastern University (1898), Suffolk University (1906), and the Boston campus of the University of Massachusetts, as well as Simmons (1899), Emmanuel (1919), and Emerson (1880) colleges, are based within the city, as are the Harvard University (1636) faculties of medicine, dentistry, public health, and business administration.

The rest of Harvard, Radcliffe College (1879), and the Massachusetts Institute of Technology (1861) are just across the Charles River in Cambridge. Boston College (1863), a Jesuit institution that is a university in everything except name, is in Chestnut Hill, only a step beyond the city limits. Tufts University (1852), although based in Medford, has its medical school in Boston. Massachusetts General, the oldest of the hospitals, has been joined, among others, by the Beth Israel, Children's, Deaconess, and Brigham and Women's hospitals and the Tufts–New England Medical Center. There are few aspects of higher education or health that are not dealt with somewhere within or close to the city.

Hospitals

CULTURAL LIFE

Boston has a rich and varied cultural life. The city has a repertory theatre group and resident ballet and opera companies; in addition, numerous road companies visit the city. Boston and its environs offer opportunities for all kinds of participatory or spectator sports, including several major-league teams.

The Boston Symphony Orchestra, which was founded in 1881 and performs in Symphony Hall, is one of the foremost orchestras in the world and the chief musical attraction of Boston. The New England Conservatory of Music is nearby, as are other music schools. Chamber music abounds, as does an interest in early music encouraged by the presence of several harpsichord and other instrument makers in the region. The summer Esplanade Concerts at the Hatch Memorial Shell by the Charles River Basin are one of the few outdoor events that have thrived consistently over a long period. Most of the concerts are given by the Boston Pops Orchestra. Overall, however, the cultural life of the city depends more upon colleges, museums, libraries, and small private groups than upon a public proliferation of the performing arts.

The Museum of Fine Arts, a major world gallery incorporated in 1870, preserves and exhibits Oriental, Egyptian, and classical collections of international distinction, as well as important examples of paintings, prints, textiles, and the decorative arts. The Isabella Stewart Gardner Museum in the Fenway is rich in Italian Renaissance painting. Since its arrangement has, under terms of its deed to the city, remained unchanged since the death in 1924 of its creator, Mrs. John Lowell Gardner, in whose home the collection is housed, it is an important monument as well in the history of taste. Across the river at Harvard, there are also a fine arts museum and several museums devoted to science and natural history. The Museum of Science at Science Park, overlooking the Charles River Basin, and the Children's Museum at Museum Wharf are aimed at the instruction of the young.

Museums and galleries

Boston is equally rich in libraries. The Boston Public Library (1854) was the first major instance in the United States of a tax-supported free library. It has been housed since 1895 in a building designed by the architectural firm of McKim, Mead, and White and is a masterpiece of 19th-century American architecture. Its interior decor, including murals by the Frenchman Pierre Puvis de Chavannes (1824–98) and the American John Singer Sargent (1856–1925), is a striking feature. The library, with a fine collection, carries out many of its functions through branches spread throughout the city. The Boston Athenaeum, a proprietary library founded in 1807, the Massachusetts Historical Society, the New England Historic Genealogical Society, the State Library, and the libraries of the colleges and universities provide remarkable resources, while, across the Charles, Harvard has one of the greatest libraries for scholarship in the world.

College crews row on the Charles River, and small boats sail on the wide basin between the Back Bay and the Cambridge shore. Little recreational use has been made of the harbour, however, for in the 19th century Boston turned its back on the sea. The Boston Redevelopment Authority has worked to reverse this trend. The downtown waterfront area contains the New England Aquarium, and a section of the A.G. Charlestown Navy Yard has been made part of the Boston National Historic Park. The fine park system designed by Olmsted has suffered from the encroachments of automobiles, except in the Arnold Arboretum in Jamaica Plain, from which they are excluded.

One of the principal forms of recreation in Boston is just looking at the city. Many thousands of visitors come annually to Boston because of its numerous historic sites and the architectural character of the city. Boston has preserved some colonial buildings and an extraordinary number of fine 19th-century structures, yet in the city and its surroundings may be seen a great variety of the works of the principal American and European architects of the second half of the 20th century.

History

THE COLONIAL PERIOD

Settlement and growth. Boston was settled in 1630 by Puritan Englishmen of the Massachusetts Bay Company, who, for religious reasons, put the Atlantic Ocean between themselves and the Church of England. Ostensibly founded for commercial reasons, the Massachusetts Bay Company, under its governor, John Winthrop (1588–1649), brought its charter—which it regarded as authorization to set up a self-governing settlement in the New England wilderness—along to the New World. The new town was named for Boston in Lincolnshire, the former home of many of the immigrants.

Through necessity rather than choice, New Englanders turned to the sea for a livelihood and became shipbuilders, merchants, seamen, and fishermen because there was little else to do. The Shawmut Peninsula, upon which Boston was settled, was an ideal setting for a seaport. It was described in 1634 by William Wood in his *New England Prospects* as "fittest for such as can Trade into England, for such commodities as the Country wants, being the chiefe place for shipping and Merchandize." With the triumph of the Puritan Party in England in 1648, people moved freely between New England and the homeland, and close ties of family and trade linked Boston and London. By the end of the 17th century, Boston's fleet of seagoing vessels was exceeded only by those of London and Bristol in the English-speaking world. Boston held its place as the largest town in British North America until the middle of the 18th century, when it fell behind the faster growing ports of Philadelphia and New York City.

Political life and revolutionary activity. During its first 50 years Boston was a homogeneous, self-governing Puritan community in which the leaders of the Massachusetts Bay Company ruled as they saw fit. The three Puritan churches, established on the congregational principle, accounted for almost all the organized religion in Boston. Religious dissidents were banished, and some Quakers who persisted in returning were hanged for their pains. Although the increasing prosperity of the colonial merchants made London quite aware of Massachusetts Bay, steps to assert royal authority there were taken only near the end of Charles II's reign, in the 1680s. The company's charter was declared null and void in 1684. In 1686, with the arrival of Sir Edmund Andros as the first royal governor of the Province of Massachusetts Bay, the authority of the crown was established in Boston itself. With this change, the Church of England first came to the town, and the Puritan isolation was over. Although the Congregational clergy, particularly the voluble father–son combination of Increase (1639–1723) and Cotton (1663–1728) Mather, still made themselves heard, the lines of authority had altered.

Protests against British rule

Boston never proved wholly docile. When word of the "Glorious Revolution" of 1688 reached them, the citizens on April 18, 1689, dumped Andros out of office and imprisoned him. The memory of the autonomous first half-century lingered. As London endeavoured to enforce navigation laws and gain revenue from the Boston trade at the expense of the colonies, the aggrieved inhabitants indulged in what they felt to be justified resistance against unlawful authority. After passage of the Stamp Act by Parliament in 1765, disaffection grew, and the governor's house was stormed and gutted, an act that destroyed many irreplaceable records of the colony's history. The Boston Massacre of 1770, in which British troops fired on a crowd of civilian hecklers and killed several persons, and the Boston Tea Party of 1773, in which colonists disguised as Indians dumped three shiploads of tea into Boston Harbor, were key incidents in measuring popular sentiment prior to the Revolution.

With the confrontations and exchange of shots at Lexington and Concord on April 19, 1775, the die was cast. When George Washington's army besieged the British in Boston during the following winter, normal life in the town was suspended. On March 17, 1776, impelled by Washington's artillery positioned on Dorchester Heights, British troops and officials left. They were accompanied by loyal supporters of the crown, including a number of the principal merchants. A constitution was framed in 1780, and John Hancock was elected the first governor of the Commonwealth of Massachusetts.

BOSTON AFTER 1776

Adjustment to independence. New men risen from obscurity by way of political or military service or ventures at sea during the Revolution quickly filled the places left vacant by departed Loyalists. Independence gravely imperilled Boston's maritime trade, for, at the close of the Revolution, Boston merchants automatically became foreigners in the ports of the British Empire. Thus, survival depended on finding new channels of trade. The crisis was solved by sending ships to distant and hitherto unfamiliar ports. The development of the China trade and other new routes, such as those to India, raised Boston to greater prosperity than ever before.

Throughout the first half of the 19th century, maritime commerce produced substantial fortunes, which were supplemented by others achieved in mercantile and manufacturing pursuits without recourse to the sea. Bostonians in the 1810s began to establish textile mills, first at Waltham in 1813 and then in new towns along the Merrimack River, where waterpower was plentiful. The advent of railroads in the 1830s brought these once-distant towns suddenly closer. The burgeoning of Boston's population was due not only to maritime commerce and manufacturing but also to the unanticipated arrival of immigrants from Europe in such numbers that the city grew more than 20-fold during the 19th century. By 1822 the traditional form of government, in which a board of selectmen administered the decisions reached by the vote of all citizens at an annual town meeting, had become unmanageable, and a city charter was obtained from the legislature.

The era of culture. The 19th century also saw Boston assume its focal position in the religious and educational life of the new nation. The rapid and large-scale infusion of immigrant groups and the loss of dominance by the Congregational descendants of the Puritan settlers were major factors in the change. When it was built in 1799, the Church of the Holy Cross was the only Roman Catholic church in town. In 1808 its founder, Jean-Louis Lefebvre de Cheverus, a refugee from the French Revolution, was created the first bishop of Boston, and in 1875, when the see was raised to the dignity of an archdiocese, there were 28 Catholic parishes.

Religious diversity

The religious climate of Protestant Boston also changed dramatically. The Anglican King's Chapel, whose Loyalist rector had left with the British in 1776, became Unitarian in 1787, though not until the first quarter of the 19th century did Unitarian doctrine produce permanent cleavage and splinter organizations in many Congregational churches. The creation in 1825 of the American Unitarian Association, in which William Ellery Channing (1780–1842) took the leading part, transformed into a separate denomination what had previously been the liberal wing of Congregationalism. From "Channing Unitarianism" it was only a step to the philosophy of Transcendentalism, which affected a great part of the region's artistic output and thought for much of the century; to the abolitionist movement championed by the outspoken writer and editor William Lloyd Garrison (1805–79) and others; and to liberal high-mindedness in social causes, which preoccupied many 19th-century Bostonians at a time when others were simply making money with great Yankee diligence. In the second half of the 19th century, the city was also the founding place of Christian Science by Mary Baker Eddy (1821–1910). It remains the site of The Mother Church and the headquarters of this faith, which grew into an international Christian denomination.

Educational and cultural institutions had a similarly rapid growth. Across the Charles River in New Towne, later Cambridge, a college had been founded in 1636 to provide the infant colony with religious scholars and ministers. It was named for the Charlestown minister John Harvard (1607–38), who bequeathed his library to the institution in 1638, and was the sole college in the area until the third quarter of the 19th century. Though Harvard retained the most prestigious position throughout the century, a host of other major institutions of higher learning were founded, and Boston became synonymous nationally with scholarship and cultural refinement. It became also the mecca for persons—from abroad or from the "less civilized" parts of the nation outside New England—who sought these qualities amid the bustling commercialism and rambunctious growth that characterized much of 19th-century America.

Financial growth. The Civil War, in which a majority of Bostonians strongly supported the Union, put an end to shipping as a major consideration in the life of Boston. Shipowners and merchants invested thenceforth in manufacturing, in railroads, and in the development of the rapidly expanding frontier. Banking and investment, with the interplay that they implied with various forms of manufacturing and of business, superseded maritime commerce as the principal occupation of Boston in the second half of the 19th century. In the early 20th century, however, the business horizons contracted. Though large sums of money continued to be invested outside of New England, fewer distant companies were controlled from Boston. The city's financial capital was as strong, but the rising strength of New York City and Chicago and of the developing states of the American West gradually reduced the proportion of capital that Boston could muster. Nevertheless, Boston's financial-management firms showed a skill in investment that caused them to be well regarded in other parts of the country. This led eventually to a major growth of those Boston companies that administered mutual investment funds. Thus, the "prudent man," whether in a private trustee's office or an investment company, has survived as a Boston asset, whereas the textile mills and railroads have proved to be less permanent. The textile industry passed into crisis in the 1920s, and the industrial cities on the Merrimack River, created by Boston investment, entered on decades of hardship. In the following years some mills went out of business entirely, while others moved to the South in search of cheaper labour and raw materials.

Problems in the early 20th century

The first half of the 20th century in Boston was a divisive and unhappy period, for, in addition to corruption in local politics, it included two world wars separated by Prohibition and the Great Depression. After World War I the increase of automobiles led more and more Bostonians to move outside the city limits, with consequent detriment to older central residential districts. Many of the defense industries that sprang up after World War II, based on the imagination of scientists from Harvard, the Massachusetts Institute of Technology, and other centres, were located outside the city limits.

BIBLIOGRAPHY. JUSTIN WINSOR (ed.), *The Memorial History of Boston, Including Suffolk County, Massachusetts, 1630–1880,* 4 vol. (1880–81), is an excellent reference work on most aspects of Boston's history. ELIZABETH M. HERLIHY *et al., Fifty Years of Boston* (1932), is a sequel for the years 1880–1930. WALTER MUIR WHITEHILL, *Boston: A Topographical History,* 2nd ed. (1968), describes the extraordinary physical changes in the city from the settlement to the mid-1960s. KILHAM, *Boston after Bulfinch* (1946); and BAINBRIDGE BUNTING, *Houses of Boston's Back Bay: An Architectural History, 1840–1917* (1967), describe characteristic aspects of Boston's buildings. SAMUEL ELIOT MORISON, *The Maritime History of Massachusetts, 1783–1860* (1921, reprinted 1979); BERNARD BAILYN, *The New England Merchants in the Seventeenth Century* (1955, reissued 1979), and, with LOTTE BAILYN, *Massachusetts Shipping 1697–1714* (1959), give the essentials about Boston shipping. OSCAR HANDLIN, *Boston's Immigrants: A Study in Acculturation,* rev. 2nd enlarged ed. (1959, reissued 1979), deals with the changes brought about by 19th-century immigration. WALTER MUIR WHITEHILL, *Boston Public Library: A Centennial History* (1956), and *Museum of Fine Arts, Boston: A Centennial History,* 2 vol. (1970), describe two pioneering institutions. MICHAEL P. CONZEN and GEORGE K. LEWIS, *Boston: A Geographical Portrait* (1976), gives an overview of the metropolitan area and of the dramatic changes in its demographics and land use. WALTER MUIR WHITEHILL, *Boston in the Age of John Fitzgerald Kennedy* (1966), briefly deals with the institutions that make modern Boston a centre of civilization. DAVID MCCORD, *About Boston* (1948, reissued 1973), is a poetic evocation of the sights and sounds of the city. (W.M.Wh./G.K.L.)

The House of Bourbon

The House of Bourbon (Spanish Borbón, Italian Borbone) is one of the greatest of the sovereign dynasties of Europe. It provided reigning kings of France from 1589 to 1792 and from 1814 to 1830, after which another Bourbon reigned as king of the French until 1848; kings or queens of Spain from 1700 to 1808, from 1814 to 1868, from 1874 to 1931, and since 1975; dukes of Parma from 1731 to 1735, from 1748 to 1802, and from 1847 to 1859; kings of Naples and of Sicily from 1734 to 1808 and of the Two Sicilies from 1816 to 1860; kings of Etruria from 1801 to 1807; and ducal sovereigns of Lucca from 1815 to 1847. The present article attempts a rapid survey of the dynasty as a whole, relying mainly on genealogical tables to display necessary details. In these tables the names and titles of sovereigns are mostly anglicized, but those of other persons are mostly given in the original form, except where princesses, having married into another country, are better known under that country's name for them. The tables also omit perforce the Bourbon bastards, whose multitude lends some colour to the popular notion that the "Bourbon nose" (larger and more prominent than the normal aquiline) betokens a "Bourbon temperament" or enormous appetite for sexual intercourse.

Origins. The House of Bourbon is a branch of the House of Capet, which constituted the so-called third race of France's kings. King Louis IX, a Capetian of the "direct line," was the ancestor of all the Bourbons through his sixth son, Robert, comte de Clermont (see Table 1). When the "direct line" died out in 1328, the House of Valois, genealogically senior to the Bourbons, prevented the latter from accession to the French crown until 1589. The Valois, however, established the so-called Salic Law of Succession, under which the crown passed through males according to primogeniture, not through females. On this principle, the senior Bourbon became the rightful king of France on the extinction of the legitimate male line of the Valois.

The first ducs de Bourbon

Robert de Clermont had married the heiress of the lordship of Bourbon (Bourbon-l'Archambault, in the modern *département* of Allier). This lordship was made a duchy for his son Louis I in 1327 and so gave its name to the dynasty. From this duchy, the nucleus of the fu-

Table 1: The Bourbon Descent from Louis IX of France

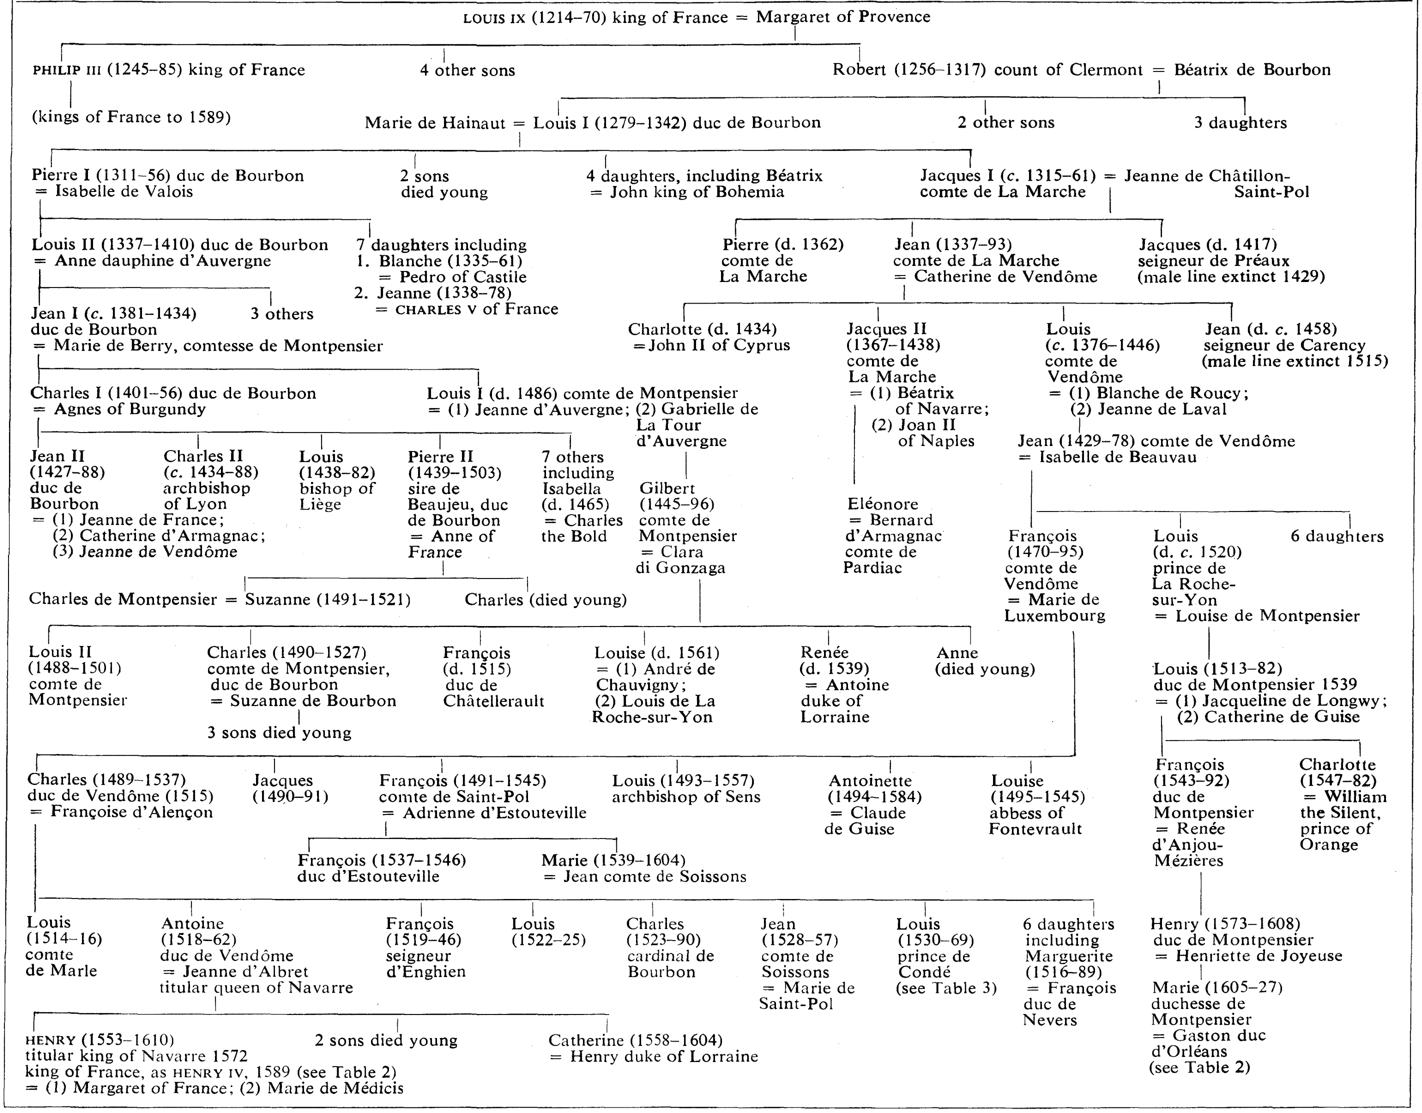


Table 2: The Bourbon Kings of France, with the House of Orléans to 1830

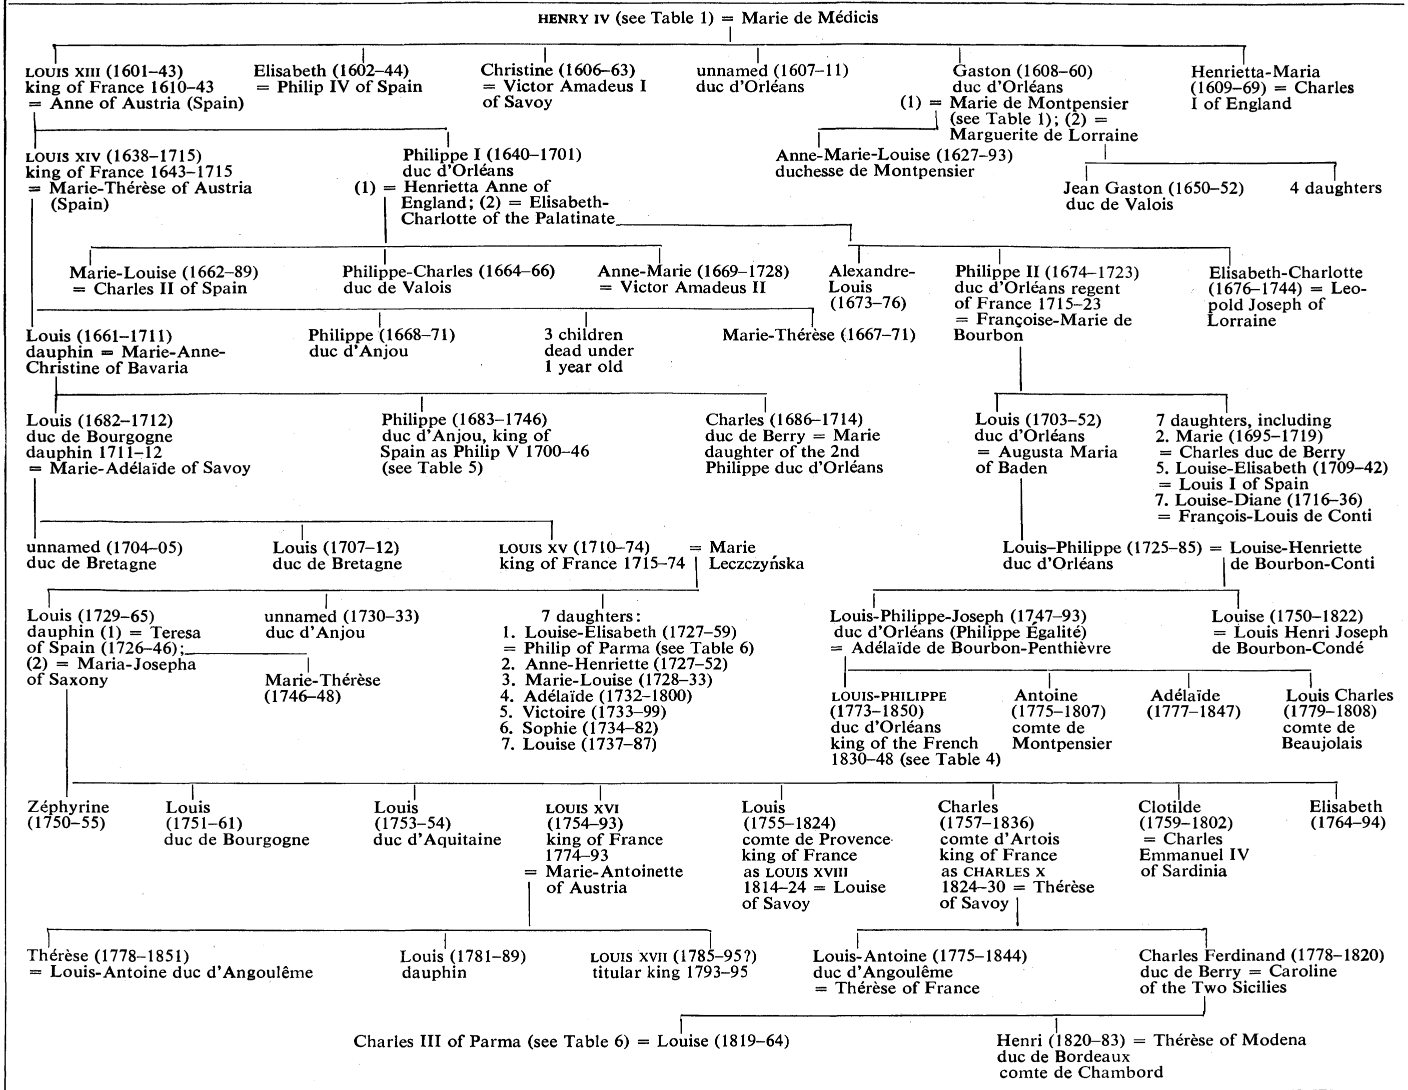


ture province of Bourbonnais, the elder Bourbons, mainly through marriages, expanded their territory southeastward and southward. On their western frontier, meanwhile, the countship of La Marche (acquired by Louis I in 1322 in exchange for Clermont) was held from 1327 by a junior line of Louis I's descendants, who soon added the distant countship of Vendôme to their holdings.

The title of duc de Bourbon passed in 1503 to Charles de Bourbon-Montpensier, who was to become famous as constable of France. His later treason led to the confiscation of his lands by the French crown in the year of his death, 1527. Headship of the House of Bourbon then passed to the line of La Marche-Vendôme (see again Table 1).

The line of La Marche-Vendôme had been subdivided since the end of the 15th century between a senior line, that of Vendôme (with ducal rank from 1515 onward), and a junior one, that of La Roche-sur-Yon. The latter line obtained Montpensier from the constable's forfeited heritage (with ducal rank from 1539).

The French kingdom

Antoine de Bourbon, duc de Vendôme and head of the House of Bourbon from 1537, became titular king-consort of Navarre in 1555 through his marriage in 1548 to Jeanne d'Albret. The son of that marriage, titular king of Navarre in succession to his mother from 1572, became king of France, as Henry IV, on the death of the last Valois king in 1589. From Henry IV descend all the Bourbon sovereigns (see Tables 2 and 4–7). The great House of Condé, with its ramifications of Soissons and of Conti (see Table 3), was descended from Louis, prince de Condé, one of Henry IV's uncles.

The Bourbon sovereignties. Henry IV's heirs were kings of France uninterruptedly from 1610 to 1792, when the monarchy was "suspended" during the first Revolution. Most illustrious among them was Louis XIV, who brought absolute monarchy to its zenith in western Europe. Table 2 displays (1) the senior line of Bourbon, or House of France, as descended from Henry IV, the succession running directly down to Louis XVII (who was titular king only and never reigned), and thereafter being resumed in the latter's uncle, Louis XVIII (brought to the throne in 1814 and again in 1815), Charles X, and the pretender Henry V (the comte de Chambord); (2) the connection, through Louis XIV's grandson Philippe, duc d'Anjou, of the Spanish Bourbons with the House of France; and (3) the descent of the collateral House of Orléans from Louis XIV's brother Philippe I to Louis-Philippe, king of the French. Louis-Philippe's descendants, including not only the potential pretenders to the French succession but also the Bourbon descendants of the heiress of the last emperor of Brazil, are shown in Table 4. The last-mentioned princes constituted the House of Bourbon-Brazil, or of Orléans-Braganza, which is not to be confused with the House of Borbón-Braganza, a Spanish branch originating in the Portuguese marriage of the infante Don Gabriel (a son of Charles III of Spain; see Table 5).

Accession in Spain

The Bourbon accession to Spain came about partly because the descendants of Louis XIV's consort, the Spanish infanta Marie-Thérèse, were in 1700 the closest surviving relatives of the childless Charles II of Spain (see HABSBURG; SPAIN); and partly because, although at her

Table 3: Condé, Conti, and Soissons

Louis I (1530–69) prince de Condé (see Table 1)
= (1) Eléonore de Roye; (2) Françoise d'Orléans-Longueville

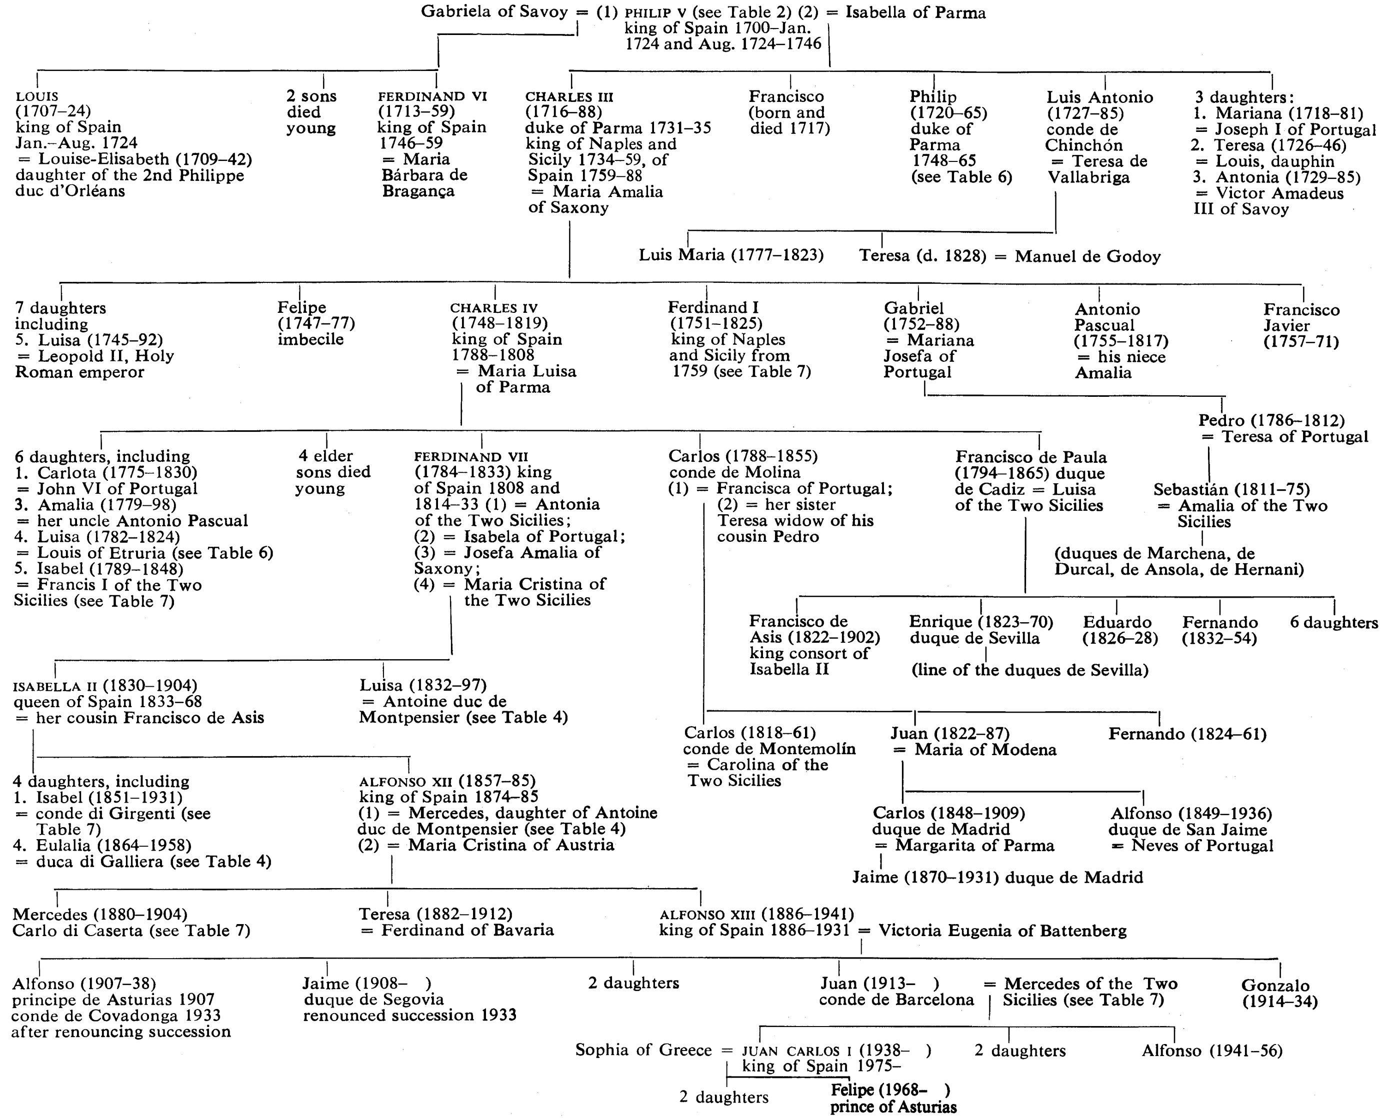
- Henry I (1552–88) prince de Condé = (1) Marie de Clèves-Nevers; (2) Charlotte de La Trémoille
  - Catherine (1574–95)
  - Eléonore (1587–1619) = Philip William of Orange-Nassau
  - Henry II (1588–1646) prince de Condé = Charlotte de Montmorency
    - Anne-Geneviève (1619–79) = Henri d'Orléans duc de Longueville
    - Louis II (1621–86) duc d'Enghien till 1646, then prince de Condé = Claire-Clémence de Maillé-Brézé
      - Henri-Jules (1643–1709) prince de Condé = Anne of Bavaria daughter of Edward of the Palatinate
        - Henri (1657–70)
        - Louis III (1668–1710) duc de Bourbon = Louise-Françoise legitimated daughter of Louis XIV
          - Louis-Henri (1692–1740) duc de Bourbon = (1) Marie-Anne de Bourbon-Conti; (2) Charlotte of Hesse-Rheinfels
            - Louis-Joseph (1736–1818) prince de Condé = Godefride de Rohan-Soubise
              - Louis-Henri-Joseph (1756–1830) duc de Bourbon = Louise d'Orléans (1750–1822; see Table 2)
                - Louis-Antoine (1772–1804) duc d'Enghien
              - Louise-Adélaïde (1757–1824) Benedictine nun
          - 2 other sons: 1. Charles (1700–60) comte de Charolais; 2. Louis (1707–71) comte de Clermont
          - 6 daughters including 2. Louise-Elisabeth = Louis-Armand II prince de Conti
        - 2 sons died in infancy
        - 6 daughters including
          1. Marie-Thérèse (1666–1732) = François-Louis de Bourbon-Conti
          4. Anne-Louise-Bénédicte (1676–1753) = Louis-Auguste duc du Maine legitimated son of Louis XIV
          5. Marie-Anne (1678–1718) = Louis-Joseph duc de Vendôme
      - 2 sons died in infancy
    - Armand (1629–66) prince de Conti = Anne-Marie Martinozzi niece of Cardinal Mazarin
      - 1 son died in infancy 1658
      - Louis-Armand I (1661–85) prince de Conti = Marie-Anne legitimated daughter of Louis XIV
      - François-Louis (1664–1709) comte de La Marche 1677–85, then prince de Conti = Marie-Thérèse de Bourbon-Condé
        - Louis-Armand II (1695–1727) prince de Conti = Louise-Elisabeth de Bourbon-Condé
          - Louis-François (1717–76) prince de Conti = Louise-Diane (1716–36) daughter of the regent duc d'Orléans (see Table 2)
            - Louis-François-Joseph (1734–1814) prince de Conti = Maria Fortunata d'Este
          - 3 sons died in infancy
          - Louise-Henriette (1726–59) = Louis-Philippe (1725–85) duc d'Orléans (see Table 2)
        - 3 sons died in infancy and 3 daughters, including 1. Marie-Anne (1689–1720) = Louis-Henri duc de Bourbon
- François (1558–1614) prince de Conti = (1) Jeanne de Coësme; (2) Marguerite de Guise
- Charles (1562–94) cardinal de Vendôme
- 5 others
- Charles (1566–1612) comte de Soissons = Anne de Montafié
  - Louis (1604–41) comte de Soissons
  - 3 daughters:
    1. Louise (1603–37) = Henri d'Orléans duc de Longueville;
    2. Marie (1606–92) = Thomas de Savoie prince de Carignan;
    3. Charlotte-Anne (1608–23)
- 2 sons died young

Table 4: The House of Orléans from 1830

LOUIS-PHILIPPE (see Table 2) king of the French 1830–1848 = Marie-Amélie of the Two Sicilies (see Table 7)

- Ferdinand (1810–42) duc d'Orléans 1830–42 = Helena of Mecklenburg-Schwerin
  - Louis-Philippe-Albert (1838–94) comte de Paris = Isabel daughter of Antoine duc de Montpensier
    - Louis-Philippe-Robert (1869–1926) duc d'Orléans = Maria of Austria
    - 4 daughters
    - Ferdinand (1884–1924) duc de Montpensier
  - Robert (1840–1910) duc de Chartres = Françoise de Joinville
    - 2 daughters
    - Robert (1866–83)
    - Henri (1867–1901)
    - Jean (1874–1940) duc de Guise = Isabelle daughter of comte de Paris
      - Henri (1908–) comte de Paris = Isabelle of Orléans-Braganza
        - Henri (1933–) comte de Clermont = Marie-Thérèse of Württemberg
          - François (1961–)
          - Jean (1965–)
          - 2 daughters
        - 4 other sons
        - 6 daughters
      - 3 daughters
- Louis (1814–96) duc de Nemours = Victoria of Saxe-Coburg
  - Gaston (1842–1922) comte d'Eu = Isabela (1846–1921) heiress of Pedro II of Brazil
    - Pedro (1875–1940) renounced succession 1908
      - Henri comte de Paris = Isabelle (1911–)
      - 4 others
    - Luis (1878–1920) = Pia, daughter of Alfonso di Caserta (see Table 7)
      - Pedro Enrique (1909–) = Maria of Bavaria
        - 6 sons
    - Antonio (1881–1918)
  - Ferdinand (1844–1910) duc d'Alençon = Sophia of Bavaria
    - 1 daughter
    - Emmanuel (1872–1931) duc de Vendôme, duc d'Alençon = Henriette of Belgium
      - 3 daughters
      - Charles Philippe (1905– duc de Nemours = Marguerite Watson
- François (1818–1900) prince de Joinville = Francesca of Brazil
  - Françoise (1844–1925) = duc de Chartres
  - Pierre (1845–1919) duc de Penthièvre
- Charles (1820–29) duc de Penthièvre
- Henri (1822–97) duc d'Aumale = Carolina daughter of principe di Salerno (see Table 7)
  - Louis (1845–66) prince de Condé
  - François (1854–72) duc de Guise
- Antoine (1824–90) duc de Montpensier = infanta Luisa (see Table 5)
  - Fernando (1859–73)
  - Antonio (1866–1930) duca di Galliera = infanta Eulalia (see Table 5)
    - 2 sons
  - Luis (1867–74)
  - 3 daughters, including
    2. Isabel (1848–1919) = comte de Paris
    3. Mercedes (1860–78) = Alfonso XII of Spain
- 3 daughters:
  1. Louise (1812–50) = Leopold I of the Belgians
  2. Christine (1813–39) = Frederick William of Württemberg
  3. Clementine (1817–1907) = Augustus of Saxe-Coburg

Table 5: The Spanish Bourbons



marriage the Infanta had renounced her Spanish rights, Charles by his testament named one of her descendants as his successor. Since the other powers, however, would not have tolerated the union of the Spanish kingdom with the French, Charles named neither Louis XIV's heir apparent nor the latter's eldest son but, rather, the second of Louis XIV's grandsons, namely Philippe duc d'Anjou, who became king of Spain as Philip V. After the War of the Spanish Succession, the Peace of Utrecht (1713) left Philip in possession of Spain and Spanish America but obliged him to renounce any natural right that he or his descendants might have to France. Table 5 shows how the Spanish Bourbons all descend from Philip V; it also shows the origin of the branches of Parma and of Naples-Sicily.

Parma and Naples-Sicily

The infante Don Carlos, the future Charles III of Spain, was the founder of the Bourbon fortunes in Italy. The eldest son of Philip V's second marriage, he became duke of Parma in 1731 by right of his mother, heiress of the last Farnese dukes; and in 1734, during the War of the Polish Succession, he conquered the Kingdom of Naples-Sicily (Kingdom of the Two Sicilies) for himself. Though the settlement of 1735–38 obliged him to renounce Parma in order to win international recognition as king of Naples-Sicily, Parma was eventually secured for his brother Philip (Don Felipe) under the Treaty of Aix-la-Chapelle in 1748—with the proviso, however, that he and his heirs should renounce it in the event that they succeeded to Naples-Sicily or to Spain. Finally, when Don Carlos became king of Spain as Charles III in 1759, he resigned Naples-Sicily to his third son Ferdinand on the express condition that that kingdom and Spain should never be united under one sovereign.

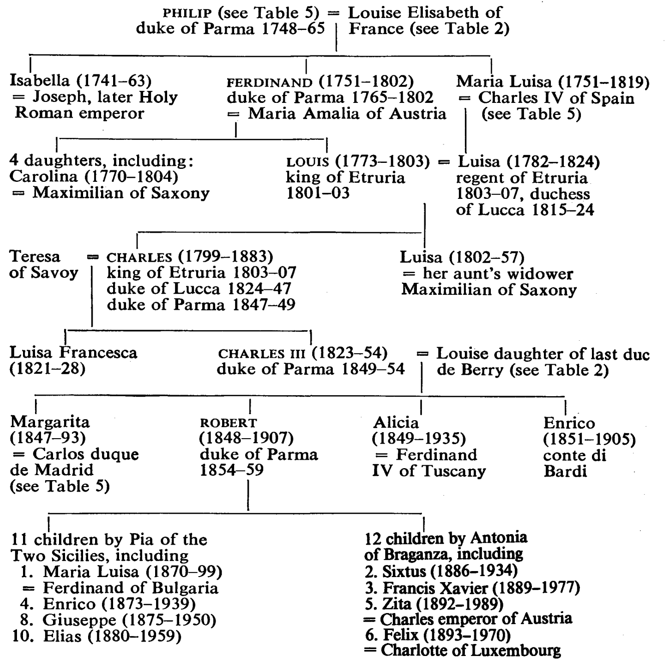
Table 6 shows the descendants of Philip of Parma, Table 7 those of Ferdinand I of Naples-Sicily.

Etruria and Lucca

The Kingdom of Etruria (1801–07) was a contrivance of the Napoleonic period. Devised by the French for the House of Bourbon-Parma in compensation for the impending annexation of Parma to France at a time when France still needed the goodwill of the Spanish Bourbons, it was dissolved as soon as Napoleon was ready to depose the latter. The Bourbon Duchy of Lucca (1815–47), on the other hand, was a creation of the Congress of Vienna: having assigned Parma to Napoleon's estranged consort Marie-Louise for her lifetime, the Congress had to find some alternative compensation for the still-dispossessed Bourbons. The Treaty of Paris of 1817, however, prescribed that on Marie-Louise's death Parma should revert to the Bourbons, who in 1847 renounced Lucca to the Habsburgs of Tuscany nine weeks before succeeding her (see again Table 6).

In France, the senior or "legitimate" line of the Bourbons, restored to sovereignty in France after the Napoleonic Wars, was deposed at the Revolution of 1830. The House of Orléans, which took the legitimate line's place, was in turn deposed in the Revolution of 1848. The Bourbons of Parma and of the Two Sicilies were dethroned in 1859–60,

Table 6: The Bourbons of Parma



in the course of the unification of Italy under the House of Savoy. The Spanish Bourbons, after many disturbances in the 19th century, lost their sovereignty in 1931; but the Law of Succession promulgated in Spain in 1947 and General Franco's subsequent choice of Don Juan Carlos as his successor (see again Table 5) resulted in the reign of Juan Carlos I, beginning in 1975.

Solidarity and discord. The accession of the duc d'Anjou to Spain would never have been secured without the resolute support of his grandfather, the French king; and similarly the Bourbon sovereignties in Italy owed their establishment chiefly to the Bourbon power in Spain. Dynastic harmony between France and Spain, however, was momentarily suspended in 1718–20, when France took part in the War of the Quadruple Alliance against Spain—for reasons arising in part from the internal affairs of the House of Bourbon. A series of sudden deaths in the French Royal House between 1704 and 1714 had produced a situation in which, on Louis XIV's death in 1715, no one but a five-year-old child, Louis XV, stood before Philip V of Spain in the natural line of succession of France; and Philip, though he had renounced that succession, still felt himself better entitled, as the child's uncle, to exercise the regency in France than the child's cousin twice removed, Philippe duc d'Orléans, against whom Spanish agents promoted a plot. The marriage (1722) of the Spanish king's son to a daughter of the French regent sealed the reconciliation.

Treaty of the Escorial

In 1733 the Treaty of the Escorial pledged the French and the Spanish Bourbons to collaborate with each other notwithstanding any previous obligations. This treaty and the similarly conceived Treaty of Fontainebleau (1743) are sometimes called the "First" and the "Second Family Compact"; and the term Family Compact, or Pacte de Famille, was actually used in a third treaty, signed in Paris in 1761, during the Seven Years' War. By this last treaty France and Spain not only guaranteed one another against all enemies but also promised like protection to the Bourbon states in Italy in the event of their acceding to the compact; and no state not belonging to the House of Bourbon was to be allowed to accede.

The cooperation between the French and Spanish Bourbons came to a miserable end during the French Revolutionary and Napoleonic Wars, and the later decades of the 19th century brought new complications. A French Bourbon prince led a force into Spain in 1823 to crush the liberalism to which Ferdinand VII was succumbing; but such Bourbon solidarity could not survive two events which were to rend both the Spanish and the French houses.

First, in March 1830, Ferdinand VII of Spain announced the revocation of the Salic Law of Succession, which Philip V had introduced into Spain in 1713. This meant that the sonless Ferdinand could be succeeded not by his brother Don Carlos conde de Molina but by his elder daughter Isabella (born after the revocation); and though Ferdinand temporarily reinstated the Salic Law in September 1832, he revoked it again 13 days later. On his death in 1833 the partisans of the disappointed Don Carlos started the first of the Carlist Wars in protest against Isabella's accession (see again SPAIN).

Carlism and the House of Orléans

Secondly, in France, the July Revolution of 1830 overthrew the "legitimate" Bourbon monarchy and transferred the throne to Louis-Philippe, head of the collateral line of Orléans. Odious enough already because Louis-Philippe's father, the self-styled Philippe Égalité, had voted in 1793 for the death sentence on Louis XVI, the House of Orléans became, by the usurpation of 1830, so much more odious to the Legitimists that some of the latter, when the "legitimate" male of France died out with the comte de Chambord in 1883, declined to recognize the head of the House of Orléans as the rightful pretender to France, as indeed he now was if the renunciation of 1713 was still to be observed (see again Tables 3 and 4); instead they preferred to disregard that renunciation and so to regard a Spanish prince as their rightful king. These Legitimists were known in France as "Blancs d'Espagne" ("Spanish Whites"). Most Legitimists, however, followed the final advice of the comte de Chambord by recognizing the rights of the House of Orléans to France.

While the dispossessed Bourbons—Spanish Carlists and French Legitimists—naturally sympathized with each other, their opponents—Queen Isabella and the House of Orléans—conversely gravitated together. One result was the crisis of the "Spanish Marriages" in the 1840s. While both Queen Isabella and her sister Luisa remained unmarried, the Spanish succession was an open prospect of great interest to governments concerned with maintaining the balance of power in Europe. If both sisters had married princes of the House of Orléans, as Louis-Philippe and the sister's mother, Maria Cristina, had originally suggested, French influence over Spain would have become too strong for the liking of the British government, which proposed instead that Isabella should marry Prince Leopold of Saxe-Coburg (more intimately linked with Great Britain than with France). Then, in 1843, the French and the British came to an understanding: Isabella should marry some "neutral" prince, preferably a Spanish Bourbon cousin; and only after the birth of a child to Isabella should Luisa marry Louis-Philippe's son Antoine duc de Montpensier. Of Isabella's eligible cousins, the conte de Montemolín was disfavoured by the Spanish government as a Carlist; the next senior was the doubtfully virile Don Francisco de Asis, who was generally thought unlikely to become a father; the third was Don Enrique duque de Sevilla, whose outspoken liberalism recommended him to the British government but not to the Spanish. Inadvertently, however, the British government in 1846 gave the French the impression that it was still secretly trying to press Prince Leopold on Spain, and the French reacted by arranging the Spanish marriages in a way quite contrary to British desire: Isabella and Luisa were married on the same day, October 10, 1846, to Don Francisco de Asis and to Montpensier, respectively. The immediate upshot was that the House of Orléans, apparently intending that Montpensier or a son of his should eventually be king of Spain, incurred the serious resentment of its former friends in Great Britain.

Isabella, who would have preferred to marry Don Enrique, spent conspicuously long periods apart from her consort and behaved indiscreetly with other men. When she bore a son in 1857, ill-wishers had little difficulty in casting doubts on his paternity. These doubts served the purposes of the extreme Carlists when the male line of Don Carlos died out in 1936, because they could argue that Isabella's male descendants were not those of Don Francisco de Asis—whose issue, under Salic Law,

Carlism and Bourbon-Parma

would have been the next male heirs. Nearly all the other Bourbon princes, however, either had already recognized Isabella's rights or were maintaining incompatible pretensions to other thrones. The Carlists therefore had to look far afield in their search for a new pretender.

Certain princes of Bourbon-Parma responded to Carlist overtures but did not at the same time renounce their Parmesan titles, which under the settlement of 1748 were incompatible with claims to sovereignty over Spain. Thus they incurred the displeasure of the House of Orléans, which had to respect the settlement of 1748 because its own pretension to France depended on the analogous settlement of 1713.

BIBLIOGRAPHY. An introduction is provided by SANCHE DE GRAMONT, *Epitaph for Kings* (1968). Those interested in genealogy many readily consult HENRI VRIGNAULT, *Généalogie de la maison de Bourbon,* 2nd ed. rev. (1957), with 12 tables, and, on the bastard branches, *Légitimés de France de la maison de Bourbon de 1594 à 1820* (1965). Vrignault's work of 1957 may be brought up to date through the successive volumes of the periodical *Genealogisches Handbuch des Adels,* series "Fürstliche Häuser," whose first article "Bourbon" appeared in 1953 (vol. 2 of the series, 3 of the collection). While the story of the French Bourbon sovereigns is too vast to be resumed collectively in any single work other than a history of France, there are helpful works in English on the Spanish Bourbons and on the Neapolitan: SIR CHARLES PETRIE, *The Spanish Royal House* (1958); supplemented by THEO ARONSON on the Carlist question, *Royal Vendetta: The Crown of Spain, 1829–1965* (1966); and HAROLD ACTON, *The Bourbons of Naples, 1734–1825* (1956, reprinted 1974), and *The Last Bourbons of Naples, 1825–1861* (1961). JOHN D. BERGAMINI, *The Spanish Bourbons* (1974); and DESMOND SEWARD, *The Bourbon Kings of France* (1976), are works for the general reader. On the physiological aspect, the reader may first consult ANDRÉ DE MARICOURT and MAURICE DE BERTRANDFOSSE, *Les Bourbons, 1518–1830: hérédités, pathologie, amours et grandeur* (1936).

(J.R.-S./Ed.)

Brazil

The Federative Republic of Brazil (Portuguese: República Federativa do Brasil), the fifth largest country in the world, is exceeded in size only by the Soviet Union, Canada, China, and the United States. It covers an area of 3,286,487 square miles (8,511,965 square kilometres), or about half of all South America. Brazil is so vast that, although it faces the Atlantic Ocean along 4,600 miles (7,400 kilometres) of coastline, it also borders on every nation of the South American continent except Chile and Ecuador. Stretching for approximately 2,700 miles from north to south and from east to west, it contains no desert, high mountain, or Arctic environments that limit the extent of human occupancy.

Most of the inhabitants of Brazil, the world's sixth most populous nation, are concentrated along the eastern seaboard. Its national capital, Brasília, however, is located inland, on the outer edge of intensive settlement. Planned from scratch, Brasília replaced Rio de Janeiro as the capital in 1960. Unique among the nations of the Americas, this former colony of Portugal did not become fragmented into separate countries, as did the British and Spanish possessions, but retained its identity through the intervening centuries and a variety of forms of government. The Portuguese language is, therefore, universal except among a few thousand native Indians in the most remote reaches of the Amazon River system.

The physical and human features of this broad land are rich and various. Because the greater part of the Amazon Basin lies within Brazilian territory, scientists from throughout the world are attracted to the region to study the Earth's largest river system and most extensive virgin rain forest. Brazil has enormous expanses of untouched tropical forest and sparsely settled savannas with a scattering of isolated villages. It is a land rich in national resources whose burgeoning cities, huge hydroelectric and industrial complexes, mines, and fertile farmlands have placed it among the world's most productive countries. In contrast, however, Brazil is also a country that has had to struggle with a rapidly growing population, an unstable economy, soaring inflation, and a highly volatile political life.

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief. The country can be readily described in terms of its highlands and their adjoining lowlands, which are separated from each other by an almost continuous series of physical barriers, the most impressive being the Great Escarpment.

The Great Escarpment. The massive fault block called the Great Escarpment extends for 1,600 miles along the eastern coast. From Rio de Janeiro southward it is known as the Serra do Mar; this segment of the Great Escarpment, presenting an almost sheer face to the sea, averages about 3,000 feet (1,000 metres) in elevation. It is flanked on the east by the tips of lower fault blocks, including Rio de Janeiro's Sugar Loaf (Pão de Açúcar) and Gávea mountains, and a string of islands, including the large ones of Santa Catarina, São Sebastião, and Grande.

Serra do Mar

Northward from Rio de Janeiro the escarpment breaks into a series of highly faulted and fractured blocks characterized by deep, steep-sided valleys ringed by high, rounded peaks and nearly vertical slabs of bare rock. It is known variously as the Orgãos Mountains northwest of Rio de Janeiro, the Aimorés Mountains along the Minas Gerais-Espírito Santo border, and, in Bahia, as the Geral Mountains. The barrier finally ends in a low scarp. Elsewhere, the escarpment ends in a rim marked by fall lines, where the rivers, forming rapids and waterfalls, plunge onto the coastal lowlands.

Lowlands. The Brazilian lowlands are composed largely of three principal regions: the Amazon lowlands, the west-central Pantanal, and the coastal lowlands. The largest of these regions by far is the Amazon lowlands, the greater proportion of which consists of the hilly *terra firme,* land composed of alluvium that was deposited as much as 2,500,000 years ago and uplifted to its present position above flood level. The most striking lowland features, however, are the annually flooded plains, or *várzeas,* along the Amazon and the Paraguay river systems. The widely dispersed grasslands of the Amazon lowlands exhibit conditions of monotonously low relief, but the active floodplains that border the Amazon River and its tributaries comprise a complex of features; these range from shallow lakes and swamps occupying old watercourses, through

mangrove woods in the tidal flats of the delta, to newly deposited land built up on the inner sides of river bends and low but fertile and well-drained levees that may be inundated for only a few weeks each year.

The Pantanal

The region called the Pantanal, an extension of the Gran Chaco plain, is an area of swamps and marshes in northwestern Mato Grosso do Sul and southern Mato Grosso states; it is dissected by the upper Paraguay river system. Noted for its striking natural beauty and its rich wildlife, the Pantanal covers an area of some 39,000 square miles. During the rainy season the Paraguay overflows its banks, spreading great sheets of water that leave only the tops of scattered levees and low hills dry.

The Atlantic lowlands, which range up to 125 miles in width in the north and narrow and finally disappear to the south, provide a wide variety of relief features: level floodplains, levees, swamps, lagoons, sand dunes, and mile after mile of white, sandy beaches here and there protected by offshore coral reefs. Where the rocky slopes of the Great Escarpment plunge directly into the ocean, there are various deep harbours. Some of the most famous harbours are Guanabara Bay, on which Rio de Janeiro and Niterói are situated, and All Saints Bay, on which Salvador is located. The Amazon itself provides deep water for oceangoing ships as far inland as Manaus and for smaller ships as far as Iquitos in eastern Peru. Another lowland feature is the older uplifted tertiary floodplain that is known as the Amazon Plateau in the north and the Barreiras Formation along the coast; it has heavy clay beds that form a nearly level surface and intermittently abut the rim of the highlands.

The highlands. The highlands, which make up the bulk of Brazil's landmass, include the Brazilian, or Central, Highlands (which are also called Planalto Central) and the country's share of the Guiana Highlands in the far north. By far the largest in area is the Brazilian Highlands. During the Paleozoic Era these highlands were peneplained—that is, they were worn down to an ancient sea level and then uplifted to their present elevation. The topography of this surface varies from level-topped plateaus, through rolling hills, to deeply incised valleys, above which rise the dissected relics of once-mighty mountain ranges that are the source of most of Brazil's abundant and varied mineral wealth.

Although none of these relic ranges is particularly high in elevation, nowhere surpassing 10,000 feet, the local relief is often extreme and the land exceptionally rugged. The Mantiqueira Mountains in southern Minas Gerais reach 9,143 feet at the Agulhas Negras Peak on the Rio de Janeiro state border, and 9,482 feet at Bandeira Peak, one of Brazil's highest points, near the Aimorés Mountains. The Espinhaço Mountains extend from central Minas Gerais into southern Bahia, where Almas Peak reaches 6,070 feet. Along the Venezuelan border Mount Roraimã attains 9,432 feet in the Guiana Highlands, and Neblina Peak, discovered in 1962, reaches 9,888 feet (3,014 metres), the highest point in Brazil.

The erosion of these and other ranges at various times deposited thick beds of sedimentary rock along the outer margins of the central core. In the south these earlier formations have been buried by diabase lava flows, abutting against the rim of the Great Escarpment and extending southward as the Geral Mountains (not the same as those of Bahia). In the west the diabase ends in a steep rim over which the Iguaçu River tumbles to form the spectacular Iguaçu Falls just before converging with the Paraná River. The Guaíra Falls were a similar attraction until the huge hydroelectric dam at Itaipú was built downstream on the Paraná River, causing the falls to be submerged.

Major river systems

Drainage. The Brazilian Highlands are drained by three major river systems, the great Amazon system in the north, the Paraguay–Paraná–Plata system in the south, and the São Francisco, which flows to the northeast. The major systems all drain into the Atlantic Ocean, as do a number of smaller rivers in the east.

The Amazon River rises from a point in the Peruvian Andes, within 100 miles of the Pacific Ocean, whence its course meanders about 4,000 miles to the Atlantic, into which it spills some 20 percent of all the Earth's fresh water. Its succession of great tributaries includes the Tocantins–Araguaia, the Xingu, the Tapajós, and the Madeira on the southern side, and the Negro River on the northern side. The Amazon lowland has the peculiarity of being widest along the eastern base of the Andes. It becomes narrower toward the east, until, east of Manaus, only a narrow ribbon of floodplain separates the Guiana Highlands to the north from the Brazilian Highlands to the south. The floodplain opens up again as it approaches the Atlantic. The Amazon is navigable all the way into eastern Peru, but the tributaries are all interrupted by falls and rapids where they descend from the highlands. In contrast to the Paraguay–Paraná–Plata system, that of the Amazon River has not been harnessed for power production except at the Tucuruí Dam, which was built in the mid-1980s across the Tocantins River south of Belém and near the Carajás Grande mining complex.

The second of the great river systems of Brazil is that of the Paraguay–Paraná–Plata. From southwestern Minas Gerais southward, the highlands are drained into the Paraná, eventually reaching the sea through the Río de la Plata. Brazil's two southernmost states are drained through the Uruguay River also to the Plata. These rivers in Brazil are navigable only for short stretches.

São Francisco River

The São Francisco River, the largest river wholly within Brazil, is the third of the country's great river systems. The São Francisco rises in the Brazilian Highlands in western

Union Press/Bruce Coleman, Inc., New York City

Canoe on the Negro River in the Amazon rain forest, Amazonas state, northern Brazil.

Minas Gerais and southern Goiás, inland from Rio de Janeiro. It flows for more than 1,000 miles northward into the state of Bahia and the border of Pernambuco before it turns eastward to the Atlantic Ocean. The river is navigable for shallow-draft riverboats between Pirapora in Minas Gerais north of Belo Horizonte and Juàzeiro in Bahia. Below Juàzeiro the river current becomes swifter as it approaches the Paulo Afonso Falls. Only the lower river is navigable for ocean ships.

Numerous rivers drain directly into the Atlantic eastward from the Brazilian interior, but, although they pass through the most populated part of the country, most of them are too short, steep, or unreliable even for hydroelectric developments, much less for water-borne traffic. The Paranaíba in the state of Piauí and the Jacuí in Rio Grande do Sul are the most important of these for navigability.

Climate. Brazil has a humid tropical and subtropical climate except for a semiarid area in the northeast, sometimes called the drought quadrilateral or drought polygon, that extends from northern Bahia to the coast between Natal and São Luís and receives only between 15 and 30 inches (375 and 750 millimetres) of precipitation a year. Most of the rest of the country gets a moderate amount of rainfall, between 40 and 70 inches a year; exceptions to this are certain parts of the Amazon Basin and the sea-facing rim of the Serra do Mar, where the rains are much heavier.

Average temperatures

Temperatures in Brazil are remarkably uniform during the summer months (November to April), averaging about 79° F (26° C) over most of the lowlands in January, and a few degrees less in the highlands, depending upon elevation. The coast of Rio Grande do Sul is also somewhat cooler, averaging around 73° F (23° C), whereas the interior of the drought quadrilateral, the hottest region of the country, averages about 84° F (29° C), with daytime temperatures over 100° F (38° C) in summer. Winter temperatures (May to October) in the Amazon lowland remain virtually unchanged from those of the summer months, but they drop to about 79° F (about 26° C) in the drought quadrilateral. In the Brazilian Highlands winter temperatures are about 68° F (20° C) and are even lower toward the south where Curitiba, at 3,000-feet elevation, averages 57° F (14° C) in June and July. The mean for those months at Pôrto Alegre is the same, but, with greater distance from Antarctic air masses in the lowlands to the north, temperatures rise rapidly, averaging 73° F (23° C) at Rio de Janeiro.

Summer air masses. In typical monsoonal fashion, the high-pressure system over the Brazilian Highlands during the summer months is replaced by a low-pressure one that pulls in warm moist air from both the South Atlantic and the North Atlantic high-pressure systems, the latter picking up more moisture as it passes over the forests of the Amazon region. Where these meet along the intertropical convergence zone (ITCZ), torrential downpours occur, amounting to more than 12 inches a month; thus, central Brazil has a wet-dry tropical climate. These are critical months in the semiarid northeastern region, which normally receives its precipitation from the easternmost edge of the shifting ITCZ; in more than half of the years, however, it either swings too far east, causing floods, or does not reach the area at all, bringing drought that is sometimes prolonged for years. This condition brings much misery to the sertão, the northeastern backcountry, and has become a major cause for migration from the sertão to the cities.

Winter air masses. During the winter months southernmost Brazil is dominated by polar air masses and their associated cyclonic storms. These generate four to five inches of monthly precipitation, occasionally in the form of snow, accompanied by regular frosts in the south and bringing near-freezing temperatures as far north as São Paulo. Further penetration is, however, blocked by a high-pressure system that forms over the Brazilian Highlands in winter, keeping precipitation there down to a desertlike measure of about one-half inch a month. Modified polar air, skirting this system, may bring cool, rainy weather along the coast as far north as Recife and, in the west, to the Pantanal. Cool air occasionally spills over from the Paraguay lowland into that of the Amazon as far north as the Guyana border, dropping temperatures by as much as 9° F (5° C).

Soils. Although complex in detail, Brazil's soils can generally be categorized as fertile and infertile.

Infertile soils. Because of the great age of so many of the country's landforms and its tropical climate, a high proportion of its soils have been intensely leached, leaving them poor in nutrients and organic matter. This is most evident on the surfaces of the Brazilian Highlands and Tertiary Plateaus, where soils, made up almost entirely of iron and aluminum silicates, can be as much as 90 feet deep, with laterites marking present or earlier water tables. Relic laterite layers on the surface may impede cultivation.

Amazonian soils

Soils of the Amazonian *terra firme* and similar landforms in the country are also leached but usually not as deeply. Their fertility depends on the closed ecological system of the rain forest, in which high temperatures and precipitation cause the immediate decay and recycling of dead organic matter. Once this cycle is broken, there is an almost immediate loss of nutrients and organic matter, and the soils quickly become sterile. For this reason, much of the once luxuriant coastal forest area is now an impoverished grassland, and there is fear among ecologists that the same fate awaits the Amazonian rain forest if its clearing continues.

Fertile soils. Within these broad zones of leached soils there are more fertile ones that have, for the most part, been created by erosion and the deposition of fresh silt along Brazil's numerous watercourses; they are scattered, however, and often not very extensive. In the highlands, fertile soils appear under two circumstances: where the ancient soils have been stripped away by erosion and younger, shallower soils have formed over the underlying bedrock, or where nutrients and organic matter have accumulated in the bottoms of swales and shallow valleys. These lower lands are usually covered with gallery forests because of the year-round availability of water, and their decaying litter adds to the fertility of the soil.

There are two major soil types of high fertility that are continuous over large areas. In the dry northeastern interior, leaching has been retarded and many of the original nutrients remain; however, these soils require more water than is generally available to make them agriculturally productive. By far the most fertile soils are located over the diabase formations that extend northward from central Rio Grande do Sul into southern Minas Gerais. There the rocks weather into a deep reddish-purple soil, known as *terra roxa,* that is highly productive even under humid conditions and is especially noted for the rich Brazilian coffee it produces.

Plant and animal life. Except in the more remote and rugged sections of Brazil's eastern highlands, little of the original flora and fauna remain south and east of the scrublands of the Brazilian Highlands and the semiarid northeastern region. The once luxuriant hardwood forests that dominated the eastern seaboard and the valleys of the interior have long since been destroyed, as have the magnificent Paraná pine, or *Araucaria,* forests that once covered the diabase plateau as far north as the terminus of regular winter frost. Monkeys, parrots, and other exotic wildlife are found only in zoos, private menageries, or small patches of relic habitats, where the original flora and fauna remain. The coastal waterways and swamps that once teemed with wildfowl and alligators have been replaced by salt pans, marinas, and condominiums.

Grassland and scrub. The grasslands of Rio Grande do Sul have been largely replaced by artificial pastures and wheat fields, but those of the Pantanal remain as natural grazing lands. There the many sloughs and watercourses still support an abundance of wildlife, including the giant pirarucu, a fish that is herded into enclosures like underwater cattle pens until needed for food. Wildfowl also abound in the Pantanal and include the ibis and the heron and wild ducks and migratory geese. On higher ground, and continuing on through the savannas of central Brazil, are the ubiquitous rheas, South American ostriches, and *siriemas,* a type of roadrunner, as well as a variety of

Pantanal fauna

game birds such as quail and partridge. There are numerous species of snakes, including the deadly fer-de-lance (jararaca) and the rattlesnake, a wide variety of lizards, some as much as a yard long, armadillos, and anteaters that also prey on termite nests, which may stand more than six feet high.

The vegetation of the savanna lands of Brazil varies considerably from treeless plains of coarse bunchgrasses and low woods of gnarled and stunted trees, where there is limited water, to gallery forests, where there is a year-round water supply. These savannas have no herds of game animals like their African counterparts, although in times past deer were plentiful. Until the introduction of cattle, deer were the principal prey of the *onças,* a type of jaguar, and of the ocelots that inhabited the edges of the galleries and neighbouring forests. These predators have been hunted mercilessly and are now endangered species.

The caatinga

In the semiarid northeastern region the scrub is known as the caatinga, from an Indian term meaning "white forest." Covered in thorns, these woods may in places attain heights of up to 30 feet with interlocking branches that present the *vaqueiro* (cowboy), who is usually clad in protective leather garments, with an almost impenetrable barrier. Where water is scarce, the caatinga may be low, widely spaced, and intermingled with cacti. Somewhat moister areas known as the *agreste* support light woods; these are located principally between the caatinga and the coast and are at higher elevations where most of the remaining moisture is wrung from the trade winds.

Amazonia. In contrast to the scrublands that border it to the south, the Amazonian rain forest and the waters that drain it have a remarkable abundance of plant and animal life, even though the ecosystem is a fragile one that can easily be destroyed. While giving the impression of monotony because of the apparently similar tree crowns that rise to a more or less uniform height of around 150 to 200 feet, these lands contain the greatest variety of plant species on Earth—many thousands, less than half of which have been identified. Furthermore, serving as a defense mechanism against blight and other natural enemies, individual plants of any species tend to be widely dispersed. A typical acre of forest in the Amazon may contain 250 or more tree species, compared, for example, with perhaps a dozen in any acre of woods in the northeastern United States.

The rain forest

Because the crowns of these forest giants form a virtually closed canopy, allowing 10 percent or less of the sunlight to filter through, there is little plant or animal life on the ground below. The trees, however, are festooned with a wide variety of epiphytes, bromeliads, and lianas, while their branches teem with animal life, from insects, snakes, and tree frogs to numerous species of monkeys and a bewildering variety of birds. Some 1,400 bird species have been identified in the immediate vicinity of the main stream of the Amazon alone, both in the treetops and within the complex ecosystem of the *várzea,* the riverine lands. There, along the riverbanks, are also found alligators, anacondas, boa constrictors, capybaras, and a number of lesser reptiles and mammals. In the waters themselves there are manatees, freshwater dolphins, and some 1,500 identified species of fish, with perhaps another 1,000 unidentified species; the variety includes many types of piranhas, not all of them flesh-eating, electric eels, and some 450 species of catfish.

The Amazon is also home to the world's largest freshwater turtle, of the genus *Podocnemis,* extinct everywhere except there and on the island of Madagascar. Weighing an average of 150 pounds (70 kilograms), these turtles were once a mainstay of the Indian diet, and they remain a highly prized food source. Although the turtles were placed on the endangered species list, illicit turtle meat has continued to be an available delicacy.

Settlement patterns. The settlement of what is now Brazil began many thousands of years ago with the arrival of the first tribes of Paleo-American Indians, migrants from North America who were probably of Asian origin. Nomadic hunters and gatherers, they inhabited the less hospitable parts of the country away from the larger rivers. By the time of the European arrival a second group had evolved, known collectively as the tropical forest Indians. Outnumbering the nomadic Indians, they were skilled farmers and fishermen who occupied the best lands of the Amazon and Paraguay river systems and most of the coastal plains, making up the bulk of the more than 2,000,000 native inhabitants of Brazil at the time of the European arrival.

Coastal settlements. The first European occupants of Brazil, around the beginning of the 16th century, settled among the coastal Indian villages or at the trading posts that were established at Salvador and Cabo Frio. They exchanged hardware and trinkets with the Indians for brazilwood, which was used for making a rich, fire-coloured dye (*brasa* is the Portuguese word for "live coals"). By the second half of the 16th century sugarcane became dominant in the colonial economy, giving rise to a scattering of urban centres, among which Olinda and Salvador were the most important. By this time the coastal Indians had been decimated, and slaves from Africa were imported to work on the rapidly expanding plantations.

The Southeast: mining and coffee. The Southeast is Brazil's most densely populated region. During the first two centuries of Brazilian colonization little attention was paid to the nearly inaccessible and seemingly unproductive highlands, although parties of explorers, known as *bandeirantes,* did traverse them from time to time, capturing Indians for slaves and searching for precious metals and stones. Taking with them a few head of cattle, which eventually expanded into the herds that came to dominate the economy from the caatinga to the Pantanal, some of the *bandeirantes* settled down in the interior and continued their search for gold and diamonds. The first gold strike came in what is now Minas Gerais in 1695, where diamonds were also found in 1729, attracting many plantation owners from the northeast who brought their slaves. They spent money lavishly on building fine towns, such as Ouro Prêto and Diamantina, and also invested in small industries to supply the mines as well as the farms that, before long, were producing a surplus for export. With the development of roads over the Serra do Mar to the coast, and the transfer of the colonial capital from Salvador to Rio de Janeiro in 1763, Brazil's economic and political centre shifted from the northeastern to the southeastern part of the country. Subsequently, during the 19th century, this was consolidated by the wealth generated by the great coffee plantations developed in the Paraíba do Sul valley.

Developing the plateau. Rio de Janeiro's population had passed 500,000 by the time the slaves were fully emancipated in 1888, while the city of São Paulo, entrepôt for all of Brazil south and west of Minas Gerais, was but a modest town of 65,000. That situation changed as a flood of European immigrants flocked to Brazil; some worked as tenants on the coffee plantations that were expanding across the *terra roxa* soils of São Paulo and northern Paraná, while others established themselves on small freeholds along the southern coast and in the forests. Whereas the latter group remained physically and culturally isolated until after World War II, the newcomers in São Paulo played a key role in building the railroads and establishing the industries that were later to give both the city and the state their preeminence in the Brazilian economy.

Settling the outback. While the more southerly parts of Brazil were expanding economically, the northeast was stagnating and beginning to feel the effects of overpopulation and an archaic landholding system under which all the best coastal lands were in the hands of a few powerful landowners. This had driven the earlier population of mixed Indian and European ancestry, the mestizos, ever deeper into what was then the sertão, or outback. They first settled the *agreste* and then the caatinga, wherever water or a small patch of moist ground was available. Severe droughts in the 1870s and 1880s forced many of these people to abandon their land, and they were recruited to tap rubber trees in the Amazon to supply the growing demand for this product. Half a century was to elapse before there were new opportunities for massive migrations from the drought-prone, impoverished northeastern region. One of these opportunities was to provide the large amount of labour that was required during the post-World War

Migration to the southeast

II period to build the constantly expanding urban centres of the southeastern region, culminating in the construction of Brasília. At the same time, northeasterners began occupying the sparsely populated forest lands along the remote northern perimeter of the Brazilian Highlands, including Rondônia and Acre. There they have been joined by emigrants from southern Brazil, who were displaced by agricultural mechanization.

The Amazon region in the north remains the most underpopulated part of Brazil, with an environment resistive to commercialization and settlement despite government development plans intended to lure more migrants. There has been a damaging trend to the ecology, nevertheless. Forestry and cattle raising, for instance, pose threats to the future of the rain forest and the Amazonian habitat.

The entire Amazon region had a population of only about 40,000 in the middle of the 19th century, but by the end of World War I this had risen, largely owing to an earlier rubber boom and the influx of northeasterners, to some 1,400,000; Belém and Manaus had grown from somnolent villages into modest-sized cities. In the late 1950s there was a minor boom along the Lower Amazon where Japanese settlers began raising jute and black pepper. The manganese deposits in Amapá were also being rapidly developed, and a new pioneer zone appeared along a highway between Belém and Brasília.

Urbanization. With its rural settlement patterns essentially defined, Brazil in the post-World War II period began a headlong drive toward industrialization, which turned the nation from an essentially rural society into one in which three-fourths of the population is urban. In 1940 less than one-third of the total population of 42,000,000 lived in urban areas; by the late 20th century more than that number lived in the São Paulo metropolitan area alone. Rio de Janeiro has the second largest metropolitan population, and other major metropolitan areas include Belo Horizonte, Salvador, Fortaleza, and Brasília. Somewhat smaller are Recife, Curitiba, Pôrto Alegre, and Belém. This rapid growth has led to a series of physical and social problems, while the demand for housing has raised land values to staggering heights. As a result, members of the middle class have been forced more and more to live in minuscule apartments in densely packed high-rises, while the poor are confined to shantytowns, so-called *favelas,* or in more distant developments that may be several hours away from the workplace. (P.E.J./R.P.Mo.)

THE PEOPLE

Ethnic groups. In Brazil the peoples of mixed race are increasing, while those of separate racial stocks are declining. The country has long been a melting pot for people of all races and a wide range of cultures. Although social interactions have not always been without strife and exploitation, the tolerance of the Portuguese Brazilians for other peoples and official policies that favoured assimilation have minimized conflicts. The Portuguese language and the Roman Catholic religion were other unifying factors. Where assimilation has not taken place, it has generally been regarded in Brazil as the choice of a particular group and not the result of any exclusionist government policy or reaction by the population. A case in point is the intransigence of a small minority of the some 200,000 remaining Indian tribal peoples, who have persistently rebuffed overtures of the National Indian Foundation.

Indians. Although none of Brazil's native Indian groups achieved the high levels of civilization and wealth of those in the Andes and Central America, the tropical forest peoples were, nevertheless, superbly adapted to their environment. From them, the Portuguese traders and early settlers learned techniques of tropical crop cultivation, especially the growing of corn (maize) and cassava, a starchy root that remains a Brazilian staple. They learned to sleep in hammocks, which are still preferred to beds by many in the more northerly regions, and to make dugout canoes and the sailing rafts, jangadas, that continue to be used along the northeastern coast. Perhaps one-third of all Brazilians have some Indian ancestors, a fact that is particularly apparent among the people living within and to the west and north of the northeastern region.

As long as the Portuguese settlers limited their activities to barter, their relationship with the Indians remained peaceful. But it changed quickly when the colonizers decided to use the indigenous population as manual workers. Incapable of submitting to the economic and social constraints of the plantation system, the Indians died or fled. They took refuge in the most distant and inaccessible areas—in the forest regions between the rivers of the Amazon Basin or in the savannas of the Mato Grosso. They did not, however, find themselves completely sheltered there, for, from the 16th to the 18th century, the Portuguese organized *bandeiras* (expeditions or raids), launched from São Paulo or the northeastern towns, to hunt down Indians and enslave them. These raids contributed to the decimation of the Indian tribes, as did simple contact with whites, since the Indians had no immunity to European diseases (influenza, measles, smallpox).

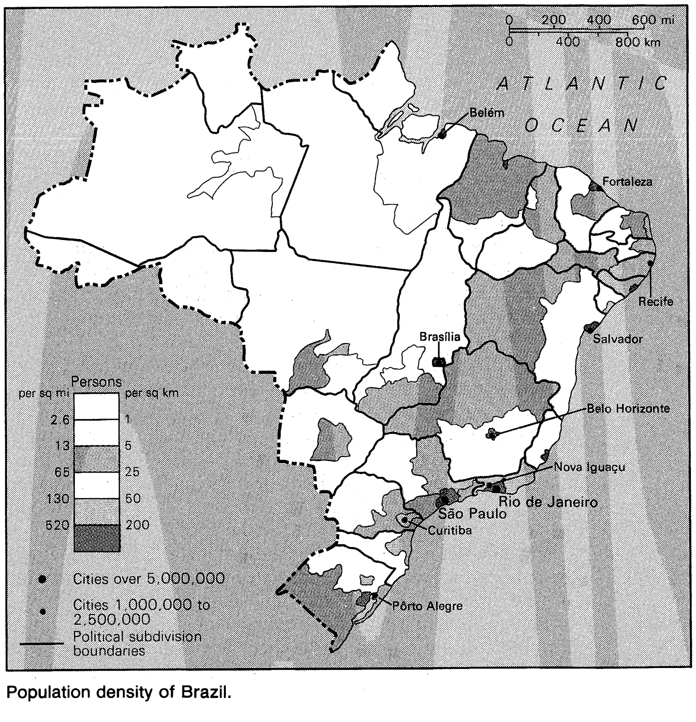
The flight to the interior

Blacks. The slave trade, between the 16th and the 19th centuries, brought 3,000,000 to 4,000,000 Africans to Brazil. The principal groups came from West Africa and from Angola. Unlike the Indians, the Africans adapted as labourers and domestics. Some, however, fled into the interior. During the 16th and 17th centuries the majority of blacks went to northeastern Brazil and were employed in the sugarcane plantations. From the 18th century onward, when the mining of gold and diamonds began, they went to Minas Gerais. After the abolition of slavery in 1888, many blacks left the regions where they had worked as slaves, either for other agricultural regions or for the towns. The black population then became more dispersed, although northeastern Brazil still has the heaviest concentration.

Historic distribution of the black population

Africans and their descendants have had a profound effect upon Brazil's racial and cultural evolution. Miscegenation was more acceptable in Brazil than in most other slave-owning countries so that in many areas, especially along the east coast, people of mixed ancestry outnumber those of pure racial stock. African music, dance, food, and religious practices have become an integral part of Brazilian culture. Nevertheless, the darker-skinned members of the population, although there are many exceptions, tend to be at the lower end of the economic hierarchy, with the whites at the top. This situation is said to be due to the perpetuation of generations of blacks in regions that have fewer economic and social opportunities. Their difficulties have been further compounded by competition from the European and Asian immigrants who have arrived in Brazil since the 19th century seeking greater opportunities.

Europeans and other immigrants. European elements



Population density of Brazil.

constitute the majority of the Brazilian population, a result of the steady influx of the Portuguese to all regions. For three centuries Lusitanian (*i.e.,* Portuguese) immigrants were practically the only Europeans to enter Brazil, and no limitation has ever been placed on their coming. They were found in all classes of society and were anxious to obtain wealth quickly in the plantations or in commerce.

It was only after the proclamation of independence in 1822 that immigrants of diverse origins were added to the Portuguese. The most numerous of the non-Portuguese European immigrants were Italians, who settled in large numbers particularly in São Paulo and northern Rio Grande do Sul. Similar to the Portuguese in many respects, the Italians were easily assimilated. The less numerous immigrants from other Mediterranean countries, including those from Spain and from Middle Eastern countries such as Syria and Lebanon, also adapted rapidly to their new homeland. With the Italians, they have made important contributions in industry, finance, politics, and the arts.

German and Japanese colonies

Immigration of Germans in the 19th and early 20th centuries and of Japanese after World War I added further diversity to the ethnic mix. In contrast to the Mediterranean peoples, however, it took the Germans and Japanese three to four generations to become assimilated. Besides the wider cultural gap that separated them from the general population, they were for many years physically isolated in rural areas. The cultural isolation of these groups was encouraged by their home governments, which had sponsored colonies and continued to supply them with teachers, and textbooks in their native languages. Since World War II, however, the people of German and Japanese descent have been largely integrated into the mainstream of Brazilian society. Other ethnic groups include Slavic peoples from eastern Europe. By the late 20th century there was little immigration, and less than 1 percent of Brazil's population was foreign born.

Language. Portuguese has undergone many transformations, both in the mother country and in its former colony, since the language was first introduced into Brazil in the 16th century. Although the two countries have, from time to time, standardized their spelling so that the written word remains mutually intelligible, pronunciations, vocabularies, and the meanings of words have diverged so widely that, it has been said, it is easier for some Brazilians to understand films in Spanish from other Latin-American countries than those from Portugal. New words and expressions in Brazilian Portuguese have been introduced by Italians, Germans, Japanese, and other immigrants and from across the borders with Spanish-speaking countries. One notable example is the universal use in Brazil of *tchau,* for farewell, adopted from the Italian *ciao.* Other words have entered through contact with foreign products and technologies.

Some authorities, however, suggest that the greatest divergence of the Brazilian language from the Portuguese goes back to contact with the Indians. The principal language spoken by the tropical forest peoples of Brazil, Tupian, or Tupí-Guaraní, became the lingua franca between the natives and the Portuguese traders, missionaries, adventurers, and administrators; it continued to be used similarly in the Amazon and western Brazil until the 19th century. The Tupian influence in Brazilian place-names is overwhelming, and it is estimated that thousands of indigenous words and expressions have entered the Brazilian Portuguese language. More generally, as a result of the Tupian influence Brazilian Portuguese became more nasal than that of the homeland, and Brazilians generally speak more slowly, pronouncing all the vowels.

Religion. Almost 90 percent of the Brazilian people are Roman Catholics, making it the largest country of that faith in the world. Roman Catholicism, however, ceased to be the official religion after the proclamation of the republic in 1889, causing the close links that existed between church and state to loosen. But the predominance of Latins among the immigrants of the 19th and 20th centuries has contributed to the lasting strength of the religion. Among the other religions, the majority are Protestants, dominated by fundamentalist and Pentacostal sects. There are also small numbers of adherents to Eastern Orthodoxy, Buddhism, Shintō, Islām, and others, all of which together are about numerically equal to the Spiritualists, whose beliefs overlap those of other religions, including the animism of the Indians.

African cults

A large number of Brazilians temper their Christianity with beliefs imported from Africa, as represented by such cults as Macumba, Candomblé, Xangô, and Umbanda. Among the more influential of these was Candomblé, which became the predominant cult of Bahia. The Nagô Candomblé sect, derived from the religion of Yoruban slaves, became particularly strong, and some of its rites were adopted by other sects and cults. Macumba and Umbanda are most widely spread in Rio de Janeiro state and Xangô in Pernambuco. The cults in general identify their deities with the saints of Roman Catholicism, and they believe that the deities intercede for them with a supreme being. Animal sacrifices are a common element of cult rites. Priests and priestesses are mostly blacks, but adherents, especially in urban centres, are drawn from every racial group and social class.

Demographic trends. For demographic and other statistical purposes the government has divided the country into five major regions: the North, which includes the states of Acre, Rondônia, Amazonas, and Pará, and the territories of Roraima and Amapá; the Northeast, containing the states of Maranhão, Piauí, Ceará, Rio Grande do Norte, Paraíba, Pernambuco, Alagoas, Sergipe, and Bahia, and the island territory of Fernando de Noronha, some 225 miles off the Atlantic coast; the Southeast, made up of the states of Minas Gerais, Espírito Santo, Rio de Janeiro, and São Paulo; the South, including the states of Paraná, Santa Catarina, and Rio Grande do Sul; and the Central-West, consisting of the states of Goiás, Mato Grosso, Mato Grosso do Sul, and Tocantins, and the Federal District, in which Brasília is located.

Population characteristics. Like most developing nations, Brazil's population is young; the percentage of people under 20, however, declined to less than half of the total population between the 1970s and the 1980s, while older age groups increased. The modernization of society has equally been a factor in the increase in life expectancy and a lowering of the birth rate, along with a general lowering of the population growth rate. Despite such changes the infant mortality rate has remained high. This rate, however, varies widely from the affluent urban districts, where it is quite low, to the *favelas* and other poor communities, particularly in the Northeast, where it is much higher.

Birth rates

The number of births to women of childbearing age (15 or over) has declined but continues to show significant regional differences. In 1940 the national average was just over six births per female of childbearing age, with a high of eight to 8.5 in the most rural states. The lowest figure in 1940 was in Rio de Janeiro state at 4.5, but by the 1980s the national average had dropped even below that figure. This decline has been attributed to improved health care, the gradual acceptance of family planning, including birth control measures, and, possibly, the declining influence of the Roman Catholic Church.

Migration. Migration from one part of the country to another has always been a feature of Brazilian society, especially when new frontiers or opportunities have presented themselves. During the late 20th century the western part of the country had the highest net influx of population, attracted especially to the Federal Capital and Rondônia. Indeed, the main purpose in creating Brasília in the country's centre was to instigate development of the hinterland. The Southeast has also received large numbers of migrants, but these have been very unevenly distributed: São Paulo and Rio de Janeiro have made notable gains, whereas Minas Gerais and Espírito Santo, the most rural southeastern states, have had steady reductions of their population through migration. The Northeast has suffered significant population loss to emigration, but this has been evenly distributed across the region except for being higher in Piauí, in the heart of the drought region, and in Maranhão, where it was much lower. The latter is somewhat of a geographic anomaly because its western half lies within the Amazonian rain forest while its eastern half is in the drought quadrilateral; thus migration into the former just about balances the exodus from the latter.

Population growth in the South

Although the North and the Central-West regions have the strongest percentage of population growth in Brazil, the South, and São Paulo in particular, has benefited significantly from substantial increases, both from internal migration and from foreign immigration. The South is the richest, the best equipped, the most industrialized, and the most vital region of Brazil; it receives the greater part of the flow of international immigration. Foreign technicians and skilled workers have generally achieved a comfortable standard of living there.

Domestic migrations are, in effect, motivated primarily by the lowering of rural income and the persistence of an archaic agrarian structure, as well as highly variable climatic conditions. Whole families of poor *sertanejos,* and also farmers from the *mata* and the *agreste,* flee toward the towns, the population of which is thus swelled by a mass of unqualified, underemployed people with a very low standard of living. A strong movement, therefore, carries Brazilians toward the cities and accelerates the mixing process in a nation becoming increasingly urban. It also induces—notably among the poorest people—a consciousness of regional economic imbalances and of excessive social inequalities. (M.Ml./R.P.Mo.)

THE ECONOMY

The sheer extent of Brazil's primary resources has made its economy, despite its relative lack of development, one of broad international significance. It is one of the world's leading agricultural nations and is especially well-known as the world's most prominent coffee-producer. Brazil is also important for what it has not yet fully exploited—its vast mineral and hydroelectric potential, its hardwood forests, and millions of acres of soil, most of which could be fertile given adequate water and fertilizer. As its manufacturing sector develops, Brazil also has taken a significant place among the world's industrial producers, its iron ore production having grown to a high world ranking. The city of São Paulo has become one of the world's major industrial and commercial centres.

Boom-and-bust economy

Despite the vastness of its land and the richness of its resources, Brazil's economic history can be largely characterized as a string of boom-and-bust periods. This was the result of being oftentimes heavily dependent on one or two major agricultural products, the markets for which were highly sensitive to fluctuations in the world economy and politics. This cyclical aspect of the economy began with the export of brazilwood in the early colonial times and was continued with the sugar boom of the 16th century, the mineral boom of the 18th century (paced especially by gold and diamond mining), the coffee boom beginning in the mid-19th century, and the rubber boom of the late 19th and early 20th centuries. In reaction to this background of economic fluctuation, based on a largely agricultural economy, Brazilian governments of the 20th century have placed heavy emphasis on programs designed to diversify the nation's production. In the process, industry has been heavily encouraged, and by the late 20th century manufacturing accounted for the largest single sector of the gross domestic product. The economy has gone through periods of remarkable growth since the mid-20th century, but serious economic problems persist and have been aggravated by political turmoil. Income distribution continues to be uneven, as it was in colonial times, with the large poor segment receiving the smallest share. Inflation, at times skyrocketing, coupled with periods of recession and one of the world's largest foreign debts became characteristic elements of the nation's economic difficulties in the late 20th century.

Resources. Brazil has an abundance of resources, which, with suitable management, could continue to yield generously for generations to come. Improved transportation has made more of these resources accessible either for export or for use by Brazil's burgeoning industries and growing population.

Mineral resources. Brazil is known to contain extremely rich mineral deposits. It has vast iron ore reserves located mostly in Minas Gerais and Pará, the latter being also the site of extensive bauxite reserves. Of the known manganese-ore deposits, most are in Mato Grosso and Amapá. Low-quality coal resources are located in Rio Grande do Sul and Santa Catarina, but only a relatively small percentage—found in the latter state—is suitable for processing to produce metallurgical coal for steel manufacture. In addition, the country has reserves of a wide variety of other metallic and nonmetallic minerals, some of which provide important exports. Brazil has oil and natural-gas reserves, which became substantial with the development of offshore fields. The mineral reserves are under constant exploration by government and private sources.

Oil and natural gas

Biologic resources. About two-thirds of the country is under forest, providing one-seventh of the world's total forest area. Hardwoods predominate in the Amazon and Atlantic coastal zone. Exploitation of the Amazon rain forest, however, has been hampered by the inadequacy of transport facilities. Arable land is not abundant, considering the size of the country. With a coastline of more than 4,600 miles and numerous well-stocked rivers, Brazil has access to substantial fishing grounds. This resource, however, is underdeveloped and productivity is low.

Hydroelectric resources. With one of the most extensive river systems in the world and with plentiful rainfall in all of the country except the Northeast, Brazil has one of the largest hydroelectric potentials in the world. Installed generating capacity is concentrated in the Southeast and the South, which consume most of the power produced in Brazil.

Since 1950 there has been a rapid expansion in total power capacity, mainly through hydroelectric development. The government has given high priority to harnessing the country's substantial hydroelectric resources, as the scope for expansion in thermal capacity is limited by the poor quality of Brazilian coal. Brazil's first nuclear reactor, Angra I, began operation in 1982 near Rio de Janeiro, and the Paraná River's Itaipú hydroelectric complex, the world's largest power station at its completion, began operating in 1984.

Agriculture. Agriculture has been declining since the mid-20th century in its share of the gross domestic product and in the number of its workers; less than one-third of Brazil's labour force is employed in farming and stock raising. The country is essentially self-sufficient in basic foodstuffs and is a leading exporter of a wide range of tropical crops. Unlike most of the other Latin-American countries, Brazil has increased agricultural production by greatly enlarging its cultivated area since World War II. Yet only about 9 percent of the land area is cultivated, much of it in small holdings using relatively primitive technology; another 20 percent is used for stock raising.

Mechanized farming is still somewhat rare in Brazil, and it is mostly employed in the South and Southeast. Few tractors are available in the Northeast although that region contains about half of Brazil's farms; most of these are less than 12.4 acres (five hectares) in size, however. Some large-scale government irrigation projects have been built in the Northeast, but they were costly and support only a limited number of farm families on individual plots or on cotton plantations.

Coffee growing

Brazil is the world's leading producer of coffee, which is its most important single export. São Paulo and Minas Gerais are the principal coffee-producing states, followed by Paraná and Espírito Santo. Soybeans and their derivative products, particularly animal feeds, have become another important export. Most of the country's soybeans are grown in Paraná and Rio Grande do Sul, but mechanization and a high crop value have made it economically feasible to fertilize the savanna soils, expanding production beyond the *terra roxa* region and making Mato Grosso do Sul a leading soybean state.

Older segments of Brazil's agriculture have also responded to economic opportunities. An example of this was the rapid expansion of sugarcane acreage, mostly in São Paulo but also along the northeastern coast, under the government's program to replace gasoline, made from costly imported fuel, with ethanol (ethyl alcohol). Processing the sugarcane in modern plants became the most successful such program in the world, and for a number

Paraná pine growing in a field of soybeans in the *terra roxa* region of Rio Grande do Sul state, southern Brazil.

Karl Kummels—Shostal Assoc.

of years virtually all new automobiles in Brazil have been engineered to run on this fuel.

Some ethanol is made from cassava, of which Brazil is the world's largest producer. It is also usually a world leader in growing edible beans, castor beans, cacao, and bananas and is the largest grower of rice in the West. Although the bulk of these products are consumed domestically, varying amounts are exported, as are such crops as jute and black pepper from the Amazon region; palm oils from the northeast coast; garlic from Minas Gerais; peanuts (groundnuts), oranges, and tea from São Paulo; and tobacco from Santa Catarina and Rio Grande do Sul. The latter state is also the centre of Brazil's meat-packing industry; vast grazing lands there and elsewhere in Brazil have given rise to one of the world's largest livestock populations.

Forestry and fishing. Brazil's abundance of plant and animal life is particularly identified with the Amazon region, yet only a small portion of the annual timber harvest comes from northern Brazil, and much of that is used for fuel. Most of the small timber yield of the Northeast is also used as fuelwood. The forests of western Maranhão and southern Bahia are important sources of charcoal, as are those of Tocantins and eastern Minas Gerais, the latter accounting for the largest share of Brazil's production of that fuel. The largest part of Brazil's timber production comes from the South and Southeast, about half of it from plantations of eucalyptus, originally introduced from Australia, with additional yields from Honduras pine and several other exotic species. Most of the harvest from these plantations is used in the manufacture of cellulose and paper products.

Fishing

Brazil has a significant freshwater fish catch, of which more than one-fourth comes from the Amazon and its tributaries. Another large segment of the country's freshwater catch is from the Northeast, much of it from reservoirs that the government has stocked with tilapia, a fast-growing fish introduced from Africa.

Whereas most of the freshwater fishing is done by individuals, more than two-thirds of the ocean catch is brought in by company-owned commercial fishing vessels. Most of these sail from Southern and Southeastern ports. In the Northeast company boats account for a considerably smaller percentage of the saltwater catch, most of which comprises lobster and shrimp caught primarily for export. In Fortaleza manufacturers use *cambulu,* a saltwater fish, and tilapia skins to make shoes, clothing, and accessories, products formerly made from the hides of alligators, which are now endangered species.

Industry. *Mining.* Almost every Brazilian political unit receives some revenue from the extraction of its minerals. The leading mining state is Minas Gerais, which, excluding oil and gas production, receives the largest single share of the country's mining revenue. This state has long been Brazil's major producer of iron ore, for internal consumption and export, from high-grade hematite found in Precambrian formations that extend from near Belo Horizonte eastward to Itabira's "Iron Mountain" in the upper Rio Doce valley. Minas Gerais' iron ore exports have been challenged by those from the huge Carajás Grande mine, located west of the Araguaia River in Pará at the end of a specially constructed, 500-mile-long railway to a port near São Luís. Most of Brazil's iron ore exports are in the hands of Brazil's giant, government-controlled mining and shipping company, the Rio Doce Valley Company. The state has controlled a number of other mining companies, but a move to denationalize them began in the mid-1980s.

Except for aluminum and manganese from the Amazon region and iron ore, Brazil's industries absorb most of its other mineral production. This includes chrome, magnesium, and quartz from Bahia; copper and lead from Bahia and Rio Grande do Sul; asbestos from Goiás; and nickel from Goiás and Minas Gerais. The latter state also supplies Brazil with zinc and graphite, in both of which the country is largely self-sufficient. Brazil is self-sufficient in cassiterite (tin ore), found along a belt south of the Amazon River, while nearly all of the country's tungsten requirements are met from Rio Grande do Norte and those for silver by Bahia and Paraná. Coal production, which is centred in Santa Catarina, supplies more than half of the country's needs. Brazil is a major gold and diamond producer, supplied mainly by Minas Gerais, but quantities fluctuate widely from year to year and place to place as deposits are located and exhausted. Minas Gerais, Bahia, and Espírito Santo are the major sources of Brazil's enormous range of gems—topazes, amethysts, opals, aquamarines, tourmalines, emeralds, and others—that make Brazil the largest world supplier of semiprecious stones.

Gemstones

Petroleum. Virtually all of Brazil's oil and natural gas fields derive from deposits laid down at various stages along a rift that developed as the South American continent began its separation from Africa. Of these, the offshore marine shales are the most productive. For the first 25 years after commercial oil production began in Brazil, in 1940, it was confined to the Bahia Basin just north of Salvador. This expanded subsequently to include offshore and onshore fields that extend from Fortaleza to Santos, although virtually all of the country's natural gas comes from Bahia and Sergipe states. In 1987 the first commercial oil well in the Brazilian Amazon, some 450 miles southwest of Manaus, began production.

More than half of Brazil's petroleum production comes from the Campos Basin on the continental shelf off Rio de Janeiro state. There Petrobrás, the government-controlled petroleum company that was established in 1953, has developed some of the most advanced deep-water drilling technology in the world. This has included test drilling on the continental slope into formations under 1,200 to 3,000 feet of water. The higher-yielding finds at this site have added considerably to the country's proven reserves.

Manufacturing. Since 1967 Brazilian industry has contributed a greater amount to the gross national product than has agriculture. Manufacturing is the most dynamic sector of the economy. Although it developed principally to serve the domestic market, Brazilian industry exports a wide range of manufactured goods.

Much industrial development that followed the Great Depression of the 1930s was the result of nationalism and developmental policies spearheaded by state corporations. Investment capital was then in short supply unless it was accompanied by foreign control, which Brazil wanted to avoid. As a result, the government took control of some of the country's largest industrial enterprises, usually in partnership with one or more local or foreign corporations. It gained the right to sell stock in government companies to private investors, which was the case with Petrobrás and the Rio Doce Valley Company.

Although government involvement in the industrial sector has been criticized for promoting political and social objectives rather than economic ones, and for its cumbersome bureaucracy and inefficiency, some thriving industries can attribute their successes in domestic and international markets to government measures. Besides direct investments, these have included tax and other incentives, protective tariffs, import restrictions, and the outright prohibition of imports.

An example of such success is the motor vehicle industry, which was established in the 1950s to replace U.S. and German imports and assembly plants. Begun with a joint government–Alfa Romeo truck factory and a series of incentives and import tariffs on automobiles, Brazil was producing more than 1,000,000 vehicles a year by the late 1980s, some of which were exported.

Another such industry is petrochemicals; the largest in Latin America and a major factor in the value of the country's industrial production, it was started by Petrobrás and subsequently opened up to national and foreign investors. The government was also instrumental in starting a modern shipbuilding program that, with private capital as well, produces various types of vessels, some of which are sold abroad. Embraer, begun with government support, built small airplanes in the days of poor road conditions and now manufactures and exports a wide range of aircraft. Government protection has also been instrumental in establishing a burgeoning microelectronics and personal computer industry.

One notable exception to Brazil's manufacture of goods primarily for domestic consumption is its armaments industry, which exports most of its production to countries throughout the world and places Brazil among the world leaders in arms sales. Arms-producing companies may be under private or government control. Their products are reputed to be of good quality, moderate complexity, and reasonable cost, making them especially suitable to their main market, Third World countries.

Textiles and clothing

Not all of Brazil's successful industries involve government participation. An example is the textile industry, which began in Bahia in 1814 and was based on local supplies of raw cotton and is now centred in São Paulo. Of equal significance is the manufacture of clothing and footwear; of the latter, Rio Grande do Sul produces most of the exports. This industry began in the 1820s with small leather works based on a surplus of hides from the meat-packing industry but now imports a portion of its raw materials from Argentina and Uruguay. Brazil's metallurgical and engineering industries originated in Minas Gerais and Rio de Janeiro during the 18th-century mining boom and have become one of the chief employment sectors in manufacturing.

With few exceptions, the Southeast contains the largest, the most varied, and the most efficient establishments in every sector of industry. It also employs the majority of the country's industrial workers, who earn most of Brazil's wages and produce the largest value of its goods; São Paulo state alone is responsible for about half of Brazil's industrial production. The next largest percentage of the nation's industrial workers, about one-fifth of the total, are in the South. The Northeast, by contrast, employs only about 10 percent of Brazil's industrial workers, and their wage scale is lower than those in the Southeast and South. Generally speaking, Brazil's factories are not large; only a very small percent employ a hundred or more workers. As might be expected, the largest firms are in the Southeast, with the next largest in the South.

Services. The service sector, including private and government services, is not only one of Brazil's largest employers, absorbing more than one-fourth of the work force, but is also its fastest growing one. The private sector has been expanding at a somewhat faster rate than the public sector. Government services include not only the usual array of national and local bureaucracies and public services but also a host of special purpose agencies. Among the largest of these are the superintendencies for the development of the Northeast, SUDENE (1959), and of the Amazon region, SUDAM (1966). These agencies funnel federal funds into development projects and oversee the tax incentives that are intended to stimulate investments of private capital, especially in manufacturing and rural enterprises. Although the overall objectives of the various government agencies remain fairly constant, specific applications may vary significantly from one administration to another. Furthermore, their functions frequently overlap, especially at the local level. In the private sector, the largest number of workers is employed in the hospitality industries (hotels, restaurants, and bars) and in repair shops of various kinds. Retail sales and personal services each account for most of the rest of the private sector workers.

Tourism. Tourism is a growing industry in Brazil, but the concept of building resorts for the exclusive use of tourists is an unfamiliar one. It has been limited for the most part to a few luxury hotels, mostly in Rio de Janeiro, that cater to foreign visitors, some long-standing spas and resorts mostly in the Minas Gerais highlands, and a facility at the relatively isolated Iguaçu Falls. The major attractions are located in or around urban centres with well-established hospitality industries and are, therefore, easily accessible. Also, the proportion of foreigners traveling to Brazil who might require special facilities is still not large compared with the number of nationals who travel within their own country, using the same type of facilities as they would for family or business visits. The larger Brazilian cities all have a wide range of accommodations. A growing number of Brazilians travel throughout the country by automobile, although during vacation periods airlines are also heavily booked.

Finance and trade. The national Monetary Council under the direction of the minister of economy is Brazil's chief financial policy-making body. It controls the Central Bank of Brazil, which issues currency and controls the money supply, credit, foreign capital, and other top-level financial matters. The federal government uses other financial institutions to implement its policies as well, the most important of which is the Bank of Brazil. It is not only the largest bank in the country, with numerous agencies at home and abroad, but is also the main source of long-term loans in such areas as rural credits and the financing of manufactured goods exports. The National Economic and Social Development Bank channels government and international loans into large-scale development projects in industry, mining, agriculture, and the infrastructure, including loans to state governments for projects that they cannot finance themselves, such as the São Paulo and Rio de Janeiro subways. The National Housing Bank provides home-building loans, and the Federal Economic Bank makes short-term loans to individuals.

Each state has its own government bank, among which the Bank of the State of São Paulo is the most important. A lesser share of Brazil's commercial banking is in the hands of private banks, which also provide short-term loans and the popular savings accounts, Carnets de Poupança, that guarantee interest yields above the rate of inflation; these are also offered by the Bank of Brazil and the state banks.

Inflation

Almost continuous high rates of inflation in the late 20th century have affected every aspect of Brazil's economic life, which is also subject to the reactions of a volatile, underregulated stock market. A number of similarly unstable commodity exchanges also operate in various cities. Outside of the market, virtually all transactions are indexed for inflation, based officially on the constantly corrected value of the government's bonds. Such corrections apply not only to savings accounts but also to tax payments, calculations of assets, debt payments, selling prices, and the like. Separate monetary corrections are used for regulating food, transport, rents, and salaries, which, in turn, determine pensions. Because the latter group may be changed arbitrarily to reflect fiscal or political policies rather than social needs, they can be the source of considerable popular unrest even though this tends to be unfocused and ineffective.

High inflation rates in Brazil came, at least in part, from heavy government financing of industrial expansion, the need for government financial institutions to subsidize business loans, and a great increase in foreign borrowing as internal credit became extremely tight. Various government plans to curb inflation, some of which introduced a new basic monetary unit, have met with limited success.

Foreign trade has been critical to the Brazilian economy throughout the nation's history and continues to play a significant role. Although exports account for only a small part of the national income, their importance is understandable in the context of the nation's need to import capital goods and raw materials, particularly crude oil. The historic dependence on agricultural products for exports has changed, however, as manufactured wares have grown to take on an increasingly greater share of the market since the mid-20th century. Brazil traditionally has had difficulty maintaining a favourable trade balance, but in the 1980s, after a period of deficits, a trend toward surpluses was established. Much of this was negated, however, by the huge foreign debt payments that had been incurred.

(E.I.U./R.P.Mo.)

Trading partners

The largest single share of the value of Brazil's imports is accounted for by petroleum from the Middle East, which is the destination for only a small share of the country's exports. The United States is the largest customer for Brazilian goods, and that country ranks with the Middle East as an exporter of products to Brazil. Other imports originate from the countries of the European Economic Community and from the other countries of South America as well as the Far East and Africa. In addition to the United States, Brazil's exports go to the European Economic Community, with the Far East and other countries of the Americas absorbing most of the remainder.

Transportation. For a country as large as Brazil, development of an efficient means of transportation has been a matter of critical importance. Throughout much of its history the nation's different regions remained isolated from one another, but this changed dramatically after World War II, first with the growth of air transport and, two decades later, with the extension of a modern road network. Most passenger and freight traffic moves over the highways, with coastal and inland shipping the next largest mode of transportation.

Roads. At the time of the construction of Brasília in the late 1950s, the number of good paved roads in Brazil was limited. A four-lane highway linked Rio de Janeiro and São Paulo, but there were no paved roads from those cities to Pôrto Alegre, Curitiba, the Northeast, or west of Belo Horizonte. During the rainy season surface communications could be interrupted along the major regional links for a week or more at a time, stranding motorists in areas with limited housing and food supplies.

The construction of Brasília, for which many bulky materials had to be airlifted in during the rainy season, alerted the country to the poor state of its roads, and when the military assumed power in 1964, the upgrading of the road system became a primary objective. As a result, an excellent system of paved roads now connects all of the major points in Brazil, including several links northward into the Amazon region.

Air transport. Brazilians were among the pioneers in flying, and they have long claimed that their countryman Alberto Santos-Dumont, not the American Wright brothers, flew the first successful airplane. Numerous airlines flourished in Brazil at one time or another, but they have been consolidated into three major ones that compete nationwide: VARIG, which since the late 1920s has been a largely employee-owned airline and is a major carrier within Brazil and also the nation's main international air service; VASP, the São Paulo State Airline, which is largely local but also has scheduled flights to the United States and the Netherlands Antilles; and Transbrasil, which is a privately-owned airline that provides mostly domestic service.

Major airports

Every capital and important city in Brazil has a major airport, and most of the smaller cities are served by jet aircraft. Few locations are without at least a dirt landing strip. Although São Paulo, Rio de Janeiro, Belo Horizonte, and Brasília are all linked by shuttle services (*ponte aérea*), overall flight frequencies and the size of terminals are everywhere at much smaller scales than at comparable centres in western Europe or North America. This is due to the relatively high cost of air fares and competition from inexpensive intercity bus services. Rio de Janeiro and São Paulo handle most international air traffic.

Railways. Except for the commuter lines to the Rio de Janeiro and São Paulo suburbs, and certain bulk ore carriers, railroads are only of minor importance in Brazil's transport network. In contrast to Brazil's dynamic highway construction program, few new railways of any significance have been built in the country since World War II, when Rio de Janeiro was linked by rail to Salvador because German submarines were taking a heavy toll of coastal shipping. The minimal construction since that time includes a branch line from Minas Gerais to Brasília and the ore-carrying line inaugurated in 1985 between the Carajás Grande mining project and Pôrto do Itaqui, near São Luis. Most of Brazil's track dates from the 19th century, when the economy was based on exports of raw materials. Because a number of different, incompatible gauges were used, integration into a national network was impeded.

Shipping. Brazilian coastal shipping was, for many years, in no better condition than its railways and, like them, was confined to carrying low-value bulk goods that could tolerate long delays and not infrequent losses. After the federal government launched a shipbuilding program in the 1960s, however, the tonnage of cargos increased markedly, and, more significantly, as the frequency and reliability of services improved, a larger percentage of higher valued goods was carried. Lloyd Brasileiro is Brazil's main shipping line, but Petrobrás and the Rio Doce Valley Company operate a significant number of special-purpose vessels, and there are several other smaller lines.

The upgrading of Brazil's shipping coincided with the construction of specialized bulk terminals, including one on Sepetiba Bay, west of Rio de Janeiro, and the Pôrto do Itaqui ore terminal. These were preceded by the iron ore terminal at Tubarão, near Vitória, and the oil terminal at São Sebastião, on the São Paulo coast. São Sebastião accounts for about half the value of the state of São Paulo's imports, a large portion of the rest being handled through the port of Santos, which has the nation's largest port activity. Other significant ocean ports include Rio de Janeiro, Paranaguá, and Recife.

River navigation

The extensive Brazilian river system has a total navigability of about 27,000 miles. Within the Amazon Basin navigable waterways are the principal means of transportation in northern Brazil, extending into the Spanish-speaking countries to the west. The two principal Amazonian ports, connected by a modern, if at times erratic, steamer service, are Belém, at the mouth of the river, and Manaus, some 1,000 miles inland. These and lesser ports are important as trade centres for the multitudinous variety of craft that ply the waters of the main rivers and some 1,000 navigable tributaries. Between its natural and man-made obstacles, the Paraguay–Paraná–Plata river system is little suited for navigation, although certain stretches were used for local transport in the early days of settlement. There is still some barge traffic, however, and the system provides access to the Atlantic Ocean through the Río de la Plata estuary in Argentina, but only for shallow-draft vessels.

The São Francisco River is navigable for about 170 miles from the sea, after which access is blocked to shipping by the Paulo Afonso Falls. Above these the river was, for many years, an important avenue of transportation; however, silting in its upper reaches due to deforestation and the diversion of its waters for a series of hydroelectric dams have diminished the river's usefulness for transportation. Of the shorter rivers flowing into the Atlantic Ocean, only the Paranaíba in the far north and the Jacuí in Rio Grande do Sul are navigable from the sea for any distance, and then only by shallow-draft or barge traffic.

(R.P.Mo.)

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Brazil is a federal republic divided into 26 states and one federal district. The constitution promulgated on Oct. 17, 1969, under Brazil's military leadership, continued in force after civilian government was restored in 1985, although some key amendments were made and a constituent assembly was formed. A new constitution was promulgated on Oct. 5, 1988, the eighth constitution since the country's independence in 1822. The product of

The constitution

a 559-member Constituent Assembly, it abolished many of the traces of the former military regime. As the fundamental law, the constitution defines the rights of the citizen and the functions of the executive, legislative, and judiciary powers. The president's power to legislate was abolished in the 1988 constitution, as were government censorship of art and the use of torture and extradition for political crimes. The voting age was lowered from age 18 to age 16, and a provision was made for a presidential election in November 1989.

According to the constitution, legislative power is exercised by the National Congress, composed of the Chamber of Deputies and the Federal Senate. Congress meets every year, in two sessions of four and a half months each. The constitution gives Congress the power to rule in all matters that come under the jurisdiction of the union, particularly those related to the political or administrative organization of the union and to fiscal policies. Congress also has the power to rule on international treaties concluded by the executive, to authorize the president to declare war, and to approve or disapprove federal intervention in the states. Bills approved by Congress can be totally or partially vetoed by the executive. Congress has 30 days to overrule a veto by a majority vote.

The Chamber of Deputies is composed of representatives of the states elected every four years by direct universal suffrage and secret ballot. The number of deputies is in proportion to the population of each state, but no state can be represented in the chamber by more than 70 or by fewer than eight deputies.

The Federal Senate is formed by representatives of the states (three from each state and the Federal District), who serve for a term of eight years. The Senate is renewed every four years, the first time by a third of its members and the second time by the other two-thirds. Senators are directly elected by the electorate of each state in a straight majority poll.

Executive power

Executive power is exercised by the president, who is assisted by ministers of state. From 1945 to 1964 the president was elected for a five-year term by direct universal suffrage and secret ballot. After the military took power in 1964 the president and the vice president were elected indirectly, first by the National Congress and later by an electoral college formed of members of Congress and representatives of state assemblies. A 1977 reform extended the mandate of the president to six years. In 1985, however, under a civilian government, an amendment was passed restoring direct presidential elections, establishing a four-year term of office for the president, and instituting other political reforms. The president's term was extended to five years in 1988.

The executive has wide powers, particularly in economic and foreign policy, finances, and internal security. The executive can decide, for example, that any of its bills submitted to the legislative branch shall be voted upon by Congress within 30 days. If Congress does not comply within this period, the bill is considered approved. The president is assisted by his cabinet, made up of the various ministers of state and several other heads of ministerial-level departments, all of whom are appointed by the executive.

Judiciary power

The judiciary power is made up of several institutions. The Federal Supreme Court is composed of 11 members named by the president with approval of the Federal Senate. It alone decides on litigations between foreign states and the different entities of the union, as well as on differences between the political or administrative divisions of the union. The court also deals with either the demands or writs of mandamus against acts of the highest authorities of the republic (the president, Congress, and judiciary) and decides on demands of habeas corpus already judged at a lower level. It also pronounces on the constitutionality of laws and decrees, and it judges common-law crimes by the president, ministers of state, members of Congress, or magistrates of higher courts.

The Federal Superior Court is composed of 33 judges appointed by the president with the approval of the Senate. It hears cases involving governors of the states and the federal district and members of the judiciary. It also decides on writs of mandamus and habeas corpus against ministers of state and members of its own court, decisions that were formerly the responsibility of the Court of Appeals. Under the 1988 constitution the Court of Appeals serves as the court of last resort for common pleas. Each state or territory, as well as the federal district, constitutes a judiciary section. The federal judges there instruct and judge in the first instance certain political crimes, crimes committed against the labour organization or crimes committed on the occasion of strikes, and cases related to public organizations. Electoral courts and judges are responsible for the registration of political parties and the control of their finances. They also fix the date of elections and prosecute and make judgments on any electoral crimes committed. Labour courts and their judges mediate in individual or collective conflicts between management and workers. Military courts and their judges mediate in cases involving the military.

Local government

The states and territories are subdivided into municipalities. The municipalities are autonomous politico-administrative units created by the states, on condition that they have a minimum of population and their own fiscal resources. The municipalities are governed by mayors (*prefeitos*) and municipal councillors, both of whom are directly elected. The federal district, Brasília, is the capital of the union. Its *prefeito* is named by the president with the approval of the Senate.

The states are ruled by autonomous laws and constitutions within the framework of the principles defined by the federal constitution. The union can intervene in the internal affairs of the states, in cases foreseen by the federal constitution. Each state has a governor and a legislative assembly. Governors and assemblymen are elected by direct vote with secret ballots.

The political party system in Brazil began to emerge in the 1940s under President Getúlio Dorneles Vargas, who established the Social Democratic Party and the Brazilian Labour Party to buffer his weakening administration. A number of other parties were organized and entered elections through the 1950s and early 1960s, but few of them developed any political power of note. Under the aegis of the military government that was established in 1964 all political parties that had been previously active were abolished in 1965. They were replaced by one government party, the National Renewal Alliance, and an opposition party, the Brazilian Democratic Movement. In 1979 the two official parties were abolished in favour of a new system that would allow participation of more parties, but still under quite restrictive regulations. After civilian government was restored in 1985 all political parties were once again legalized. (L.Ms./Ed.)

Education. The educational system in Brazil is overseen by the Ministry of Education and its policy-making body, the Federal Council of Education. Education is free and compulsory at the primary level (grades one through eight, starting at age seven) and is also free at the middle, or secondary, level (three grades and an optional fourth). A broad educational gap exists in Brazil between the higher income groups and the masses in the lower income groups. About 20 percent of the people are illiterate, and about two-thirds have only four years of education or more. An attempt to correct some of the inequities in the system was made through reforms instituted in 1971, but results have been limited.

Primary education

Brazil's pre-primary schools are about equally divided between state, municipal, and private institutions. Of the primary schools nearly one-half are located in the Northeast, although they enroll only about one-third of the nation's primary students; whereas the Southeast, with about 40 percent of the primary students, has one-fourth of the schools. The primary schools of the Northeast, and in the North and Central-West as well, are smaller, more dispersed, and in the hands of less qualified teachers than those in the South and Southeast. Furthermore, the schools in the former areas tend to be financed out of meagre municipal budgets, whereas in the latter they are predominantly state-supported. For example, in Bahia there are six times as many primary schools supported by municipalities than are funded by the state; in São Paulo the balance is reversed. Private schools generally account for a small percentage of primary school enrollments. The federal government also operates a small number of primary schools, mostly in the Amapá and Roraima territories and in the city of Rio de Janeiro, the latter a legacy from the days when it was the federal capital.

Only about 10 percent of the primary students in Brazil continue on to the secondary level, and, of these, most do not complete the three- to four-year program because many of the curricula involve short-term vocational training. Low overall secondary school enrollment is caused not only by the necessity of entering the work force at an early age (the census includes children as young as 10) but also by the fact that these schools are generally located in the larger towns. Attendance therefore can involve the considerable financial burden of living outside the home community. This is particularly true in the Northeast, where there are few secondary schools. About one-half of Brazil's secondary students are in the Southeast.

Higher education

Compared with developed countries, university enrollments are small in Brazil, whether in relation to the overall population or to that of the cities in which they are located; higher education remains largely the prerogative of the wealthy and of the more ambitious members of the middle class. Every political subdivision, be it state, territory, or the Federal District, with the exception of Fernando de Noronha, has at least one university, although in many cases these are limited to those established by the federal government. The largest of the national institutions is the Federal University of Rio de Janeiro, which has a modern campus located on an island in Rio's Guanabara Bay, near the international airport. The universities of Minas Gerais and Rio Grande do Sul are the next largest federal institutions, followed by those of several cities in the Northeast. The largest and most important state university, with the country's largest graduate student population, is the University of São Paulo. It has a main campus in the city of São Paulo and branch campuses around the state. Students may also attend a number of private institutions, many of them run by the Roman Catholic Church.

Welfare and health. Although Brazil is a homogeneous country relative to its overall cultural institutions, the social gap between its small privileged upper class and the masses at the bottom of the earnings scale is vast. Sandwiched in between them is a modest-sized middle class.

Because of inflation, salaries are expressed as multiples of the official minimum wage. Two-thirds of the working population earns two minimum salaries or less. About one-third of the northeastern work force earns only one-half the minimum, or less, compared with much lower numbers elsewhere. Food prices and wages do not rise synchronously, and the buying power of one-half of the minimum salary may mean as little as the equivalent of one loaf of bread and one quart of milk a day.

The majority of workers are covered by various benefits: health, unemployment insurance, retirement and severance pay, forced savings, and holiday pay. These are paid by the employer to the National Social Security Institute on the workers' behalf and can add significantly to labour costs. Brazil customarily spends a greater percentage of its gross national product on social services than it does on its military budget. There are, however, widespread complaints about the level and quality of benefits received. The majority of the working population leads a meagre life, a situation that is exacerbated in the cities by high housing and transportation costs.

Many of Brazil's health problems stem from widespread undernourishment and endemic diseases such as malaria, yellow fever, dengue, amoebic dysentery, tuberculosis, schistosomiasis, and the dread Chagas' disease, which is transmitted by the bite of an insect that infests the walls of wattle-and-daub houses. The majority of these, however, are largely absent at higher elevations and in the subtropical climate zones. Brazil's major research institute for tropical diseases, the Oswaldo Cruz Foundation, is located in Rio de Janeiro.

Although most endemic tropical diseases have been eradicated in the major cities, their reintroduction by migrants from infected areas has become a serious problem as far south as São Paulo. This has been exacerbated by poor sanitary and housing conditions, particularly among Brazil's millions of shantytown dwellers, or *afavelados,* who are concentrated in and around the larger cities. Programs at all administrative levels, supplemented by privately supported clinics, have been established for the purpose of improving health conditions in the *favelas,* particularly in prenatal and infant health care.

Hospitals

Most of the hospitals in Brazil are public institutions, only about one-fifth being private. The number of doctors per person increases progressively from the North and Northeast through the South and Central-West and reaches the highest ratio in the Southeast. In terms of services available, the greater proportion of the country's doctors and hospitals are concentrated in the urban areas. There is also a wide gap between the quality and promptness of services provided for those in the upper-income groups by the private sector and that available generally through public institutions, even though Brazil's physicians generally devote a part of their practice to public service. Numerous state and national agencies operate a variety of health care services, although often with limited programs. The one with the broadest mandate is the National Institute for Medical Assistance and Social Welfare, which operates hospitals, clinics, and laboratories in both rural and urban areas.

CULTURAL LIFE

The cultures of the Indians, the Africans, and the Portuguese have together formed the modern Brazilian way of life. By far the most dominant of these cultures is that of the Portuguese, from whom Brazilians acquired their language, their religion, and most of their traditional customs.

Indian and African influence

The influence of the aborigines and Africans is still apparent, however. Tupí-Guaraní, the language that was spoken by most of the Brazilian Indians, was adapted by 16th-century missionaries for teaching the catechism and for a time was spoken widely throughout the interior of northern Brazil by Indians, mestizos, Portuguese, and blacks. Many words in modern Brazilian Portuguese have their origin in the Indian language. The Indian contribution to Brazilian culture is, however, perhaps most apparent in the Amazon Basin.

African influence on the Brazilian way of life is strongest in the plantation region north along the coast from Rio de Janeiro. Particularly in Bahia, there are traditional dishes of African origin, such as *vatapá*—made of rice flour, coconut oil, fish and shrimps, red peppers, and many condiments. Evident in northern coastal cities are religious cults of African origin. African influence is also reflected in Brazilian popular music, especially in the rhythmic sambas.

Government involvement in virtually every aspect of Brazilian life has failed to lessen the individualism and initiative of the people. Despite numerous social and economic problems, Brazilians continue to be exuberant in their celebrations, their art forms, and in support of their favourite football (soccer) teams. Although among the oldest and most stable of the European-derived cultures in the Americas, Brazil is a country that adapts readily to rapid changes and new opportunities.

Daily life. The rapid, large-scale urbanization of Brazil during the post-World War II period has altered the lifestyle of the majority of the country's inhabitants. In most ways, large Brazilian cities differ little from others in the Western world, but their greater degree of crowding and large volume of pedestrian traffic may in some cases compare more closely with the cities of China than of North America.

Brazilians' family ties, both immediate and extended, generally remain stronger than in North America; family members customarily live in relatively close proximity to one another, holding frequent reunions or going to the family farm or ranch on weekends and holidays. However, this traditional system of kinship ties depends upon a certain degree of wealth and stability for its preservation, and it is no longer as strong as it once was, given the increased mobility and urbanization of the Brazilian people. In the *favelas,* various members of an extended family may occupy the same dwelling, but this may be of necessity in some cases, rather than tradition.

The arts. Brazil has had many world-renowned literary figures whose cumulative writings are regarded by many to be richer than Portugal's because of their variety of racial and regional themes. Best known in the 19th century were Joaquim Machado de Assis' romantic novels of the Brazilian people. In the 20th century, the Northeast has produced a particularly wide range of superb writing, including that of Gilberto Freyre on the subject of life under slavery, Graciliano Ramos' tragedies about the drought quadrilateral, and Jorge Amado's light-hearted stories set in the cacao-growing zone of Bahia. Érico Veríssimo's tales of southern Brazil have also been translated into many languages.

Architecture

The landscape architect Roberto Burle Marx has made urban Brazilians especially aware of the splendours of their natural environment by replacing the traditional, formal European-style gardens containing imported plants with a profusion of native species in close approximations of their natural settings. Some of Marx's landscapes have been used to set off the imaginative structures of Brazil's world-renowned architect Oscar Niemeyer. Among his works, Niemeyer designed a striking array of public buildings in Brasília, in collaboration with Lúcio Costa, the creator of the capital's original layout. Brazil also cherishes numerous splendid structures from its colonial and imperial past, from the tiled houses and ornate churches of Salvador to the palaces and public buildings of Rio de Janeiro. Among the most revered of these are the 18th-century churches in Minas Gerais that were adorned by facades, biblical scenes, and statues carved in soapstone by Antônio Francisco Lisboa, better known as Aleijadinho, the "Little Cripple."

Painting

Painting began developing in Brazil in the 18th century, but it was in the 19th century with the works of Belmiro de Almeida, Jr., that a truly original Brazilian art style began to develop, influencing a trend toward realism. In the 20th century the painter Cândido Portinari was influential in developing a uniquely Brazilian style, blending the abstract techniques of Europe with the real people and landscapes of his native land. The classical composer Heitor Villa-Lobos was also a powerful force in breaking with tradition to create distinctively Brazilian compositions by weaving into his music folk themes and rhythms of Portuguese, Indian, and African origins. In contemporary music, João Gilberto introduced the world to bossa nova rhythms, and Sérgio Mendes successfully blended the samba beat into North American and British popular songs.

Not only have the larger Brazilian cities been the scene of contemporary musical extravaganzas, but in Rio de Janeiro, São Paulo, Belo Horizonte, and elsewhere free outdoor concerts of classical music attract multitudes of listeners. Theatres are also widespread and well-attended, from the bawdy regional comedies in neighbourhood theatres to lavish classical productions in Rio de Janeiro's opera house. Art exhibitions range from modest displays in local museums and art galleries, to the prestigious International Biennial of São Paulo; established in 1951, it regularly attracts participants from more than 50 countries. Among the numerous learned societies that have arisen across the country, the Brazilian Academy of Letters, with its headquarters in Rio de Janeiro, is generally regarded as the most prestigious.

Recreation. The most famous Brazilian holiday is celebrated during the four-day, pre-Lenten Carnival. The combination of this Roman Catholic festival with the exuberant celebrations of people of African ancestry has become a lively tradition among the general populace. Carnival evolved principally in the urban centres of the former plantation areas, along the coast between Recife and Rio de Janeiro. In the latter, with its carnival groups, the so-called samba schools (*escolas de samba*), each involving several thousand people, the celebrations have attained their most extravagant expression.

There are various other official and church holidays during the year, including Independence Day, on September 7, and St. John's Night (Noite de São João) in June. The latter is celebrated with bonfires, fireworks, and the launching of small paper hot-air balloons, although the latter are nominally prohibited in the cities because of the fire hazard. Another important festival along the coast is that of the African cult diety Iemanjá, Goddess of the Oceans (also, St. Barbara, patron of seamen); on New Year's Day (a national holiday) fishing vessels head out to sea with offerings that are thought to determine the success or failure of the coming year's catch.

Sports

Class distinctions are not important during celebrations, or among those who attend football (soccer) games, or among those who flock to the country's many beaches. The latter are social gathering spots for young people, where the more athletic play football and various racket games, and for whom municipal governments often provide volleyball courts and other recreational paraphernalia. But football is the nation's most popular sport, and Brazilians are highly enthusiastic fans. It is played virtually everywhere by young and old and amateur and professional, drawing huge crowds to international matches at stadia in the major cities; the largest of these, the Maracanã stadium in Rio de Janeiro, has a capacity of 200,000. Brazilian teams are consistently among the top contenders for the World Cup, and from Brazil came the world-renowned Pelé, one of the greatest players of all time. There are also numerous public parks, both within the cities and at nearby scenic areas, that are used for casual recreation and by family or group picnics.

Parks

In general, state and even national parks are located near urban centres and tend to be heavily provided with amenities. At the other extreme, however, are the newer national parks, which are located in remote areas, particularly in the headwaters of various Amazonian tributaries where they may be adjacent to biologic reserves or Indian reservations. They are not intended for any great number of visitors, and facilities are limited or nonexistent. Park boundaries have been modified when they stand in the way of a new highway or some other development, but since the early 1960s the federal government has become more aware of the need for conservation areas, and a Special Secretariat for the Environment has been established. Among the more popular parks are Itatiaia National Park, Iguaçu National Park, and Serra dos Órgãos National Park.

Press and broadcasting. Brazil's principal newspapers are the *O Estado de São Paulo* and the *Folha de São Paulo,* both in that city, and the *Jornal do Brasil, O Globo,* and *O Dia* in Rio de Janeiro, but numerous others are published in the smaller cities and towns. There are also a number of weekly magazines, including the newsmagazine *Visão* and the glossy pictorial *Manchete.*

Press and broadcasting are intimately linked in Brazil, including television's TV Manchete network and the TV Globo, which, with Rádio Globo, is the largest and most influential of the country's broadcasting media. There are also several lesser networks in radio and television as well as a large number of regional and local stations. An educational network broadcasts to a limited number of major cities. Common television fare includes the tremendously popular prime-time *novelas* (daily hour-long soap operas), sporting events, news, special reports, foreign movies dubbed into Portuguese, and children's programs. In many ways television, in conjunction with massive urban migration, has furthered the homogenization of Brazilian culture and the modification of regional differences.

For statistical data on the land and people of Brazil, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL. (C.W.W./T.L.S./R.P.Mo.)

History

PRE-EUROPEAN BRAZIL

The enormous land area that became Brazil was sparsely populated with indigenous Indians at the time of its discovery by Europeans in the year 1500. Sources have varied in their estimate of the Indian population, although an estimate of more than 2,000,000 is generally recognized. Living for the most part in small tribal groups, the Indians generally were divided into two different groups: the tropical forest peoples and those of marginal cultures. The former group, largely inhabitants of the Amazon

Basin, were somewhat more culturally advanced, having achieved some skill in farming and fishing. The marginal groups lived mainly by hunting and gathering in the drier savanna regions.

The Tupí

Among the more significant of the tropical forest groups were the Tupí, inhabitants of the coastal areas. When the Portuguese arrived, it was the Tupí that they first encountered, and for a considerable period the newcomers carried on their main dealings with that tribal group. Indeed, it may be said that the Tupí were the most important single Indian influence in the early Brazilian colonial period and in the Brazilian culture that developed subsequently. This accomplishment, however, did little to ameliorate the harsh treatment they suffered under European domination.

EARLY PERIOD

Discovery and settlement. The European discovery and early settlement of Brazil appear in the larger perspective of history as episodes in the great movement of Portuguese colonial expansion to the East. Vasco da Gama's discovery of an all-water route to the Indies and the Spice Islands by the Cape of Good Hope in 1498 led the Portuguese crown to dispatch to India an imposing armada under Pedro Álvares Cabral, whose sailing directions had been drawn up by da Gama himself. To avoid the calms off the Gulf of Guinea, Cabral bore so far to the west that on April 22, 1500, the mainland of South America was sighted, and the region was promptly claimed by Portugal, because it lay well within the zone assigned to Portugal by the Treaty of Tordesillas (1494). Portugal's new possession was at first called Vera Cruz (True Cross), a name soon abandoned in favour of Brazil, after the valuable red dyewood (*pau-brasil*) in which the country abounded.

Vespucci's voyage along Brazil's coast

The tidings of Cabral's discovery aroused great enthusiasm, and further explorations were undertaken. One of these expeditions had as its pilot Amerigo Vespucci, whose small fleet sailed along the coast of Brazil and for the first time realized the extent of the land. Vespucci, calendar in hand, baptized the different points on the coast with the names of the saints on whose days they were discovered.

For some years following Vespucci's voyage, interest in Brazil waned. Although a desultory trade with the Indians for brazilwood had begun, the failure to discover precious metals in Brazil focused Portuguese attention on their much more lucrative trade with Asia. Portugal's rivals quickly took advantage of that neglect. The French, in particular, trespassed on Portugal's claims in South America and shipped the valuable red dyewood to Europe. Brazil became a sort of no-man's-land over which the Portuguese crown wielded only a shadowy control. This apathy ended, however, with the accession of John III (reigned 1521–57), and the interest in colonial affairs gradually shifted from Asia to America.

The first systematic effort to establish an organized government in Brazil was made in 1533. Brazil was divided into 15 hereditary captaincies, or fiefs, extending 50 leagues along the coast and an indefinite distance inland. These grants were distributed to favoured persons, chiefly courtiers, who took the names of *donatários*. Their rights and privileges were extensive. The captaincy system failed to realize the hopes of the crown, however, only two of them being truly successful. The most flourishing of the settlements was that of São Vicente, south of the present city of Santos. By the middle of the 16th century this captaincy had a population of about 5,000, including the growing port of Santos and the village of São Paulo on the Serra do Mar's fertile plateau of Piratininga. In northern Brazil, Duarte Coelho Pereira had converted the captaincy of Pernambuco into a great sugar-producing region, offering the first example of a profitable agrarian export from the New World to Europe. To the annoyance of the crown, however, Europeans continued to trespass, threatening Portugal's claims to the New World.

Royal control. King John III determined to substitute for the inefficient rule of the *donatários* a unified, centralized administration. To strengthen royal control, he appointed a governor general for Brazil. Tomé de Sousa, a Portuguese noble with impressive experience in India, took up those duties in 1549, founding a capital for the colony, Bahia (Salvador), from which governors general, later viceroys, governed for the next 214 years. Local officials, responsible to the governor general, were placed over the captaincies, and strategic points along the coast were fortified. In the cities, municipal organizations, similar to those in Portugal, were established. Brazil then began to attract settlers in increasing numbers. By 1600 Bahia and Pernambuco (Recife) each had a population of 2,000 whites, with more than twice as many black African slaves and converted Indians.

Jesuit missionaries

A factor of great importance in the progress of the colony was the labour of the Jesuits. At the request of John III several fathers accompanied Tomé de Sousa to Bahia. Among them was Manuel da Nóbrega, the first of a long line of missionaries who devoted their lives to the protection and conversion of the Indians and to raising the moral level of the colonists. As rapidly as the Indians were converted, they were settled in villages, or *aldeias,* similar to the missions in Spanish America. Jesuit control over a valuable labour supply aroused the ire of the colonists, who did not hesitate to enslave Indians. The conflict between Jesuits and colonists over control of the Indians reverberated throughout the colony. Both parties appealed to the crown. The Jesuits won a partial victory in the royal decree of 1574, granting them full control over the Indians in the *aldeias* while permitting the colonists to enslave Indians captured in legitimate warfare. In the north, the storm centre of a somewhat similar conflict was Father António Vieira, who in the 17th century established a chain of missions in the Amazon Valley. The restrictions on Indian labour stimulated the introduction of black African slaves, a movement that steadily gathered momentum after the middle of the 16th century.

Dutch and French incursion. Brazil had hardly been brought under royal authority before a determined effort was made by the French to establish a permanent colony. In 1555 the French took possession of the beautiful harbour of Rio de Janeiro, which the Portuguese had strangely neglected to occupy. Meanwhile, the Portuguese had come to realize the extent of the French menace. A large force under Mem de Sá, the governor general, blockaded the entrance to the harbour and forced the French garrison to surrender. To ward off future attacks, Mem de Sá in 1567 founded the city of Rio de Janeiro.

From 1580 to 1640 Portugal was united to Spain, and, as a part of the Spanish colonial empire, Brazil was naturally exposed to attacks by Spain's enemies. Among these were the Dutch, who had just succeeded in establishing their independence. They seized and briefly held Bahia in 1624–25, and in 1630 a fleet sent out by the Dutch West India Company captured Pernambuco, the centre of the rich sugar-growing district in the north. As governor of its new possession the company chose Johan Maurits, graaf von Nassau-Siegen, a prince of the House of Orange and perhaps the ablest man in the Netherlands. Distinguished artists and scientists were invited to make known to Europe the resources and beauties of Brazil. But the directors of the company, intent on a policy of greed and gain, refused to support their enlightened governor, and he resigned in 1644. A rebellion launched by a wealthy plantation owner, João Fernandes Vieira, proved beyond the power of Maurits' incompetent successors to crush. The Brazilians themselves defeated and expelled the Dutch in 1654, an achievement that enhanced growing nationalistic sentiments among them.

Westward expansion

Expansion and unification of Brazil. Perhaps the most impressive development of the colonial period was the vast expansion of Brazil beyond the line of Tordesillas (a vertical line drawn 370 leagues west of the Cape Verde Islands)—an expansion that reached westward to the slopes of the Andes and north and south to the Amazon and the Río de la Plata. In the north the movement was led by missionaries, who, in seeking to convert the Indians to Christianity, established missions along the Amazon in the 17th century. In the northeast, cattlemen from the sugar zones of Pernambuco and Bahia pushed inland into the present area of Piauí, Maranhão, and Goiás in search of new pastures. The brunt of the "march to the west," however, was borne by the Paulistas, as the settlers of São Paulo were called. With the purpose of capturing Indian slaves and of finding gold and precious stones, they organized great expeditions into the interior, known as *bandeiras*. Some of the more spectacular *bandeiras* took the Paulistas as far as the silver-mining region of Peru and even to the area of Bogotá in Colombia. In the 17th century they explored the area of Mato Grosso and attacked the Indian *reducciones* (Indian missions) of Misiones and southern Brazil. For the most part they met with resistance from the Indians and their Jesuit protectors; only about the Río de la Plata, in modern Uruguay, did the Spanish settlers resist the invaders, and there eventually the Paulistas were pushed back. The *bandeirante* expansion contributed significantly to the unification of the huge subcontinent of Brazil.

Portuguese as the common language

Other factors added to the growing unification. A unique Luso-Afro-Indian culture emerged. The Portuguese language formed a common bond between plantation residents, cattlemen, miners, slaves (both Indian and black), slave hunters, and city dwellers from the Amazon to the Río de la Plata and distinguished them from their Spanish-speaking counterparts elsewhere in South America. The expanded, patriarchal family structure, also derived from Portugal, was nearly uniform throughout Brazil, and power was exercised in all regions by the heads of those families that controlled the land, slaves, cattle, and, later, mines that produced the wealth of the colony. Despite regional differences, Brazilian society and economy were rurally based. This pattern persisted for a century after the colonial period. The population was divided unevenly between the few who possessed landed wealth and the majority who were dependent upon them. Only three important cities, Bahia, Rio de Janeiro, and Recife, grew up in Brazil during the colonial period. Moreover, contact with Portugal, although at times intermittent, was maintained with all parts of Brazil, and little trade or other regular contact existed between Brazil and neighbouring Spanish colonies. These common factors proved stronger than regional variants when Brazilian unity was under stress in the second quarter of the 19th century.

The colonial economy of Brazil was marked by two major cycles, that of sugar and that of gold. Both reflected the significant role of exports in the Brazilian economy. As mentioned above, the sugar industry, confined primarily to the northeast, was introduced into Brazil early in the 16th century, and it was the principal basis for the wealth of the colony for more than 200 years. Throughout the entire period of Portuguese control in Brazil, sugar produced substantially more revenue for the crown than did any other export product, including gold. A plantation product, sugar called for a large capital investment in land, slaves, and machinery, and consequently it was concentrated in the hands of a relatively small number of wealthy families. Tobacco and cattle raising, conducted chiefly by independent freemen around the periphery of the sugar plantations, became important industries before the end of the colonial period. In the 18th century, cotton and coffee, originally produced by small landholders, were also becoming significant exports.

Discovery of gold in Minas Gerais

Gold, which was sought by colonists in Brazil from the period of first settlement, was not found until 1695 in what is now the state of Minas Gerais. The deposits were the wealthiest that had been discovered to that date, and their discovery set off a gold rush that anticipated in many ways the days of 1849 in California and those of 1851 in Australia. In the hitherto unbroken wilderness, towns sprang up as if by magic, while large sections of the littoral or coastal region were virtually denuded of their inhabitants. African slaves from the sugar plantations and directly from the gold-working regions of Africa introduced many of the techniques employed by Brazilian miners. The yield of the mines during the 18th century has been variously estimated at between £50,000,000 and £200,000,000. The impact of the gold mines upon the Brazilian economy was largely responsible for the transfer of the capital of the colony from Salvador to Rio de Janeiro in 1763. The search for gold led to the discovery of diamonds in the early 18th century in Minas Gerais, Bahia, and Mato Grosso. The gold rush tapered off as the original deposits were depleted, but some gold and diamonds were still being mined in the 20th century.

Colonial reforms. The treaties of Madrid (1750), Pardo (1761), and Ildefonso (1777) with Spain gave some legality to Portuguese claims including the conquests of the *bandeiras*. During this period, Sebastião José de Carvalho e Mello, marquês de Pombal, the prime minister of King Joseph, introduced into Brazil a number of reforms that profoundly affected the social, administrative, and religious life of the colony. The last rights of the *donatários* were absorbed by the crown, the capital was transferred from Bahia to Rio de Janeiro, the Indians were placed on a legal equality with the whites, immigration from the Azores and Madeira was encouraged, two privileged companies were created, and a monopoly of the diamond fields was established. Pombal expelled the Jesuits from Brazil in 1759. Through their protection of the Indians and their various commercial ventures, they had stirred up widespread resentment, and when they attempted to thwart some of Pombal's reforms, the all-powerful minister banished them from both Portugal and Brazil with brutal thoroughness. With an increased centralization of power and by strengthening the lines of command, Pombal progressed toward the unification of Brazil during the final decades of Portuguese rule.

Expulsion of the Jesuits

THE INDEPENDENCE OF BRAZIL

In 1789 the first rebellion against the Portuguese was instigated by José Joaquim da Silva Xavier, who was known as Tiradentes (Tooth Puller) because he occasionally extracted teeth. The uprising was put down, and Tiradentes, who became a national hero, was executed.

Despite its isolation, Brazil could not escape the effects of the revolutionary and Napoleonic epoch in Europe. In 1807 Napoleon invaded Portugal, a traditional British ally, largely to tighten the European blockade of Great Britain. The Portuguese prince regent Dom John, afterward King John VI, decided to take refuge in Brazil, the only time a colony ever served as the seat of government for its mother country. He sailed from the Tagus on Nov. 29, 1807, under the protection of the British fleet. Accompanied by the royal family and a horde of nobles and functionaries, he arrived at Rio de Janeiro on March 7, 1808.

Arrival of Dom John in 1808

The colonists, convinced that a new era had dawned for Brazil, welcomed their sovereign. The Prince Regent promptly decreed a number of reforms that altered the status of the colony. The Portuguese commercial monopoly on Brazilian trade was abolished in 1808, and Brazilian harbours were opened to the commerce of all friendly nations. That same year prohibitions on Brazilian manufacturing were terminated.

To accommodate the imperial administration and to answer local demands, a ministry and a council of state were installed in Rio de Janeiro, and a supreme court of justice, a court of exchequer and royal treasury, the royal mint, the Bank of Brazil, and the royal printing office were established. A royal library, a military academy, and medical and law schools were founded. The status of Brazil was reflected in the decree of Dec. 16, 1815, by which the Portuguese dominions were designated the United Kingdom of Portugal, Brazil, and the Algarves, thus making Brazil coequal with Portugal. In 1816 the queen, Maria I, died, and the Prince Regent became king.

The regency of Dom Pedro

The presence of John VI in Portugal was imperative if the crown was to maintain its authority there. On April 22, 1821, he appointed his son Dom Pedro regent and two days later set sail for Lisbon. Meanwhile, antagonisms between the Portuguese and Brazilians were becoming increasingly bitter, republican propaganda was active, and Dom Pedro had to face the responsibility of a separation of Brazil from Portugal as a result of the shortsighted policy of the Cortes at Lisbon. The majority of this assembly favoured the restoration of Brazil to its former status of colonial dependence. Without waiting for the Brazilian deputies, they proceeded to undo most of the reforms introduced into Brazil by John VI. Fearful that Dom Pedro might head a movement for independence, the Cortes ordered him to return to Europe.

These acts aroused great indignation in Brazil. Supported by the majority of Brazilians, Dom Pedro defied the Cortes by his refusal to return to Lisbon. In January 1822 he formed a ministry in which the chief portfolio was held by the distinguished Paulista, José Bonifácio de Andrada e Silva. Known as the Patriarch of Independence, he was a scholar of European reputation and proved at this critical juncture a tower of strength to the young regent. Events followed rapidly. On June 3 Dom Pedro convoked a legislative and constituent assembly. On September 7, on the plain of Ipiranga, near the city of São Paulo, he solemnly proclaimed the independence of Brazil, and on Dec. 1, 1822, he was crowned the nation's emperor.

The new nation achieved quick recognition, which came first from the United States, in 1824. After the Portuguese acknowledged Brazilian independence in 1825, other European monarchies established diplomatic relations. The relative ease by which Brazil entered nationhood stood in sharp contrast to the experiences of the Spanish-language nations of the New World.

THE BRAZILIAN EMPIRE (1822–89)

The con-
stitution of
Pedro I

The first years of independence were difficult. The nation was without experience in self-government, and the Emperor was inclined to be despotic and arbitrary. When the constituent assembly proved unmanageable, Pedro I dissolved it in 1823 and sent the radical Andrada e Silva and his two brothers into exile. With the aid of the Council of State, Pedro wrote a constitution, considered both liberal and advanced for the period. It provided for the centralization of government, placing strong powers into the hands of the emperor. After the municipal councils debated and approved the document, Pedro promulgated it in 1824. The constitution proved versatile enough to last throughout the imperial period. The popularity of the impulsive Pedro was diminished, however, by a number of occurrences, including the loss of the Cisplatine Province (the present republic of Uruguay) as a result of a costly war with Argentina (1825–28), the humiliating treaties with Great Britain that kept import duties low and exacted a promise to abolish the slave trade, the continuous appointment of Portuguese-born officials to high office, the preoccupation of the Emperor with Portuguese affairs, and the inability of the Emperor to get along with the legislature. As a result, Pedro formally abdicated on April 7, 1831, in favour of the heir apparent, Dom Pedro de Alcântara (Pedro II), then only five years of age.

The regency (1831–40). The next decade proved the most agitated period in Brazilian history. From 1831 to 1835 a triple regency tried in vain to end civil war in the provinces and lawlessness and insubordination in the army. In 1834 the constitution was amended to grant a measure of decentralization to the provinces, through the creation of provincial assemblies with considerable local power, and to provide for a sole regent to be elected for four years. For this office in 1835 a priest, Diogo Antônio Feijó, was chosen. For two years he struggled against disintegration, but he was forced to resign in 1837 and was succeeded by Pedro de Araújo Lima. Sentiment began to crystallize in favour of a declaration of majority of the young Dom Pedro. The Brazilians, impatient with the regency, hoped to find in the Emperor a symbol to which the entire nation might rally. On July 23, 1840, both houses of parliament passed a declaration that Pedro de Alcântara had attained his majority.

Prestige
and
progress
under
Pedro II

Pedro II. The reign of Pedro II, lasting practically a half century, constitutes perhaps the most interesting and fruitful epoch in Brazilian history. The prestige and progress of the nation were due largely to the enlightened statesmanship of its ruler. Though not without personal distinction he was always simple, modest, and democratic. He possessed an insatiable intellectual curiosity and was never happier than when conversing with scholars. He was generous and magnanimous to a fault. One of his favourite occupations was inspecting schools. He was wont to declare, "If I were not emperor I should like to be a schoolteacher." Yet this kindly, genial, and scholarly ruler took his prerogatives and duties as sovereign with great seriousness, and in all matters of first importance he was the final arbiter. According to the moderative power granted to the executive under the constitution of 1824, the emperor had the right to dissolve the Chamber of Deputies, to select the members of the life senate from triple lists submitted by the province, and to appoint and dismiss ministers of state. A kind of parliamentary government functioned under the watchful eye of the Emperor.

Pedro's government took a keen interest in the affairs of the Plata republics, especially of Uruguay, which it sought to control through indirect measures. Brazil aided in the overthrow of the Argentine dictator Juan Manuel de Rosas in 1852. In 1864 Brazil intervened in Uruguayan internal affairs, precipitating war with Paraguay. In alliance with Argentina and Uruguay, Brazil successfully waged the costly and bloody Paraguayan War of 1864–70, eventually overthrowing the Paraguayan dictator Francisco Solano López. This war of the Triple Alliance was the longest and bloodiest war in South American history, and its consequences in Brazil were profound. The empire's relations with the United States and with Europe were generally cordial, Pedro personally visiting Europe in 1871, 1876, and 1888 and the United States in 1876.

Dissension
over
slavery

The empire's major social and economic problems were related to slave-based plantation agriculture. Real political power remained with large rural landholders, who formed the core of the social and economic elite of Brazil. Industrialization was still economically insignificant, and, with the decline of gold mining, agriculture was unrivaled as the source of Brazil's wealth. Cotton, and increasingly after 1840, coffee, competed with sugar as the leading export crop. The rural landholders were largely insulated from the antislavery current of the times. Although manumission was common, and the number of freedmen and their descendants far surpassed the number of slaves in Brazil, the slave owners as a group resisted pressures for the complete abolition of slavery. Partly as a result of pressure from Great Britain, Brazil had agreed to abolish the slave trade in 1831, but it was not until 1851 that slave traffic completely ceased. Agitation to abolish slavery as such began in the 1860s. Pedro was opposed to slavery, but he had to reckon with the slave owners. Yet the ending of slavery internally seemed the next logical step after stemming the importation of slaves. Accordingly, in 1871, the Law of the Free Womb was enacted, declaring free all children born to slaves. The legislation condemned slavery to eventual extinction. But, although agitation subsided briefly, this concession did not satisfy many of the abolitionists. Led by a young lawyer and writer, Joaquim Nabuco de Araújo, they demanded immediate and complete abolition. Nabuco's book *O Abolicionismo* (1883; *Abolitionism*) endeavoured to prove that slavery was poisoning the very life of the nation. In 1884 Ceará and Amazonas freed their slaves; in 1885 all slaves over 60 years of age were liberated. Finally, complete emancipation without compensation to the owners was decreed by the Princess Regent in the absence of the Emperor on May 13, 1888. About 700,000 slaves were freed.

The collapse of the empire. Under Pedro II's wise guidance Brazil had progressed considerably. His rule witnessed a growth in population from 4,000,000 to 14,000,000, a 14-fold increase in public revenues, and a 10-fold increase in the value of the products of the empire. Railroad mileage in 1889 exceeded 5,000 miles; that year more than 100,000 immigrants entered Brazil. Yet there were grave causes of dissatisfaction. The fall of the monarchy has often been ascribed to a restive military, a brooding landed aristocracy, and a resentful clergy. Indeed, those three powerful groups voiced increasingly frequent complaints. Perhaps more pertinent, however, was the widening gulf between a neo-feudal countryside and the more progressive cities and coffee planters during the closing decades of the century, an indication of institutions under severe stress. The urban middle class, the military, and the coffee planters regarded the monarchy as too closely tied to the traditional landed class. The monarchy represented the past; a republic better suited the goals of emerging coffee and industrial capitalism. A conspiracy of those who would propel Brazil toward greater modernization counted on the military to remove the Emperor, and the officers

Abolition of slavery

did so on Nov. 15, 1889. Pedro II abdicated and sailed into a European exile. The abolition of slavery in 1888 and the overthrow of the monarchy in 1889 terminated the two major institutions that had shaped Brazil's past; in so doing they initiated a period of social, economic, and political change that accelerated modernization. Accordingly, the period between 1888 and 1922 witnessed the emergence of a "new Brazil."

BRAZIL SINCE 1889

With support of the military, the nascent middle class, and the prosperous coffee planters, Marshal Deodoro da Fonseca governed Brazil. He established a republic, separated church and state, and, on Feb. 24, 1891, promulgated a new constitution, characterized as presidential, federal, democratic, and republican. The new states of the republic exercised more power than had the empire's provinces.

The "coffee presidents." In 1891 Congress elected Deodoro da Fonseca as president, but he proved unable to govern under the new constitution. His act of forcibly dismissing a dissenting Congress raised such public outcry that he resigned. The popular vice president, Marshal Floriano Peixoto, ascended to office on Nov. 23, 1891. By defeating several monarchist and military revolts, he restored tranquillity and order to the nation. In 1894 he turned over the presidency to the first civilian president, Prudente de Morais, the first republican governor of coffee-rich São Paulo. Under the successive "coffee presidents," primarily from the states of São Paulo or Minas Gerais, Brazil enjoyed peace, financial reform, and mounting coffee exports.

Growing dependence on coffee exports

The economic and political centres of the nation had shifted from the old sugar regions of the Northeast to the new coffee regions of the Southeast. In an economy overly dependent on exports for its vitality, coffee dominated, accounting for 46 percent of the exports by 1901 and 53 percent by 1908. Everything went smoothly for the coffee planters and the national economy until the early years of the 20th century, when overproduction threatened coffee—and, thus, national—prosperity. To counter that threat, representatives of the three major coffee-producing states, São Paulo, Minas Gerais, and Rio de Janeiro, signed a federal government-backed agreement at Taubaté in 1906 to guarantee a fair world market price for coffee. The agreement inaugurated the scheme of coffee valorization—the purchase of excess coffee and its removal from the market in order to maintain its price.

The trends of immigration and urbanization accelerated. The rubber boom in the distant Amazon Basin changed isolated Manaus into a cosmopolitan city with electricity, streetcars, cinemas, a grandiose opera house, and an international society. Under the direction of prefect Francisco Pereira Passos, Rio de Janeiro was transformed into one of the world's most beautiful cities, and also a more healthful one, due to the eradication of yellow fever by the distinguished physician and scientist Oswaldo Cruz. Coffee prosperity metamorphosed São Paulo, whose population jumped from 35,000 in 1883 to 350,000 in 1907, into the bustling commercial centre of the nation. Santos became one of the world's busiest ports, sending coffee exports to the cities of Europe and North America.

During the time that great material change was taking place, Brazil was also undergoing a literary renaissance. The intellectuals at the turn of the century fixed their eyes on the new Brazil and analyzed it carefully. Two of the foremost novelists, Joaquim Maria Machado de Assis and Afonso Henriques de Lima Barreto, took a penetrating look into Brazilian society. In his masterpiece, *Os Sertões* (1902; *Rebellion in the Backlands*), Euclides da Cunha described the clash between the backlands with their timeless tradition and the cities as the focus of modernity: the conflict between the "two Brazils."

Territorial gains of Rio Branco

Under the brilliant leadership of the barão do Rio Branco, José Maria da Silva Paranhos, a diplomat who became foreign minister, the Luso-Brazilian policy of territorial expansion reached its fruition between 1895 and 1909. Using the principle in international law of uti possidetis, which grants territory to the power that absolutely controls it, he advantageously closed the 9,000 miles of borders separating Brazil from its neighbours and won Brazil's claims to approximately 342,000 square miles of territory, an area larger than France. Somewhat more difficult to measure, but of greater importance, was his elimination of the potential causes for war, misunderstanding, and dispute. As foreign minister in 1902–12, Rio Branco shifted Brazil's diplomatic axis from London to Washington, D.C. Sympathetic to the Allied cause, Brazil declared war on Germany on Oct. 26, 1917. Brazil participated in the peace conference and held a temporary seat on the Council of the League of Nations.

Rebellion against the coffee elite. Resentful of the political and economic institutions favourable to the coffee planters, the growing urban middle class agitated for changes. So did the military, particularly the junior officers. In the elections of 1922, urban groups and the military united in an unsuccessful effort to wrest the presidency from the coffee elite. Thereafter, violent protest erupted in Brazil. In July of 1922, shortly after the coffee interests had once again imposed their presidential preference on the nation, a handful of junior officers revolted in Rio de Janeiro in a poorly planned effort to overthrow the moribund republic. It signaled the beginning of an eight-year period of unrest that came to a climax in 1930 with the fall of the old republic. Military uprisings of a more threatening nature—once again dominated by junior officers—broke out in 1924. Survivors of that rebellion marched thousands of miles through the interior in the mid-1920s attempting to stir up revolt. The countryfolk were still too dominated by the local landowners to be enlisted into the ranks of rebellion. The countryside never had been the place to foment change in Brazil, and the failure of the efforts in the mid-1920s proved that it still was not.

It was in urban Brazil that the demand for social and political progress grew. Sharpened by cultural nationalism, especially promoted by the Modern Art Week in São Paulo in 1922, criticism of the "coffee governments" mounted within the cities. The nationalists denounced the selfish regional monopolization of power, manipulated elections, and continuation of colonialism.

The *tenentes*

By 1926 the movement of the junior military officers, known as *tenentes* (meaning "lieutenants"), had acquired a somewhat more identifiable, though imprecise, nationalistic philosophy of political and economic development. The *tenentes* maintained a mystical faith that somehow the military could alter the habits of the country and provide the impetus to propel it into the modern age. Their primary concern was not democracy but reform and development. They wanted to retire the entrenched politicians and begin the modernization process; then would they consent to return the nation to constitutional rule. They hoped to expand the base of the government and to eradicate regionalism, while favouring a strong, centralized government. Revealing social democratic tendencies, the *tenentes* proposed government recognition of trade unions and cooperatives, a minimum wage, maximum working hours, child-labour legislation, agrarian reform, nationalization of natural resources, and expanded educational opportunities. Obviously much of the program advocated by the *tenentes* favoured the goals of the urban middle-class groups. Those groups, however, failed to understand that the military rebellions and movements in the 1920s could have been turned to their advantage; they were unable to coordinate their desires for modernization with the similar desires of the young officers. It was, finally, two related events that ended the monopoly of political power held by the coffee elites. The first was the precipitous decline of coffee prices caused by the international financial crisis of 1929–30; the second was the determination of the politicians of São Paulo to impose yet another one of their group as president of the nation in 1930. These movements and events combined to bring to an end the old republic and mark the beginning of a new era.

The Vargas era. When the administration-sponsored presidential candidate was officially declared winner in the 1930 election, a revolt broke out. This successful rebellion was led by Getúlio Vargas, governor of the state of Rio Grande do Sul, who was to remain central in Brazilian national life until his suicide in 1954.

The Estado Nôvo

Vargas held office as chief executive on two occasions, 1930–45 and 1951–54. Early in the first of these periods, the country's difficulties were essentially economic, accentuated by a policy of subsidizing coffee production, and the tremendous powers of the states served as steady irritants to the country. In 1934 a new constitution gave the central government greater powers. Three years later, President Vargas seized practically absolute power and set up still another constitution, under which he continued as president. The new administration, known as the Estado Nôvo (New State), so concentrated power in Vargas' hands that he was able to suppress all manifestations of popular will. Vargas stripped Brazil of most of the trappings through which it might eventually hope to become a democracy. However, social legislation was enacted, with positive benefits to the labouring class.

Vargas' policy concentrated upon curtailment of states' rights, emphasis on nationalism, and the transfer of the locus of power from the country to the city. The states were increasingly subordinated to the central government, politically, economically, and socially. His government urged greater diversification of agriculture and the further development of industrialization, whose import-substitution phase accelerated impressively.

After the outbreak of World War II in 1939, Vargas' government supported inter-American solidarity; on Aug. 22, 1942, it declared war against Germany and Italy. Besides participating in the defense of the South Atlantic, Brazil sent an expeditionary force to Italy in July 1944 that distinguished itself in several battles. Brazil also allowed the United States to use certain Brazilian naval and air bases during the war. Agreements were signed between the two governments for the economic development and production of Brazilian raw materials.

On Oct. 29, 1945, the military forced President Vargas to resign as it began to appear more likely that he would attempt to retain power. From his resignation there initiated a period of experimentation with democracy.

The democratic interlude. General Eurico Gaspar Dutra, Vargas' own choice, won the presidential election in December 1945. Vargas himself was elected to a seat in the Senate. In September 1946 a new constitution was promulgated, Brazil's fifth and the fourth of the republican era. In reaction to the Vargas experience, the new constitution sought to prevent the rise of another overpowering president. While the presidency remained the key institution, the office was sufficiently circumscribed to inhibit a future leader from abuse of power. The new constitution separated the three branches of government, ensuring Congress of its independence and freedom in the election of its members. Restrictions were put in place to prevent abusive federal intervention in the internal affairs of the states.

Return of Vargas to power

The general elections of 1950 returned Vargas to power, however, by a substantial margin. While he failed to secure a clear majority in the four-way race, he polled 1,500,000 more votes than the runner-up and nearly as many as the combined total for the three rival candidates. Accordingly, despite serious reservations by the military leaders who had deposed him in 1945, he was installed in the presidency once more on Jan. 31, 1951. During his second period in power, Vargas was unable to dominate the political forces of the country or to exploit social and economic trends to his advantage; he endeavoured to abide by the constitution of 1946 and was criticized in some quarters for weak leadership. Lacking a firm majority in the Congress, he could neither enact his own program nor resist the contradictory pressures of his supporters and opponents. The most serious continuing problem was economic. Brazilians agreed upon the need for more rapid industrial development and measures to ameliorate the effects of gradual monetary inflation, which persisted as government expenditures consistently outran revenues. Vargas maintained a precarious balance between the advocates of greater state intervention in the economy and those who insisted upon a favourable climate for domestic and foreign private investment. The situation was complicated by the campaign to nationalize the natural resources of the country. The campaign culminated in the creation of the national petroleum corporation, Petrobrás, in 1953, a formidable nationalist victory.

Vargas' suicide

For three years Vargas' popularity largely protected him from attack by political adversaries, who directed their criticism against members of his administration. João Goulart, Vargas' young protégé and vice president of the Brazilian Labour Party (Partido Trabalhista Brasileiro; PTB), who became minister of labour in 1953, was accused of using his office to transform organized labour into a political machine loyal to Vargas. His sponsorship of a decree doubling the minimum wage, thus strengthening labour–administration ties and contributing to the inflationary spiral, led to his dismissal in 1954. A series of crises that followed reached a climax on Aug. 5, 1954, by the murder of an air force officer and the attempted assassination of opposition newspaper editor Carlos Lacerda. Investigation revealed that the assassins had been hired by the President's personal guard. The exposure of widespread corruption within the administration caused a wave of antipathy for the former dictator. A group of army officers presented Vargas with a demand for his resignation; Vargas complied on Aug. 24, 1954, and later that day committed suicide.

Kubitschek's administration. Vice President João Café Filho served out the remainder of Vargas' term. Much of the Café Filho administration was occupied by preparations for the presidential election of Oct. 3, 1955. After the failure of attempts to find a single candidate around whom all major political parties might rally, three strong candidates for the presidency emerged: former Minas Gerais state governor Juscelino Kubitschek de Oliveira, popularly regarded as Vargas' political heir; former São Paulo state governor Ademar de Barros, with broad backing from financial and commercial groups; and Marshal Juárez Távora, considered as the representative of conservative military and civilian groups. In the 1955 election Kubitschek was the victor with slightly more than one-third of the total vote; in the separate vice-presidential election, João Goulart won with a large plurality. The election was widely interpreted as a popular vindication of the Vargas position. The illegal but active Communist Party, which had thrown its unsolicited support to Kubitschek, claimed to have provided his margin of victory. Rumours of a Café Filho administration plot to use unconstitutional means to prevent the inauguration of Kubitschek and Goulart were not proved, but the conservative press—which regarded Kubitschek as a dangerous radical—added to the tension. President Café Filho suffered a mild heart attack and on Nov. 8, 1955, transferred power temporarily to his constitutional successor, Carlos Luz, speaker of the Chamber of Deputies. The following day Luz indicated that he would dismiss the war minister Marshal Teixeira Lott to resolve a conflict of authority between the executive and the war minister. This was interpreted by Kubitschek's backers as the signal for a coup d'état by anti-Kubitschek forces. On Nov. 11, 1955, Teixeira Lott and Marshal Odílio Denys, commander of army troops in Rio de Janeiro, staged a "countercoup" to guarantee Kubitschek's inauguration. Luz was deposed, and Kubitschek and Goulart took office as scheduled and without incident on Jan. 31, 1956.

Spread of nationalism

During his term of office Kubitschek encouraged the widespread spirit of nationalism, appealing to the popular demand for economic development and to the belief that Brazil was destined to become a great power among the nations of the world. Kubitschek felt that the national government should play a vital role in economic areas unattractive to private capital; thus, his administration undertook ambitious developmental programs for the construction of highways and hydroelectric power projects, the expansion of iron, steel, petroleum, and coal production, and assistance to the private industrial sector. Perhaps his outstanding accomplishment was the construction of Brasília 580 miles northwest of Rio de Janeiro. Brasília was dedicated as the official capital of Brazil on April 21, 1960. The purpose of Brasília was to focus attention on the interior of the country and to hasten settlement of the region and the development of its untapped resources. The new capital was denounced by residents of Rio de Janeiro, but Brazilians elsewhere generally regarded it as a symbol of the nation's future greatness. In inter-American relations, the Kubitschek administration proposed the adoption of Operation Pan America, a cooperative program for the economic development of Latin America, which foreshadowed the Alliance for Progress.

The great material progress during the Kubitschek period was achieved at a high cost in terms of inflation and repeated foreign borrowing. The cost of living and the volume of currency in circulation tripled between 1956 and 1961, while Brazil's large foreign debt nearly doubled. The gross national product rose to unprecedented levels, but living standards for much of the population remained stationary or actually declined. At the same time, indications of large-scale graft and favouritism in public office disturbed even the normally tolerant Brazilian electorate.

Political turmoil. In the hotly contested elections of 1960, the National Democratic Union (União Democrática Nacional; UDN), the largest conservative party, nominated Jânio Quadros, a maverick politician who had governed São Paulo successfully. He triumphed at the polls. At the same time, João Goulart, the vice-presidential candidate of Vargas' PTB and heir to the political mantle of Vargas, won. Those two politically divergent politicians took office on Jan. 31, 1961.

Control by anti-Vargas groups

The election of Quadros was hailed as a revolution by ballot. For the first time in three decades, anti-Vargas political groups controlled the presidency. Quadros took office in an atmosphere of popular expectation, but almost immediately he encountered resistance from the Congress, where parties loyal to the Vargas tradition still commanded a large majority. Quadros' arbitrary and autocratic manner, which soon alienated many of his former adherents, further reduced the possibility of enacting a meaningful reform program or effective measures to retard inflation. In foreign affairs Quadros was more successful; his foreign policy, which was applauded by ultranationalists and deplored by moderates, seemed designed to move Brazil toward neutralist nations and away from the traditional ties with the United States. He opposed any inter-American action to censure the Castro regime in Cuba and initiated proceedings to resume or establish diplomatic and commercial relations with the Soviet Union and its European satellites. On Aug. 25, 1961, after less than seven months in office, Quadros resigned unexpectedly, alleging that "terrible forces" had deterred him. The Congress promptly installed Pascoal Ranieri Mazzilli, speaker of the Chamber of Deputies, as temporary president. Vice President Goulart, the constitutional successor, was then en route home from a state visit to China.

Succession crisis

Brazil stood at the brink of civil war. Many military commanders and conservatives regarded Goulart as too radical to be entrusted with the nation's highest office, while the great majority of civilian political leaders upheld his constitutional right to the presidency. War Minister Odílio Denys now emerged as the chief spokesman of the anti-Goulart forces, demanding that the Congress declare the office of vice president vacant and hold new elections. The Congress refused. In southern Brazil the commanders of the powerful army and air force units defied orders from the capital and sided with Goulart. Goulart arrived in Pôrto Alegre, insisting that he was already president of Brazil. Faced with the prospect of armed conflict, the Congress and the anti-Goulart group in the military agreed upon a compromise solution: that Goulart be allowed to take office, but only as a figurehead. On Sept. 2, 1961, the parliamentary system of government was adopted, and most presidential powers were transferred to the newly created post of prime minister. Provision was made for a national plebiscite on the parliamentary experiment, and Goulart was confirmed as president.

After the congressional elections of October 1962 failed to indicate a clear mandate for or against the administration's reform proposals, the opponents of parliamentarianism, led by Goulart, demanded a quick return to presidential rule. On Jan. 6, 1963, a national plebiscite by a margin of more than five to one gave Goulart full presidential powers. Goulart was unable to secure majority support for his legislative program, however, and new plans for economic and social development did nothing to restrict inflation, which reached alarming proportions. During Goulart's administration, there was a 10-fold drop in the dollar value of the currency, the cost of living tripled, and the growth of the gross national product, which had been rising by 6 to 7 percent yearly, was brought to a complete halt.

Opposition to Goulart

Military intervention. As the situation grew more desperate, cooperation between the regime and its critics became more difficult. The administration identified itself increasingly with the ultranationalistic left, while most of the military officer corps sympathized with the moderate and conservative opposition. Goulart surrounded himself with left-wing advisers. He sought to neutralize the armed forces by frequent command changes and by developing a personal following among noncommissioned officers and enlisted personnel. After failing to obtain authorization for a state of siege, which would have enhanced his powers, Goulart appealed directly to the people for support. At a mass rally in Rio de Janeiro in March 1964, he instituted a controversial agrarian reform and nationalized certain privately owned oil refineries. Many military officers and opposition political leaders had already become convinced that Goulart was seeking to establish a dictatorship of the left. During 1963 active plotting began among separate civilian and military groups in different parts of the country. Governor José de Magalhães Pinto of Minas Gerais state and Marshal Humberto de Alencar Castelo Branco, chief of staff of the army, emerged as the chief coordinators of the conspiracy. The administration's refusal to suppress a strike by naval enlisted men in late March 1964 was regarded by the opposition as intolerable, for military authority and discipline were considered the last check on Goulart's alleged ambitions. On March 31, 1964, Magalhães Pinto proclaimed a rebellion against the government by the civil and military forces in Minas Gerais; he was joined by key political leaders and by most of the armed forces. On April 2 Goulart fled into exile and the Congress declared his office vacant; Ranieri Mazzilli was again designated as interim president.

The First Institutional Act

Military dictatorship. With the fall of Goulart, real power passed to the leaders of the rebellion, who instituted sweeping political changes. The commanders set out to restore economic and financial order, to eliminate what the generals claimed was "Communist infiltration," and to purge corrupt and subversive elements; they desired to retain a modified form of representative government. On April 9, 1964, these goals were combined in the First Institutional Act, a modification of the 1946 constitution. The executive was granted temporary authority to cancel the mandates of elected officials, to dismiss public servants, and to revoke for 10 years the political rights of those found guilty of subversion or misuse of public funds.

During the six months these provisions were in effect, thousands were arrested, and hundreds of persons—including union and government officials and former presidents Goulart, Quadros, and Kubitschek—were deprived of political rights. The Congress was retained as a legislative body with power to debate and to amend but not to reject proposals submitted to it by the executive. On April 11, 1964, Castelo Branco was elected president by the Congress. (L.W.B./A.S.G./G.I.B./R.E.P./E.B.B.)

Castelo Branco's extended term was regarded by the military as a transition period during which sweeping political and economic reforms should be enacted before the nation could again be entrusted to a popularly elected government. The new leaders agreed on goals, such as the curtailment of multiple political parties, but they were divided over the best means to attain their ends. The President's determination to achieve reform by legislation, while permitting normal political activities, was challenged by civilian and military extremists, who called for dissolution of Congress, abolition of political parties, and suspension of all partisan activities until the military regime could consolidate its power.

The test came in October 1965, when gubernatorial elections were held in 11 states, and opposition candidates were elected by substantial majorities in the key states of Minas Gerais and Guanabara. The extremists interpreted the results as a great setback for the government, and they demanded that Castelo Branco annul the two elections they had lost. When he refused to comply with these demands, they plotted a coup d'état. At this point, Marshal Artur da Costa e Silva, the war minister, intervened and persuaded the dissident leaders to keep the peace in return for Castelo Branco's promise that he would embrace the military's reform program.

On Oct. 27, 1965, Castelo Branco signed the Second Institutional Act, which suspended all existing political parties and restored the president's emergency powers for the remainder of his term, and set Oct. 3, 1966, as the date for new presidential elections. An artificial two-party system was created. The new political parties were the National Renewal Alliance (Aliança Renovadora Nacional, called ARENA), sponsored by the government, and an opposition party, the Brazilian Democratic Movement (Movimento Democrático Brasileiro; MDB). ARENA attracted a grouping of pro-administration elements, while the MDB came to be composed largely of politicians who had broken with the military regime. Because the president was elected by the ARENA-dominated Congress, the MDB refused to nominate candidates. The administration candidate, Costa e Silva was elected and was scheduled to replace Castelo Branco in 1967.

Castelo Branco in December 1966 called an extraordinary session of Congress to approve a new constitution drafted by a government-appointed commission. The new document, promulgated on Jan. 24, 1967, incorporated much of the military's program and confirmed the expansion of the power of the executive and of the central government. Important changes included the indirect election of the president and vice president from a single ticket, reduction of the presidential term from five to four years, the use of military courts to judge civilians charged with violation of national security laws, the granting of authority to the president to issue emergency decrees without consulting Congress, and denial to the Congress of the right to delay action on legislation requested by the executive.

Constitution of 1967

The Castelo Branco administration engaged in unprecedented economic planning in order to contain inflation and to revive the flagging economy. It employed emergency powers to limit and regulate sources of credit, to restructure the tax system and collection procedures, and to impose wage and salary controls. At the same time the government poured investments into electric power and transportation to provide for continued orderly economic development. Although the administration did not achieve all of its goals, Brazil's credit rating abroad was firmly reestablished, the annual rise in living costs fell from 86 percent in 1964 to 41 percent in 1966, and the increase in the gross national product rose significantly. With the significant exception of labour, every major sector of the economy was expanding when Castelo Branco left office.

Administrations of Costa e Silva, Médici, and Geisel. Although Costa e Silva promised to humanize the military government, he did not depart markedly from the course set by his predecessor. His administration rejected petitions for a general amnesty, resisted proposals to amend the new constitution to restore direct elections, quashed attempts to form a second opposition party, and suppressed student disturbances. More serious political opposition, however, was muted in part by the government's economic achievements.

The political situation deteriorated rapidly late in 1968. Faced with a resurgence of public and congressional criticism, Costa e Silva seized emergency powers. The Fifth Institutional Act issued on December 13 suspended all legislative bodies indefinitely, authorized the executive to rule by decree, and provided the legal basis for a new purge of outstanding political critics. (R.E.P./E.B.B.)

Growing opposition

In August 1969 Costa e Silva suffered a stroke, and the government was run by the three armed forces ministers until October, when the government selected General Emílio Garrastazú Médici as the new president. Elections for federal and state senators and deputies and municipal officials in November 1970 showed a clear victory for Médici and the ARENA party. Disturbances continued through 1970 and 1971, kidnapping of foreign consular and diplomatic officials being added to the arsenal of the dissidents.

Médici in 1971 presented the First National Development Plan, which was aimed at 8 to 10 percent annual economic growth and development of the Northeast and the Amazon area, especially by means of road construction and redistribution of land. An electoral college was created in 1973, and on Jan. 15, 1974, the ARENA party's General Ernesto Geisel was elected president.

The 10th anniversary of the military coup d'état was celebrated by lifting the prohibition on political activities of 106 leaders of the former regime, among them Kubitschek, Quadros, and Goulart. The Fifth Institutional Act, however, remained in force. A surprising victory for the MDB in the congressional elections in November 1974, in which the opposition gained 20 seats in the Senate, was not repeated in the municipal elections of November 1976.

In April 1977 President Geisel dismissed Congress when it failed to pass judicial reforms that he had requested. He then used the emergency powers of the Fifth Institutional Act to institute those reforms and other electoral and constitutional changes. Among the reforms were provisions for the indirect election of state governors and one-third of the federal senators and the increase of the presidential term to six years. The number of members of the Chamber of Deputies was to be based on the total population of the states instead of on the number of registered voters, and constitutional amendment could be effected by an absolute majority of Congress rather than the two-thirds vote of two successive sessions formerly required.

Reforms under Geisel

Transition to democracy. In November 1978 Geisel's handpicked successor, General João Baptista de Oliveira Figueiredo, won the election for president. Before leaving office, Geisel repealed all emergency legislation, including the presidential decree (of 1969) providing for the banishment of persons accused of political crimes. (The Fifth Institutional Act had been repealed by constitutional amendment in October 1978.) In 1979 Congress enacted an amnesty, restoring political rights to all who had lost them since 1961. Political freedom returned, and a reinvigorated freedom of expression sparked lively political debate. Deeper transformations also characterized Brazil. It had become one of the major industrial nations of the world, boasting the world's 10th largest gross national product by the early 1980s. At the same time, fully 70 percent of the population was urban. The transportation infrastructure had expanded impressively, and road networks in particular reached out to previously isolated corners of the vast nation. New groups played increasingly influential roles, notably organized labour, and the social structure had become more widely diverse and complex.

Still, Brazil followed in the 1980s well-delineated patterns of the past. The few still governed the many and enjoyed most of the benefits of society. The large estates grew in size and number as Brazil's agricultural frontier moved ever westward and through the Amazon. The export sector still dominated and shaped the economy. Poverty characterized the lives of the overwhelming majority of Brazilians. Indeed, Brazil did not escape the economic crises shaking Latin America in the 1980s. Its foreign debt ranked as the largest in the Third World. The nation emerged from the period of military dictatorship with a triple-figure inflation. Nor had the military governments resolved the problems of illiteracy, malnutrition, and high infant mortality that plagued the majority of the people.

Return of civilian government. In an indirect election in January 1985, the electoral college selected the candidates of the MDB, Tancredo de Almeida Neves for president and José Sarney for vice president, thus repudiating the candidates favoured by the military. Before Neves could assume office in mid-March 1985, he died from the effects of an illness. Subsequently, Vice President Sarney was inaugurated as Brazil's first civilian president since 1964. The period of military dictatorship had ended, and Sarney presided over the inauguration of the "new republic" as a constituent assembly prepared a new constitution. The political crisis of redemocratization; the economic crises of debt, inflation, recession, and unemployment; and the social crises of poverty and injustice confronted him and, in a larger sense, challenged the nascent democracy.

The Sarney administration

After Sarney took office rapid economic expansion took place as agricultural production rose and the country reacted favourably to new economic and political policies. Progressive steps taken by the government included a measure that would provide land to several million peasants by the year 2000 and new legislation that legalized all political parties and paved the way for direct presidential elections. Sarney's approval rating ran high as his government imposed the Cruzado Plan, an anti-inflationary control package including wage and price freezes that further fueled the economy. By the end of 1986, however, the government allowed price increases to brake the overheated economy. Inflation immediately began to rise, precipitating massive protests against the government. The crisis took place right after a new congress had been elected (November 1986) and endowed with the task of producing a new constitution.

The Constituent Assembly began its deliberations in February 1987 as the failed Cruzado Plan ended. A year and a half later, on Oct. 5, 1988, Brazil's eighth constitution was promulgated. The document provided for many new public freedoms, such as freedom of assembly and thought, the right of workers to strike and engage in collective bargaining, and the abolition of government censorship of art and literature. The principle of habeas corpus was introduced, and the voting age was lowered to 16. One of the most hotly debated questions of the assembly had been the length of the presidential mandate, which was finally set at five years. The constitution also provided for a presidential election in November 1989 and prohibited the president from enacting laws by decree. A plebiscite was to be held in 1993 on whether to keep Brazil's presidential system of government or to change to a parliamentary form or a monarchy. (E.B.B./Ed.)

World concern for the rain forests

World attention was increasingly drawn to Brazil by the continued destruction of the Amazon rain forests by cattle ranchers, miners, lumber companies, and rubber companies, especially after the murder in December 1988 of the internationally known labour leader and ecologist Francisco "Chico" Mendes Filho. In response to international pressure, Sarney created a 2,000-member National Environment Guard and promised to use the armed forces as well as the federal police to deter further deforestation.

The presidential elections dominated 1989. Early favourites and major party leaders Leonel Brízola, of the Democratic Labour Party, and Ulysses Guimarães, head of the MDB Party, the largest party, did not do well in the November elections. Instead, the race was essentially between Luís Inácio da Silva ("Lula"), leader of the Workers' Party, and Fernando Collor de Mello of the newly formed National Reconstruction Party. No candidate received a majority of votes, however, and a runoff between Lula and Collor was held in December. Collor, a former governor of the northeastern state of Alagoas and a centrist, won the election with about 43 percent of the vote. Lula received 38 percent, mostly from the larger cities. The remaining ballots were disallowed or left blank.

Collor, who took office without a parliamentary majority, faced severe problems with the Brazilian economy. Immediately upon taking office on March 15, 1990, he announced a series of measures to eliminate inflation, control the enormous debt, and encourage economic growth. Collor saw excessive government spending, the practice of income indexing, widespread financial speculation, and trade barriers as the root causes of the country's economic problems. (Ed.)

BRYANT (comp.), *Brazil* (1985).

Basic geographic information can be found in PRESTON E. JAMES, C.W. MINKEL, and EILEEN W. JAMES, "Portuguese South America," in *Latin America,* 5th ed. (1986), pp. 463–533; JOHN P. DICKENSON, *Brazil* (1982), an economic geography of Brazilian industry; FUNDAÇÃO INSTITUTO BRASILEIRO DE GEOGRAFIA E ESTATÍSTICA DEPARTAMENTO DE GEOGRAFIA, *Geografia do Brasil,* 5 vol. (1977); and MARVIN HARRIS, *Town and Country in Brazil* (1956, reprinted 1971), a good account of population settlement. Background on Brazilian agriculture is provided in G. EDWARD SCHUH, *The Agricultural Development of Brazil* (1970). See also ALLEN W. JOHNSON, *Sharecroppers of the Sertão: Economics and Dependence on a Brazilian Plantation* (1971).

The problems of northeastern Brazil are explored in MANUEL CORREIA DE ANDRADE, *The Land and People of Northeast Brazil* (1980; originally published in Portuguese, 1963), a comprehensive geography; KEMPTON E. WEBB, *The Changing Face of Northeast Brazil* (1974); and JOSUÉ DE CASTRO, *Death in the Northeast* (1966, reissued 1969), on the impact of drought on the inhabitants of the northeastern interior. The ecology and development of the Amazon region are discussed in ALEX SHOUMATOFF, *The Rivers Amazon,* rev. ed. (1986); JOHN HEMMING (ed.), *Change in the Amazon Basin,* 2 vol. (1985); and in ROGER D. STONE, *Dreams of Amazonia* (1985, reissued 1986).

Ethnographic studies include, on Brazil's native peoples, JULIAN H. STEWARD (ed.), *Handbook of South American Indians,* 7 vol. (1946–59, reprinted 1963), an indispensable reference work; JOHN HEMMING, *Red Gold: The Conquest of the Brazilian Indians* (1978), a masterful study of the European-Indian encounter and its tragic effects on the Indians; and BETTY J. MEGGERS, *Amazonia: Man and Culture in a Counterfeit Paradise* (1971), a classic study of the life-style of native peoples in the Amazon. On African peoples and slavery, see MANUEL RAIMUNDO QUERINO, *The African Contribution to Brazilian Civilization,* trans. from Portuguese (1978); JOAQUIM NABUCO, *Abolitionism: The Brazilian Antislavery Struggle* (1977; originally published in Portuguese, 1883), the most important Brazilian document favouring manumission; CARL N. DEGLER, *Neither Black nor White: Slavery and Race Relations in Brazil and the United States* (1971, reprinted 1986), a masterpiece of comparative history; and FLORESTAN FERNANDES, *The Negro in Brazilian Society* (1969; originally published in Portuguese, 1964), a historical study. On the peasants, see SHEPARD FORMAN, *The Brazilian Peasantry* (1975), a series of explorations of the life-styles of rural peoples, and *The Raft Fishermen: Tradition & Change in the Brazilian Peasant Economy* (1970), a study of continuity and innovation in this group. See also PIERRE-MICHEL FONTAINE (ed.), *Race, Class, and Power in Brazil* (1985), thoughtful and far-ranging essays, many of them strongly revisionist.

(*The economy, and government and social conditions*): Brazil's economic history is chronicled in WERNER BAER, *The Brazilian Economy: Growth & Development,* 2nd ed. (1983), an overview; JOE FOWERAKER, *The Struggle for Land: A Political Economy of the Pioneer Frontier in Brazil from 1930 to the Present Day* (1981); MARTA CEHELSKY, *Land Reform in Brazil: The Management of Social Change* (1979), on a basic and continuing problem in Brazil; GEORGE-ANDRÉ FIECHTER, *Brazil Since 1964—Modernisation Under a Military Regime: A Study of the Interactions of Politics and Economics in a Contemporary Military Régime* (1975; originally published in French, 1972); and CELSO FURTADO, *The Economic Growth of Brazil: A Survey from Colonial to Modern Times* (1963, reprinted 1984; originally published in Portuguese, 1959).

Problems of development and industrialization are discussed in WILLIAM G. TYLER, *The Brazilian Industrial Economy* (1981); and JANET D. HENSHALL and R.P. MOMSEN, *A Geography of Brazilian Development* (1974, reprinted 1976), a regional statistical survey of Brazil's economic evolution.

Studies of urbanization include JUNE E. HAHNER, *Poverty and Politics: The Urban Poor in Brazil, 1870–1920* (1986), a unique account of the urban masses during a period of accelerating immigration and urbanization; T. LYNN SMITH, *Brazilian Society* (1974), a general discussion of the population as it shifts from rural to urban society; and CHARLES WAGLEY, *Amazon Town: A Study of Man in the Tropics* (1953, reissued 1976), a detailed study of life in a typical small Amazonian town.

The history of education is described in FAY HAUSSMAN and JERRY HAAR, *Education in Brazil* (1978). An introduction to science and medicine in Brazil is found in NANCY STEPAN, *Beginnings of Brazilian Science: Oswaldo Cruz, Medical Research and Policy, 1890–1920* (1976, reissued 1981).

(*Cultural life*): The literature of Brazil is explored in AFRÂNIO COUTINHO, *An Introduction to Literature in Brazil* (1969; originally published in Portuguese, 1959), an appraisal of the country's literature from the late colonial period to mid-20th century; and SAMUEL PUTNAM, *Marvelous Journey: A Survey of*

Four Centuries of Brazilian Writing (1948, reissued 1971), a standard text. Art forms are the subject of RANDAL JOHNSON, *Cinema Novo x 5: Masters of Contemporary Brazilian Film* (1984), a study of five major filmmakers; WALMIR AYALA, *O Brasil por Seus Artistas: Brazil Through Its Artists* (1980/81), with emphasis on people and landscapes in art, particularly in the 1960–80 period; SELDEN RODMAN, *Genius in the Backlands: Popular Artists of Brazil* (1977), a brief but intriguing introduction to folk painters and their significance; and LEOPOLDO CASTEDO, *The Baroque Prevalence in Brazilian Art* (1964), a profusely illustrated essay. See also GILBERTO FREYRE, *New World in the Tropics: The Culture of Modern Brazil* (1959, reprinted 1980), which explains how the Brazilians view their society; and FERNANDO DE AZEVEDO, *Brazilian Culture* (1950, reissued 1971; originally published in Portuguese, 1943), a rich and detailed study of nearly every aspect of Brazilian culture.

Luso-Afro-Indian religious beliefs are introduced in ROGER BASTIDE, *The African Religions of Brazil: Towards a Sociology of the Interpenetration of Civilizations* (1978; originally published in French, 1960), the classic text; and SETH LEACOCK and RUTH LEACOCK, *Spirits of the Deep: A Study of an Afro-Brazilian Cult* (1972, reissued 1975). The political role of the Roman Catholic Church is detailed in SCOTT MAINWARING, *The Catholic Church and Politics in Brazil, 1916–1985* (1986); and THOMAS C. BRUNEAU, *The Political Transformation of the Brazilian Catholic Church* (1974), and a companion volume, *The Church in Brazil: The Politics of Religion* (1982).

History: Overviews of Brazilian history are given in LESLIE BETHELL (ed.), *The Cambridge History of Latin America* (1984–), an extensive work of which 5 vol. had appeared by 1987; E. BRADFORD BURNS, *A History of Brazil*, 2nd ed. (1980), a comprehensive interpretation; and E. BRADFORD BURNS (ed.), *Perspectives on Brazilian History* (1967), a collection of translated essays by major Brazilian historians, and *A Documentary History of Brazil* (1966), translated excerpts from historical documents, 1494 to 1964. Further bibliographic information can be found in FRANCIS A. DUTRA, *A Guide to the History of Brazil, 1500–1822: The Literature in English* (1980); and ROBERT M. LEVINE, *Brazil, 1822–1930: An Annotated Bibliography for Social Historians* (1983), and *Brazil Since 1930: An Annotated Bibliography for Social Historians* (1980).

Brazil's colonial past is detailed in BAILEY W. DIFFIE, *A History of Colonial Brazil, 1500–1792* (1987), on the origins and growth of colonial Brazil; GILBERTO FREYRE, *The Masters and the Slaves: Casa-Grande & Senzala: A Study in the Development of Brazilian Civilization*, 2nd ed. rev. (1970, reissued 1986; originally published in Portuguese, 1933), a classic study of life under slavery in the plantation house; STUART B. SCHWARTZ, *Sugar Plantations in the Formation of Brazilian Society: Bahia, 1550–1835* (1985), an analysis of an important factor in the development of Brazil's social institutions; KENNETH R. MAXWELL, *Conflicts and Conspiracies: Brazil and Portugal, 1750–1808* (1973), a significant interpretive study of the background to Brazilian independence; and CAIO PRADO JÚNIOR, *The Colonial Background of Modern Brazil* (1967; originally published in Portuguese, 1942), a discussion of the predominant institutions implanted during the long colonial past and their impact on Brazil on the eve of independence.

The imperial period is the subject of GILBERTO FREYRE, *The Mansions and the Shanties: The Making of Modern Brazil* (1963, reissued 1986; originally published in Portuguese, 1936); NEILL MACAULAY, *Dom Pedro: The Struggle for Liberty in Brazil and Portugal, 1798–1834* (1986), a rich biography of the first emperor and an examination of his times; EMILIA VIOTTI DA COSTA, *The Brazilian Empire: Myths and Histories*, rev. ed. (1985; originally published in Portuguese, 1977), a review of the 19th century; and CLARENCE H. HARING, *Empire in Brazil: A New World Experiment with Monarchy* (1958, reissued 1968), an introduction to the period.

An overview of the 18th and 19th centuries is provided by GILBERTO FREYRE, *Order and Progress: Brazil from Monarchy to Republic* (1970, reissued 1986; originally published in Portuguese, 2 vol., 1959). Covering topics within the 19th and early 20th centuries are STANLEY J. STEIN, *Vassouras, a Brazilian Coffee County, 1850–1900* (1957, reprinted 1985), on the plantation economy; RICHARD GRAHAM, *Britain and the Onset of Modernization in Brazil 1850–1914* (1968, reprinted 1972), a study of the British influence on modernization; and WARREN DEAN, *The Industrialization of São Paolo, 1880–1945* (1969), which links industrialization and coffee exports.

PETER FLYNN, *Brazil, a Political Analysis* (1978), gives a detailed overview of political conditions from the 1930s. Works covering the same period include; THOMAS E. SKIDMORE, *Politics in Brazil, 1930–1964: An Experiment in Democracy* (1967, reissued 1969), a detailed political study of the period, and *The Politics of Military Rule in Brazil, 1964–1985* (1988), covering the period of transition from military dictatorships to democracy. (R.P.Mo./E.B.B.)

Broadcasting

Broadcasting is the transmission of radio and television programs that are intended for general public reception, as distinguished from private signals that are directed to specific receivers. In its most common form, broadcasting may be described as the systematic dissemination of entertainment, information, educational programming, and other features for simultaneous reception by a scattered audience with appropriate receiving apparatus. Broadcasts may be audible only, as in radio, or visual or a combination of both, as in television. Sound broadcasting in this sense may be said to have started about 1920, while television broadcasting began in the 1930s. With the advent of cable television in the early 1950s and the use of satellites for broadcasting beginning in the early 1960s, television reception improved and the number of programs receivable increased dramatically.

The scope of this article encompasses both the technical and the nontechnical aspects of broadcasting. It traces the development of radio and television broadcasting, surveys the state of broadcasting in various countries throughout the world, and discusses the relationship of the broadcaster to government and the public. Discussion of broadcasting as a medium of art includes a description of borrowings from other media. In addition, the article highlights important developments in radio and television technology and delineates principal systems and equipment. For more detailed information about electronic components and techniques used in radio and television communications, see the articles ELECTRONICS and TELECOMMUNICATIONS SYSTEMS. (J.A.Ca./Ed.)

For coverage of related topics in the *Macropædia* and the *Micropædia*, see the *Propædia*, sections 735 and 10/32, and the *Index*.

The article is divided into the following sections:

History

RADIOBROADCASTING

The United States. The first known radio program in the United States was broadcast by Reginald Aubrey Fessenden from his experimental station at Brant Rock, Massachusetts, on Christmas Eve, 1906. Two musical selections, the reading of a poem, and a short talk apparently constituted the program, which was heard by ship wireless operators within a radius of several hundred miles. Following the relaxation of military restrictions on radio at the conclusion of World War I, many experimental radio stations—often equipped with homemade apparatus—were operated by amateurs. The range of such broadcasts was only a few miles, and the receiving apparatus necessary to hear them was mostly in the hands of other experimenters, who, like the broadcasters, pursued radio as a hobby. Among the leading personalities of this early period was David Sarnoff, later of the Radio Corporation of America and the National Broadcasting Company, who first, in 1916, envisaged the possibility of a radio receiver in every home.

Growth of commercial radio. From this beginning the evolution of broadcasting was rapid; many persons who wanted to hear music from the air soon created a demand for receivers that were suitable for operation by the layman. The increase in the number of listeners in turn justified the establishment of stations especially for the purpose of broadcasting entertainment and information programs. The first commercial radio station was KDKA

First commercial radio station

in Pittsburgh, which went on the air in the evening of November 2, 1920, with a broadcast of the returns of the Harding–Cox presidential election. The success of the KDKA broadcast and of the musical programs that were initiated thereafter motivated others to install similar stations; a total of eight were operating in the United States by the end of 1921.

The popularity of these early stations created two possible sources of financial support to offset the operating costs of broadcasting. First, there were possibilities for profit in the manufacture and sale of radio receiving equipment; and, second, the fame attained by the organizations operating the first broadcasting stations called attention to the value of broadcasting as an advertising medium. Advertising eventually became the principal means of support for broadcasting in the United States.

Between 1921 and 1922 the sale of radio receiving sets and of component parts for use in home construction of such sets began a boom that was followed immediately by a large increase in the number of transmitting stations. By November 1, 1922, 564 broadcasting stations had been licensed.

Interconnection of stations. The use of long-distance wire telephone lines in 1922 to connect a radio station in New York City with one in Chicago to broadcast a description of a football game introduced a new idea into radiobroadcasting. In 1926 the National Broadcasting Company purchased WEAF in New York and, using it as the originating station, established a permanent network of radio stations to which it distributed daily programs. Some of these programs were sponsored by advertisers and furnished revenue to both the network and its associated stations, while others were supported by the network, with a portion of the time being set aside for public-service features.

Government regulation. Although the growth of radiobroadcasting in the United States was spectacularly swift, in the early years it also proved to be chaotic, unplanned, and unregulated. Furthermore, business arrangements that were being made between the leading manufacturers of radio equipment and the leading broadcasters seemed to threaten monopoly. Congress responded by passing the Radio Act of 1927, which, although directed primarily against monopoly, also set up the agency that is now called the Federal Communications Commission (FCC) to allocate wavelengths to broadcasters. The government's attack on monopoly resulted eventually in four radio networks—the National Broadcasting Company, Columbia Broadcasting System, Mutual Broadcasting System, and American Broadcasting Company—while the FCC permitted orderly growth and assured the survival of educational radio stations.

First trans-Atlantic broadcast

The United Kingdom. *Early development.* Radiobroadcasting in Great Britain eventually developed in quite a different way from that in the United States. The first initiatives after World War I were taken by commercial firms that regarded broadcasting primarily as a means of point-to-point communication. The first successful broadcasting of the human voice, from a transmitter in Ireland across the Atlantic in 1919, led to the erection of a six-kilowatt transmitter at Chelmsford, Essex. From this spot two daily half-hour programs of speech and music, including a well-received broadcast by the opera singer Dame Nellie Melba, were broadcast for about a year between 1919 and 1920. Opposition from the armed services, fear of interference with essential communications, and a desire to avoid the "commercialization" of radio led, however, to a ban on the Chelmsford broadcasts, which the Post Office claimed the right to impose. Experimental broadcasts, the Post Office ruled, had to be individually authorized. Nevertheless, about 4,000 receiving-set licenses and 150 amateur transmitting licenses issued by the Post Office by March 1921 were evidence of growing interest. When these amateurs, grouped into 63 societies with a total of about 3,000 members, petitioned for regular broadcasts, their request was granted in a limited form: the Marconi Company was authorized to broadcast about 15 minutes weekly.

The first of these authorized broadcasts, from a hut at Writtle, close to Chelmsford, took place on February 14, 1922; the station call signal was 2MT. Shortly thereafter an experimental station was authorized at Marconi House in London, and its first program went on the air May 11, 1922. Other stations were soon to follow.

Revenue sources of the British Broadcasting Company, Ltd.

Formation of the British Broadcasting Company. By this time developments in the United States had demonstrated the commercial possibilities of radio but also suggested a need for greater order and control. The Post Office took the initiative in encouraging cooperation among manufacturers, and on October 18, 1922, the British Broadcasting Company, Ltd., was established as a private corporation. Only bona fide manufacturers were permitted to hold shares, and the directors of the firm, all of whom represented manufacturing interests, met under an independent chairman. The company's revenue came from half of the 10-shilling license fee for receivers and a 10-percent royalty on the sale of receiving sets and equipment. Provincial stations were provided for, and all stations were to broadcast "news, information, concerts, lectures, educational matter, speeches, weather reports, theatrical entertainment. . . ."

Already several precedents had been established that were later followed in many other countries; of these the license revenue was the most important, but the royalty on sets and equipment was also adopted elsewhere, even after its abandonment in Britain. Because the British Broadcasting Company was a monopoly and because British radio as a result developed in a more orderly manner than elsewhere, such problems and issues of broadcasting as control of finance, broadcasting of controversy, relations with government, network organization, and public-service broadcasting became apparent, and solutions were sought in the United Kingdom earlier than elsewhere.

In 1927, upon recommendation of a parliamentary committee, the company was liquidated and replaced by a public corporation, the British Broadcasting Corporation (BBC), answerable ultimately to Parliament but with day-to-day control left to the judgment of the Board of Governors appointed on the basis of their standing and experience and not representing any sectional interests. A key figure, the chief executive of the original company and director general of the corporation, was John Reith (later Lord Reith), whose concept of public-service broadcasting prevailed in Britain and influenced broadcasting in many other countries. The BBC retained its monopoly until the creation of the Independent Television Authority (ITA) in 1954. The BBC experimented with local radio in the late 1960s and expanded the number of local stations in the early 1970s. In 1972 the ITA became the Independent Broadcasting Authority (IBA), which assumed responsibility for establishing and regulating independent radio and television stations. Regional and network production companies are appointed by the IBA; the companies sell advertising time, but advertisers are not allowed to sponsor programs.

Radio developments in other countries. Even before the pioneer station in Pittsburgh commenced operations, regular broadcasts began from The Hague, running from November 1919 until 1924. In Canada the first regular broadcasts from Montreal began in 1920, while in Australia a small station in Melbourne opened in 1921, though the official start occurred in Sydney in 1923. In New Zealand several low-powered stations were operating in 1921, though the Radio Broadcasting Company was not founded until 1927. In Denmark experimental amateur stations went on the air in 1921, and the official State Broadcasting System was instituted in 1925. France began regular transmissions from the Eiffel Tower in 1922, and the first Soviet station commenced broadcasts from Moscow in the same year. By the end of 1923 there also were radio stations established in Belgium, Czechoslovakia, Germany, and Spain. The list of countries lengthened rapidly, with Finland and Italy beginning broadcasts in 1924 and Norway, Poland, Mexico, and Japan in 1925. In India organized broadcasting began in 1926; the Indian Broadcasting Company had stations in Bombay and Calcutta in 1927.

The problem of control

In most of these countries, the problem of control arose. In some countries private enterprise was given free rein, subject to licensing by a government department or agency and to agreement upon the wavelengths or frequencies to be used. In others there was closer control (*e.g.,* France) or encouragement to cooperation between potentially conflicting interests (*e.g.,* Germany and Japan). Britain's example was followed in Denmark, Sweden, several Commonwealth countries, and some British colonies. In Canada and France state and private enterprise operated side by side. Private stations were well established in Canada, for example, before the Canadian Broadcasting Commission was formed in 1936.

In France the Administration of Posts and Telegraphs handled early broadcasts; although a state monopoly was declared in 1923 and state broadcasting remained a department of the Administration of Posts and Telegraphs until World War II, some private stations were granted licenses, including Radio Normandy, which broadcast to the United Kingdom. Some of these private commercial stations continued in operation, broadcasting under government control until 1945, when their licenses were withdrawn and radio became a complete state monopoly, independent of the Administration of Posts and Telegraphs but answerable to the government.

In Germany the Ministry of Posts controlled and owned all technical equipment, while private companies started programs in various cities. Soon the Reich Broadcasting Company acquired controlling interests in these companies; in 1932 all were nationalized.

International conferences. The wavelength problems that created so much confusion in the United States and provided a strong argument for monopoly in Britain also arose internationally, particularly in Europe, where the concentration of heavily populated and advanced sovereign nations compelled international agreement. Telegraphy had led to an early conference in Paris in 1865 that created what became later the International Telecommunications Union. This event was followed by the Berlin conference of 1885 to discuss international telephone communications, two further conferences in Berlin in 1903 and 1906 on radiotelegraph, and still another in London in 1912 to cover the whole field of radio communications. An informal conference of 10 countries held in London in 1925 created the Union Internationale de Radiophonie. The union was based in Geneva, with a BBC representative as president and another as secretary general, and was the first international broadcasting organization. The use of wavelengths, copyright problems, and international program exchanges inevitably were discussed, and a plan was drawn up.

Agreement on wavelength allocation, implemented in November 1926, was based on a formula involving area, population, and the extent of telephone and telegraph traffic. In spite of its dominating position, the BBC, which had been using 20 medium wavelengths, emerged with one long wavelength, 10 medium wavelengths, and five further medium wavelengths shared with others but below the Post Office limit range for broadcasting of between one megahertz and 600 kilohertz (300 and 500 metres). (Long waves range from 30 to 300 kilohertz; medium waves from 300 kilohertz to three megahertz; and shortwaves from three to 30 megahertz.) All of the more advanced of the participating countries (which had risen to 16: Austria, Belgium, Czechoslovakia, Denmark, Finland, France, Germany, Hungary, Ireland, Italy, The Netherlands, Norway, Spain, Sweden, Switzerland, and the United Kingdom) had to make some sacrifices, and some, such as the United Kingdom, had to persuade their post offices to agree to the use of wavelengths outside the broadcasting range; but the principle of international agreement had been established. The Washington Conference of 1927 widened the area of cooperation in respect to radiotelegraph, broadcasting, and the international allocation of wavelengths, or frequencies. It was followed by the Madrid Conference of 1932, which codified the rules and established the official international frequency list. This agreement stabilized the situation until World War II, after which the European scene was substantially changed, and a conference in Copenhagen in 1948 reallocated frequencies in the European Broadcasting Area. The Atlantic City Conference in 1947 had already created the International Frequency Registration Board. A conference in Buenos Aires in 1952 prepared the text of the International Telecommunications Convention. The text was revised at Geneva in 1959, where radio regulations were also revised. Geneva also was the site of the 1963 conference for the allocation of frequency bands for space and Earth–space communications.

International organizations. The International Telecommunications Union, created in 1865, has worldwide membership. In 1947 it became a specialized agency of the United Nations. Within the union are the International Frequency Registration Board, the International Telegraph and Telephone Consultative Committee, and the International Radio Consultative Committee. Apart from the International Telecommunications Union, a number of organizations have been established, primarily on a regional basis, since World War II. When tensions between the East and West made the Union Internationale de Radiophonie almost unworkable, a strong organization, the European Broadcasting Union, was created by the countries of western Europe in 1950, and it has a membership that now includes not only all nations of western Europe but also Cyprus, Greece, Iceland, Israel, Lebanon, Morocco, Tunisia, Turkey, and Yugoslavia; associate members include the United States and most Commonwealth and former French colonial countries, as well as Japan and several Latin-American countries. A parallel organization, the International Radio and Television Organization, was created in 1950 to serve nearly all Communist countries (excluding Yugoslavia) and allies of the Communist bloc. The European Broadcasting Union is based in Geneva, while the International Radio and Television Organization has its headquarters in Prague.

Asian and African organizations

The Asia-Pacific Broadcasting Union, which was formally established in 1964 as a union of national broadcasting organizations in Asia and the Pacific, includes Japan, Australia, New Zealand, and the Philippines, as well as Iran, Turkey, Egypt, and most of the non-Communist countries of Asia; its headquarters are in Kuala Lumpur, Malaysia. The Union of National Radio and Television Organizations of Africa, which was formed in 1962, includes most former French and British colonies. The union is based in Dakar, Senegal, and has its technical centre at Bamako, Mali. The Arab States Broadcasting Union was formed in 1969 as an intergovernmental organization within the framework of the Arab League; the secretariat is in Cairo, and the technical centre is located in Khartoum, The Sudan. The Asociación Internacional de Radiodifusión primarily covers North, Central, and South America but includes some European countries. Its central office is in Montevideo, Uruguay. The Commonwealth Broadcasting Association, established in 1945 as a standing association of national public-service broadcasting organizations in the independent countries of the Commonwealth, bases its secretariat in London. The North American National Broadcasters Association, with its headquarters in Ottawa, Canada, began as an ad hoc group in 1972 and became a formal organization in 1978. Its members are Canada, Mexico, and the United States. The Caribbean Broadcasting Union is headquartered in Christ Church, Barbados, and is an association of National Broadcasting Systems of the Commonwealth, Caribbean, and Other Regional States. The International Broadcasting Society was formed in 1985 to improve the information flow between Third World and advanced countries and to foster cooperation among developing countries. Its headquarters are in Seoul, South Korea.

There are other international broadcasting bodies, including the United Nations Department of Public Information and the Culture and Communication Sector of the United Nations Educational, Scientific, and Cultural Organization (UNESCO). The International Broadcast Institute, created in 1968 as a nonprofit and nongovernmental association supported by charitable foundations, with headquarters in London, fosters a free flow of communications for informational, cultural, and educational purposes. There are also a substantial number of religious broadcasting bodies, some of regional and some of worldwide proportions; among the most important are the World Association for Christian Communications, set up in 1968 and based in London, and the Association Catholique Internationale pour la Radio, la Télévision, et l'Audiovisuel, based in Brussels. Radio Free Europe, based in Munich and financed by U.S. government funds, was established to broadcast pro-Western propaganda to the Communist countries of eastern Europe.

TELEVISION BROADCASTING

First practical television system

Early developments. Through a series of technical developments in Great Britain, Europe, the Soviet Union, and the United States, television reached a state of technical feasibility by 1931. In that year a research group was established in Britain under Isaac (later Sir Isaac) Shoenberg, an inventor with vast experience in radio transmission in the Soviet Union. He fostered the evolution of a complete and practical television-broadcast system based on a camera tube known as the Emitron and an improved cathode-ray tube for the receiver. Shoenberg saw the need to establish a system that would endure for many years, since any subsequent changes in basic standards could give rise to severe technical and economic problems. He therefore proposed a system that, though ambitious for its day, was fully justified by subsequent events. Shoenberg's electronic scanning proved far superior to the mechanical scanning method that had been developed by the pioneer John Baird. The government authorized the BBC to adopt Shoenberg's standards (405 lines) for the world's first high-definition service, which was launched in London in 1936. So adequate were they that they formed the sole basis of the British service until 1962, when they gradually were superseded by the European continental standard of 625 lines. The first notable outside broadcast by the BBC was the procession of the coronation of King George VI from Hyde Park Corner in November 1937; a portable transmitter mounted on a special vehicle made its first public appearance. Several thousand viewers saw the transmission.

Television developments were slower in the United States. It was not until April 30, 1939, at the opening of the New York World's Fair, that a public demonstration was made by the National Broadcasting Company, which announced in that year that it was ready to begin broadcasting for two hours per week. The Columbia Broadcasting System and the Dumont network began telecasting in 1939 and 1940, respectively. By mid-1940 there were 23 television stations in the United States. World War II, however, brought nearly all activity to an end, as electronics factories were converted to wartime production. The Federal Communications Commission had authorized only limited commercial operation (the first sponsored television broadcasts began in 1941), and gradually stations closed down; only six were left with limited programs to serve the owners of about 10,000 sets. When wartime restrictions governing the manufacture of receivers were removed in 1946, the stage was set in the United States for a rapid growth of the television-broadcasting industry. By 1949 there were 1,000,000 receivers in use; the 10,000,000 mark was passed in 1951 and the 50,000,000 mark eight years later. In England the BBC's television service was resumed in June 1946; by 1949 there were 126,567 television licenses, and by 1950 there were 343,882, equal in proportion to 1,000,000 in the United States. Other nations did not begin television broadcasting on anything resembling a wide scale until the 1950s.

Transoceanic broadcasts. The initial attempt to interconnect the television networks of Europe and North America came in 1962, when the American Telephone and Telegraph Company used its satellite, Telstar, to relay television signals between Andover, Maine; Goonhilly Downs, Cornwall; and Pleumeur-Bodou, Brittany. The first transmission, of a purely experimental nature, originated in the United States on July 10, 1962, and this was followed the next day by transmissions to the United States from France and England; the first colour transmission occurred on July 16. Reception was limited to about 15 minutes, the period during which the satellite was within sight of the sending and receiving stations. To maintain continuous transmissions, the planners of the system proposed using a series of satellites, so that at least one would always be in position to relay signals. In the mid-1960s, however, an alternative technique came to the fore: a single relay satellite in a "stationary" orbit, so adjusted that it would remain always above the same point on the surface of the Earth. The first public demonstration of this system was on October 10, 1964, when television coverage of the opening ceremonies of the Olympic Games was relayed from Tokyo to North America via a Syncom satellite positioned above the Pacific Ocean. The so-called synchronous communications satellite maintained an altitude of about 23,000 miles (37,000 kilometres), its position fixed with respect to the Earth, their periods of rotation being identical. In the early 1970s, such satellites were so placed that virtually any area of the Earth was within reach of any other by space-relay circuits. The transmitters and receivers used in space are capable of carrying many television channels simultaneously, in addition to telephone and other communications. The landing on the Moon by the American astronauts in 1969 was carried by satellite to an estimated audience of more than 100,000,000 viewers (see also TELECOMMUNICATIONS SYSTEMS).

Broadcasting the Olympic Games

Broadcasting systems

THE BROADCASTER AND THE GOVERNMENT

Most observers recognize that no broadcast organization can be wholly independent of government, for all of them must be licensed in accordance with international agreements. Although broadcasters in democratic countries pride themselves on their freedom in respect to their governments, they are not always free of stockholder or advertiser pressure, nor are producers and editors truly independent if senior executives, under pressure from whatever source, interfere with their editorial functions. Independence, therefore, is a relative term when it is applied to broadcasting.

In a monograph that was written for the European Broadcasting Union, broadcasting systems are classified under four headings: state operated, those that work under the establishment of a public corporation or authority, those whose systems are a partnership blend of public authorities and private interests, and those under private management. A brief summary of these systems provides an indication of the complex variations that have arisen.

State operation. Grouped under this heading are broadcasting systems that are operated by a government department or delegated to an administration, perhaps with a legal personality and even possibly independent in financial and administrative matters, but subject to the government and not essentially autonomous. Under this heading is listed the Soviet Union, where a special committee was set up in 1957 to be in charge of Soviet radio and television under the direct authority of the U.S.S.R. Council of Ministers. Similar arrangements were made in Czechoslovakia and Poland, except that the committees were given a legal personality. Romania has delegated broadcasting to a committee attached to the Council of Ministers. All-India Radio is a department of the Ministry of Information and Broadcasting. Similar arrangements have been common in most Communist countries and in most countries that were colonies but have gained their independence since World War II.

Establishment of a public corporation or authority. The BBC has been the prototype of this kind of system. Provided it abides by the charter and terms of the license under which it operates, the BBC has maximum independence as regards the disposal of its funds (although its revenue is subject to governmental decision as to the cost of the license that is required for every television or radio receiver), the production and scheduling of programs, and, above all, editorial control. Certain residual government powers are either hedged around with agreed provisos or never exercised. Its income, save for profits on the sale of programs abroad and the sale of various phonograph records and publications, is exclusively derived from licenses. External broadcasting (*i.e.*, broadcasting to areas outside national boundaries) is separately financed. The chairman and Board of Governors constitute the legal personality of the BBC; they are chosen by the government, not as representatives of sectional interests but on the basis of their experience and standing. Political parties in office have been careful to avoid political prejudice in these appointments.

Canadian Broadcasting Corporation

The Canadian Broadcasting Corporation (CBC)—or Société Radio-Canada—also has substantial independent powers as determined by the Broadcasting Act of 1958, though over the years producers often have been restive due to political pressures, and Canadian broadcasting has been affected by the problems arising from the aspirations of some French-speaking Canadian citizens. The CBC is dependent on an annual parliamentary grant for its finance, supplemented by an income derived from advertising that amounts to nearly a quarter of its annual revenue. Canadian broadcasting as a whole is a mixed system, with private broadcasting companies operating alongside the CBC.

The Japan Broadcasting Corporation, like the BBC, once had a monopoly on broadcasting but has since lost it. By a series of acts in 1950 the Nippon Hōsō Kyōkai (NHK) was charged with the task of conducting "its broadcasting service for the public welfare in such a manner that its broadcasts may be received all over Japan." The NHK Board of Governors is appointed by the prime minister with the consent of both houses of the Diet. The system is financed almost exclusively from the sale of licenses for receiving sets.

Though West German broadcasting is properly included in this category, the situation there is substantially different, for the basic radio and television services are not a matter for the federal government but for the individual states (*Länder*). The nine state broadcasting organizations are also grouped together in a national organization to cooperate in the first television network. In each state, though there are some variations, there is a broadcasting council that is appointed by the legislature or nominated by churches, universities, associations of employers or trade unions, political parties, or the press; an administrative council; and a director general. Their revenue comes from receiving-set licenses and sometimes also from advertising.

Belgian broadcasting

The broadcasting system in Belgium provides an interesting example of a device that has been used successfully for coping with a two-language country. There are three public authorities: one for French broadcasts; a second for Flemish; and a third that owns the property, owns and operates the technical equipment, and is responsible for the symphony orchestra, record library, and central reference library.

Partnership of public authorities and private interests. In many cases this partnership is nominal and historical rather than substantial and actual. The outstanding example is Radiotelevisione Italiana (RAI), originally founded in 1924. In 1927 an agreement was made with the government for a 25-year broadcasting concession. The charter was extended to cover television in 1952, and two years later a government agency acquired control and more than 75 percent of the shares. A board of managers includes 10 members elected by a special parliamentary commission, and the remaining six are chosen by the General Assembly. Inevitably, therefore, RAI is subject to close government surveillance, but an ad hoc committee of 30, appointed from all political parties by the presidents of the two legislative chambers, is responsible for ensuring political independence and objective news reporting. The organization must also prepare an outline of programs on a quarterly basis for approval by the Ministry of Posts and Telecommunications, aided by an advisory committee concerned with cultural, artistic, and educational policies. A separate organization runs the broadcast advertising business, which, together with receiving-set licenses, provides the revenue of RAI. By the early 1980s there were about 500 private television stations operating in Italy alongside the RAI.

Ownership of Swedish radio

In Sweden the broadcasting monopoly is technically a privately owned corporation in which the state has no financial interest, thus emphasizing the independence of Sveriges Radio from the government. The shares of the corporation must be held by the Swedish press (20 percent), large noncommercial national bodies or movements (60 percent), and commerce and industry (20 percent). The board of governors is made up of a chairman and government nominees and an equal number elected by the shareholders; there also are two employee representatives of Sveriges Radio on the board. The government reserves the right to determine the amount of revenue from receiving-set licenses on an annual basis and thus controls both investment and the amount of broadcasting. The government, however, does not control how that revenue is spent. On balance, Sveriges Radio has a substantial measure of freedom.

In Switzerland, too, there are elements of partnership between private interests and public authorities, but the federal constitution, the need to broadcast in three languages, and geographical factors have led to a system by which the Swiss Broadcasting Corporation is composed of three regional societies based in Lausanne, Zürich, and Lugano-Besso.

Private management. Most of the broadcasting organizations under this heading are commercial firms that derive their revenue from advertising, which takes the form of brief announcements scheduled at regular intervals throughout the day. In some cases a program, such as a sports event or concert, may be sponsored by one advertiser or group of advertisers. Methods and degree of government control vary, and no general characteristics may be isolated. Private-enterprise radio predominates in the United States and Latin America.

Subject to similar controls in these countries are many nonprofit educational stations, financed by universities, private subscriptions, and foundations. There is a public-service network, the Public Broadcasting Service, in the United States.

Other methods of distributing sound and vision programs by wire and cable are not strictly broadcasting. In the main, wire-diffusion enterprises concentrate on giving efficient reception in densely populated areas, large blocks of buildings, and in hotels of programs that are being broadcast. A tall apartment building, for example, may have one television antenna on its roof to which residents may attach their receivers. "Pay TV," the provision of such programs as sports, special events, films, and theatrical performances via direct cable lines to subscribers, has been growing in popularity. Cable television reached about 21,000,000 homes in the United States by the early 1980s and has created two industries in broadcasting: one to hook up homes, the other to supply the programs. Cable television has drawn viewers away from the major commercial television networks, whose share of the prime-time audience has fallen and is expected to decline further.

THE BROADCASTER AND THE PUBLIC

Nature of the broadcast audience. The psychology and behaviour of a radio or television audience, which is composed principally of individuals in the privacy of their own homes, differs considerably from that of an audience in a theatre or lecture hall. There is none of the crowd atmosphere that prevails in a public assembly, and listeners are only casually aware that they are actually part of a large audience. This engenders a sense of intimacy that causes the listener to feel a close personal association with the speaker or performer. Furthermore, many people will not accept in their own homes many of the candid forms of expression that they readily condone or support on the stage or in literature.

Because it owes its license to operate to the state, if indeed it is not state operated, and because of its intimate relationship to its audience, broadcasting functions in a quasi-public domain, open in all its phases to public scrutiny. It is therefore held to be invested with a moral as well as a legal responsibility to serve the public interest and must remain more sensitive to public sentiment and political opinion than most other forms of public expression.

Audience measurement. For economic reasons, as well as those outlined above, evaluation of audience opinion and response to radio or television programs is important to the broadcaster. Audience measurement presents difficult problems, because there is no box office by which to determine the exact number of listeners. Mail received comes principally from those who have the time and inclination to write and cannot be regarded as wholly representative. Audience-measurement information may also be obtained by telephone-sampling methods, interviews in the home by market-research organizations, or by special recording devices attached to individual receiving sets. The latter, installed with the owner's consent, record the amount of time the set is used, when it is turned on and off, and the stations tuned in. These devices are expensive, however, and do not necessarily indicate whether someone is actually watching or listening, and they are therefore limited to small samples of the total audience. Whatever the method of rating, commercial broadcasters are quick to alter or discontinue any program that shows lack of audience appeal, and the listeners are thus influential in determining the nature of the programs that are offered to them. In commercial broadcasting, sponsored programs also are affected by their apparent success or failure in selling the goods advertised.

Audience-measuring devices

Educational broadcasting. It is difficult to give an account of educational broadcasting in countries where broadcasting is largely or wholly a matter of private management and where the larger and more important stations and networks are private commercial enterprises. Nevertheless, considerable numbers of educational transmissions are made in the United States and Latin America by universities and colleges and sometimes by municipal or state-owned stations. The Public Broadcasting Service in the United States has increased the amount of educational and generally more thought-provoking material available on the air, and in Latin America some countries use broadcasts not only to support the work of teachers in schools but also to combat illiteracy and to impart advice to isolated rural populations in matters of public health, agricultural methods, and other social and practical subjects. The Roman Catholic Church has been in the forefront of the latter activity, operating, for example, the Rede Nacional de Emissôras Católicas in Brazil and the Acción Cultural Popular in Colombia. A similar use of broadcasting is made in most of the tropical countries of Africa and Asia.

Japan's educational broadcasting

Japan's NHK has the most ambitious educational-broadcasting output in the world. Each of its two television and AM radio services is devoted wholly to education, while general television services and FM radio also transmit material of this nature. Japan prepares programs for primary, secondary, and higher education, special offerings for the mentally and physically handicapped, and a wide range of transmissions under the general heading of "social education," which includes foreign languages, vocational and technical instruction, advice on agriculture, forestry, fisheries, and business management, plus special programs for children, adolescents, and women. The educational broadcasts of NHK reach more than 90 percent of Japan's primary and secondary schools.

In Europe the French state broadcasting service devotes more than one-half of its radio output to educational and cultural broadcasts in the arts, letters, and sciences; and on television about 14 percent of its first and second networks are devoted to adult education. Primary and secondary instruction is offered, as are refresher courses for teachers and university-level courses.

Although Italian radio devotes less than 1 percent of its output specifically to educational programs for children, nearly 20 percent is given to cultural and allied offerings. Educational television began in Italy in 1958 with courses of a vocational nature, followed by transmissions aimed at secondary schools. In 1966 special programs were initiated for areas where there are no secondary schools. By the early 1980s, 17 percent of Italian television time was devoted to educational and school broadcasts and 4 percent to cultural programs.

Swedish radio offers a comprehensive service of educational and cultural broadcasting, with the output on television higher than that on radio. There is also a substantial output of adult education at the primary, secondary, and university levels, with about 1,400 school broadcasts a year, and Sweden has concentrated on vocational training and refreshment for teachers. German broadcasting, by contrast, has been used much less for formal education. In The Netherlands more than two and a half hours of school and continuing education broadcasting are broadcast weekly on the radio; in addition, nearly eight hours of educational television are transmitted every week.

The BBC pioneered in education; its work, in both radio and television, has steadily expanded. The BBC offers primary and secondary students more than 100 radio series and nearly 40 television series. The BBC also offers a wide range of biweekly programs especially designed for study in degree courses with the Open University, created and financed by the government, with the broadcast teaching supplemented by publications and correspondence work. By the mid-1970s, BBC broadcasts for the Open University averaged 16 hours weekly on radio and more than 18 hours on television. In addition, the Independent Broadcasting Authority in the United Kingdom has required the commercial-program companies to contribute educational material both for schools and for adults; by 1970 this amounted to 10 hours weekly during periods totalling 28 weeks of the year.

In Australia there is a small educational output on the commercial stations, both radio and television, but by far the greater part of educational broadcasting is undertaken by the Australian Broadcasting Corporation. Educational programming accounts for about 4 percent of radio time and 18 percent of television output, the majority of which is broadcast to schools and kindergartens. The Canadian Broadcasting Corporation is required to provide educational programs in both English and French and does so on its AM and FM radio networks, as well as on television.

Broadcasts for external reception. International broadcasting—the transmission of programs by a country expressly for audiences beyond its own frontiers—dates from the earliest days of broadcasting. The Soviet Union began foreign-language transmissions for propaganda purposes in the 1920s. Fascist Italy and Nazi Germany made such broadcasts at a later date. France, Great Britain, and The Netherlands were next in the field among European countries, though their first use of shortwave broadcasting was aimed at French-, English-, or Dutch-speaking populations overseas. Great Britain began foreign-language broadcasting early in 1938 with a program in Arabic and transmissions in Spanish and Portuguese directed to Latin America. By August 1939, countries broadcasting in foreign languages included Albania, Bulgaria, China, France, Germany, Great Britain, Hungary, Italy, Japan, Romania, the Soviet Union, Spain, the United States, and Vatican City.

Radio propaganda

During World War II foreign-language broadcasting continued; the programs of the BBC in particular, because of their reliability and credibility, had an important effect in maintaining morale among the countries that were under German occupation. The continuance of international tension after World War II led to remarkable growth of foreign-language services. In 1950, for example, all of the Communist countries of eastern Europe except East Germany had launched external services, although these were on a small scale, and even the Soviet Union was transmitting a total of more than 500 hours of broadcasts weekly in all foreign languages. The United Kingdom's output, which had once led the field, had been reduced to slightly more than 600 hours a week and the Voice of America to less than 500 hours per week. By the early 1980s the situation had changed radically. The Soviet Union alone broadcast more than 2,000 hours per week, and the output of all Communist countries of eastern Europe (excluding Yugoslavia) totalled about 1,500 hours. The United Kingdom logged 744 hours in 1981, West Germany 785 hours, and the United States broadcast over the Voice of America and Radio Free Europe/Radio Liberty 1,925 hours a week. The output of China had risen from 66 hours weekly in 1950 to 1,375 hours by 1981. The increase in Chinese broadcasts reflected in part the rising tension between China and the Soviet Union; significantly, the output of China's ally for much of this period, Albania, rose from 26 to 560 hours weekly during the same period. By the early 1980s Japan was transmitting for 263 hours, while Australia and Canada also sponsored external broadcasts.

Monitoring and transcriptions. A logical development following from external broadcasting is the monitoring of foreign broadcasts and their analysis for intelligence purposes. The BBC in particular has a highly developed monitoring service; this activity often yields valuable information. The Central Intelligence Agency of the United States is also active in monitoring and analyzing foreign broadcasts. Transcriptions (recordings) of programs produced in either the domestic or the external services of one country can be acceptable for broadcast in others. Radiobroadcasts of an educational nature can be used in different countries speaking the same language. Although many radio transcriptions are supplied free, in television the situation is different, and there is a substantial trade in television films.

Pirate and offshore stations. In some countries where broadcasting in general or radio alone is a monopoly, radio has had to compete for brief periods with independent commercial stations mounted on ships anchored at sea outside territorial waters. Sweden, Denmark, The Netherlands, and the United Kingdom have been the countries most affected by these stations, which have made use of unauthorized wavelengths, thus endangering other radio communications and operating free of any copyright obligations in respect to any of their broadcast material. Government action gradually has forced closure of such operations: in Sweden a competitive service of popular music proved effective; and in Denmark naval police action (the international legality of which may be questioned), followed by confiscation and heavy penalties, brought an end to the pirate station. The United Kingdom combined legislation penalizing any party who advertised or supplied such ships with the launching by the BBC of Radio 1, substantially a popular music service, to solve the problem. The French have had a particular problem of competition from the so-called *postes périphériques,* which include Europe No. 1 in the Saar and Radio Andorra in the Pyrenees, not to mention the French-language broadcasts of Monaco, Belgium, Luxembourg, and Switzerland. The strongest competition came from Europe No. 1, in which the French government finally purchased a controlling interest. (J.A.Ca./Ed.)

The problem of *postes périphériques* in France

Broadcasting as a medium of art

The artistic potential of any medium is determined by the unique form it offers and forces on the artist and its capacity as an effective vehicle of communication in its own right. The form of any art includes the circumstance through which it reaches its public. William Shakespeare's stage was little more than an open platform on which any action he cared to represent could be compassed provided he gave his actors the necessary words to indicate the place, circumstance, and atmosphere of the action. But his plays would have been null as practical drama without the circumscribing enclosure of the Elizabethan circular theatre auditorium—the "wooden O"—which gathered the audience around the platform, sealing them off from the outside world and concentrating their attention on the performance. As active auditors they became an integral part of the drama, and one must be constantly aware of them in the very writing, structure, and timing of the plays. Shakespeare's art was born of the discovery of the potentialities of the actor–audience relationship.

THE ART OF RADIO

In a similar way the art of radio began to be discovered when those engaged in broadcasting became aware of the nature of the medium in which they were working and of their special relationship to their audience. The discovery took time. (The artistic potential of radio was not explored until the 1930s.) Radio was the only medium in which performers were invisible to their audience. Broadcasters tended at first to adopt the manner of the stage or the pulpit: thinking in terms of a mass audience, the inexperienced broadcaster gave his voice and style an artificial inflation totally unsuited to the new medium. His actual audience was composed of small groups and individuals, usually at home or in informal circumstances, often doing other things at the same time. The basic art of radio consisted in adapting manner and style to these new circumstances. Few programs could expect to take their audiences for granted.

News broadcasts were among the exceptions, and news broadcasts in most countries came to be delivered in a fixed, impersonal manner, the newsreader suppressing his personality as far as possible and adopting a "team" voice. Most other spoken radio formats required using the voice in such a way as to hold the attention of the listener, and this in turn meant recognizing the nature of the microphone as a medium. The public's span of attention was found to be limited. The news summary was allotted five or 10 minutes, while a talk might last 15 minutes, or in special instances up to 30 minutes. Much consideration was also given to the appropriate styles for various audiences, depending on the classes of listeners to whom broadcasts were addressed.

The art of radio emerged in Britain—and in certain other countries adopting the same "public service" approach—as a medium nominally addressed to everyone but actually resembling a kind of broad-based national journal with special sections addressed to specific interests and tastes, some more demanding on the intelligence than others. The popular radio talk (a form of spoken journalism, or essay, often excellently composed and delivered) was shorter and more informal in style than that of the "serious" or purely educational talk. Broadcasting offered unique opportunities for bringing the nation's highest intelligences into the living rooms of so-called minority audiences (often amounting to millions) who were prepared to listen to concentrated exposition and argument. From this developed, particularly in Europe, channels specializing for part or all of the day in minority interests. The listeners supported the service by paying an annual license fee. In the United States, on the other hand, privately owned broadcasting companies got their revenues from advertising and tied their programming to the advertiser's desire to reach the widest possible public. In Japan there were both public and commercial broadcasting services, the former being financed, as in Europe, by license fees from owners of receiving sets. In the Soviet Union broadcasting was recognized, in the words of *Pravda,* as "one of the most powerful weapons of the cultural revolution." Under Stalin virtually all receivers were wired to local exchanges so that the listener could choose only among approved programs. The service had to be regionalized since the U.S.S.R. includes populations speaking about 80 principal languages. Aside from news and commentary, the broadcasts were generally cultural rather than directly propagandistic.

The development of radio as an art form was thus dependent on the way it was organized and financed. There were rich new fields to be opened up in drama, light entertainment, and documentary programming, conceived specifically for the medium, while at the same time some traditional art forms (notably stage drama and music) were transmitted with success. Fiction and poetry reading also became a staple part of sound broadcasting.

THE ART OF TELEVISION

Television compared with film

In the 1950s and 1960s radio was overtaken by television. At first television was considered to be little different as a medium from the film. But although television was a hungry user of film, it needed film in forms that differed from those required by the theatres.

The difference between film and television as art forms stemmed from the physical and financial conditions governing production, distribution, and exhibition. The relationships between the media and their publics were also different. The initial difference lies in the cameras and their function in production. The film camera supplies a record on celluloid in the form of a two-dimensional image, which, suitably edited, can be subsequently projected onto a screen. The television camera accepts and makes available for immediate transmission a two-dimensional image that remains unrecorded and passes with the event, like the image in a mirror (though this image can, by using additional equipment, be recorded on film or videotape). The film camera is associated with a lengthy effort of photographing, cutting, editing, and dubbing—an elaborate process of selection and assembly that may involve months of work. Although television images may also be stored and edited through videotape, the essential television form is the immediate transmission to the public of events occurring at the moment—political and social events, news summaries, commentary, and discussion.

The basic art of television is the control of this immediate flow of images. They can be preselected insofar as the cameras may be set up at chosen vantage points; after that, however, the director must select among the images they give him. The director-editor uses his skill to secure an immediately effective flow of images from the multiple viewpoints his cameras and their lenses collectively represent. In the film the same end is achieved by the quite different process of fragmenting and recording the action piecemeal, thus creating a succession of images that can be subsequently put together by editing and dubbing.

Those who first struggled with the practical aesthetics of television attempted to see the medium on the one hand as a kind of visual radio and on the other as a form of "diluted cinema," a rather poor cousin of the theatrical film. This was in part because they came either from radio or from filmmaking and saw the medium in relation to their previous occupations. Writers, directors, and performers from radio tended at first to reduce the television image to a "talking head," with the addition of occasional still pictures, film clips, or cut-ins from other broadcasting stations. This was especially the case in countries in which television initially lacked adequate financing (such as France) and directors could not afford costly pictorialization. On the other hand, personnel coming from filmmaking were appalled at the speed with which they were required to prepare and mount their television programs.

Television differs most from film in its relationship to the audience. The film is an event designed for a theatre with an audience specially assembled for the performance. Television, on the other hand, resembles a private performance in the home. The attitude of a person sitting perhaps alone and often for hours on end before a comparatively small picture screened in the familiar surroundings of his living room is quite different from that of a person who has gone out to share the special audience experience of a theatre. The tension is more slack; concentration is constantly threatened by irrelevant interruption. Whereas one is absorbed by a good film in a theatre to the exclusion of all else, one merely "watches" television. The television audience is preoccupied not so much with an individual item as with the free flow of item after item. Television is like a talking picture magazine, going on daily and nightly, asking little, giving out along with its entertainment a quantity of easily assimilated information ranging from formal news coverage to informal, gossipy discussions of the lighter affairs of the day.

Television also differs from film with respect to its visual impact. In the movie theatre a highly magnified image fills the central part of the field of vision in an otherwise darkened hall, exciting curiosity and response to a degree far beyond that obtained by a standard-size television screen in a relatively undarkened, and much smaller, living room. The great, fully loaded images of the big screen, from D.W. Griffith's *Intolerance* of 1916 to the Russian *War and Peace* of 1968, have involved the investment of large sums of money in what is called "production value"—the accumulated content of those images with their crowds of people and their elaborate sets. Skilled viewers in the movie theatre perceive and appreciate an astonishing amount of detail. In comparing television, however, one has only to watch a film produced for big-screen theatre to realize the limitations of the small television screen, in which the actors, speakers, or commentators must occupy most of the visual field.

TECHNIQUES AND BORROWINGS

The various media compared

It is useful to view all of the media together, ranging from the individual performer appearing in the flesh before his audience to the complex presentations of the electronic and allied media. They may be compared in terms of the relationship of the performer to his audience as shown in Table 1. The media also vary in the kind of performance on which they can draw, either derivatively or creatively, as shown in Table 2.

Table 1: Relationship of a Performer to His Audience

performer	audience	relationship
individual speaker, storyteller, or singer	assembled group or audience in any place	direct; performer to audience
company of players, singers, dancers, or musicians	assembled audience in a theatre or concert hall	direct; in an enclosed area
performance by an actor or performer recorded on film; factual film with commentator	assembled audience in a motion-picture theatre, hall, classroom, or other formal place	remote; through a photographed and projected two-dimensional image on either a large or small screen, with recorded sound
radio broadcast by an actor, aural performer, newsreader, or commentator	dispersed audience, located mainly in their own homes	remote; through a signal broadcast in sound only
televised presentation by an actor, singer, dancer, performer, or commentator	dispersed audience, located mainly in their own homes	remote; through a two-dimensional image on a small screen, accompanied by sound

The tables make clear the extent to which the various media borrow from each other. Just as the Greek drama drew on ancient myths and legends and the Renaissance drama on classical and contemporary material alike, so the voracious demands of the new 20th-century media have driven producers and scriptwriters to acquire the rights to existent material in other media, particularly the novel and the drama. Radio and television have overlapped increasingly with journalism, many journalists becoming broadcasters and commentators.

But much of the borrowing has been mechanical and technical rather than artistic in nature. Radio broadcasting exploited the phonograph record as a means of preserving sound; in a similar way, television drew upon the film. The invention of magnetic tape for recording both sound and video signals has now linked together all of the mech-

Table 2: Relationship of the Medium to the Performance

medium	nature of presentation	type of material
rostrum	visible, audible performance by a single person	oratory, preaching, recital; the speech, sermon, song, reading, monologue, monodrama
live theatre; concert hall	visible, audible performance by a group or company	drama, opera, ballet, revue, circus, *etc.*, with or without music; the concert
motion pictures (silent)	visible, but not audible performance presented by means of cinematograph projection	mimed drama with titles, documentary presentation, news record, or animated film; presented with "live" sound (music, commentator)
motion pictures (sound)	visible, audible performance presented by means of a cinematograph projection	original screenplays or material adapted from theatrical, fictional, or other sources; according to degree of adaptation, the sound film supervenes on the form of its source, making something new; also news, factual, and documentary material
sound radio	audible but not visible broadcast performance	the whole range of human activity, from the news bulletin, report, commentary, discussion, talk, or actuality recording to the complete cycle of the audible arts—story and poetry reading, drama and documentary, music and opera, including material specially created for the medium
television	visible and audible broadcast performance	includes all of the above, but seen as well as heard

anized media—phonograph, telephone, radio, sound film, and television—and made available a virtually complete record of the sights, sounds, arts, and culture of modern society.

Preservation by recording is in itself not a creative art but a service to art created elsewhere. A principal function of radio and television broadcasting has been the dissemination of works of art created for other media. This is particularly true of radio; in television these works are more often transformed to meet the requirements of the medium and become different art forms. When an opera is performed in a television studio in a way that meets the potentialities of the electronic cameras, the result is television opera—a different form from stage opera. When an opera is commissioned and composed specifically for television (as was Benjamin Britten's *Owen Wingrave*), then television may be considered an artistic medium in its own right.

Storytelling

Dramatic techniques. Radio began by restoring the ancient art of the storyteller. Writers for radio next learned how to suggest place and time by word of mouth, accompanied by the impressionistic use of sound and music. Thus was born the genre of radio drama. The radio dramatist must address himself to the imagination of listeners who are unable to see what they are experiencing. This limitation carries with it a certain freedom. Just as Shakespeare's independence from stage decor left him free to move his action widely in time and space (*Antony and Cleopatra,* for example, has 42 wide-ranging changes of scene), so radio has been free to create its own plastic continuities of action and time-space reference. Radio has been highly creative in the fields of drama and documentary and also in quite new forms of imaginative light entertainment.

Television, on the other hand, adapted techniques already established by the sound film of the 1930s and 1940s. In the initial rivalry between film and television, economic and technical factors both played a part. The first television plays were like the simplest kind of film dialogues; they avoided elaborate sets or large casts, because the screen was not large enough and because they cost too much. Television material was highly expendable, like newspapers and journals that are discarded after a single use. Only gradually did the international distribution of selected television programs, particularly within the large Anglo-American market, permit more money to be spent on "production value" in television.

Television drama came into its own during the 1950s with the emergence of writers and directors who shook themselves free from the old models and began to develop their own techniques—an extension of the two-dimensional image with sound into fields that the cinema could not or would not enter. The creativity of television in the purely artistic sense lies in the unique opportunities it offers the maker. These opportunities were beyond the reach of the filmmaker, who had no way of impelling his sponsor to finance him in such ventures. Here art and the nature of sponsorship can be said to overlap, as is so often the case in the history of art.

Use of videotape

Film techniques. The basic principles that the television image shares with the film image are, of course, its freedom to select the compass of each individual shot and its freedom to determine the nature of the movement within it. The form of presentation depends in both cases on a continuity of such shots in order to build up a narrative flow. Film and television narrative are based on the same principles of mobile composition—the selective (or edited) flow of selective shots of the action. Despite the technological differences in their production, they are aesthetically closely linked and will continue to have a close relationship with each other. This relationship naturally extends into the technical field. Television adopted videotape in order to achieve an immediate high-quality record of the electronic image. This seemed at first to be a threat to the use of film in television, but that has not proved to be so; the film camera is indispensable in many branches of television production. On the other hand, filmmakers have found videotape to be useful in cinema production, since it provides the capability of checking the shot before the film is processed.

The development of television as an art form has not excluded its use as a channel for works produced in other media. On the contrary, production in other media increasingly has been financed out of revenues from its subsequent transmission on television. Since the earliest years of its existence, television has depended on the regular screening of a vast backlog of movie films. The high rentals paid on old films have induced television interests themselves to undertake the production of new films to be shown in theatres and subsequently on the television channels they operate. The feature films they produce often have relatively small casts and a higher ratio of in-close shooting, making them suitable for the smaller TV screen, just as most films now shot for wide screens keep the essential action in the centre so that they can later be shown on television. (R.M.)

Broadcasting operations

TYPES OF PROGRAMS AND DEVELOPMENT OF STUDIOS

There are a number of distinguishable types of programs that are broadcast, but they often overlap in technique, subject matter, and style. Radio, for example, broadcasts speech and music, but in an endless number of combinations. Television adds the visual element, greatly increasing the number of possible program forms. Most sizable broadcast organizations, however, have several categories for administrative convenience. But the definitions cannot be too precise, and lines of demarcation are necessarily vague.

Entertainment. Entertainment can include comedy, impossible wholly to differentiate from drama; quizzes, not always easily distinguished from relatively serious programs of information and education; popular music, in which the frontier with jazz and serious music is anything but rigid; and variety, or a series of unrelated acts, nearly always linked by a popular presenter or established performer.

From the early days of radio there was a tendency to make use of a variety format, and, as this approach represented an extension of old music-hall traditions, success was achieved by many programs in this vein. From the music-hall–variety-type program emerged the "gang show," in which a cast of performers remaining the same from week to week would make use of a series of humorous situations or catchphrases, gradually building up a familiar background against which the incongruities of the script could exploit humour to the full. A further development was the "situation comedy," in which a number of characters, such as the members of a family, remain in the same situation week after week but experience comic adventures. Though these laughter programs lost popularity on radio as television gained popular acceptance, they have become the mainstays of television. A contemporary phenomenon has been the comedy program involving substantial amounts of political and social satire. The situation comedy has also been influenced by this trend.

Situation comedy

The many types of comedy entertainment programs that are produced around the world all have one common characteristic: not only have the performers needed the stimulus of a studio audience, but also the listeners and viewers are stimulated by the laughter and applause of the audience. This has led to some abuses, such as the superimposition of laughter and applause on prerecorded programs, a practice that is frowned upon but still practiced. It has also meant that large studios are required to accommodate not only the performers, frequently including more than one music combination, but also the audience. In television there must be room for settings that have become increasingly ambitious and for dancers and choruses. Broadcasting organizations have generally been able to build studios of appropriate size, though radiobroadcasters in the early days preferred to purchase or rent small theatres.

In their form and structure, children's entertainment shows resemble those for adults. Animated cartoons, however, represent an exception to this rule; the Hungarians, Poles, and French have achieved genuine distinction in this area.

Drama. Radio and television drama is not best produced in a theatre; the nature of the studio is therefore different. Early radio drama was produced in a relatively small studio, often with a single microphone, just as early television plays were produced with a single camera. Radio engineers soon began to employ a control panel with inputs from more than one studio and sound effects ingeniously achieved; their counterparts in television expanded their use of cameras and sets. Mixing in radio from one studio to another and in television from one set to another, plus increasingly sophisticated sound effects and background music, have all become accepted techniques in drama production. Inevitably, television drama has borrowed substantially from the techniques of film production.

Feature films, usually originally made for the cinema, continue to form an accepted and important element in television schedules throughout the world. Both radio and television occasionally broadcast live stage plays from theatres, but there is a general feeling that such offerings do not adequately exploit the advantages of either medium. From the earliest days of radio and television, the studio-produced drama has been an important ingredient in program schedules; in television, as in films, it was not long before shooting on location also became an accepted practice. Offerings have included classical Greek drama, Shakespeare and other Elizabethan dramatists, the Spanish and French theatre, Russian and Scandinavian plays, and modern works.

Serial presentations on television and radio have included adaptations of famous works of literature, such as the novels of Charles Dickens, Honoré de Balzac, and Leo Tolstoy, the *Forsyte Saga* of John Galsworthy, historical costume dramas based on the lives of such figures as Henry VIII and Elizabeth I of England, and, of course, the romantic melodramas aimed largely at the daytime viewer or listener, known as "soap operas." Radio and television serials of fantasy and adventure are also produced for children.

Three other distinguishable types of drama have achieved almost universal popularity: western adventures; shows involving gangsters, crime, and police; and shows set in hospitals and other medical situations. Violent episodes in some crime and western adventure programs have drawn criticism from those who believe that such violence is harmful to children. In response, many broadcasting organizations have introduced codes of practice to minimize such scenes.

Violence on television

Western adventure programs, largely produced in the United States, have been popular with studios because of their relatively low production costs and ready salability abroad. Dramatic series of this type have been shown all over the world, often with dubbed sound tracks. Although these exported U.S. productions are often much less expensive than home-produced programs, Australia has been able to produce some western-type series, and Canada has exploited its legendary "Mounties." So many U.S. television programs have been exported, however, that broadcasting organizations in some nations, such as Japan and the United Kingdom, have taken steps to assure that home-produced dramas should have priority in terms of percentage of schedule hours and prime time (peak placing).

Spoken word. Spoken-word programs have included entertainment types, such as "This Is Your Life" and many of the "talk shows," in which a personality interviewer questions celebrities, sometimes with interludes of music or comedy or with serious discussions, documentaries, or lectures. A fear of controversy, the problem of maintaining an overall impartiality, and sometimes the belief that the mass audience would be alienated by programs demanding a conscious effort and concentration, combined, in the early days of radio, to limit the time given to serious spoken-word programs. It was not long, however, before many broadcasters developed a sense of pride and responsibility in their function and regarded it as their duty to provide information and opinion. In countries where broadcasting achieved a substantial measure of independence, some broadcasters gradually became concerned not only with the exposition of fact and controversy but also with the task of exposing the ills and abuses of their society.

News broadcasts

News continues to be the most important element in spoken-word radio. Since it was inescapable that broadcast news would affect the industry, newspaper proprietors in the early days of radio either made efforts to restrict the sources of news and the times at which it could be broadcast or sought themselves to enter the field. In areas where broadcasting was commercialized, the press was further concerned, because radio competed with it for advertising revenues and because radio could almost always get a story to the public before the newspapers could. Nevertheless, there is no evidence that radio news reduced the circulation of newspapers; some have even maintained that radio whetted the appetite of listeners for news and increased newspaper sales. It would seem, however, that television has adversely affected the daily press and, even more so, weekly or monthly magazines. Long before television outstripped radio, broadcasting organizations were employing reporters and special and foreign correspondents and were supplementing the service received from news agencies. Some broadcast reporters became public personalities in their own right.

Television news presented additional production problems; the announcer at the microphone reading from a script or TelePrompTer was not satisfactory, and it was not long before the greater part of television news was appropriately accompanied by relevant pictures. The need for film shots and the cost and difficulty of obtaining them were, and to some extent remain, serious problems. In spite of substantial expenditure on the supply of such shots, television news is open to the criticism that news values and objectivity are distorted by the availability or nonavailability of pictures.

Emotive effect of television news

In general, however, broadcasting organizations have adjusted to the much higher cost of television news. The syndication of film reports, the development of live networks on an international basis, such as Eurovision, and satellite communications have overcome most problems of news reporting on television. On the other hand, it has become apparent that the psychological impact of film shots of war and civil disturbance, as of accidents and disasters, is far greater than that of the radio report. Television reports of, for example, the Vietnam War did far more to influence public opinion than radio news bulletins could have done. Radio has the advantage, however, of not requiring the same degree of attention; the trend has been toward frequently repeated short bulletins. In the United States there are radio stations that restrict themselves entirely to news, usually in a continuous magazine format, plus, of course, the advertising spots. The news magazine, or newsreel, in radio was introduced even earlier on BBC. A series of brief reports, interviews, and extracts from speeches, making use of many voices and exploiting the technique of frequent renewal of stimulus, proved to be a successful formula. This technique has spread into news bulletins and is increasingly used in the coverage of current affairs, both in radio and television. In all these programs of news and comment, one of the problems has been that of the anchors, or presenters, and the degree to which they may be given freedom to project their personalities or express their views. In the United States there have been fewer inhibitions in this area than in countries where broadcasting is or has been a monopoly and where the need for and tradition of impartiality have been dominant. In the case of the BBC, newsreaders were long anonymous; but on television the identity of a newsreader, or of the presenter of a magazine of news or comment, cannot be concealed, and these inhibitions have broken down. Nevertheless, in western Europe and Commonwealth countries the impartiality of broadcasting services remains an issue of greater importance than in the United States or Latin America. In Britain, when the Independent Television Authority was created, it was enjoined to see that in the coverage of controversial matters each program should be balanced in itself. The BBC, with greater freedom, makes no effort to ensure balance in any one program, provided that an overall balance in respect of any issue is achieved over a reasonable period of time. In all developed countries elaborate programs are prepared to report the results of elections, though it is in the United States and the United Kingdom that these are most ambitious.

In radio straight talk persists in some countries, though less so than in the heyday of the medium. Nevertheless, some successful lectures at much greater length have been scheduled occasionally on television and in some countries on radio. Straight talk of 10 minutes or more does not lend itself to exciting television production, unless accompanied by filmed illustrations to the point where it all but becomes a documentary.

Another pattern popular in many countries involves a panel of distinguished figures under a chairman, answering questions of a topical nature from members of a studio audience. In some cases a parabolic microphone is employed so that questions may be asked from any part of the studio or hall in which the program is mounted; others may call for written queries in advance so that questioners can be conveniently seated in the first row. Some radio panel programs also solicit queries from members of the listening audience who call them in on the telephone.

The documentary program

Development of the radio documentary stemmed from drama, as writers searched for new material especially appropriate for broadcasting. Not surprisingly, early documentary was in dramatic form, and most of it was based on well-known historical events, of which the programs were in effect dramatic reconstructions. Production of radio documentaries was simplified by the invention of magnetic recording tape that was far easier to edit and use on location than its predecessors, the wax-coated disc and the wire recorder. Ironically, just when these technical advances had made the best form of radio documentary possible, the television documentary on contemporary themes began to supplant its radio counterpart. Documentaries have become more expository of public (current) affairs concerned with international relations, domestic politics, and social problems.

Religion. There have been, in the main, two types of religious program: devotional and information–discussion. The former comprises prayer, religious services, or hymn singing, either mounted in a studio or as outside broadcasts from a church, chapel, or hall. A third type is the dramatization of a religious theme, though the tendency has been to devote a good proportion of religious broadcasting time to documentaries, discussions, and interviews. Some sects have produced broadcasts that combine political and religious material. Missionary bodies, mostly under the control of one of the many international or regional religious broadcasting organizations, either buy time on commercial stations or operate stations in many parts of the world, including Latin America, Africa, and Asia.

Outside broadcasts. Although broadcasts do not constitute a distinct and definable form, they nevertheless have been since the birth of radio the most popular and arresting of all material transmitted on either medium. Sports of every description and ceremonial and political events have exercised an unfailing appeal and, in general, attract the largest audiences. Outside broadcasts have stimulated the imagination and taxed the ingenuity of television-broadcasting engineers to such an extent that they have accustomed the public to feats unimaginable to the pioneers of radio. The improvement of line communications, the development of mobile transmitters, and, above all, the use of satellite communications have given the outside broadcast an elasticity and an almost limitless range.

Effects on musical life

Music. Radio has had two important effects on the musical life of the world: it has widened the audience for all forms of music and has made easier the development of new forms, such as electronic music. Music remains a staple ingredient of radio in its own right, whereas in television, though there are programs of music as such, it is more often an adjunct to something else, as, for example, dancing, or as a small component of a mixed program. In the field of popular music, radio has immensely aided the rapid changes of fashion, which have coincided with technical advances in the making of recordings and their popularity and sales. A recognition by recording companies of the enormous power of radio in popularizing a song or performer has led to some abuses. In the United States "payola," or bribes, were given to prominent radio personalities by record companies in return for promotion of their songs.

The development of stereophonic sound techniques has revolutionized the record industry and has played an important role on radio, though earliest in the field of serious music. Frequency modulated (FM) radio broadcasts of serious music, and later of other forms of music, have been popular in many areas; some recordings are broadcast stereophonically but can be received on monophonic radios (see SOUND).

Opera, too, has profited from broadcasting, and outside broadcasts from opera houses, as well as studio performances on both radio and television, have done much in European and many other countries to bring this form of music to a large public. Music programs have presented more difficulties than most others in the matter of studios, partly because of the size of studio required for a full symphony orchestra and partly because of the delicate balancing of acoustics for proper reproduction of such performances.

RELATIONS WITH ARTISTS, SPEAKERS, AUTHORS, AND UNIONS

In the early days of radio, problems of fees, royalties, performing rights, copyright, and relations with unions rarely were regarded. Entertainers performed largely for publicity purposes. Only gradually did performers appreciate radio's effect, first, as a threat to their theatre earnings and, second, as a highly lucrative substitute. To try to trace how a modus vivendi was reached in these matters in different countries would present a picture of baffling complexity in the light of the different prevailing laws and different union structures. Generally speaking, copyright issues have revolved around the rights of record manufacturers and fees for composers. Rates and fees for reproducing recordings often have been the subject of disputes with the unions. Radiobroadcasters soon found that purchasing records or making their own recordings from live musical performances meant substantial economies; these, however, came at the expense of the musicians. Consequently, the musicians' unions sometimes attempted to prevent use of phonograph records or recording of live performances. In some countries, such as The Netherlands, the repeat problem has been solved by the performers receiving a fee for each repeat, the fee rising with each successive use of the recording until it ceases to represent an advantage to the broadcaster.

Copyright fees

Relations of the broadcasting organizations with their staffs have also been complex. In Canada attempts to exercise a restrictive control have led to revolts and resignations, while in France editors and producers who have been unwilling to conform to government policy have been removed from their jobs, though often under other pretexts. The position of staff is particularly vulnerable in those countries where broadcasting is a state monopoly: an example is Czechoslovakia, where senior broadcasting officials were ousted after the fall in 1968 of Premier Alexander Dubček, who had attempted to liberalize the Communist regime.

INTERNAL ORGANIZATION, ADMINISTRATION, AND POLICY CONTROL

Functions of the broadcast administration

The organization and administration of broadcasting bodies can, in the case of a small independent station, be relatively simple, and the policies can be implemented with ease. Sizable organizations, however, have a complex problem because it is not possible to determine success or failure purely on the basis of financial returns. Monopoly organizations, though in theory their sole purpose is public service, in practice often must take into account the views of the government. In the case of nonprofit–public-service operations dependent upon license fees for revenue but with commercial competition, ratings cannot be completely ignored, and these organizations must compete for mass audiences to some extent in order to justify their existence at the expense of the listening and viewing public.

The broadcasting administration has two essential functions: first, programming—*i.e.,* allocation of funds and setting of schedules—and, second, production, the preparation of programs. The former is in effect a branch of direction, and those in charge of planning program schedules and allocating funds have a power that if not checked can be absolute. On the other hand, these planners are dependent on the goodwill of the production and supply departments.

A main problem arises in the treatment of controversial subjects in the field of current affairs. Where broadcasters are under no obligation to be impartial, as in The Netherlands, or where, as in totalitarian countries, only one point of view may be aired, the problem does not arise. In democratic countries, however, where the broadcaster has independence and where there is a need to achieve an overall impartiality, the problem is very serious. Even though decisions may be reached by discussion and a consensus of opinion, the responsibility usually has to be carried by one person. No broadcasting organization has been able to find a complete solution to the problem that does not involve rigid control and intrusion on the independence of the editorial and production staff.

Administration must also deal with routine matters, such as staff pay and conditions of service, recruitment, finance, accounting, negotiations with unions, procurement of equipment, and provision of office and studio space. In general, it has been found best to subordinate such routine management operations to the needs of those directly concerned with the principal function of broadcasting. Much the same may be said of engineering and technical staff, though their research work and technical advances influence the decisions of direction and development of broadcasting.

THE STATE OF BROADCASTING IN SELECTED COUNTRIES

Argentina. Broadcasting in Argentina is wholly controlled by the government but only partly operated by government agencies. Partly for historical reasons, the method of control is not clear-cut: all broadcasting is subject to the approval of the Consejo Federal de Radio y Televisión (Federal Radio and Television Council), a body working under the State Secretary of Communications, though the Secretary of Information can and does intervene on behalf of the president of the republic. All political activities were suppressed between 1966 and 1971, and, even after the government of Alejandro Agustín Lanusse lifted the ban, the restored freedom was not reflected in broadcasting. Of the approximately 150 radio stations in the country, nearly half are grouped into two large networks: an official cultural noncommercial network with about 30 stations, some strategically placed in relation to broadcasts from other countries; and a government-controlled commercial network. There are more than 70 private commercial stations; some are small and low-powered. Television is primarily commercial, and many channels are administered by the state. LS82 Canal 7 in Buenos Aires is state-owned; the other three stations in that city have separately owned provincial affiliates. Argentina has more than 80 television stations, about 20 of them private.

Sources of Argentine programs

Early television in Argentina depended on U.S.-produced telefilms dubbed into Spanish, but today, though U.S.-dubbed feature films are still used, Argentine-produced programs dominate the market. Some material comes from Spain, Italy, and the United Kingdom. Argentine-produced programs can rarely be exported, because the Argentine accent in Spanish, particularly that of Buenos Aires, is not acceptable elsewhere in Latin America.

Australia. Australian broadcasting comprises four sectors: the national sector, the public sector, the commercial sector, and the Special Broadcasting Service. National broadcasting is the responsibility of the Australian Broadcasting Corporation (formerly the Australian Broadcasting Commission), which provides a wide range of programming—including educational, news, sports, religious, and entertainment—designed to promote Australian culture. Public broadcasting serves specific interest groups and is sometimes associated with a college or university. Its primary outlet is radio. Commercial broadcasting seeks a wide appeal, and almost 50 percent of it is locally produced, as required by law. The Special Broadcasting Service provides programming in more than 50 languages for Australia's ethnic communities. Both the Australian Broadcasting Corporation and the Special Broadcasting Service are unlicensed, publicly funded government instrumentalities empowered under the Broadcasting and Television Act of 1942. Public broadcasting is funded by subscription, sales of air time to community groups, and sales of publications. Public stations are not-for-profit. Commercial stations are funded primarily through advertising. Both public and commercial broadcasting stations are subject to licensing renewal review every three years. Until it was abolished in 1976, the Australian Broadcasting Control Board was responsible for all aspects of broadcasting in Australia. Since that time, however, the Australian government's Department of Transport and Communication has overseen that organization's planning and technical aspects, while an independent, statutory authority, the Australian Broadcasting Tribunal, is responsible for regulation and licensing as well as for determining programming and advertising standards.

The Australian Broadcasting Corporation operates about 240 radio stations and 360 television stations. In addition, Australia has about 140 commercial radio stations and 50 commercial television stations. Public broadcasting is heard on about 70 radio stations. The Special Broadcasting Service has two radio stations and two television stations and is Australia's only UHF (ultrahigh frequency) outlet. Radio Australia broadcasts in nine different languages to foreign countries, primarily in Asia and in the Pacific. It operates 13 shortwave stations. The Australian National Satellite System has been in operation since 1985 with the launching of AUSSAT-1 and AUSSAT-2. Through the Australian Broadcasting Corporation it provides television and radio broadcasting to homes in outback regions as part of the Homestead and Community Broadcasting Satellite Service. An additional satellite, AUSSAT-3, launched in 1987, supplements the program with a similar commercial service known as the Regional Commercial Television Service.

Brazil. There are more than 2,400 radio and about 180 television stations in Brazil; the majority are commercial. In general they are under the authority of the Ministry of Communications. All broadcasting is subject to censorship, and any station that runs counter to the government's wishes can be closed. There are radio stations of the Ministry of Education in Rio de Janeiro and Brasília; some of the states have official radio outlets, and a few have television installations. There are also some university radio stations and a few television stations, apart from the Roman Catholic educational radio network. The remaining stations are private commercial enterprises, operating independently or linked to one of the networks, of which the best known are associated with large newspaper concerns, such as Diarios Associados or O Globo. The larger radio networks use shortwave broadcasting, which permits simultaneous transmissions on medium-wave provincial stations. Provincial television stations prepare their newscasts, often in cooperation with a local newspaper and radio station. The others employ film, telefilm, and videotape to supplement local production. All radio stations must devote one hour each day to "The Voice of Brazil," a government news program supplied by the official Agencia Nacional; radio stations must also broadcast at least five hours a week of educational programs. Television stations may be called upon to broadcast programs produced by the Agencia Nacional, consisting mainly of government statements and ministerial and presidential speeches. In 1975 the government created Radiobras, the Brazilian Broadcasting Company, which broadcasts to the remote regions of the Amazon Basin, bringing those regions into closer contact with the political and cultural mainstream of Brazil. Television entertainment consists substantially of Brazilian-produced serials, supplemented by U.S.-produced and dubbed films and telecine programs. Brazil's first communications satellites, Brasilsat I and Brasilsat II, were launched in 1985.

Official news on Brazilian stations

Canada. Canadian broadcasting is overseen by the Canadian Radio-Television and Telecommunications Commis-

The Canadian Broadcasting Corporation

sion, which administers, regulates, and supervises the country's broadcasting. The principal broadcasting organization is the Canadian Broadcasting Corporation (CBC), which is financed primarily by public funds supplemented by television advertising. The CBC has two main television networks, one in French and another in English, and two main AM and FM radio networks, one in each language. In addition, there are small FM networks and some shortwave transmission. The CBC has more than 90 principal radio stations and more than 600 low-power relay transmitters; in addition, more than 60 privately owned stations are affiliated with it and are paid for transmitting its output. The CBC has more than 25 television stations and more than 600 rebroadcasters. There are more than 250 private affiliates and rebroadcasters. In addition to the CBC television network, there are four commercially operated networks: CTV Network broadcasts in English from coast to coast; TVA and the Réseau de Télévision Quatre Saisons broadcast in French across Quebec; and the Global Communications Ltd. network broadcasts in English in parts of Ontario. In 1972 Canada became the first country in the world to offer a domestic communications satellite system with the establishment of its satellite company, Telesat, and the launching of its first Anik satellites. Remote communities receive satellite broadcasts through its CANCOM program. External services are smaller than in most comparable countries; there are broadcasts on shortwave to the Canadian armed forces overseas and an international service, Radio Canada International, in English, French, German, Spanish, Portuguese, Czech, Slovak, Hungarian, Polish, Ukrainian, and Russian for listeners in Europe, Asia, Latin America, the Caribbean, the Middle East, Africa, and the United States.

France. Until it was disbanded in 1974, the Office de Radiodiffusion Télévision Française (ORTF), under the direction of the Minister of Information, oversaw all aspects of French broadcasting. It was replaced first by seven independent state-financed companies, then by a nine-member committee, followed in 1986 by the 13-member Commission Nationale de la Communication et des Libertés (CNCL). The CNCL was finally replaced by the Conseil Supérieur de l'Audiovisuel, which is charged with supervising all aspects of French broadcasting, including administration, programming, distribution of networks and frequencies, licensing, deregulation, and allocation of concessions for privatized channels. The following organizations are responsible for other aspects of French broadcasting: Télédiffusion de France operates the national transmitters; the Institut National de la Communication Audiovisuelle is responsible for broadcasting research and professional training as well as archival work; Radio Télévision Française d'Outre-Mer controls broadcasting to French overseas départements and territories; Société Française de Production et de Création Audiovisuelles is the national production company; Société France Media International is the national distribution company; and La Sept produces programs broadcast via satellite. Radio France comprises six national radio networks: (1) France-Inter, network A, a 24-hour service of entertainment and news, integrated with Inter-Variétés on regional transmitters and carrying programs produced by regional stations and France-Inter Paris, a morning program of popular music, and news flashes for Paris and the surrounding area; (2) Network B, a medium-wave network that includes Radio Bleue (programs for the elderly), programs for foreign workers, school programs, and university broadcasts; (3) France-Culture, network D, information and public affairs along with cultural programs; (4) France-Musique, network E, musical programming; (5) regional stations, network F, music and news, based in six major cities, along with Sorbonne R. France, with university lectures for the Paris region; and (6) France Info, 24-hour news and information. Radio France International broadcasts 24 hours daily to Europe, Africa, North America, Latin America, and Asia in seven different languages. There are also more than 1,500 private radio stations.

State-run television channels

Regular television service began in 1938, was interrupted by World War II, and recommenced in 1945. Colour television was inaugurated in 1967. France has two state-run television channels, Antenne 2 and France Régions 3, and four private stations. The formerly state-run Télévision Française 1 was privatized in 1987. Canal Plus was the country's first private channel in 1984. It is financed by subscription and broadcasts mostly films and sporting events. La Cinq broadcasts foreign light entertainment programs, sports, and films. M6 broadcasts general interest programs. TV5 broadcasts programs via satellite for Francophones in foreign countries. There are three private local stations. Cable television has been slow to develop in France and is primarily concentrated in the Paris region.

Italy. The origin and development of Radiotelevisione Italiana (RAI) is discussed above. Regular television broadcasts began in January 1954. RAI has three radio services on national networks on AM and FM: a First, or National, Program offering a balanced output; a Second Program essentially of entertainment; and a Third Program, which is educational. In addition, there is a substantial regional output. There are three television services: the first, on VHF (very high frequency), broadcasting 63 hours weekly, is the National Program; the Second Program also transmits 63 hours weekly on UHF; the Third Progam transmits 19 hours a week on Wednesdays and Sundays. The RAI provides limited regional television on special occasions only, except for a daily one and one-half hours in German for the German-speaking minority of the Trentino-Alto Adige region. RAI has 18 production centres and 21 regional offices. The Trieste and Bolzano offices are responsible, respectively, for radio output weekly in Slovene for the Friuli-Venezia Giulia region and, apart from the German television output, for broadcasts in German and in Ladin (Romansh) for the Trentino-Alto Adige region. RAI's revenue comes from a proportion, determined by the government, of the proceeds of the sale of radio- and television-receiving licenses and from advertising. Advertising is closely regulated and may not "prejudice the good quality of programs"; it is guided by a code, and the percentage of time given to it is limited. RAI devotes 70 percent of its radio output to light entertainment, 16 percent to news and information, 4 percent to cultural programs, and 1 percent to youth and educational programs. On television 36 percent is news and information, 19 percent is entertainment, 4 percent is cultural, and 17 percent is programs for schools and education.

Radio Roma broadcasts to Europe, Asia, Africa, the Middle East, the Mediterranean, Latin America, Australia, and New Zealand in 27 languages.

Japan. Nippon Hōsō Kyōkai (NHK) is the sole broadcast authority in Japan. A noncommercial, not-for-profit public station, it has two television and three radio networks (two AM and one FM), of which one television and one AM network are almost entirely devoted to education. The General Television program gives a balanced service, as does the First (AM) Radio service, while the FM (VHF) service is concerned mainly with cultural and local music programs. There is relatively little political broadcasting in Japan, and the first occasion on which candidates for election to the Japanese Diet were able to present their political views on television was in December 1969.

Japanese program scheduling

NHK has installed a system of computerized automation for its scheduling, resource allocation, and transmitting operations, probably the most advanced in the world, with a view to giving its production staff a maximum freedom for creative work. In 1978 the organization installed the 12,000,000,000-hertz (2.5-centimetre) wave for metropolitan area broadcasting and for broadcasting two television sound outputs simultaneously so that a single television image can be received with sound in either of two languages. NHK has 173 medium-wave transmitters for the First Radio network, 141 for the Second, and 474 for the VHF-FM network. General and educational television use about 2,800 transmitters each, most of which are rebroadcasting or relay stations. The so-called regional broadcasting is not so much regional as local and concerned mainly with news and practical information. Local television output averages one and a half hours, and local radio averages more than three and a half hours daily. In addition to NHK there are more than 130 broadcasting organizations that are members of the National Association of Commercial Broadcasters in Japan. They offer about 6,200 television stations and about 300 radio stations.

NHK is also responsible for Japan's external services, which are divided into a general service—*i.e.,* a worldwide service in English and Japanese that broadcasts daily—and a regional service for the Americas, Europe, Asia, Africa, and Australasia, in about 20 languages.

Mexico. There are about 850 radio stations in Mexico. Most are commercial, and more than 120 are grouped into two nationwide networks. There is a smaller number of television stations, constantly growing, many of which are grouped into networks of varying size. There are two nationwide networks, Televisa, which combined the former Telesistema Mexicano and Televisión Independiente de Mexico and is seen around the world, and the state-owned Imevision. Television, too, is nearly all commercial, though there are some university stations, of which the best known is Radio Universidad, run by the Universidad Nacional Autónoma de México in Mexico City; in addition, the Instituto Politécnico Nacional operates a cultural station in the capital. In theory there is no government control over broadcasting, but in practice there is no political broadcasting critical of the government or of the leading political party. Most stations carry the Hora Nacional, an hour-long officially produced program, every Sunday morning. The government has the right to use 12.5 percent of the total transmitting time of all radio and television stations. This right so far has not been fully exercised, though the announced intention is that the Comisión de Radiodifusión should acquire the resources to make full use of the time. Except for the few noncommercial stations, the majority of radio stations do little more than broadcast recorded popular music, news, and spot advertisements.

Television, with few exceptions, is substantially devoted to entertainment; a good proportion of material originates in the United States, though the government has banned some of the more violent shows. Production of programs for other Spanish-speaking countries is on the increase, with programs made for Puerto Rico, the Dominican Republic, Central American countries, Venezuela, Peru, Colombia, Ecuador, Argentina, Chile, and the Hispanic community in the United States. The government has proposed a network of officially operated small stations to provide cultural and educational programs.

The Netherlands. In all democratic countries, governments have found it difficult to reflect minority views in broadcasting. The Netherlands has made perhaps the most determined attempt to deal with this problem. The Dutch system basically consists of two national organizations, the Nederlandse Omroepprogramma Stichting, which is responsible for the transmission of general-interest programs and the promotion of Dutch broadcasting interests, and the Nederlandse Omroepproductie Bedrijf, an independent production company, and eight broadcasting societies (or organizations) that, through the size of their membership, have earned the right to produce a proportion of the foundation's output. The Broadcasting Act of 1966 called upon the responsible minister to allocate time on the air, in both radio and television, to bodies that fulfilled certain conditions, in particular a sufficient membership, and that, by October 1971, included: broadcasting associations or organizations, groups aspiring to recognition as broadcasting societies, churches, associations of a nature comparable to churches, political parties, other reputable associations of approved purpose, an advertising foundation, and educational bodies. As far as the full-fledged associations are concerned, the amount of time they have on the air is determined by their category, in turn dependent upon the number of subscribers, whose subscriptions pay for a weekly program bulletin. Some of the other bodies with time on the air may prepare their own programs or have them produced by groups with more experience. Organizations with at least 60,000 members may petition to broadcast from one hour per week to four hours. The government, however, has moved to restrict access to broadcasting, with legislation requiring aspirant broadcasting groups to offer innovative proposals to the existing range of programs in order to qualify. The financing of broadcasting, when production time is allocated among so many, presents a complex problem of accountancy. The revenue comes from the sale of receiving-set licenses and from advertising profits. Advertising on radio and television was first permitted in 1967 and is provided by the Stichting Ether Reclame.

Dutch broadcasting associations

The Netherlands has five radio networks and three independent television services. There is no regional television, but there are several regional radio organizations. The main categories of overall radio output are 25 percent news, public affairs, and information, 22 percent classical music, 14 percent light music, and 28 percent entertainment and other light programs. Television output is more diversified, with 32.3 percent entertainment (of which more than half is of foreign origin), 2.9 percent Dutch-produced drama, 5 percent films (mostly foreign), and 31.2 percent news, public affairs, and information.

Radio Nederland Wereldomroep (Radio Netherlands International) broadcasts daily shortwave transmissions to most areas of the world in Dutch and eight other languages (Portuguese, Spanish, Sranan Tongo, Papiamento, Arabic, English, French, and Indonesian).

New Zealand. In New Zealand the relatively small population means that broadcasting personnel are closely in touch with their audience, whose demand for a high-standard broadcasting service presents financial problems. The National Broadcasting Service, a government department set up in 1936, was faced by the competition of the National Commercial Broadcasting Service a year later. The two were amalgamated and reorganized as a government department, the New Zealand Broadcasting Service, in 1946. The service had some degree of independence from the start, and the inauguration of a television service in June 1960 provided the opportunity for the Broadcasting Act of 1961, by which was created the New Zealand Broadcasting Corporation, with a far greater constitutional autonomy. It is financed by license fees and advertising revenue. In 1977 the Broadcasting Corporation of New Zealand was created, incorporating two previously independent networks. Radio New Zealand has two radio medium-wave networks that include some broadcasts in Maori, Samoan, Tongan, Niuean, and Tokelauan. The corporation has more than 50 radio stations in more than 30 cities and towns. Television New Zealand operates two television networks, TV 1 and TV 2. It has more than 10 television stations with more than 600 relay stations, mainly low-powered. TV 3 is a private commercial station. The corporation is also responsible for the Foreign Service (Radio New Zealand), which broadcasts to Australia, the Pacific Islands, and the Ross Dependency in the Antarctic in English, twice a week to Samoa in Samoan, and once a fortnight to the Cook Islands, in Rarotongan, and to Niue, in Niuean. There are nine private radio stations.

New Zealand's external services

Soviet Union. The State Committee for Television and Radio Broadcasting operates a substantial undertaking under the Soviet Union's Council of Ministers. The chairman of the committee has four deputies, one each for television, external services, domestic radio, and for administration and finance, and there is an editorial board of 13 members. The committee controls output and is responsible for the equipment of television centres and for all personnel, but all lines, radio stations, and studios are under the control of the Ministry of Communications. Under the committee, domestic radio is run by seven Chief Editorial boards: program planning and presentation; propaganda; information (news); children; youth; literature and drama; and music, comedy, and satire. There is a joint radio and television department for sports. No program may go on the air without the approval of the editor in chief (or his deputy) of the appropriate editorial board. Though regional stations have a measure of autonomy, the committee controls the work of the regional committees handling radio in the various republics, regions, and districts. Radio in the Soviet Union requires between 300 and 400 transmitters for its networks and regional broadcasts. To achieve maximum coverage, it makes use of long waves, medium waves, and shortwaves, as well as FM. Moscow is responsible for five outputs as follows:

Program I is a mixed program covering the entire union.

Program II is a 24-hour musical service with news and commentaries every half-hour, also covering the entire population. Program III is primarily a musical and literary program for the European regions of the Soviet Union and reaches more remote regions by shortwaves and FM. There is also a local output of some three half-hours a day for the Moscow area on some of the channels used for Program III. Program IV is on FM and offers classical music nine hours a day. Program V is directed toward Soviets abroad. The regional effort is impressive, with broadcasts in about 70 languages in use within the territory of the Soviet Union. There are 23 principal regional stations. With so diverse an output there is no means of making a meaningful percentage breakdown of program categories, but Soviet radio on the whole devotes more time to information, educational, and cultural programs and less to entertainment than other countries.

The Moscow television station began broadcasting in 1939 and claims to have been the first European television station to renew operation after the World War II interruption. Colour was introduced in 1967. About four-fifths of the population are within reach of a television signal, for which there are about 900 main and 4,000 relay transmitters. In most of the principal cities there are at least two outputs to choose from. The satellites Molniya I and Ekran, combined with 90 Orbita ground and relay stations, greatly increased the size of the potential audience. At the Moscow television centre, Ostankino, there is a 1,739-foot (530-metre) tower used for television and other communications. The services broadcast cannot be easily analyzed, and it is claimed that from Moscow six can be broadcast simultaneously. There are four main channels: the First Program, all-Union since 1962; the Second Program, all-Union since 1982; the Third Program, educational at primary, secondary, and university levels; and the Fourth Program, which features locally produced programs in the various regional languages.

Soviet foreign-language transmissions

The external services described above are probably the largest of any country. The output can be divided into six types: (1) for foreign countries from Moscow, (2) for foreign countries from regional stations, (3) relays of domestic services for listeners abroad, (4) broadcasts for Soviets abroad, under the aegis of the Committee for Cultural Relations, (5) a service for the Merchant Marine and for fishermen, and (6) the "Peace and Progress" station. It is the Moscow output, supplemented by the foreign services from the regional stations, that has the widest coverage and makes use of more than 70 languages, including more for Africa and Asia than any other country and including even, for example, Quechua (for Peru). The "Peace and Progress" output is in German and English for Europe; in Persian, Azerbaijani, and English for Asia; in Arabic and Hebrew for the Middle East; and in Spanish, Portuguese, Creole (for Haiti), and Guaraní (for Paraguay) for Latin America. In 1978 Soviet broadcasting initiated its "World Service in English."

Sweden. Two important developments affecting Sveriges Radio, the Swedish broadcasting corporation, occurred in 1967, embodied in the Broadcasting Law, effective from July 1 of that year. Public authorities and agencies were specifically forbidden to examine programs in advance or to attempt to prevent them from being broadcast; this meant that the government had not even the power of veto. The legal responsibility for any program rests not on the organization, its board of directors, or even the director general but on the program supervisor, and no program may be broadcast against his will. Program content is ultimately controlled by the Radio Council, which supervises both radio and television. The Radio Council may only rule on shows that have already been aired, thus avoiding a role of censorship. The financing is almost entirely from licenses for receiving sets (a small amount of revenue is derived from the international sale and distribution of some radio and television programs), but the proceeds are allocated by Parliament to Sveriges Radio, which produces most of the programs; the Swedish Telecommunications Administration, which transmits them; and the Swedish General Services Administration, which is responsible for the construction of broadcasting facilities. In 1979 Sveriges Radio was broken up into several subsidiary companies: Swedish Radio Company, Swedish Television Company, Swedish Local Radio Company, and Swedish Educational Broadcasting Company. Sveriges Radio became the parent company responsible for long-range planning and development and the distribution of finances to the subsidiaries.

Sweden's television networks

Sweden has three radio and two television networks. A substantial number of stations and transmitters on long waves, medium waves, and shortwaves ensures national coverage of the three radio services, as well as allowing for regional broadcasting. Twenty-four regional stations have a substantial autonomy and their own budgets, but they must negotiate with the heads of the national networks to opt out, with their own regional programs, for up to a total of 25 percent of the network programming. In radio, one network broadcasts spoken-word programs almost exclusively, with some classical music during the day; the second consists of education and light as well as classical music in the evening; and the third, a 24-hour operation, features popular music, news, light entertainment, and regional broadcasts. The two television networks offer a wide variety of features, which include information (17.9 percent), drama and film (13.6 percent), entertainment (13.1 percent), programs for children (10.8 percent), news (9.6 percent), sports (9.5 percent), and education (8.9 percent). Colour television was inaugurated in April 1970.

Sveriges Radio is also responsible for Sweden's external services, the cost of which (as with the cost of educational broadcasts) is separately budgeted and paid for from government funds. The broadcasts are in Swedish and six foreign languages: English, French, German, Spanish, Portuguese, and Russian. They are beamed as appropriate to all parts of the world.

United Kingdom. *British Broadcasting Corporation.* A monopoly until 1954, the BBC operates under a royal charter. It is funded from a fixed-term license fee paid by households with a television set. The BBC has four national radio networks: Radio 1, broadcasting mostly popular music, mainly during the day; Radio 2, primarily transmitting light music, sports, and entertainment; Radio 3, broadcasting mainly classical music and news during the day and cultural programs in the evening; and Radio 4, scheduling spoken word primarily, school programs in the midmorning and early afternoon, and a mixed program in the evenings. The main ingredients of overall output are: 42.9 percent entertainment and music; 21.2 percent classical music; 9.1 percent news and outside broadcasts; 4.8 percent drama; 3.6 percent education; and 2.2 percent features. Some 30 local radio stations have been added to the BBC since 1967. The BBC has two national television services, which together transmit more than 200 hours a week; both have mixed programs that are coordinated to avoid conflicts. The main ingredients are news, documentaries, and information (31 percent); British and foreign films and series (15.5 percent); outside broadcasts, substantially sports, and sports news (14 percent); drama (8 percent); "family" programs and light entertainment (13.5 percent); education (11.1 percent); and religion (2.2 percent).

There is substantial regional activity in both media. Of the six regions in the kingdom that formerly operated with a fair degree of autonomy, only the "national" regions remain for Scotland, Wales, and Northern Ireland. In place of the other three regions, North, Midland, and West and South, there are 20 production centres for both radio and television. Regions broadcast their own programs by opting out of Radio 4 or BBC 1 and using their own section of the corresponding network. Radio Cymru broadcasts in the Welsh language for Wales. There are about 50 local FM (VHF) stations as authorized by the government: these are mostly placed to cover the larger city areas. Many competitive commercial local stations have been set up under the supervision of the Independent Broadcasting Authority.

The BBC is also responsible for the United Kingdom's external services, which are paid for by annual grants-in-aid from the Foreign and Commonwealth Office. Though no longer among the leaders in quantity of output, the

BBC remains among them in terms of penetration. Seventy transmitters, of which 13 are overseas relay stations, provide a shortwave worldwide service and a medium-wave service in many areas, including Europe (from Berlin), Asia, East Africa, and Latin America. Of the weekly output of about 740 hours, roughly one-third in the World Service is in English, and the remainder is in nearly 40 foreign languages, of which the main ones are Arabic (119 hours), French for Europe and Africa (more than 45), Russian and German (55 and 30), Spanish for Spanish-speaking America (28), Polish and Czech (24 and 15), Hungarian (16), and Portuguese for Brazil and Portugal (23).

Independent Broadcasting Authority. The Independent Broadcasting Authority (originally called Independent Television Authority) was established by act of Parliament in 1954; broadcasting began under its control a year later. Although the authority has substantial independence, it does not produce any programs or advertising; these tasks are performed by commercial program companies. These latter, organized on a regional basis, supply all the material broadcast except for news, for which a separate group, Independent Television News, was created, jointly owned and financed by the program companies. TV-am originated in 1983 and operates outside the system with an early morning breakfast-show format. Channel 4 is a wholly owned subsidiary of the International Broadcasting Authority and is funded through compulsory annual subscriptions of Independent Television companies in exchange for advertising rights. It was authorized by the Broadcasting Act of 1980 and began broadcasting in 1982. A separate Welsh fourth channel was authorized at the same time.

Control of the British program companies

The program companies are under a substantial measure of control from the Independent Broadcasting Authority, which is responsible for the appointment of program companies, control of program and advertising output, and its transmission. The authority enforces codes with respect to advertising and violence on the screen. Television companies broadcast throughout the week within their respective areas, except for two that share the London area. The program companies are entirely financed by spot advertising (sponsored programs are forbidden by law) in "natural breaks" in and between programs; they pay a rental to the authority to cover the latter's transmitting and administrative costs and a fiscal levy to the exchequer. The program companies cooperate in a network committee, and a substantial number of the principal programs are broadcast by all companies. The contribution to the network made by each company varies in accordance with its size and resources. The revenue of each company is substantially dependent upon the number of homes with television receivers able to receive the Independent Broadcasting Authority signal in the area it covers, which varies from 32,000 in the Channel Islands to 2,630,000 in the Midlands and 4,300,000 in the London area. So diversified an output makes valueless any percentage analysis of program categories; but the principal types of output, in order of size, are as follows: drama, including telefilm series; light entertainment; children's programs; news, news magazines, features, and documentaries; sports; feature films (British and foreign); education; and religion. The Television Act of 1964 established the present authority situation for 12 years, and its license has since been extended. The authority has also been given the task of supervising local commercial radio (hence its change of name).

The Cable Authority oversees cable television and began operations in 1985.

United States. Broadcasting in the United States is regulated by the Federal Communications Commission, created in 1934, which assigns frequencies and grants licenses. So great is the broadcasting operation in the United States, so many are the stations, both radio and television, and so extensive are the ramifications and links with other industries that it is not possible to produce a summary on the lines of those for countries where broadcasting has been more tightly organized. Some idea of the magnitude of the broadcasting scene is provided by the number of broadcasting stations in operation in the late 1980s, as authorized by the Federal Communications Commission: radio AM, about 5,000; radio FM, about 4,000; educational radio FM, about 1,200; commercial television, about 1,000; educational television, about 300; and television relay stations, more than 4,000. In most categories more stations have been authorized than are operating. The largest proportional increase has been in educational radio FM. Commercial broadcasting on television, as on radio in the past, is dominated by the three great national networks: the American Broadcasting Company, Columbia Broadcasting System, and the National Broadcasting Company. In radio, where the networks are no longer dominant, there is also the Mutual Broadcasting System; the majority of radio stations are as independent of the large networks as of the government, and many of the commercial stations specialize in a single type of output, which may be one or other of various kinds of popular music, classical music, news, or even traffic information. A few are owned by or affiliated with the national networks or with smaller local networks; some even are small local stations offering a basic fare of neighbourhood gossip interspersed with recorded music and spot advertising. After a slump following the major onset of television, radio, even network radio, has again become profitable. In television the three major networks own and operate their own stations in some of the larger cities and substantially control a majority of affiliates.

U.S. noncommercial broadcasting

Noncommercial broadcasting has risen in the United States. The National Association of Educational Broadcasters serves educational stations with transcriptions produced by its members and by other domestic as well as foreign broadcasters. The National Public Radio is also largely educational, supported by donations from foundations and other sources. There are radio stations supported by donations and subscriptions from listeners, in particular the Pacifica group. The Public Broadcasting Service has a loose organization. Its production facilities are not jointly organized, and it makes use of noncommercial stations for its network. Its revenue is uncertain; it received $137,000,000 in 1982 from a congressional appropriation, which must be renewed annually, and the rest from foundations, public contributions, and individual stations.

Another system is community antenna television (CATV), increasingly known as cablevision, or cable TV, originally set up in areas of poor reception or where the choice of receivable television services was poor and cablevision could offer additional choices from elsewhere. By 1964, about 1,000 such systems were in operation. At the time, no one thought of "cablecasting"—*i.e.,* that the cablevision companies should originate their own programs—but in many areas cablecasting has proved a success. Cablevision, transmitted via direct cables connected to each television set, offers viewers a large choice of programs, as well as excellent reception.

Official external services are operated by the Board for International Broadcasting, known as the Voice of America. They are broadcast to all parts of the world and have a number of relay stations overseas. Apart from English, 41 languages are used. There is also the foreign-based Radio Free Europe/Radio Liberty, which broadcasts 1,000 hours a week to eastern Europe and to the Soviet Union. In addition there is the International Broadcast Station, KGEI, offering a shortwave service to Latin America in English, Spanish, and German and in Russian, Byelorussian, Polish, and Ukrainian to Asia; Radio New York World Wide, with a commercial service to Europe and Africa in English and to the Caribbean in English and Spanish; and World International Broadcasters, whose shortwave commercial service with a religious background is broadcast in English to Europe, the Middle East, and North Africa. The United States Armed Forces Radio and Television Service has a network of shortwave stations broadcasting a worldwide service; stations are located in Alaska, Canada, Europe, North Africa, Ethiopia, the Caribbean, East Asia, the Middle East, Antarctica, the North Atlantic, and the Pacific.

Germany's provincial organization

West Germany. Though Germany was one of the first countries to begin radio transmissions (October 1923), the state organization owes nothing to earlier development. It was the occupying powers at the end of World War II that established the present system based on nine state (*Länder*) organizations. All state organizations have a First Radio service on medium wave, supported by FM. Five have a Second, Third, and Fourth Radio service on FM, and the Cologne group has a Fifth. Berlin has an AM channel, as well as FM for each of its three radio services. In many cases, two or more *Länder* organizations cooperate and broadcast simultaneously a single output on one of their FM services. The latter in most cases is broadcast for only three to four hours daily and is substantially, sometimes entirely, devoted to foreign languages for foreign workers in West Germany. The output of the First and Second Radio services is to some extent mixed, but the Second focuses on more serious output.

The First German Television service is nationally coordinated with contributions from each *Land* organization. Each organization broadcasts a substantial amount of regional material for its own audience. The Second Television service is centrally planned and produced, with headquarters in Mainz; schedules are coordinated to give the viewer a maximum choice. Each organization has also a Third Television service for only a few hours a day, often of an educational nature; this service, like the radio Third service, is sometimes produced and simultaneously broadcast by groups of two or three *Länder* organizations. The Federal government has no authority for the control of broadcasting within the West German territory, and legislative and administrative competence for broadcasting rests with the *Länder*. But even the *Land* governments and parliaments are legally barred from intervening beyond a statutory supervision and may not interfere with the basic independence of the broadcasting organizations.

There are two external service organizations. Deutschlandfunk broadcasts to France, the United Kingdom, The Netherlands, and northern and eastern Europe in 12 languages. Deutsche Welle broadcasts in 34 foreign languages to most areas of the world for a total of about 800 hours weekly. (J.A.Ca./Ed.)

Radio systems and equipment

BASIC PHYSICAL PRINCIPLES

Electromagnetic radiation includes light as well as radio waves, and the two have many properties in common. Both are propagated through space in approximately straight lines at a velocity of about 300,000,000 metres (186,000 miles) per second and have amplitudes that vary cyclically with time; that is, they oscillate from zero amplitude to a maximum and back again. The number of times the cycle is repeated in one second is called the frequency (symbolized as f) in cycles per second, and the time taken to complete one cycle is $1/f$ seconds, sometimes called the period. To commemorate the German pioneer Heinrich Hertz, who carried out some of the early radio experiments, the cycle per second is now called a hertz so that a frequency of one cycle per second is written as one hertz (abbreviated Hz). Higher frequencies are abbreviated as shown in Table 3.

Frequency

A radio wave being propagated through space will at any given instant have an amplitude variation along its direction of travel similar to that of its time variation, much like a wave traveling on a body of water. The distance from one wave crest to the next is known as the wavelength.

Wavelength and frequency are related. Dividing the speed of the electromagnetic wave (c) by the wavelength (designated by the Greek letter lambda, λ) gives the frequency: $f = c/\lambda$. Thus a wavelength of 10 metres has a frequency of 300,000,000 divided by 10, or 30,000,000 hertz (30 megahertz). The wavelength of light is much shorter than that of a radio wave. At the centre of the light spectrum the wavelength is about 0.5 micron (0.0000005 metre), or a frequency of 6×10^{14} hertz or 600,000 gigahertz (one gigahertz equals 1,000,000,000 hertz). The maximum frequency in the radio spectrum is usually taken to be about 45 gigahertz, corresponding to a wavelength of about 6.7 millimetres. Radio waves can be generated and used at frequencies lower than 10 kilohertz ($\lambda = 30{,}000$ metres).

Table 3: Frequency Terms and Their Abbreviations

term	cycles per second	abbreviation	equivalent
1 hertz	1	1 Hz	
1 kilohertz	1,000	1 kHz	1,000 Hz
1 megahertz	1,000,000 (10^6)	1 MHz	1,000 kHz
1 gigahertz	1,000,000,000 (10^9)	1 GHz	1,000 MHz

Mechanism of wave propagation. A radio wave is made up of electric and magnetic fields vibrating mutually at right angles to each other in space. When these two fields are operating synchronously in time, they are said to be in time phase; *i.e.*, both reach their maxima and minima together and both go through zero together. As the distance from the source of energy increases, the area over which the electric and magnetic energy is spread is increased, so that the available energy per unit area is decreased. Radio-signal intensity, like light intensity, decreases as the distance from the source increases.

A transmitting antenna is a device that projects the radio-frequency energy generated by a transmitter into space. The antenna can be designed to concentrate the radio energy into a beam like a searchlight and so increase its effectiveness in a given direction (see ELECTRONICS).

Function of transmitting antenna

Frequency bands. The radio-frequency spectrum is divided arbitrarily into a number of bands from very low frequencies to superhigh frequencies (see Table 4). Sections of the spectrum have been allocated to the various users (see Table 5), such as telegraph, telephonic speech, telemetry, and radio and television broadcasting.

Table 4: Frequency Band Designations

frequency designation	frequency range	wavelength range
Very low frequencies (vlf)	3–30 kilohertz	100,000–10,000 m
Low frequencies (lf)	30–300 kilohertz	10,000–1,000 m
Medium frequencies (mf)	300–3,000 kilohertz	1,000–100 m
High frequencies* (hf)	3–30 megahertz	100–10 m
Very high frequencies (vhf)	30–300 megahertz	10–1 m
Ultrahigh frequencies (uhf)	300–3,000 megahertz	1 m–10 cm
Superhigh frequencies (shf)	3–30 gigahertz	10–1 cm

*Also called shortwaves.

The radio-frequency bandwidth is the range of frequencies covered by the modulated radio-frequency signal. The information carried by the signal has a certain bandwidth associated with it, and the carrier must have a channel width at least as great as the information bandwidth. For regular amplitude-modulated (AM) broadcasting the radio-frequency bandwidth must be twice the information-frequency bandwidth. Teleprinter and telex operation requires only a small bandwidth, on the order of 200 hertz, depending on the maximum speed of the pulses forming the information code. Telephonic speech must have high intelligibility, but naturalness (high fidelity) is not of great importance. Tests have shown that the main components of speech lie between about 300 and 3,500 hertz, and telephonic channels carried by radio are therefore normally confined to a bandwidth of about four kilohertz. The smaller the information bandwidth employed the more speech channels can be carried in a given carrier bandwidth and the more economical the system will be.

Young people can hear audio frequencies ranging from about 30 hertz to 18 kilohertz, but as humans grow older, hearing ranges from about 100 hertz to 10 kilohertz. For high-quality (high-fidelity) reproduction of voice or speech, the range should be not less than about 30 hertz (the lowest frequency of a large organ pipe) to 15 kilohertz (piccolo, cymbal, triangle). Acceptable audio quality under certain circumstances may be achieved with a bandwidth as small as five kilohertz, as in AM radio; a much larger bandwidth is needed for transmitting a moving picture because it is necessary to convey the overall average light content of a picture as well as the picture detail. The average light content requires frequencies as low as 20 hertz to be transmitted, and picture detail demands frequencies up to five megahertz for a standard television picture.

Minimum acceptable bandwidths

Modulators and demodulators. A carrier wave is a radio-frequency wave that carries information. The information is attached to the carrier wave by means

Table 5: Utilization of Radio-Frequency Spectrum

very low frequencies (vlf)		time signals, standard frequencies
	30 kHz	
low frequencies (lf)		fixed, maritime mobile, navigational, radio broadcasting
	300 kHz	
medium frequencies (mf)		land, maritime mobile, radio broadcasting
	3 MHz	
high frequencies (hf)		fixed, mobile, maritime and aeronautical mobile, radio broadcasting, amateur
	30 MHz	
very high frequencies (vhf)		fixed, mobile, maritime and aeronautical mobile, amateur, radio and television broadcasting, radio navigation
	300 MHz	
ultrahigh frequencies (uhf)		fixed, mobile, maritime and aeronautical mobile, amateur, television broadcasting, radio location and navigation, meterological, space communication
	3 GHz	
superhigh frequencies (shf)		fixed, mobile, radio location and navigation, space and satellite communication
	30 GHz	

of a modulation process that involves the variation of one of the carrier-frequency characteristics, such as its amplitude, its frequency, or its duration. (All of these processes are discussed in greater detail in the article TELECOMMUNICATIONS SYSTEMS.)

In amplitude modulation the information signal varies the amplitude of the carrier wave, a process that produces a band of frequencies known as sidebands on each side of the carrier frequency. These sidebands (a pair to each modulation frequency) cover a range of frequencies equal to the sum and difference between the carrier frequency and the information signal.

Frequency modulation involves varying the frequency (the number of times the wave passes through a complete cycle in a given period of time, measured as cycles per second) of the carrier in accordance with the amplitude of the information signal. The amplitude of the carrier wave is unaffected by the variation; only its frequency changes. Frequency modulation produces more (often many more) than one pair of side frequencies for each modulation frequency.

The variation of carrier frequency is known as the frequency deviation, and for very-high-frequency broadcasting it can reach ± 75 kilohertz. The greater the frequency deviation the greater is the effective modulation. Though theoretically its maximum value need not be limited to 75 kilohertz, any increase beyond this value requires a wider channel, which adds to the cost of reception and reduces the number of transmitters that can be accommodated in the band. The total channel width is approximately twice the sum of the maximum deviation frequency and modulating frequency. If channel width is restricted in either transmitter or receiver circuits, distortion of the information signal occurs.

A radio broadcast normally consists of only one information signal. The listener hears what he would hear at the microphone position if only one of his ears was functioning; *i.e.*, it is a monaural system. In such a system it is not possible to gain any impression of the position of the instrument groupings in an orchestra, nor can lateral movement be indicated, though movement toward or away from the microphone is conveyed by a change in sound volume.

Stereophonic broadcasting requires two microphones, one to collect sounds from the left and one from the right; the two sets of information must be separable in the receiver pnd be fed to loudspeakers on the left and on the right at the listening position. For high-fidelity reproduction the full audio range up to 15 kilohertz is transmitted; this can only be achieved satisfactorily at very high frequencies with frequency modulation. The broadcast signal is received on monaural receivers by making one set of information the sum of left and right signals (L + R). The other set of information is the difference of left and right (L − R). Summation of the two sets of information at the receiver output recovers the left (L) signal and subtraction recovers the right (R) signal.

Pulse code modulation

Another system of modulation switches the carrier on and off in pulses, the duration or position of the pulse being determined by the information signal. This system of pulse-coded modulation can provide better protection from noise, and a number of separate speech channels can be combined by allocating specified groups of pulses for each information channel and then interleaving these pulses in a process called time division multiplex. To accomplish this, a comparatively wide transmission channel is needed, and the carrier must be an ultrahigh or superhigh frequency.

The ionosphere. An English mathematician, Oliver Heaviside, and a U.S. electrical engineer, Arthur Edwin Kennelly, almost simultaneously predicted in 1902 that radio waves, which normally travel in straight lines, are returned to Earth when projected skyward because electrified (ionized) layers of air above the Earth (the ionosphere) reflect or refract (bend) them back to Earth, thus extending the range of a transmitter far beyound line of sight. In 1923 the suggestion was proved to be accurate when pulses of radio energy were transmitted vertically upward and returning pulses were received back from the reflecting layer. By measuring the time between the outgoing and returning pulses, it was possible to estimate the height and number of layers. Three layers can normally be distinguished at distances from 50 to about 400 kilometres (30 to 250 miles) above the Earth's surface. The layers result from a breakdown of gas atoms into positively charged ions and free electrons caused by energy radiated from the Sun. The electrons maintain a separate existence in the lower layers for as long as the Sun's energy is being received, and in the upper layers some can remain free throughout the hours of darkness.

The three layers are designated D, E, and F. The D layer is approximately 80 kilometres (50 miles) high and exists only during daylight hours. Because it absorbs medium frequencies and the lower frequencies of the shortwave bands, it limits the range of such stations during daylight. The E layer, about 110 kilometres (68 miles) high, maintains its reflectivity for four or five hours after the Sun sets and so extends the range of such stations to as much as 1,000 kilometres (620 miles). This layer also serves as a good reflector of shortwaves during the day and into the night, until its reflectivity drops.

Most important of the three layers is the F layer, which has considerable power to reflect the higher frequencies. During the day it often splits into two layers (F_1 and F_2) at about 200 and 400 kilometres (125 and 250 miles), but at night only one layer is generally present at a height of about 300 kilometres (190 miles).

Radio noise, fading, and interference. Any sudden discharge of electrical energy, like that of lightning, produces transient (short-duration) radio-frequency waves, which are picked up by antennas. These packets of radio-frequency energy produce the crackle heard on an amplitude-modulated radio receiver when an electrical storm is nearby and may be classed as natural noise.

Switching of high-voltage power lines can produce similar effects; the lines help to carry the noise-producing signals over long distances. Local switching of lights and electrical machinery can also produce the familiar crackle when the receiver is close to the noise-producing source. These sources are classed as man-made noise.

Filters in noise production

Generally noise of both types decreases as the frequency is increased. An exception is automobile ignition noise, which produces maximum effect in the very-high-frequency range, causing a sound in nearby loudspeakers every time a spark plug fires. Many countries have legislation requiring the suppression of man-made noise by means of filters that reduce the amount of radio-frequency energy released at the source. Metallic shielding of leads to and from the noise source curtails the radiated interference. It is also possible to install various noise-reducing devices at the input to radio receivers.

Noise is also caused by irregularities in the flow of electrons in metals, transistors, and electron tubes. This source of noise ultimately limits the maximum useful signal amplification that can be provided by a receiver. Noise due to the random movement of electrons causes a hiss in the loudspeaker. Radio noise can also be picked up from outer space as a hiss similar to random electron noise.

Fading of a signal, on the other hand, is due to variation in the propagation characteristics of the signal path or paths. This is particularly true when propagation depends on reflection from the ionosphere as it does for shortwaves. Propagation of waves in the very-high-frequency range and above, which penetrate the ionosphere, can be affected by temperature changes in the stratosphere, that part of the atmosphere up to about 15 kilometres (nine miles) from the Earth's surface. The fading effect can be greatly reduced at the receiver loudspeaker by various electronic controls, such as automatic gain control.

The phenomenon of interference occurs when an undesired signal overlaps the channel reserved for the desired signal. By interaction with the desired carrier, the undesired information may cause speech to become unintelligible. Countermeasures include narrowing the desired channel, thus losing some information but preventing overlap, and using a directional antenna to discriminate against the undesired transmission.

DEVELOPMENT OF RADIO TECHNOLOGY

Maxwell's prediction. Early in the 19th century, Michael Faraday, an English physicist, demonstrated that an electric current can produce a local magnetic field and that the energy in this field will return to the circuit when the current is stopped or changed. James Clerk Maxwell, professor of experimental physics at Cambridge, in 1864 proved mathematically that any electrical disturbance could produce an effect at a considerable distance from the point at which it occurred and predicted that electromagnetic energy could travel outward from a source as waves moving at the speed of light.

Maxwell's prediction verified

Hertz: radio-wave experiments. At the time of Maxwell's prediction there were no known means of propagating or detecting the presence of electromagnetic waves in space. It was not until about 1888 that Maxwell's theory was tested by Heinrich Hertz, who demonstrated that Maxwell's predictions were true at least over short distances by installing a spark gap (two conductors separated by a short gap) at the centre of a parabolic metal mirror. A wire ring connected to another spark gap was placed about five feet (1.5 metres) away at the focus of another parabolic collector in line with the first. A spark jumping across the first gap caused a smaller spark to jump across the gap in the ring five feet away. Hertz showed that the waves travelled in straight lines and that they could be reflected by a metal sheet just as light waves are reflected by a mirror.

Marconi's development of wireless telegraphy. The Italian physicist Guglielmo Marconi, whose main genius was in his perseverance and refusal to accept expert opinion, repeated Hertz's experiments and eventually succeeded in getting secondary sparks over a distance of 30 feet (nine metres). In his experiment he attached one side of the primary spark gap to an elevated wire (in effect, an antenna) and the other to Earth, with a similar arrangement for the secondary gap at the receiving point. The distance between transmitter and receiver was gradually increased first to 300 yards (275 metres), then to two miles (three kilometres), then across the English Channel. Finally, in 1901, Marconi bridged the Atlantic when the letter *s* in Morse code travelled from Poldhu, Cornwall, to St. John's, Newfoundland, a distance of nearly 2,000 miles (3,200 kilometres). For this distance, Marconi replaced the secondary-spark detector with a device known as a coherer, which had been invented by a French electrical engineer, Edouard Branly, in 1890. Branly's detector consisted of a tube filled with iron filings that coalesced, or "cohered," when a radio-frequency voltage was applied to the ends of the tube. The cohesion of the iron filings allowed the passage of current from an auxiliary power supply to operate a relay that reproduced the Morse signals. The coherer had to be regularly tapped to separate the filings and prepare them to react to the next radio-frequency signal.

The Fleming diode and De Forest Audion. The next major event was the discovery that an electrode operating at a positive voltage inside the evacuated envelope of a heated filament lamp would carry a current. The American inventor Thomas A. Edison had noted that the bulb of such a lamp blackened near the positive electrode, but it was Sir John Ambrose Fleming, professor of electrical engineering at Imperial College, London, who explored the phenomenon and in 1904 discovered the one-directional current effect between a positively biased electrode, which he called the anode, and the heated filament; the electrons flowed from filament to anode only. Fleming called the device a diode because it contained two electrodes, the anode and the heated filament; he noted that when an alternating current was applied to the diode, only the positive halves of the waves were passed—that is, the wave was rectified (changed from alternating to direct current). The diode could also be used to detect radio-frequency signals since it suppressed half the radio-frequency wave and produced a pulsed direct current corresponding to the on and off of the Morse code transmitted signals. Fleming's discovery was the first step to the amplifier tube that in the early part of the 20th century revolutionized radio communication.

Fleming failed to appreciate the possibilities he had opened up and it was the American inventor Lee De Forest who in 1906 conceived the idea of interposing

Invention of the Audion

an open-meshed grid between the heated filament and positively biased anode, or plate, to control the flow of electrons. De Forest called his invention an Audion. With it he could obtain a large voltage change at the plate for a small voltage change on the grid electrode. This was a discovery of major importance because it made it possible to amplify the radio-frequency signal picked up by the antenna before application to the receiver detector; thus, much weaker signals could be utilized than had previously been possible.

Early research by commercial companies. The first commercial company to be incorporated for the manufacture of radio apparatus was the Wireless Telegraph and Signal Company, Ltd. (England) in July 1897 (later changed to Marconi's Wireless Telegraph Company, Ltd.); other countries soon showed an interest in the commercial exploitation of radio.

Among the major developments of the first two decades of the 20th century was De Forest's discovery in 1912 of the oscillating properties of his Audion tube, a discovery that led to the replacement of the spark transmitter by an electronic tube oscillator that could generate much purer radio waves of relatively stable frequency. By 1910, radio messages between land stations and ships had become commonplace, and in that year the first air-to-ground radio contact was established from an aircraft. A landmark transmission came in 1918, when a radiotelegraph message from the Marconi long-wave station at Caernarvon, in Wales, was received in Australia, over a distance of 11,000 miles (17,700 kilometres).

Though early experiments had shown that speech could be transmitted by radio, the first significant demonstration was not made until 1915 when the American Telephone & Telegraph Company successfully transmitted speech signals from west to east across the Atlantic between Arlington, Virginia, and Paris. A year later, a radiotelephone message was conveyed to an aircraft flying near Brooklands (England) airfield. In 1919 a Marconi engineer spoke across the Atlantic in the reverse direction from Ballybunion, Ireland, to the United States.

From 1920 onward radio made phenomenal progress through research activities in Europe, North America, and Asia. The invention of the electron tube and later the transistor (1948) made possible remarkable developments.

Hand wiring. In the early days of radio and up to the end of World War II, radio receivers consisted of resistors, capacitors, inductors (coils), and electronic tubes joined together by wires with coloured insulation. A colour code, whereby a particular colour was assigned to a particular circuit connection, such as black leads for filaments, green for grid, was adopted throughout the world to facilitate manufacture and the tracing of faults. Later, wires cut to the right length were laced together into a harness to speed assembly. Plugs and sockets were employed for connecting one major part with another. Printed circuit wiring, developed during the 1940s, eliminated much of the hand work and produced important manufacturing economies.

Printed circuits. With printed wiring, the layout of the circuit is planned with component size and position in mind, and connections are made by suitably shaped copper strip or foil bonded to an insulating board or substrate. An extension of this technique was the printed component; resistors, capacitors, and low value inductors became a part of the printing process.

The development of the transistor simplified the exploitation of printed circuitry by eliminating one of the bulkiest components, the vacuum tube. Further development led to the manufacture of the integrated circuit in the 1960s. Compact circuits of this type can perform a multiplicity of tasks such as amplification and switching. They are widely used in computers where space is at a premium. Integrated-circuit amplifiers are likely to become more important because of their ability to amplify very high frequencies.

The size of a portable receiver constructed from microminiature circuits is now dictated almost entirely by the loudspeaker and the quality of reproduction required. The smaller the loudspeaker the lower the power it can accept and the less the output of low audio frequencies.

RADIO CIRCUITRY

Components. The basic operating principles of the major circuitry and active and passive components used in radio are described in the article ELECTRONICS. In this section, only enough description is included to permit the reader to understand the applications to radio circuitry.

Primary function of the electron tube

Active devices: vacuum tubes and transistors. An electron tube or transistor, designated an active element, functions basically as an amplifier, and its output is essentially an amplified copy of the original input signal. The simplest amplifying electron tube is the triode, consisting of a cathode coated with material that provides a copious supply of electrons when heated, an open-mesh grid allowing electrons to pass through but controlling their flow, and a plate (anode) to collect the electrons. The plate is maintained at a positive voltage with respect to the cathode in order to attract the electrons; the grid usually has a small negative voltage so that it does not collect electrons but does control their flow to the plate. The output voltage is usually many times greater than the input voltage to the grid. The tube must be pumped to a high degree of vacuum, or the plate current flow is erratic.

Other electrodes, also in the form of open-mesh grids, may be included in the tube to perform various special functions. An example is the four-electrode tube known as the tetrode, in which an open-mesh grid (screen grid) maintained at a positive voltage is placed between plate and control grid. This reduces the effect of plate voltage on electron flow and increases the amplifying property of the tube. Introduction of a third grid, known as a suppressor grid, produces the pentode (five-electrode tube), which can provide even greater amplification.

The transistor, which has largely replaced the electron tube as the active element in low-voltage electronic circuits, is made from semiconductor materials—that is, substances that are neither good conductors nor good insulators. Two common semiconductor materials are germanium and silicon, to which small amounts of impurities such as indium, gallium, arsenic, or phosphorus are added to impart electrical charges to them. Arsenic and phosphorus, for example, provide extra negative charges, giving *n*-type (signifying excess negative charges) material; indium or gallium yield a shortage of electrons or an excess of positive charges or holes, giving *p*-type (signifying excess positive charges) material.

A transistor is a sandwich of semiconductor materials with the same impurity in the two outer layers and a different impurity in the centre layer providing current carriers of opposite charge to those produced by the outer layers.

If the outer layers are reservoirs of positively charged current carriers (*p* type) and the centre layer provides an excess of electrons (*n* type), the transistor is known as a *p–n–p* (positive–negative–positive carriers) type. If the *p* and *n* layers are reversed, the transistor is an *n–p–n* type. The two outer layers are termed the emitter and collector, and the centre layer is known as the base.

A transistor is an amplifier of current; the vacuum tube, in contrast, is an amplifier of voltage. The transistor produces an adequate supply of current carriers (electrons and holes) at room temperature and does not require a heated cathode as does the vacuum tube. Thus the power required from the power supply is much reduced, less heat is produced, and the transistors and their circuitry can be packed into a smaller container and takes up less space. Transistors are also physically much smaller than comparable electron tubes. Thus the transistorized portable radio can fit in a pocket—a distinct advantage over the cumbersome tube radio it has replaced.

In its early form the transistor was capable of amplifying only comparatively low frequencies because the exchange of electrons and positive charges across the sandwich was slow. Modern techniques however, have overcome this difficulty so that amplification up to frequencies over 1,000 megahertz is commonplace.

Tuned circuits and the superheterodyne principle. For information (voice, music, television) to be transmitted, it must be attached to a radio-frequency carrier wave, which is then transmitted in a given frequency channel. The carrier wave and information can be picked up by a receiver tuned to this channel. The process by which the information is attached to the carrier wave is modulation. Modulated carriers are isolated in their separate slots or channels; if transmitters are geographically close to each other, they must not use the same channel or overlap each other's channels. If such overlap occurs, serious interference results—two radio programs may be heard simultaneously or one may form a distorted background to the other.

Modulation

In most modern radio receivers, reception is based on the superheterodyne principle. The incoming radio frequency is mixed (heterodyned) with the output of an oscillator the frequency of which is adjusted so that the difference between it and the incoming signal is constant; the result is the intermediate frequency. Amplification is thereafter carried out at this intermediate frequency. Both preliminary selection of the incoming frequency and adjustment of the local oscillator frequency are accomplished by variable tuned circuits consisting of inductance and capacitance. Tuning may be accomplished by varying the capacitance, which consists of interleaved metal plates separated by air spaces with one set of plates movable. Another method of tuning involves varying the inductance by insertion or withdrawal of an iron dust or ferrite core in a cylindrical coil of copper wire. To simplify the tuning procedure, the variable elements of all stages requiring tuning are ganged together and coupled to a tuning knob. The intermediate-frequency amplifier stages always operate at the same frequency and so require tuning only when the receiver is manufactured or serviced. The intermediate frequency is usually around 455 kilohertz for AM receivers, 10.7 megahertz for FM receivers, and 38 megahertz for television receivers. Most of the amplification in a radio receiver is carried out in the intermediate-frequency stages, and most of the selectivity (ability to separate adjacent stations) is obtained in these stages.

Oscillators. A self-oscillating circuit consists of a vacuum tube or transistor, a tuned circuit, and some form of positive feedback (energy fed from the output back to the input in such a way as to increase the input). Since both tubes and transistors can function as amplifiers, they can also function as oscillators. For receiver circuits, adequate oscillator stability can be obtained with conventional tuned circuits, but the transmitter oscillator must be highly stable, and a circuit made up of inductance and capacitance, tuned to the desired frequency, is not sufficiently stable. A piezoelectric crystal oscillator (a device that vibrates or oscillates at a given frequency emitting radio waves when voltage is applied to it) or its equivalent is ordinarily used.

Amplifiers. Amplifiers may be classified in a number of different ways: according to bandwidth (narrow or wide); frequency range (audio, intermediate, or radio frequency); or output parameter requirement (voltage or power).

Wide-band radio-frequency amplifiers are not needed for audio signals unless a frequency-modulated system is used. Amplitude-modulated signals for sound broadcasting should have a radio-frequency bandwidth of ±10 kilohertz though on medium waves it is often limited to about ±5 kilohertz (total bandwidth of 10 kilohertz). High-quality frequency-modulated audio needs a bandwidth of about ±100 kilohertz.

Audio-frequency amplifiers present few design problems, and negative feedback of the output into the input can overcome distortion problems. Radio-frequency amplifiers, which can be tuned, suffer from variation of selectivity (ability to separate adjacent stations) and gain (amplification) over the tuning range. Selectivity tends to broaden and gain to increase as capacitance is decreased, and instability can be troublesome at the highest tuning frequency. Intermediate-frequency amplifiers do not suffer from these defects since the tuning frequency is fixed.

Use of negative feedback to minimize distortion

The main problem with radio-frequency amplifiers in receivers is the possibility of cross modulation—that is, the mixing of two information channels, which can occur if an undesired modulated signal enters the radio-frequency input together with the desired signal.

Antennas. The antenna is an essential part of a radio transmission and reception system. Its purpose at the transmitter is to project electromagnetic energy into space and at the receiver to extract energy from the travelling electromagnetic wave produced from the transmitter antenna.

The size of the antenna relative to the wavelength of the electromagnetic radiation is important. The wavelength of medium waves is about 300 metres (1,000 feet), and a vertical transmitting mast or self-supporting tower 150 to 210 metres (490 to 690 feet) high may be used with a high-power transmitter (200 kilowatts or more). An equally tall receiving antenna would be ideal but impractical. A vertical rod or suspended wire about six metres (20 feet) long is a workable solution. If the transmitting antenna is vertical, the receiving antenna must also be vertical; if the former is horizontal the receiving antenna must be horizontal. This rule applies at all radio frequencies except shortwaves because the plane of their electromagnetic field can be twisted in its passage through the ionosphere, and a vertical shortwave antenna may pick up a good signal from a horizontal transmitting antenna. The antenna system becomes progressively smaller as the transmitting frequency is increased, and at ultrahigh frequencies (300 megahertz or more) the individual antenna may be only about 50 centimetres (20 inches) long.

For normal amplitude-modulated broadcasting, the receiver antenna may be composed of a fairly short coil of wire wound on a powdered iron or ferrite core. This type of design permits adequate signal pickup with a very small antenna which may be located in a small space, a necessity for small, battery-operated portable receivers.

Antennas may have their directional characteristics modified by employing multiple elements. Thus an antenna may be omnidirectional (transmitting in all directions) horizontally but narrowly beamed vertically, or it may be bidirectional (transmitting in two directions) in a figure eight pattern with two main directions of energy projection at 180°. It may be unidirectional, having energy projected to one side, or the energy may be concentrated in a relatively narrow beam both horizontally and vertically.

Directional characteristics

In point-to-point communication, as from one network centre to another, highly directional antennas are used. Local broadcasting uses an omnidirectional antenna, radiating equally in all directions, except in such special cases as a coastal location or proximity to a neighbouring transmitter.

Broadcasting planned to serve distant areas, employing shortwaves and depending on reflection from the ionosphere, normally uses a relatively narrow beam of energy projected skyward at an angle from 5° to 10° to the horizontal. A reflecting curtain is placed behind the antenna to prevent loss of energy in the reverse direction. The beam is divergent (spreads out) so that after two or three reflections between ionosphere and Earth it covers a relatively large area.

Transmission lines. The lines that carry radio waves from the radio transmitter to the antenna are known as transmission lines; their purpose is to convey radio-frequency energy with minimum heating and radiation loss. Heating losses are reduced by conductors of adequate size. Only the outer layers of the conductor carry radio-frequency current.

Concepts of selectivity and sensitivity. Radio-frequency communication requires the receiver to reject all but the desired signal. Were the number of frequency channels equal to the demand, each channel could be given its correct width in the tuning stages of a receiver. Thus, for audio broadcasting each carrier channel should be 20 kilohertz wide to accommodate both side bands, and each transmission carrier should be 20 kilohertz, separated from those on either side. In much of the world, the medium-wave and shortwave bands are in such demand that transmitters must share the same channel and channels thus must overlap. Though efforts have been made to arrange sharing by geographically separated transmitters, the congestion has forced receiver manufacturers to reduce the receiver bandwidth to about eight kilohertz (±four kilohertz).

Very-high-frequency transmissions can generally be received at full bandwidth because their signals are confined to line of sight and are, in effect, local-station signals to the receiver. Frequency-modulated transmissions must be received on full bandwidth (about 200 kilohertz) if serious distortion is to be avoided on loud programs.

Effect of noise on sensitivity

Receiver sensitivity is the ability of a receiver to pick up weak signals. Though a communication receiver should always have a high sensitivity, there is a maximum determined by the noise generated inside the receiver itself. Little value is gained by increasing sensitivity if noise at the receiver output is already considerable and comparable with desired signal output. Normally, radio broadcasting systems operate with the signal voltage at least 10 to 50 times greater than the noise. To take full advantage of high sensitivity, receiving antennas for communications links are usually located in an area where there is little man-made noise. A receiver intended only for local-station reception can have a much lower sensitivity than a shortwave receiver intended for picking up signals from the other side of the world. (K.R.S./Ed.)

Television systems and equipment

The purpose of a television system is to extend the senses of vision and hearing beyond their natural limits. Television systems are designed, therefore, to embrace the essential capabilities of these senses, with appropriate compromises between the quality of the reproduction and the costs involved. The aspects of natural vision that must be considered in a television system include the ability of the human eye to distinguish the brightness, colours, details, sizes, shapes, and positions of the objects in the scene before it. The aspects of hearing include the ability of the ear to distinguish the pitch, loudness, and distribution of sounds. The television system must also be designed to override, within reasonable limits, the effects of interference and to minimize visual and aural distortions in the transmission and reproduction processes. The particular compromises adopted for public television service are embodied in the television standards adopted and enforced in each country by the government agency responsible for broadcasting.

How television differs from the human eye

Television technology deals with the fact that human vision employs many hundreds of thousands of separate electrical circuits, in the optic nerve from the retina to the brain, to convey simultaneously in two dimensions the whole content of the scene on which the eye is focussed, whereas in electrical communications it is feasible to employ only one such circuit (*i.e.,* the broadcast channel) to connect the transmitter and the receiver. This fundamental disparity is overcome in television by a process of image analysis and synthesis, whereby the scene to be televised is first translated into an electrical image, and the latter is then broken up into an orderly sequence of electrical impulses that are sent over the channel one after the other. At the receiver the impulses are translated back into a corresponding sequence of lights and shadows, and these are reassembled in their correct positions on the viewing screen.

This sequential reproduction of visual images is feasible only because the visual sense displays persistence; that is, the brain retains the impression of illumination for about 0.1 second after the source of light is removed from the eye. If, therefore, the process of image synthesis occurs within less than 0.1 second, the eye is unaware that the picture is being reassembled piecemeal, and it appears as if the whole surface of the viewing screen were continuously illuminated. By the same token, it is then possible to re-create more than ten complete pictures per second and to simulate thereby the motion of the scene so that it appears to be continuous.

In practice, to depict rapid motion smoothly, it is customary to transmit from 25 to 30 complete pictures per second. To provide detail sufficient to accommodate a wide range of subject matter, each picture is analyzed into 300,000 or more elementary details. This analysis implies that the rate at which these details are transmitted over the television system exceeds 4,000,000 per second. To provide a system suitable for public use and also capable of such speed has required the full resources of modern electronic technology.

DEVELOPMENT OF TELEVISION SYSTEMS

Mechanical systems. Early ideas for the realization of television assumed the transmission of every picture element simultaneously, each over a separate circuit (as, for example, a system suggested by George Carey of Boston in 1875); but in about 1880 the important principle—subsequently adopted in all forms of television—of rapidly scanning each element in the picture in succession, line by line and frame by frame, with reliance on persistence of human vision, was proposed, notably by W.E. Sawyer in the United States and Maurice Leblanc in France. This established the possibility of using only a single wire or channel for transmission.

Nipkow system

In 1873 the photoconductive properties of the element selenium were discovered; that is, the fact that its electrical conduction varied with the amount of illumination. This appeared to provide an important clue to the secret of practical television and led in 1884 to a patent by Paul Nipkow in Germany of a complete television system. The distinctive feature of Nipkow's system was the spirally apertured rotating disk that provided, at both sending and receiving ends, a simple and effective method of image scanning. Until the advent of electronic scanning, all workable television systems depended on some form or variation (*e.g.,* mirror drums, lensed disks, etc.) of the mechanical sequential scanning method exemplified by the Nipkow disk.

As illustrated in Figure 1, the image to be televised is focussed on a rotating disk having square apertures arranged in a spiral. As the disk rotates, the outermost aperture traces out a line across the top of the image, and the light passing through the aperture varies in direct proportion to the light and shade (*i.e.,* brightness values) of that line of the image as it is traversed by the aperture. When the outermost aperture has passed over the image, the next inner aperture traces out another line, parallel to and immediately below the line just traced. The changes in the light passing through the second aperture represent, in sequence, the brightness values present in the image along this second line. As the disk continues to rotate, successive lines are traced out, one beneath the other, until the whole area of the image has been explored, one line at a time. The process is repeated with each rotation of the disk; the more apertures, and hence lines, the greater the detail that can be analyzed.

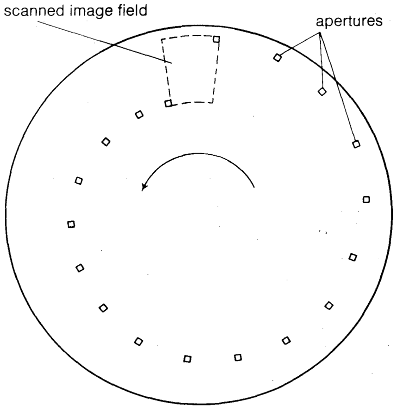

Figure 1: Nipkow disk for an 18-line picture.

In this way the detail of the whole image is sequentially explored in an orderly manner. The light passing through the apertures enters a photoelectric cell that translates the sequence of light values into a corresponding sequence of electric values. These are transmitted over a single circuit to the receiver, where the electrical impulses cause light to be produced by a lamp (such as a gas-discharge lamp) capable of reproducing the sequence of light values. The light from the lamp is projected onto the surface of a disk similar to that at the transmitter. This disk must rotate in precise synchronism, and, by a scanning process the reverse of that already described, the brightness values are reassembled in their proper positions and the original image is reproduced. Provided the rotation is at sufficient speed, persistence of vision enables the eye to see the image as a whole rather than as a series of moving points. The need for exact synchronism between camera and receiver scanning speeds is fundamental not only to the mechanical system but to every television system.

Selenium, when used as the photosensitive material for the photoelectric cell, had a serious handicap: its response to changes of light was very slow. Researches in Germany resulted (1913) in a potassium hydride-coated cell with both an improved sensitivity and the ability to follow rapid changes of light. This made possible for the first time a practical working system.

In 1897 K.F. Braun of Germany had introduced a cathode-ray tube with a fluorescent screen; that is, a screen that produced visible light when struck by a beam of electrons. The Russian scientist Boris Rosing in 1907 suggested its use in the receiver of a television system that, at the camera end, made use of mirror-drum scanning. Rosing succeeded in transmitting and reproducing some crude geometrical patterns and so ranks as an important pioneer.

In 1904 the English physicist J.A. Fleming invented the two-electrode valve; the American inventor Lee De Forest added the grid in 1906 and made amplification possible, another essential step toward practical television.

Swinton's proposals

In 1908 came a most remarkable contribution by the Scottish electrical engineer A.A. Campbell Swinton, who outlined a method that, in all essentials, is the basis of modern television. Lack of amplifiers and other difficulties confined this to what Swinton called "an idea only," but he clarified and elaborated it in an address to the Röntgen Society of London in 1911. He proposed, in essence, the use of cathode-ray tubes, magnetically deflected, at both camera and receiver. In the former was a mosaic screen of photoelectric elements; the image of the scene to be transmitted was focussed onto this screen, the back of which was then discharged by a cathode-ray beam tracing out a line-by-line scanning sequence. Swinton's brilliant ideas were too advanced for early application, and it was left to others to put them into practice many years later.

Meanwhile, experimenters in Europe and the United States were trying to make a less ambitious beginning. The neon gas-discharge lamp, produced by D.M. Moore of the United States in 1917, made it possible to vary the light intensity at the receiver by varying the electrical input to the neon lamp, thus in effect producing modulated light. It was adopted by J.L. Baird in England and C.F. Jenkins in the United States, both of whom in 1923 began experimenting with mechanical methods using the Nipkow principle. In 1926 Baird gave the first demonstration of true television by electrically transmitting moving pictures in halftones. These pictures were formed of only 30 lines, repeating approximately 10 times per second. The results, though inevitably crude—flickering badly and with a dim receiver screen a few inches high—nevertheless became the start of television as a practical technology and did much to stimulate further research, while also forming the basis of some experimental broadcasting in England between 1929 and 1935.

Electronic systems. Mechanical systems lacked sensitivity, as became progressively manifest with attempts to increase the number of lines and thus the degree of definition of the pictures. Swinton and others had pointed out that television pictures, for good quality and definition on a screen of reasonable size, would need to be analyzed into at least 100,000 and preferably 200,000 elements. Since the number of elements is approximately equal to the square of the number of lines, it can be seen that any system using 30 or even 100 lines would be inadequate—300 being more nearly the minimum. Although mechanical systems were with difficulty made to operate on 200 and more lines, thought increasingly turned toward the greater potential of electronic methods. A most important landmark was V.K. Zworykin's patent, first filed in 1923, for the iconoscope camera tube. Later, he constructed such a tube; and by 1932 the Radio Corporation of America (RCA), with an improved cathode-ray tube for the receiver, demonstrated all-electronic television (initially on 120 lines), so proving the soundness of Swinton's theoretical ideas. The compactness and convenience of the electronic camera were remarkable, and its sensitivity, greatly aided by the unique "storage" feature of the iconoscope, was comparable with motion-picture cameras of the time.

Continuing work on electronic systems was greatly stimulated. In the United States the development was mainly carried out in the RCA laboratories; very soon the number of scanning lines was increased to 343, and other improvements followed rapidly. German investigators also were active, especially in the development of high-vacuum cathode-ray tubes. By 1935 a regular broadcasting service had begun in Germany, though with medium definition only—180 lines. In The Netherlands, too, the Philips Laboratories took up television research.

In Great Britain, Electric and Musical Industries (EMI) set up in 1931 a television research group under Isaac Shoenberg. The team produced a complete and practical system, including all of the complex electronics surrounding the camera and receiver tubes, as well as the intervening control and amplifying circuits. Shoenberg saw the need to establish a system that would endure for many years, since any subsequent changes in basic standards—particularly the number of scanning lines and their repetition rate—could give rise to severe technical or economic problems. He therefore proposed the use of 405 lines with 50 frames per second, and interlaced scanning to give 25 pictures per second without flicker. The government authorized the British Broadcasting Corporation to adopt these standards, as well as the complete EMI system. Initially, and for a short time only, the system was under comparison with alternate broadcasts from a 240-line, 25-picture system developed by the Baird company. The latter employed mechanical scanning methods in the camera and suffered from lack of sensitivity as well as other limitations.

United States and European standards

By the mid-1930s electronic television was fast advancing in all its aspects. Important questions were the settling of basic standards (number of lines and frames per second) before the introduction of public broadcasting services in the United States and elsewhere, though these questions were not everywhere fully resolved until about 1951. The United States soon adopted a picture repetition rate of 30 per second, while in Europe it became 25. These two standards have been perpetuated, and all the countries of the world use one or the other, though technical advances have now obviated the original need for disparity. The arguments in relation to the number of lines were based on the need for an effective compromise between, on the one hand, adequate picture definition, and, on the other, a frequency bandwidth that could be technically and economically acceptable. World standardization has never been achieved, though for new television services all countries are adopting one of two main standards, namely, 525 lines per picture at 30 pictures per second—the United States standard—and 625 lines at 25 pictures per second, usually known as the European standard. Complications arise when programs are transmitted between countries using different standards.

Technical advances have been continuous, particularly the great improvements in camera tubes (*e.g.,* the image orthicon and the Vidicon, the latter of which was at last able effectively to exploit the photoconductivity principle) that were made from 1945 onward. By the early 1950s technology had progressed so far, and television had become so widely established, that the time was ripe to tackle in earnest the problem of creating television images in natural colours.

The development of colour television. Colour television was by no means a new idea, since its attraction and possibility early engaged the imaginations of inventors. A German patent in 1904 contained the earliest proposal, while in 1925 Zworykin filed a patent disclosure for an all-electronic colour television system. The first practical demonstration of television in colour was given by Baird in 1928; he used mechanical scanning with a Nipkow disk having three spirals of 30 apertures, one spiral for each primary colour in sequence. The light source at the receiver was composed of two gas-discharge tubes, one of mercury vapour and helium for the green and blue colours, and a neon tube for red. In 1929 H.E. Ives and colleagues at Bell Telephone Laboratories transmitted 50-line colour television images between New York City and Washington, D.C.; this also was a mechanical method, but one that sent simultaneously the three primary colour signals over three separate circuits. In the same year Frank Gray, also of Bell Laboratories, applied for a patent that described a method of transmitting two or more signals over a single channel; this introduced important new principles that were to be the foundation of modern (compatible) colour television as it was developed about 20 years later.

It soon became apparent that two basic approaches to colour television were possible. One was the frame-by-frame sequential transmission of signals corresponding to each of the three primary colours. This method was in most respects relatively simple to achieve but involved an increased rate of scanning in order to avoid colour flicker, with resulting transmission difficulties from both the higher bandwidth and the inability to use existing black-and-white receivers to reproduce any pictures originated in colour. This kind of system is therefore usually described as noncompatible. The alternative approach—practically much more difficult, even daunting at first—recognized the advantage to be derived from a colour transmission system in which signals representing the three primary colours were transmitted simultaneously and which could also be compatible with existing black-and-white transmissions. Such a system would mean that any pictures originated in colour could still be receivable (in black and white) on a black-and-white receiver.

Compatible and noncompatible colour television

In 1938 Georges Valensi of France pioneered the path to compatible colour television when he patented a method that enabled

> the output from a single transmitter to be received not only by television receivers provided with the necessary equipment but also by the ordinary type of receiver which is more numerous and less expensive and which reproduces the pictures in black and white.

Although Valensi's proposals have not been precisely adopted in practice, they were influential in later approaches to the problem of compatibility.

Experimental work on colour (on high-definition standards) was taken up in both Great Britain and the United States during the late 1930s. Similar methods were explored by Baird in Great Britain and Peter Goldmark of the Columbia Broadcasting System (CBS) in the United States, both of whom demonstrated sequential systems using rotating colour filters on the cameras and the receivers. The CBS method was used for some experimental broadcasts before World War II, and these were resumed in 1951 as a service authorized by the Federal Communications Commission (FCC). Public interest was small, however, and after only a few months the broadcasts were abandoned.

Serious attention was then given by the National Television Systems Committee (NTSC) in the United States to the development of a fully compatible simultaneous system. The committee's work led in 1953 to a system capable of operating within the current black-and-white standards and was accepted by the FCC. The essentials of this system, known as the NTSC system, have formed the basis of colour systems throughout the world. The basic principle is the combination of two image transmissions: one carrying information about the brightness, including the finest details of the televised scene, to which black-and-white receivers respond; the other, of coarser structure, carrying the colour information. This second component has no appreciable effect on black-and-white sets, while colour receivers use a combination of the two image transmissions. Since the ability of the human eye to perceive detail is most acute when viewing white light, the brightness component of the colour images carries the impression of fine detail, and the superimposed coarse colour information does not substantially alter the sharpness of the resulting colour picture.

In the United States, public broadcasting using the NTSC system began in 1954. The same system was adopted by Japan, where it came into service in 1960. Other countries favoured modifications of the NTSC system. One such was devised by W. Bruch of the German Telefunken Company; known as PAL (phase alternation line), this utilized a small but subtle variant of the NTSC method. The other, SECAM (*système électronique couleur avec mémoire*), differing rather more radically, had been put forward earlier by Henri de France in Paris. Both alternatives aimed at reducing the sensitivity of the colour system to certain forms of distortion encountered in transmission and broadcasting, and had special application to European conditions. Countries were divided in their preferences: in 1967 Great Britain and the Federal Republic of Germany began colour broadcasting using the PAL system, while in the same year France and the Soviet Union also introduced colour, adopting the SECAM system. One or the other of these three systems was adopted by all countries in the 1970s.

The SECAM system

Colour television is technically much more complex than black and white. In the early 1970s most cameras embodied either three or four pickup tubes, while in the receiver a shadow-mask, three-gun, cathode-ray tube, first demonstrated in 1950, formed a successful and widely adopted type of display device for domestic purposes. Widespread purchase of colour receivers began in the United States in 1964. (T.H.B.)

PRINCIPLES OF PICTURE TRANSMISSION AND RECEPTION

Basic factors. The quality and quantity of television service are limited fundamentally by the rate at which it is feasible to transmit the picture information over the television channel. In modern practice the televised image must be capable of being dissected, within a few hundredths of a second, into more than 100,000 picture elements. This implies that the electrical impulses corresponding to the picture elements must pass through the channel at a rate as high as several million per second. Moreover, since the picture content may vary, from frame to frame, from simple close-up shots having little fine detail to comprehensive distant scenes in which the limiting detail of the system comes into play, the actual rate of transmitting the picture information varies from time to time, from a few impulses per second to several million per second. The television channel must be capable, therefore, of handling information over a continuous band of frequencies several million cycles wide. This is testimony to the extraordinary comprehension of the human sense of sight. Hearing is comparatively crude. The ear is satisfied by sound produced by impulses that can be carried over a channel only 10,000 cycles wide.

In the United States, the television channel occupies a width of six megacycles (6,000,000 hertz, or cycles per second) in the radio spectrum. This is 600 times as wide as the channel used by each standard sound broadcasting station. In fact, each television station uses nearly six times as much spectrum space as all the commercial amplitude-modulation (AM) sound broadcasting channels combined. Since each television station must occupy so much spectrum space, few channels are available in a given locality. Moreover, the quantity of service is in conflict with the quality of reproduction. If the detail of the television image is to be increased, other parameters of the transmission being unchanged, the channel width must be increased proportionately, and this decreases the number of channels that can be accommodated in the spectrum. This fundamental conflict between quality of transmission and number of available channels dictates that the quality of reproduction shall just satisfy the typical viewer under normal viewing conditions. Any excess of performance beyond this ultimately would result in a restriction of program choice.

Flicker. The first requirement to be met in image analysis is that the reproduced picture shall not flicker, since flicker induces severe visual fatigue. Flicker becomes more evident as the brightness of the picture increases. If flicker is to be unobjectionable at brightness suitable for home viewing during daylight as well as evening hours (25 to 100 footlamberts), the successive illuminations of the picture screen should occur no fewer than 50 times per second. This is approximately twice the rate of picture repetition needed for smooth reproduction of motion. To avoid flicker, therefore, twice as much channel space is needed as would suffice to depict motion. The same disparity occurs in motion-picture practice, in which satisfactory performance with respect to flicker requires twice as much film as is necessary for smooth simulation of motion.

rojecting
ach pic-
ure twice

A way around this difficulty has been found, in motion pictures as well as in television, by projecting each picture twice. In motion pictures, the projector interposes a shutter briefly between film and lens while a single frame of the film is being projected. In television, each image is analyzed and synthesized in two sets of spaced lines, one of which fits successively within the spaces of the other. Thus the picture area is illuminated twice during each complete picture transmission, although each line in the image is present only once during that time. This technique is feasible because the eye is comparatively insensitive to flicker when the variation of light is confined to a small part of the field of view. Hence flicker of the individual lines is not evident. If the eye did not have this fortunate property, a television channel would have to occupy about twice as much spectrum space as it now does.

It is thus possible to avoid flicker and simulate rapid motion by a picture rate of about 25 per second, with two screen illuminations per picture. The precise value of the picture-repetition rate used in a given region has been chosen by reference to the electric power frequency that predominates in that region. In Europe, where 50-hertz power is the rule, the television picture rate is 25 per second (50 screen illuminations per second). In North America the picture rate is 30 per second (60 screen illuminations per second) to match the 60-hertz power that predominates there.

The higher picture-transmission rate of North America allows the pictures there to be about five times as bright as those in Europe for the same susceptibility to flicker, but this advantage is offset by a 20 percent reduction in picture detail for equal utilization of the channel.

Image structure. The second aspect of performance to be met in a television system is the detailed structure of the image. A printed halftone engraving may possess several million halftone dots per square foot of area. Such reproductions are intended for minute inspection, and the dot structure must not be apparent to the unaided eye even at close range. Such fine detail would be a costly waste in television, since the television picture is viewed at comparatively long range (five to 15 feet, or 1.5 to 4.5 metres, in the typical home setting) and the picture area is not greater than about two square feet (1,800 square centimetres). Under these conditions, a picture structure of about 200,000 halftone elements is a suitable compromise. This detail is about equal to that provided by 16-millimetre home motion pictures and substantially exceeds that of the eight-millimetre film widely used for amateur cinematography.

Picture shape. The third item to be selected in image analysis is the shape of the picture. This has been standardized universally as a rectangle the width of which is one-third longer than its height. This 4:3 ratio (aspect ratio) was originally chosen to match the dimensions of standard 35-millimetre motion-picture film (prior to the advent of the wide-screen cinema) in the interest of televising film without waste of frame area. The width of the screen rectangle is greater than its height, as in the proscenium of a theatre, to accommodate the horizontal motion that predominates in virtually all televised events.

Scanning. The fourth determination in image analysis is the path over which the image structure is explored at the camera and reconstituted on the receiver screen. In the original Nipkow disk, this path was a series of arcs of circles (Figure 1). In modern television, the pattern is a series of parallel straight lines, each progressing from left to right, the lines following in sequence from top to bottom of the picture frame. The exploration of the image structure proceeds at a constant speed along each line, since this provides uniform loading of the transmission channel under the demands of a given structural detail, no matter where in the frame the detail lies. The line-by-line, left-to-right, top-to-bottom dissection and reconstitution of television images is known as scanning, from its similarity to the progression of the line of vision in reading a page of printed matter. The agent that disassembles the light values along each line is called the scanning spot, and the path it follows is the scanning pattern, or raster.

The geometry of the modern scanning pattern is shown in Figure 2. It consists of two sets of lines. One set, marked A, is scanned first, and the lines are so laid down that an equal empty space is maintained between lines. The second set, marked B, is laid down after the first and is so positioned that its lines fall precisely in the empty spaces of set A. The area of the image is thus scanned twice, but each point in the area is passed over once. This is known as interlaced scanning, and it is used in all the television broadcast services of the world. Each set of alternate lines is known as a scanning field; the two sets together, comprising the whole scanning pattern, are known as a scanning frame. The repetition rate of field scanning is standardized in accordance with the frequency of electric power, as noted above, at either 50 or 60 fields per second. Corresponding rates of frame scanning are 25 and 30 frames per second. The localities for various scanning standards are listed in Table 6.

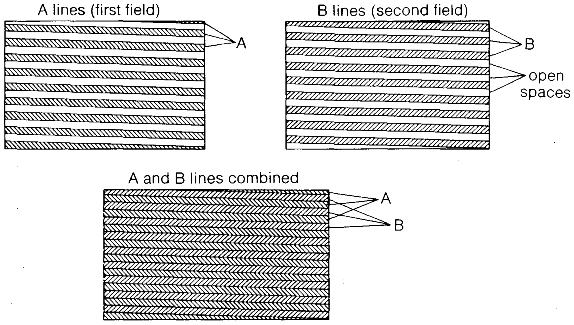

Figure 2: Interlaced scanning, combining two separate scanning cycles (fields) to form a complete picture.

Interlaced
scanning

The total number of lines in the scanning pattern has been set to provide a maximum pictorial detail of the order of 200,000 picture elements. Since the frame area is four units wide by three units high, this figure implies a pattern of about 520 picture elements in its width (along each line) and 390 elements in its height (across the lines). This latter figure would imply a scanning pattern of about 400 lines, were it not for the fact that many of the picture details, falling in random positions on the scanning pattern, lie partly on two lines and hence require two lines for accurate reproduction. Scanning patterns are designed, therefore, to possess about 40 percent more lines than the number of picture elements to be reproduced on the vertical direction. Actual values in use in television broadcasting in various regions are 405 lines, 525 lines, 625 lines, and 819 lines per frame, as listed in Table 6. These values have been chosen to suit the frequency band of the channel actually assigned in the respective geographical regions.

The scanning spot is made to follow the paths shown in Figure 2 by imparting two repetitive motions to the spot simultaneously (Figure 3). One is a horizontally directed

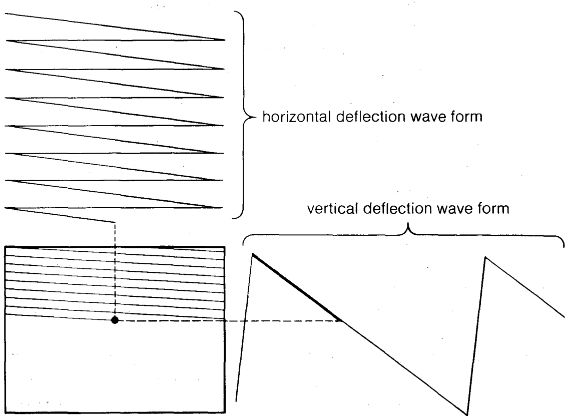

Figure 3: Scanning pattern and wave forms for horizontal and vertical deflection in sequential parallel-line scanning.

back-and-forth motion. The spot is moved at constant speed from left to right and then returned as rapidly as possible, while extinguished and inactive, from right to left.

Simultaneously, a vertical motion is imparted to the spot, moving it at a comparatively slow rate from the top to the bottom of the frame. This motion spreads out the more rapid left-to-right scans, forming the first field scan of alternate lines and empty spaces. When the bottom of the frame is reached, the spot moves vertically upward as rapidly as possible, while extinguished and inactive. The next top-to-bottom motion then spreads out the horizontal line scans so that they fall in the empty spaces of the previously scanned field. Precise interlacing of the successive field scans is facilitated if the total number of lines in the frame is an odd number. All the numbers of lines used in ordinary transmissions (see Table 6) were chosen for this reason.

The return of the scanning spot from right to left and from bottom to top of the frame, during which it is inactive, consumes time that cannot be devoted to transmitting picture information. This time is then used to transmit synchronizing control signals that keep the scanning process at the receiver in step with that at the transmitter. The amount of time lost during retracing of the spot proportionately reduces the actual number of picture elements that can be reproduced. In the 525-line scanning pattern used in the United States, about 15 percent of each line is lost in the return motion, and about 35 out of the 525 lines are blanked out while the spot returns from bottom to top of two successive fields. The scanning area that is actually in use for reproduction of the picture contains a maximum of about 435 picture elements along each line and has 490 active lines, capable of reproducing 350 picture elements in the vertical direction. The frame can accommodate at maximum, therefore, about 350 × 435, or 152,000, picture elements. The detail-transmission capacity of the scanning patterns of several other systems is listed in Table 6.

Time needed for scanning

The time taken by the scanning spot to move over the active portion of each scanning line is of the order of 0.00005 second (50 microseconds). In the United States system, 525 lines are transmitted in one-thirtieth of a second, which is equivalent to about 64 microseconds per line. Up to 15 percent of this time is consumed in the horizontal retrace motion of the spot, leaving 54 microseconds (54×10^{-6} seconds) for active reproduction of as many as 435 picture elements in each line. This represents a maximum rate of $435 \div 54 \times 10^{-6} \cong 8{,}000{,}000$ picture elements per second.

Table 6: Television Systems of the World

region or country	number of lines per frame	number of pictures per second	maximum detail (picture elements per frame)	available picture band-width (MHz)	channel band-width (MHz)
United Kingdom	405–625	25	130,000–210,000	3–6	5–8
North America, South America, Japan	525	30	130,000	4	6
Europe, Australia, Africa, Eurasia	625	25	210,000	6	8
France and French dependencies	625–819	25	210,000–440,000	6–10.4	8–14

Two picture elements can be approximately represented by one cycle of the transmission signal wave. The signal must therefore be capable of carrying components as high as 4,000,000 hertz (four megahertz, MHz). The United States six-megahertz television channel provides a sufficient band of frequencies for this (plus an additional two megahertz for transmission of the sound program, to protect against interference, and to meet the requirements of vestigial side-band transmission).

The relationship between the ideal and actual scanning patterns is shown in Figure 4. The part shown as darker is lost as the spot retraces. The remaining area of the pattern is actively employed in analyzing and synthesizing the picture information and is adjusted to have the four by three dimensions of the standard aspect ratio. In practice, some of the active area may also be hidden behind the decorative mask that surrounds the picture tube of the receiver, as shown by the dashed line.

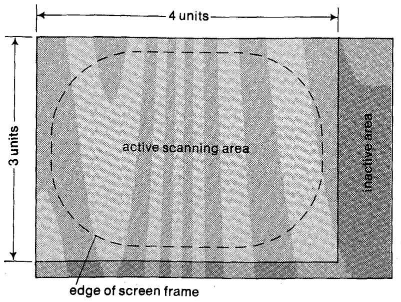

Figure 4: Active and inactive portions of scanning pattern.

The television picture signal. The signal wave form (the sequence of electrical impulses that makes up a television picture signal) embodies all the picture information to be transmitted from camera to receiver screen as well as the synchronizing information required to keep the receiver and transmitter scanning operations in exact step with each other. The television system, therefore, must deliver the wave form to each receiver as accurately and as free from blemishes as possible. Unfortunately, almost every item of equipment in the system (amplifiers, cables, transmitter, the transmitting antenna, the radio wave in space, the receiving antenna, and the receiver circuits) conspires to distort the wave form or permits it to be contaminated by "noise" or interference.

Distortion and interference

Among the possible distortions in the signal producing the picture are: (1) failure to maintain the rapidity with which the wave form rises or falls as the scanning spot crosses a sharp boundary between light and dark areas of the image, producing a loss of detail or smear in the reproduced image; (2) the introduction of overshoots, which cause excessively harsh outlines; and (3) failure to maintain the average value of the wave form over extended periods, which causes the image as a whole to be too bright or too dark.

Throughout the system, amplifiers must be used to keep the television signal strong relative to the random electrical currents (noise) that are everywhere present. These random currents, caused by thermally induced motions of electrons in the circuits, cause interference having a speckled appearance, known as "snow." Pictures received from distant stations are subject to this form of interference, since the radio wave is then so weak that it cannot override the random currents in the receiving antenna. Interference of a striated type may be caused by the signals of stations other than that to which the receiver is tuned. Care in the design of the receiver tuner and amplifier circuits is necessary to minimize such interference, and channels must be allocated to neighbouring communities at sufficient geographical separations and frequency intervals to protect the local service.

The television signal wave form can be conveyed within transmitting and receiving apparatus, and over short distances, by wires and cables. For transmission over greater distances, however, as in network connections and over the air, the television signal wave form must be imposed on a high-frequency carrier wave. The broadcast transmitter, for example, is actually a generator of very-high-frequency or ultrahigh-frequency radio waves. When such a current (known as the carrier current) is passed through the transmitting antenna, it produces a radio wave of the same frequency that travels through space and induces a weaker, but otherwise identical, current in the receiving antenna.

At the transmitter the picture signal wave form changes the strength, or amplitude, of the high-frequency carrier current by a process known as amplitude modulation. The alternations of the carrier current are thus constrained to take on a succession of amplitudes that match the shape

mpli-
ying the
vave form

of the signal wave form. The functions of the television system that generate, transmit, and utilize the television signal wave form are shown in Figure 5. The scene to be televised is focussed by a lens on a camera tube, located within the camera. A scanning spot within the camera tube is passed over the image in the scanning pattern that is shown in Figure 3, its motion being controlled by the synchronization generator. The latter equipment also renders the scanning spot inactive during its retrace motions and generates the necessary synchronization signals. The camera produces the signal wave form; the synchronizing signals are then added, and the complete signal wave form is established. The signal is then amplified as required, by amplifiers that are capable of operating over the wide band of frequencies (from a few hertz to as many as 4,000,000 or 5,000,000 hertz) that are necessary to preserve the precise shape of the wave form. In travelling along a transcontinental network, the signal may pass through more than 100 such amplifiers in tandem before it finally reaches the transmitter. There the wave form is amplified to a high power level. At the same time, the carrier current is generated by other circuits of the transmitter. The signal wave form and carrier current are then combined in the modulator, which imposes the wave form on the carrier. The modulated carrier current may then be further amplified (typically to 10,000 watts or more) and finally passed through the transmitter antenna, which radiates the television radio wave. A similar but enormously weaker current is induced in any receiving antenna that may be located within the service area. Reception of excellent quality is possible when the power picked up by the receiving antenna is as low as 0.00000001 (10^{-8}) watt. The power picked up from a distant station may be as low as 10^{-11} watt; but even this low power is capable of producing reception of acceptable quality.

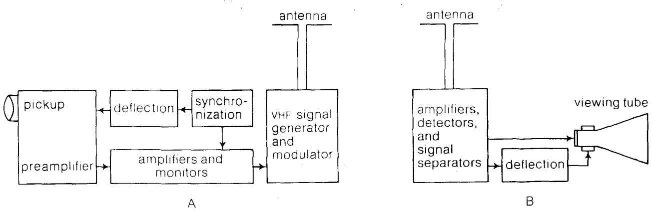

Figure 5: Essential elements of (A) transmitter, and (B) receiver.

The transmitter antenna must be placed to stand as high and in as exposed a location as possible, since the radio waves tend to be intercepted by solid objects that stand in their path, including the Earth's surface at the horizon. Reception beyond the horizon is possible, but the signal at such distances becomes rapidly weaker as it passes to the limit of the service area.

In the receiver, the current from the antenna is passed through a tuner that separates it from other currents of different carrier frequencies that may be present from other stations. The desired current is then amplified in several successive amplifier stages, while still in the amplitude-modulated form. Passage through a detector follows. The picture signal wave form is thereby recovered and is passed through still another amplifier before passing to the picture tube. The picture screen displays a scanning spot the brightness of which is controlled by the picture signal. Simultaneously, the signal is applied to synchronizing circuits, which abstract from it the synchronizing signals. These are used to control the motion of the scanning spot so that it traces out the scanning pattern in precise synchronism with the motion of the scanning spot in the camera.

The operations governing transmission and reception of the sound program accompanying the television's picture signal are accomplished by the use of apparatus similar to that used for frequency-modulated (FM) radio broadcasting. The carrier frequency for this sound channel is usually spaced 4.5 megahertz from the picture carrier and is separated from the picture carrier in the receiver by appropriate circuitry.

The amount of amplification conferred on the picture and sound currents by a typical television receiver is extremely large. When tuned to a station at a distance of 50 miles (about 80 kilometres), the power picked up by the antenna is typically 10^{-11} watt, as noted above, whereas the signals fed to picture tube and loudspeaker, after amplification, are of the order of one watt; that is, the receiver produces a faithful amplification of the order of 100,000,000,000 times.

Common
elements of
television
camera
tubes

Television camera tubes. The television camera tube is an electronic device that converts an optical image into a sequence of electrical impulses; *i.e.,* it produces the television picture signal. Three types of television camera tube are in wide use: the image orthicon, the orthicon, and the Vidicon. These devices differ to some extent in detail, but all have in common the following elements: (1) a photosensitive surface (on which the scene is focussed) that converts each light value into a corresponding value of electric charge and forms thereby an electrical image; (2) a means of storing the electrical image—that is, a way of causing the charge to accumulate during the interval of several hundredths of a second between successive scannings of each line in the image; (3) an electron beam, formed in an electron gun and deflected over the electrical image, following the scanning pattern of Figure 2; and (4) a mechanism for producing an electrical current or voltage that is proportional at every instant to the electric charge accumulated at the point passed over by the electron beam at that instant.

The television camera tube is also capable of extinguishing the scanning beam during its retrace motions, so that no television signal is then generated. A television pickup device that does not store the electrical image is called the flying spot scanner.

Iconoscope. The iconoscope is a type of camera tube that is no longer used, since it is not as sensitive as the image orthicon and its images are subject to uneven shading and flare. But it is well suited to introduce the concepts of electron image storage and scanning in simple form. The iconoscope is housed in a dipper-shaped, vacuum-tight glass envelope, as shown in Figure 6. Within the wide end is a flat sheet of mica. A uniform metallic coating, called the signal plate, is placed on the rear surface of this sheet, away from the image. The front surface of the mica is covered with a mosaic composed of many hundreds of thousands of tiny globules of silver.

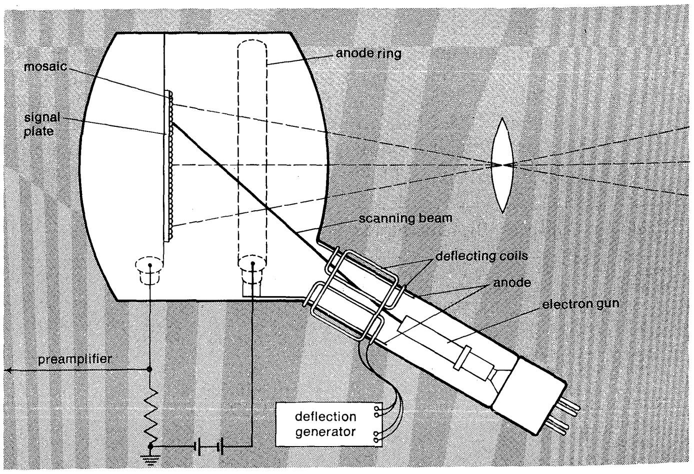

Figure 6: Iconoscope camera tube.

During the manufacture of the tube the mosaic is treated with cesium vapour and oxygen, so that each globule has a surface of the oxides of silver and cesium. This combination of elements provides a surface from which electrons are readily liberated, by the photoelectric effect, when light falls on it. Since the globules are insulated from each other and from the signal plate by the mica, the loss of electrons under illumination causes the globules to assume and hold a positive charge, the charge on each globule being proportional to the strength of the illumination falling on it and to the time it has been illuminated.

When an optical image is focussed on the treated mosaic, the whole surface assumes a distribution of positive charge that corresponds to the distribution of light in the image. The amount of charge at each point on the surface steadily increases, if the optical image is maintained, until the scanning spot passes over the globule of silver at that point.

Iconoscope scanning spot

The scanning spot of the iconoscope is formed by a narrow beam of electrons, shot out of an electron gun in the side arm of the tube. On its way to the mosaic, this beam passes within two sets of electromagnet coils. Currents like those of Figure 3 are passed through these coils, causing the beam to be deflected horizontally at a rapid rate and vertically at a relatively slower rate. The extent of the horizontal motion is adjusted from top to bottom of the mosaic, so that the pattern traced out by the electron beam on the mosaic is a rectangular pattern like that shown in Figure 2.

As each globule is passed over by the beam, it undergoes a sudden change in electrical potential, the amount of the change being proportional to the light falling on it. The change in potential of the globule is transferred through the mica support to the signal plate behind it, the globule and plate forming in effect the plates of an electrical capacitor. Thus, as the beam passes in succession over the globules lying along a given scanning line, the signal plate assumes a succession of voltages (the picture signal) that match the corresponding succession of light values along that line. The signal plate is connected to an amplifier, external to the iconoscope, that increases the strength of the picture signal.

The phenomenon of charge storage, by which the magnitude of the electrical image is continually increased between successive scannings of each line, is of the utmost significance in television technology. The spirally apertured rotating Nipkow disk (and other non-storage television pickup devices) employs only the light that is present at a given point in the image at the instant the scanning spot passes over that point. Since in modern television the area of the scanning spot is only about one two-hundred-thousandth of the area of the scanning pattern, only this small fraction of the light of the image can be used. But when the image charge is stored in increasing amount for the full interval between successive scannings of a given point, the accumulated charge is then theoretically increased by about 200,000 times the single charge that can be accumulated during the time the beam moves through its own width.

Orthicon. The orthicon camera tube was the first successor to the iconoscope. This tube (Figure 7) is housed in a cylindrical glass structure, on one end of which the optical image is focussed on a mosaic. This mosaic is similar to that of the iconoscope but is made up of a precise array of squares of photosensitive material, formed by evaporation of the material onto a transparent support. A transparent metal coating on the reverse side serves as the signal plate.

By courtesy of RCA

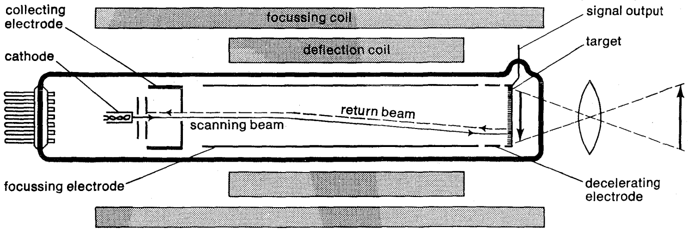

Figure 7: Orthicon camera tube.

The optical image is focussed on the signal plate, passing through it and the support to the mosaic, where it creates and stores a positive electrical charge image, in the manner of the iconoscope. The electron beam is directed toward the mosaic and deflected by electromagnet coils surrounding the tube, so that it passes over the mosaic in the standard interlaced scanning pattern. The electrons are accelerated by a low voltage, so that they strike the mosaic with a low velocity and do not liberate any substantial number of secondary electrons. Instead, the negative electrons in the beam land on the mosaic squares, neutralizing the stored positive charge and ultimately building up a negative charge. The electrons in the beam are then repelled and return to the opposite end of the tube, where they are removed by a positive collecting electrode that surrounds the electron gun. The change in electrical potential, undergone by each mosaic element as its charge is neutralized, is transferred by capacitive action, as in the iconoscope, to the signal plate. The latter thereby undergoes a succession of voltage changes that constitute the picture signal and that are passed to amplifier stages external to the tube.

Sensitivity of the image orthicon

Image orthicon. The image orthicon is the most highly developed of the television camera tubes and is perhaps the most remarkable electronic device in existence. In its most refined form, its sensitivity to light is phenomenally great. It can respond to light levels far below those capable of exposing motion-picture film or affecting the eye itself. Less sensitive image orthicon tubes are used in broadcasting practice; they serve to produce satisfactory image quality under any light levels likely to be encountered in studio and outdoor scenes.

The image orthicon, shown in Figure 8, is similar to the orthicon but includes an additional electrical-imaging process and contains a high-gain amplifier based on the phenomenon of electron multiplication. It is housed in a cylindrical glass envelope having an enlarged section on one end, which is closed by an optically flat glass plate on the inside of which is deposited a continuous photosensitive coating (photocathode). The optical image is focussed through the glass support onto the coating, where it liberates electrons by photoelectric emission, the emission at each point matching the amount of light in the image at that point.

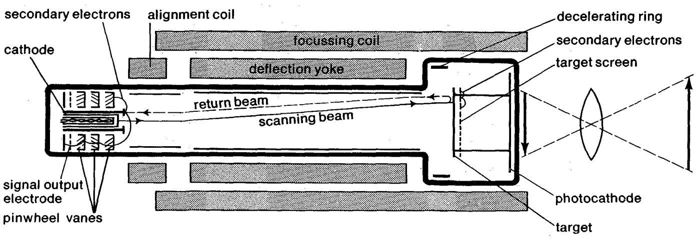

Figure 8: Image orthicon camera tube.

The liberated electrons stream away from the photosensitive surface of the glass plate, passing through the enlarged cylindrical portion of the tube, until they encounter the target electrode, a piece of very thin glass of uniform thickness. The streams of electrons induce secondary emission of electrons from the surface of the glass, and these secondary emissions are collected by a fine-mesh screen that lies parallel and close to the glass target. The streams of image electrons then pass through the screen on their way to the target.

The changes in electrical potential induced by secondary emission are transferred to the opposite face of the target, where they are scanned by the electron beam. Because of the characteristics of the glass target, the fine structure of the electrical image is preserved throughout the scanning interval. Moreover, as the streams of electrons from the photocathode continue to fall on the target glass, the intensity of the electrical image continually increases; that is, storage of charge occurs.

Both the photocathode and the glass target are continuous surfaces and in themselves they contribute no structural limit to the detail of the image. The fine-mesh screen that collects the secondary electrons from the glass target could, however, impose a limit on detail, and consequently the holes in the screen must be substantially smaller than the scanning spot. Actually, the screen possesses a total of nearly 1,000,000 holes in an area of 1.5 square inches (about 10 square centimetres), compared with the roughly 200,000 picture elements into which the optical image is dissected.

The stored charge image on the reverse side of the target is scanned by an electron beam that, like that of the orthicon, is accelerated at lower voltage and is actually slowed down before hitting the target, so that the scanning electrons have a very low velocity when they strike the target. Consequently, the secondary emission caused by scanning is negligible.

In the standard interlaced scanning pattern the electron beam is magnetically deflected over the electrical image by coils external to the tube. When the beam electrons hit the target, they neutralize the stored positive charge, as in the orthicon, and when equilibrium is reached, further electrons may not land on that spot. Thereafter, the electrons in the beam are turned around at the target and return to the vicinity of the electron gun at the other end of the tube. At this juncture the action differs from that of the image orthicon. Instead of taking the picture signal from a signal plate at the glass target, the return beam of electrons is used. The number of electrons returning from each point in the scanning pattern is conditioned by the prior positive charge neutralization occurring at that point. Consequently, the return beam constitutes a picture signal current.

The return beam

When the return beam reaches the opposite end of the tube, it is passed through an amplifier structure that contributes greatly to the sensitivity of the tube. This structure, known as an electron multiplier, is composed of several metal pinwheels. The surfaces of the pinwheel vanes are treated to emit secondary electrons copiously when the return-beam electrons hit them; more electrons are emitted than strike the surface. The electron multiplier's pinwheel shape causes the secondary electrons liberated at the first vane to be deflected to the next vane in the same structure, where still further emission of secondary electrons occurs. The magnified stream then passes to the next pinwheel structure to the rear, where the process repeats and the electron stream is cumulatively multiplied. The amplified current at the final stage of the electron multiplier is passed out of the tube to a conventional vacuum-tube or transistor amplifier.

Vidicon. The Vidicon camera tube, first used in the early 1950s, was the first camera device to employ the phenomenon of photoconductivity. In its early form it was sluggish (that is, objects in motion were reproduced with noticeable smear), and hence for a time it was limited to industrial applications. Later versions were free of this defect, and the Vidicon now enjoys wide use in broadcasting, in both monochrome and colour service. The tube elements (Figure 9) are contained in a cylindrical glass envelope, substantially smaller than the image orthicon and hence more adaptable to portable cameras. At one end of the envelope, a transparent metallic coating serves as a signal plate. Deposited directly on the signal plate is a photoconductive material (*e.g.*, a compound of selenium or lead) the electrical resistance of which is high in the dark but becomes progressively less as the amount of light increases.

By courtesy of RCA

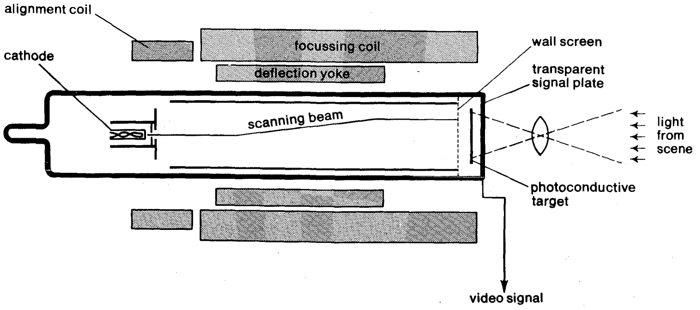

Figure 9: Vidicon camera tube.

The optical image of the Vidicon

The optical image is focussed on the end of the tube and passes through the signal plate to the photoconductive layer, where the light induces a pattern of varying conductivity that matches the distribution of brightness in the optical image. The conduction paths through the layer allow positive charge from the signal plate (which is maintained at a positive voltage) to pass through the layer, and this current continues to flow during the interval between scans. Charge storage thus occurs, and an electrical charge image is built up on the rear surface of the photoconductor.

An electron beam, deflected in the standard interlaced scanning pattern, scans the rear surface of the photoconducting layer. The beam electrons neutralize the positive charge on each point in the electrical image, and the resulting change in potential is transferred by capacitive action to the signal plate, from which the television signal is derived.

The electron beam scanning spot size imposes the only limit on the image detail. It is possible, therefore, to derive an image of broadcast quality (200,000 or more picture elements) from a photosensitive area no larger than 0.2 square inch (1.3 square centimetres). This permits the use of small and comparatively inexpensive lenses, with correspondingly large depth of focus for a given lens opening. The internal structure of the tube is very simple, and this, with its small size, makes it adaptable to a wide range of camera arrangements in broadcasting, industrial, and military applications.

Flying spot scanner. Another form of television pickup device, used to transmit images from film transparencies, either still or motion pictures, is the flying spot scanner shown in Figure 10. The light source is a cathode-ray tube in which a beam of electrons, deflected in the standard scanning pattern, impinges on a fluorescent phosphor surface. The beam produces thereby a spot of light that moves in the scanning pattern on the face of the tube. The light from this spot is focussed optically on the surface of the photographic film transparency to be televised. As the image of the spot moves, it traces out a scanning line across the film, and the amount of light emerging from the other side of the film at each point is determined by the degree of transparency of the film at that point. The emerging light is collected and caused to enter a photoelectric cell, which produces a current proportional to the light entering it.

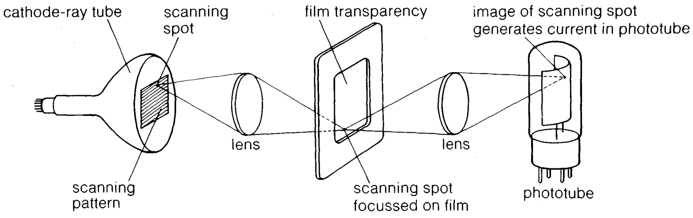

Figure 10: Flying spot camera system.

This current thus takes on a succession of values proportional to the successive values of film density along each line in the scanning pattern; that is, it is the picture signal current. No storage action occurs, so the light from the cathode-ray tube must be very intense and the optical design very efficient to secure noise-free reproduction. The flying spot system may be used with motion-picture film if an optical immobilizer is used.

Video amplification. The picture signal wave form produced by the television camera is initially very weak, of the order of a few hundredths of a volt, and is therefore vulnerable to the random currents (noise) present in the succeeding transmission circuits. Immediately upon leaving the camera, therefore, the picture signal must be strengthened, and this process must be repeated at intervals throughout the transmission to the picture tube at the receiver. The strengthening process, known as video amplification, takes place in electron tubes or transistors (see ELECTRONICS).

Video amplifiers, of both the tube and transistor varieties, can be designed to cover a remarkably comprehensive range, amplifying a picture signal consisting of any combination of frequency components lying from 10 hertz to as high as 10,000,000 hertz. This implies not merely that the amplitudes of all such components are uniformly increased but that their relative times of occurrence are strictly preserved. Only if these requirements are met can the fine structure, as well as the gross outline, of the picture signal wave form be preserved from the camera to the receiver picture tube.

Side bands

The television channel. When the band of frequencies in the picture signal is imposed on the high-frequency broadcast carrier current in the modulator of the transmitter, two bands of frequencies are produced, above and below the carrier frequency as described earlier. The side bands are identical in frequency content; that is, both carry the complete picture signal information. One of the side bands is superfluous and, if transmitted, would wastefully consume space in the broadcast spectrum. Therefore, the major portion of one of the side bands is removed, and the other is transmitted in full. Complete removal of the superfluous side band is possible, but this would complicate receiver design. Hence, a vestige of the unwanted side band is retained to serve the overall economy of the system. This technique is known as vestigial side-band transmission. It is now universally employed in all of the television broadcasting systems of the world.

The television channel for a black-and-white picture (monochrome) contains the picture carrier frequency, one complete picture side band, and a vestigial portion of the other picture side band. In addition, the carrier for the sound transmission and its side bands is included within the channel. Since the band of frequencies needed to convey the sound is a very much narrower band than that needed for the picture, it is feasible to include both sound-carrier side bands. Frequency modulation is employed to transmit the sound information. To avoid mutual interference between sound and picture, the picture and sound side bands must not overlap. Moreover, some space must be allowed at the edge of the channel to avoid interference with the transmissions of stations occupying the adjacent channels.

These requirements are met in the television channel shown in Figure 11. Each contains the following bands:

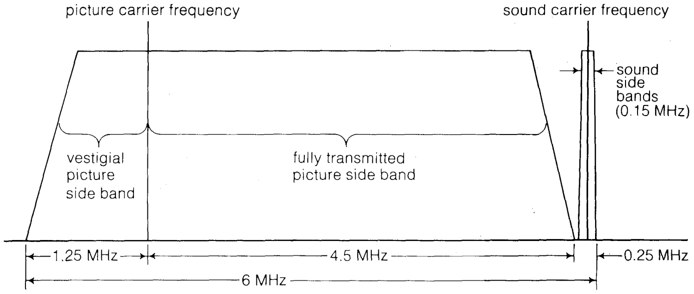

Figure 11: Allocation of television channel for monochrome broadcasting in the United States.

4.5 megahertz for the fully transmitted picture side band, 1.25 megahertz for the vestige of the other picture side band, 0.15 megahertz for the sound carrier and its two side bands, and the remaining 0.1 megahertz to guard against overlap between picture and sound and between channels. In compatible colour transmissions an additional colour-information signal, shown as the chrominance subcarrier, is included within the fully transmitted picture side band.

The television channels of the United States are assigned 6 megahertz each in the following segments of the spectrum: VHF (very-high-frequency) channels 2, 3, and 4, 54–72 megahertz; 5 and 6, 76–88 megahertz; 7 through 13, 174–216 megahertz; and the UHF (ultrahigh-frequency) channels, 14 through 83, 470–890 megahertz. These channels are allocated to communities according to a master plan established and administered by the Federal Communications Commission. No more than seven VHF channels are provided in any one area (this number is allocated only to New York and Los Angeles). Many smaller cities must be content with one or two channels.

In the major cities of Europe, fewer channels (typically two to four per city) are provided, because the higher population density and closer spacing of cities precludes more assignments within the available spectrum and because fewer program services are offered. In most countries the programs are produced solely by government agencies, in contrast to the commercial sources of the United States. Program services competitive to the government outlets exist in Great Britain, Canada, Japan, and in some countries of South America. Tokyo, for example, has seven channels.

The television transmitter. The task of the television transmitter is to produce the picture and sound carriers, and their side bands, in conformity with the arrangement of the channel assigned to it. The electronic equipment that performs these functions is shown in Figure 12. The central element is the synchronizing generator, which controls the timing of the scanning of the camera and produces the synchronizing impulses. It applies three control functions to the camera: timing for horizontal (line-by-line) deflection of the scanning beam; timing for vertical deflection (field-by-field); and the blanking impulses that extinguish the scanning spot during its retrace motions. The camera, under the control of the synchronizing generator, produces the picture signal without the synchronizing impulses. The picture signal is passed first through a preamplifier within the camera housing and then through additional amplifiers in the control room of the studio, where it is combined with the synchronizing impulses. At this point, it is customary to inspect the quality of the reproduced image by feeding the signal to a monitor that displays the image on a picture tube. The monitor screen is viewed by the program director and operating personnel so that shortcomings can be corrected.

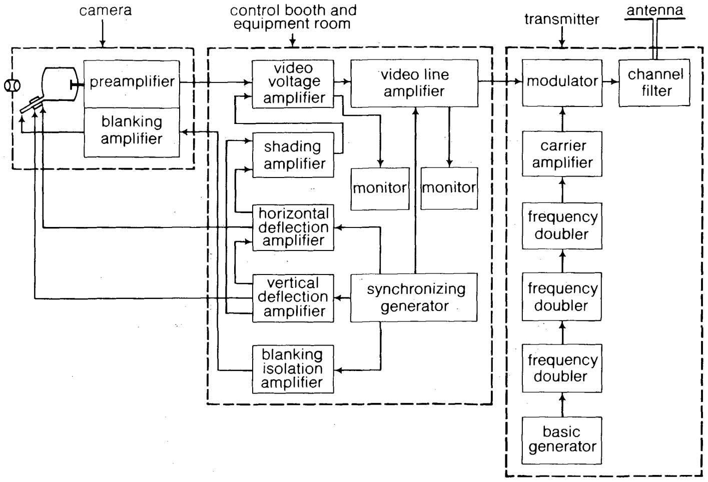

Figure 12: Block diagram of monochrome television transmitter.

The synchronizing generator

The adjusted picture and sound signals are fed to the network that interconnects stations or, in local broadcasts, to cables leading directly to the transmitter. The transmitter is usually located at some distance from the studio to permit the placing of the transmitting antenna in as favourable a location as possible in order to maximize the intended service area.

The transmitter performs two functions: generation of the carrier currents for picture and sound, and imposition of the sound and picture signals on the respective carrier currents. Precautions are taken to assure that the frequencies of the carrier waves have precisely the values assigned to the channel in use. The carrier currents have frequencies accurate to roughly one part in 200,000.

The carrier current and the picture signal are combined in the modulator. The modulated carrier contains two identical side bands; the major portion of one of these (that occupying frequencies below the carrier) is removed by a wave filter, and the remaining part, plus the picture carrier current and the fully transmitted sideband currents, is passed to the transmitting antenna. A similar arrangement produces the sound carrier current and its side bands. These are also fed to the transmitting antenna, which is designed to direct the radiated waves along the surface of the Earth and to minimize radiation toward the sky.

The television receiver. At the receiver the sound and picture carrier waves are picked up by the receiving antenna, producing currents that are identical in form to those flowing in the transmitter antenna, but much weaker. These currents are conducted from the antenna to the receiver by a lead-in transmission line, typically a one-half-inch (12-millimetre) ribbon of polyethylene plastic in which are embedded two parallel copper wires. This form of transmission line is capable of passing the carrier currents to the receiver, without relative discrimination between frequencies, on all the channels to which the receiver may be tuned.

At the antenna terminals of the receiver, the picture and sound signals are at their weakest, so particular care must be taken to control noise at this point. The first circuit in the receiver is a radio-frequency amplifier, particularly designed for low-noise amplification. The channel-switching mechanism (tuner) of the receiver connects one of several individual circuits to this amplifier, each tuned to its respective channel. This amplifier magnifies the voltages of the incoming picture and sound carriers and side bands in the desired channel by about 10 times, and it discriminates by a like amount against the transmissions of stations on other channels.

From the radio-frequency amplifier, the signals are passed to a mixer that transposes the frequencies of the sound and picture carriers to values better suited to the subsequent amplification processes. The transposed frequencies (intermediate frequencies) remain the same, no matter what channel the receiver is tuned to. In typical receivers they are located in the band from 41 to 47 megahertz.

Automatic gain control

Since the tuning of the subsequent amplifiers (intermediate-frequency amplifiers) need not be changed as the channel is switched, they can be adjusted for maximum performance in the 41–47-megahertz range. Two to four stages of such amplification are used in tandem, increasing the voltage of the picture and sound carriers by a maximum of 25 to 35 times per stage, representing an overall maximum amplification of the order of 10,000 times. The amplification of these intermediate-frequency stages is automatically adjusted, by a process known as automatic gain control, in accordance with the strength of the signal, full amplification being accorded to a weak signal, less to a strong signal. After passage through the intermediate amplifiers, the sound and picture carriers and their side bands reach a relatively fixed level of about one volt, whereas the signal levels applied to the antenna terminals may vary, depending on the distance of the station and other factors, from a few millionths to a few tenths of a volt.

From the last intermediate amplifier stage, the carriers and side bands are passed to another circuit, known as the video detector. An averaging circuit or filter then forms, from the detector output, (1) a picture signal, which is a close replica of the picture signal produced by the camera and synchronizing generator in the transmitter, and (2) a frequency-modulated sound signal. Thus far, the picture and sound signals are handled simultaneously in each amplifier and detector circuit. Both may be passed through a video amplifier, if necessary, which increases their voltage by about 10 times.

At this point the picture and sound signals are separated. Another video amplifier passes the picture signal to the picture tube, where it controls the brightness of the scanning spot. Simultaneously, the picture signal wave form is passed to a circuit (the synchronizing signal separator) that selects the blank periods in the wave form containing the superimposed synchronizing signals.

Finally, the sound signal is passed through a sound intermediate amplifier and frequency detector (discriminator, or ratio detector) that converts the frequency modulation back to an audio signal current. This current is passed through one or two additional audio-frequency amplifier stages to the loudspeaker.

Meanwhile, at the synchronizing signal separator the synchronizing signals are passed through circuits that separate the horizontal and vertical synchronizing impulses. They are then passed, respectively, to the horizontal and vertical deflection generators, which produce the currents that flow through the electromagnet deflection coils, causing the scanning spot of the picture tube to be deflected across the viewing screen in the standard scanning pattern.

The synchronizing signals control the timing of these currents, causing the scanning spot of the receiver to move synchronously with that of the camera. Pains are taken in the synchronizing action of the receiver to prevent the scanning motion from being disturbed by interference, since such disturbances would displace the picture elements from their correct positions in the pattern. It is one of the achievements of the modern television system that the scanning pattern is stably reproduced even when the picture signal is so weak and infested with noise that the picture elements themselves are barely recognizable. This fact is of particular significance in colour transmissions.

In addition to the amplifiers, detectors, and deflection generators, the receiver contains two power-converting circuits. One of these (the low-voltage power supply) converts the alternating current from the power line into the direct current needed for the tube or transistor circuits; the other (high-voltage power supply) produces the high voltage, typically 15,000 to 20,000 volts, needed to create the scanning spot in the picture tube.

Viewer's receiver controls

The receiver controls commonly provided for adjustment by the viewer are: (1) the channel switch, which connects the required circuits to the radio-frequency amplifier and superheterodyne mixer to amplify and convert the sound and picture carriers of the desired channel; (2) a fine-tuning control, which precisely adjusts the superheterodyne mixer so that the response of the tuner is exactly centred on the channel in use; (3) a contrast control, which adjusts the voltage level reached by the picture signal in the video amplifiers, producing a picture having more or less contrast (greater or less range between the blacks and whites of the image); (4) a brightness control, which adjusts the average amount of current taken by the picture tube from the high-voltage power supply, thus varying the overall brightness of the picture; (5) a horizontal-hold control, which adjusts the horizontal deflection generator so that it conforms exactly to the control of the horizontal synchronizing impulses; and (6) a vertical-hold control, which performs the same function for the vertical deflection generator. Additional adjustments provided for the serviceman include adjustments for the height and width of the picture (magnitudes of the deflection currents) and adjustments (linearity controls) to secure precisely uniform rates of horizontal and vertical scanning to avoid distortion of the shapes of the objects in the picture. Colour receivers have additional controls to allow for adjustment of hue and intensity.

Television picture tubes. A typical television picture tube is illustrated in Figure 13. The tube is a highly evacuated, funnel-shaped structure. The viewing screen is located inside the tube face, a slightly curved glass plate that closes the wide end of the funnel. The screen itself, in monochrome receivers, is typically composed of two fluorescent materials, such as silver-activated zinc sulfide and silver-activated zinc cadmium sulfide. These materials, known as phosphors, glow with blue and yellow light, respectively, under the impact of high-speed electrons. The phosphors are mixed, in a fine dispersion, in such proportion that the combination of yellow and blue light produces white light of slightly bluish cast. A water suspension of these materials is settled on the inside of the face plate of the tube during manufacture, and this coating is overlaid with a film of aluminum sufficiently thin to permit the bombarding electrons to pass without

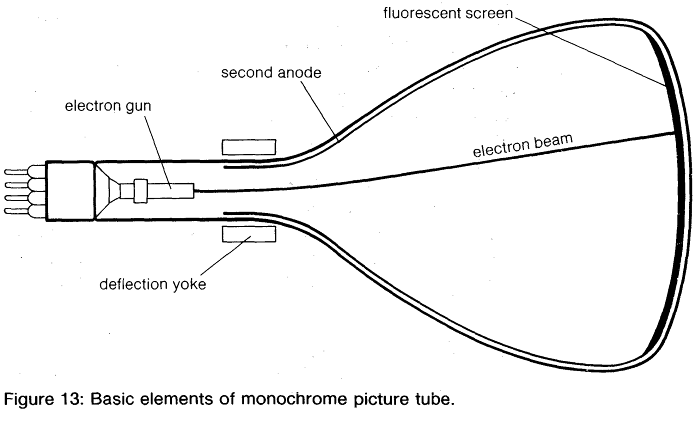

Figure 13: Basic elements of monochrome picture tube.

hindrance. The aluminum provides a mirror surface that prevents the backward-emitted light from being lost in the interior of the tube and reflects it forward to the viewer.

At the opposite end of the tube is the electron gun, a cylindrical metal structure that generates and directs a stream of free electrons, the electron beam.

The electron gun

A part of this gun is a cylindrical sleeve made electrically positive with respect to the cathode (the element that emits the electrons). The positively charged sleeve (first anode) draws the negative electrons away from the cathode, and they move down the sleeve toward the viewing screen at the opposite end of the tube. They are intercepted, however, by a flat disk (the control electrode) having a small circular aperture at its centre. Some of the moving electrons pass through the aperture; others are held back.

The television picture signal is applied between the control electrode and the cathode. During those portions of the picture signal wave form that make the potential of the control electrode less negative, more electrons are permitted to pass through the control aperture, whereas during the more negative portions of the wave, fewer electrons pass. The brightness control applies a steady (but adjustable) voltage between control electrode and cathode. This voltage determines the average number of electrons passing through the aperture, whereas the picture signal causes the number of electrons passing through the aperture to vary from the average and thus controls the brightness of the spot produced on the fluorescent screen.

As the electrons emerge from the sleeve, each electron experiences a force that directs it toward the centre of the viewing screen. The electron beam is thus brought to focus on the screen, and the light there produced is the scanning spot. Additional focussing may be provided by an adjustable permanent magnet surrounding the neck of the tube. The scanning spot must be intrinsically very brilliant, since (by virtue of the integrating property of the eye) the light in the spot is effectively spread out over the whole area of the screen during scanning.

Scanning is accomplished by two sets of electromagnet coils. These coils must be precisely designed to preserve the focus of the scanning spot no matter where it falls on the screen, and the magnetic fields they produce must be so distributed that deflections occur at uniform velocities.

The current in the horizontal deflection coil must change rapidly in order to provide a rapid retrace of the scanning spot on the face of the picture tube. This rapid rate of change of current causes pulses of high voltage to appear across the circuit feeding current to the coil, and the succession of these pulses, smoothed into direct current by a rectifier tube, serves as the high-voltage power supply.

The two sets of deflection coils are combined in a structure known as the deflection yoke, which surrounds the neck of the picture tube at the junction of the neck with the funnel section.

Variation in picture tubes

Picture tubes vary widely in screen size and are usually characterized by measurements made diagonally across the tube face. Tubes having diagonals from as small as three inches (7.5 centimetres) to 18 inches (46 centimetres) are used in typical transistor portable receivers, whereas tubes measuring from 23 to 27 inches (58 to 69 centimetres) are used in table- and console-model receivers. The design trend has called for greater angles of deflection, with correspondingly wider funnel sections and shallower overall depth from electron gun to viewing screen. The increase in deflection angle from 55° in the first (1946) models to 114° in models produced nowadays has required corresponding refinement of the deflection system because of the higher deflection currents required and the greater tendency of the scanning spot to go out of focus at the edges of the screen.

COMPATIBLE COLOUR TELEVISION

Basic principles—United States system. The technique of compatible colour television utilizes two transmissions. One of these, the luminance (brightness) transmission, employs methods essentially identical to those of the monochrome television system. The second, the chrominance (colour) transmission, has virtually no effect on monochrome receivers. When used with the luminance transmission in a colour receiver, however, it produces an image in full colour.

The luminance–chrominance method of representing colour values is one of several alternative ways in which coloured light may be analyzed and synthesized. This method is particularly appropriate in a television system since it produces a compatible signal that can serve both black-and-white and colour receivers by the same broadcast.

Historically, compatibility was of great importance because it allowed colour transmissions to be introduced without obsolescence of the many millions of monochrome receivers in use. In a larger sense, the luminance–chrominance method of colour transmission is advantageous because it utilizes the limited channels of the radio spectrum more efficiently than other colour transmission methods.

To create the luminance–chrominance values, it is necessary (in the present state of technology) first to analyze each colour in the scene into primary colours. Coloured light may thus be analyzed by passing the light through three coloured filters, typically red, green, and blue. The amounts of light passing through each filter, plus a description of the colour transmission properties of the filters, serve uniquely to characterize the coloured light.

The fact that virtually the whole range of colours may be synthesized from only three primary colours is essentially a description of the process by which the eye and mind of the observer recognize and distinguish colours. Like visual persistence, this is a fortunate property of vision, since it permits a simple three-part specification to represent any of the 10,000 or more colours and brightnesses that may be distinguished by human vision. If vision were dependent on the energy versus wavelength relationship (the physical method of specification), it is doubtful if colour reproduction could be incorporated in any mass-communication system.

By transforming the primary-colour values, it is possible to specify any coloured light by three other numbers: (1) its luminance (brightness or "brilliance"); (2) its hue (the redness, orangeness, blueness, or greenness, etc., of the light); and (3) its saturation (its vivid versus pastel quality). If the intended luminance value of each point in the scanning pattern is transmitted by the methods of the monochrome television system, it is only necessary to transmit, via an additional two-valued signal, supplementary information giving the hue and saturation of the intended colour at the respective points in the scanning pattern.

Chrominance, defined as that part of the colour specification remaining when the luminance is removed, represents two independent quantities, hue and saturation.

The chrominance signal

In the colour television system of the United States, the chrominance signal is an alternating current of precisely specified frequency (3.579545 ± 0.000010 megahertz), the precision permitting its accurate recovery at the receiver even in the presence of severe noise or interference. Any change in the amplitude of its alternations at any instant corresponds to a change in the saturation of the colours being passed over by the scanning spot at that instant, whereas a shift in time of its alternations (a change in the "phase angle" of the alternations) similarly corresponds to a shift in the hue. The colour information in the European (PAL and SECAM) systems is carried on a chrominance signal frequency of 4.43+ megahertz. In the United States system, as the different saturations and hues along each scanning line are successively uncovered by scanning in the camera, the amplitude and phase, respectively, of the chrominance signal change accordingly. The chrominance signal is thereby simultaneously modulated in amplitude and in phase. This doubly modulated signal is imposed on the picture signal carrier current, along with the luminance signal.

The television channel, when occupied by such a compatible colour transmission, appears as shown in Figure 14 (compare this with the channel when occupied by a black-and-white transmission, Figure 11). The chrominance signal takes the form of a subcarrier located precisely 3.579545 megahertz from the picture carrier frequency.

The picture carrier is thus simultaneously amplitude-modulated by the luminance signal to represent changes

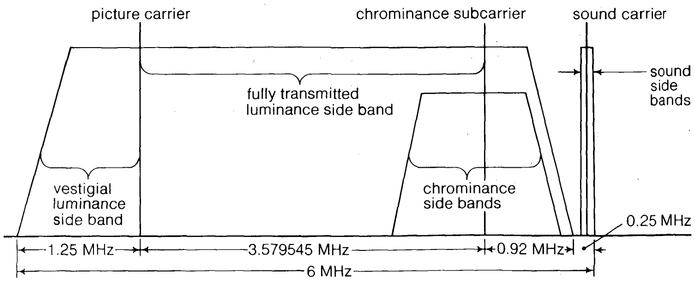

Figure 14: Allocation channel for compatible colour transmission in the United States.

in the intended luminance, and by the chrominance subcarrier that, in turn, is amplitude-modulated to represent changes in the intended saturation and phase-modulated to represent changes in the intended hue.

When compatible colour transmissions are received on a monochrome receiver, the receiver treats the chrominance subcarrier as though it were a part of the intended monochrome transmission. If steps were not taken to prevent it, the subcarrier would produce interference in the form of a fine dot pattern. The dot pattern, fortunately, can be rendered almost invisible in monochrome reception by deriving the timing of the scanning motions directly from the source that establishes the chrominance subcarrier itself. The dot pattern of interference from the chrominance signal, therefore, can be made to have opposite effects on successive scannings of the pattern; that is, a point brightened by the dot interference on one line scan is darkened an equal amount on the next scan of that line, and the net effect of the interference, integrated in the eye over successive scans, is virtually zero. Thus, the monochrome receiver, in effect, ignores the chrominance component of the transmission. It deals with the luminance signal in the conventional manner, producing from it a monochrome image. This monochrome rendition, incidentally, is not a compromise; it is essentially identical to the image that would be produced by a monochrome television system viewing the same scene.

The channel for colour transmissions, when used by colour receivers, would appear to be affected by mutual interference between the luminance and chrominance components, since these occupy a portion of the channel in common. Such interference is avoided by the fact that the chrominance subcarrier component is rigidly timed to the scanning motions. The luminance signal, as it occupies the channel, is actually concentrated in a multitude of small spectrum segments, by virtue of the periodicities associated with the scanning process. Between these segments are empty channel spaces of approximately equal size. The chrominance signal, arising from the same scanning process, is similarly concentrated. Hence it is possible to place the chrominance channel segments within the empty spaces between the luminance segments, provided that the two sets of segments have a precisely fixed frequency relationship. The necessary relationship is provided by the direct control by the subcarrier of the timing of the scanning motions. This intersegmentation is known as frequency interlacing. It is one of the fundamentals of the compatible colour system, and without it the superposition of colour information on a channel originally devised for monochrome transmissions would not be feasible.

Frequency interlacing

When a colour receiver is tuned to the transmission represented in Figure 14, the picture signal is recovered in a video detector in the usual manner. An amplifier stage, tuned to the 3.58-megahertz chrominance frequency, then selects the chrominance from the picture signal and passes it to a detector that recovers independently the amplitude-modulated and phase-modulated components.

European colour systems. The United States colour system has been adopted by Canada, Mexico, Japan, and several other countries. In Europe, two alternative systems have been developed and introduced. The PAL (phase alternation line) system has been adopted in the United Kingdom and most of the countries on the Continent. France, the Soviet Union, and their allied countries and dependencies have adopted the SECAM (*système électronique couleur avec mémoire*) system.

The PAL and SECAM systems embody the same principles as the United States system, including matters affecting compatibility and the use of a separate signal to carry the colour information at low detail superimposed on the high-detail luminance signal. The European systems were developed, in fact, to improve on the performance of the United States system in only one area, the constancy of the hue of the reproduced images.

It has been pointed out that the hue information in the U.S. system is carried by changes in the phase angle of the chrominance signal, and that these phase changes are recovered in the receiver by synchronous detection. The transmission of the phase information, particularly in the early stages of colour broadcasting in the United States, was subject to incidental errors arising in broadcasting stations and network connections. Errors are also caused by reflections of the broadcast signals by buildings and other structures in the vicinity of the receiving antenna. In recent years, transmission and reception of hue information has become substantially more accurate in the United States through care in broadcasting and networking, as well as by automatic hue-control circuits in receivers. The PAL and SECAM systems are inherently less affected by phase errors.

In the PAL and SECAM systems, the nominal value of the chrominance signal is 4.43+ megahertz, a frequency that is derived from and hence accurately synchronized with the frame-scanning and line-scanning rates. This chrominance signal is accommodated within the six-megahertz range of the fully transmitted side band. By virtue of its synchronism with the line and frame scanning rates, its frequency components are interleaved with those of the luminance signal, so that the chrominance information does not affect reception of colour broadcasts by black-and-white receivers.

PAL system. The PAL system resembles the United States system in that the chrominance signal is simultaneously modulated in amplitude to carry the saturation (pastel versus vivid) aspect of the colours and in phase to carry the hue aspect. In the PAL system, the phase information is reversed during the scanning of successive lines. Thus if a phase error is present during the scanning of one line, a compensating error (of equal amount but in the opposite direction) is introduced during the next line. Thus the average phase information, presented by the two successive lines taken together, is free of error.

Two lines are thus required to depict the corrected hue information, and the vertical detail of the hue information is correspondingly lessened. This produces no serious degradation of the picture when the phase errors are not too great, since, as noted above, the eye does not require fine detail in the hues of colour reproduction, and the mind of the observer averages out the two compensating errors. If the phase errors are more than about 20°, visible degradation does occur. This effect can be corrected by introducing in the receiver (as in the SECAM system) a delay line and electronic switch.

SECAM system. In the SECAM system, the luminance information is transmitted in the usual manner, and the chrominance signal is interleaved with it. But the chrominance signal is modulated in only one way. The two types of information required to encompass the colour values do not occur concurrently, and the errors associated with simultaneous amplitude and phase modulation do not occur. Rather, in the SECAM system (SECAM III), alternate line scans carry information on luminance and red, while the intervening line scans contain luminance and blue. The green information is derived within the receiver by subtracting the red and blue information from the luminance signal. Since individual line scans carry only half the colour information, two successive line scans are required to obtain the complete colour information, and this halves the colour detail, measured in the vertical dimension. But, as noted above, the eye is not sensitive to the hue and saturation of small details, so no adverse effect is introduced.

To subtract the red and blue information from the luminance information to obtain the green information, the red and blue signals must be available in the receiver simultaneously, whereas they are transmitted in time sequence. The requirement for simultaneity is met by holding the signal content of each line scan in storage (or "memorizing" it, hence the name *système électronique couleur avec mémoire*). The storage device is known as a delay line; it holds the information of each line scan for 0.000064 second. To match successive pairs of lines, an electronic switch is also needed. When the use of delay lines was first proposed, such lines were expensive devices. Recent advances have reduced the cost, and the fact that receivers must incorporate these components is no longer viewed as decisive.

Since the SECAM system reproduces the colour information with a minimum of error, it has been argued that SECAM receivers do not require receiver controls for hue and saturation. Such adjustments, however, are usually provided to permit the viewer to adjust the picture to his individual taste and to correct for signals that are in error as broadcast, due to such factors as faulty use of cameras, lighting, and networking.

Colour camera and picture tube. The terminals of the colour television system, the camera and picture tube, analyze and synthesize, respectively, the colour quantities present at each point in the scanning pattern. The television camera in its current state of development does not produce the luminance, hue, and saturation values directly. Rather it produces three picture signals, representative of the amounts of three primary colours present at each point in the image pattern. From these signals the luminance and chrominance components are then derived by manipulation in electronic circuits.

Optical system of a colour television camera

The typical colour television camera (Figure 15) contains three image orthicon tubes, with an optical system that casts an identical image on the sensitive surface of each of the three tubes. The optics consist of a lens and four mirrors that reflect the image rays from the lens onto the three camera tubes, as shown. Two of the mirrors are of a colour-selective type (dichroic mirror) that reflects the light of one colour and transmits the remaining colours. The mirrors, augmented by colour filters that perfect their colour-selective action, direct a blue image to the first tube, a green image to the second tube, and a red image to the third tube.

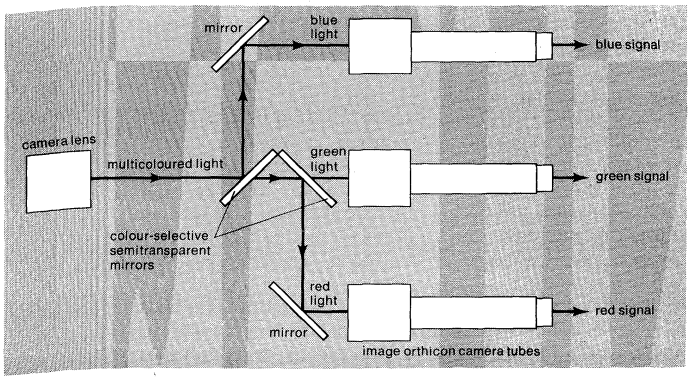

Figure 15: Diagram showing selective separation of light in colour camera.

The deflection systems of the three camera tubes are arranged to produce identical scanning patterns in each tube, so the picture signals developed by the respective tubes represent images of the same geometrical shape, differing only in colour. The respective primary-colour signals are passed through video preamplifiers associated with each camera tube and emerge from the camera as separate entities. If compatibility were not required, and if sufficient space were available in the radio spectrum, the three signals might be transmitted to the receiver over separate channels. Actually, as mentioned above, the primary-colour signals are recast into luminance and chrominance components; at the receiver the latter are converted back into primary-colour signals before application to the colour picture tube. In the mid-1960s, colour cameras employing four camera tubes were introduced, particularly for studio work. The fourth tube is exposed directly to the scene without an intervening mirror or filter and thus produces a luminance signal of high quality. The three remaining tubes are then confined to the less demanding functions of producing the primary-colour signals. Three-tube cameras based on this principle have also been developed.

Much attention has been paid to the design of camera tubes for colour service, and greatly improved colour rendition, particularly of subtle variations in skin tone, has resulted. The Plumbicon version of the Vidicon, developed in The Netherlands, is particularly noteworthy in this respect.

The colour picture tube (Figure 16) contains three electron guns, which produce three separate electron beams. These are deflected simultaneously in the standard scanning pattern over the viewing screen. One of the beams is controlled by the red primary-colour signal and produces a red image. The second beam produces a blue image, and the third, a green image.

Colour picture tube screen

To permit three primary-colour images to be formed simultaneously, the screen is composed of three sets of individual phosphor dots, which glow respectively in the three different colours and which are uniformly interspersed over the screen (Figure 16). The "red" beam impinges only on the red-glowing phosphor dots, being prevented from hitting the other two colours, with similar restriction of the other two beams to the blue and green dots, respectively.

The sorting out of the three beams so that they produce images of only the intended primary colour is performed by a mask that lies directly behind the phosphor screen. This mask contains about 200,000 precisely located holes, each accurately aligned with three different coloured phosphor dots on the screen in front of it. Electrons from the three guns pass together through each hole, but each electron beam is directed at a slightly different angle. The angles are such that the electrons arising from the gun controlled by the red primary-colour signal fall only on the red dots, being prevented from hitting the blue and green dots by the shadowing action of the mask. Similarly, the "blue" and "green" electrons fall only on the blue and green dots, respectively. A major improvement consists in surrounding each colour dot with an opaque black material, so that no light can emerge from the portions of the screen between dots. This permits the screen to produce a brighter image while maintaining the purity of the colours. This type of screen (black matrix screen) is more expensive to produce, but it has been widely used in larger colour tubes.

Thus three separate primary-colour images are formed simultaneously, as the scanning proceeds. The colour dots of which each image is formed are so small and so uniformly dispersed that the eye does not detect their separate presence, although they are readily visible through a

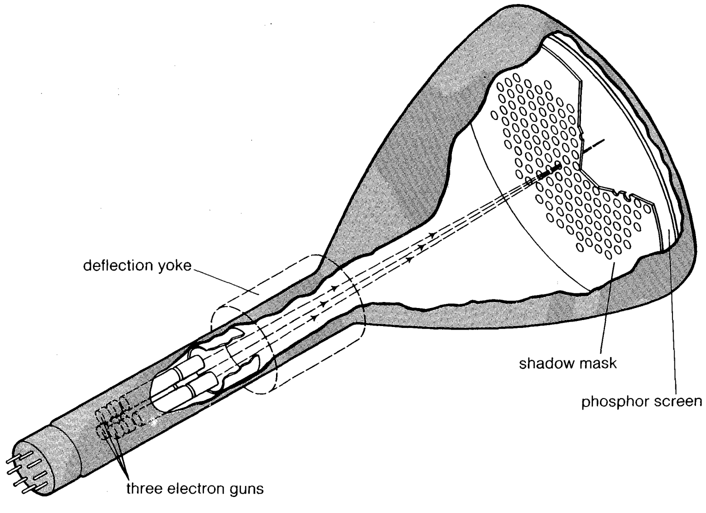

Figure 16: Colour picture tube employing the shadow-mask technique.

magnifying glass. The primary colours in the three images thereby mix in the mind of the viewer and a full-colour rendition of the image results.

The shadow-mask tube

This type of colour tube is known as the shadow-mask tube. It has several shortcomings: (1) the electrons intercepted by the mask cannot produce light, and the image brightness is thereby limited; (2) great precision is needed to achieve correct alignment of the electron beams, the mask holes, and the phosphor dots at all points in the scanning pattern; and (3) precisely congruent scanning patterns, as among the three beams, must be produced. In the late 1960s a different type of colour tube, the Trinitron, was introduced in Japan. In this tube the shadow-mask is replaced by a metal grille having vertical slits extending from the top to the bottom of the screen. The three electron beams pass through the slits to the coloured phosphors, which are in the form of vertical stripes aligned with the slits. The grille directs the majority of the electrons through the slits, causing a much lower percentage of the electrons to be intercepted by the grille, and a brighter picture results. The electron gun of the Trinitron tube remains in fine focus throughout the scanning of the image, since a major portion of the focus mechanism is common to all three beams.

Colour transmitter and receiver. Figure 17 shows the essential elements of the colour transmitter, as they differ from the monochrome transmitter shown in Figure 12.

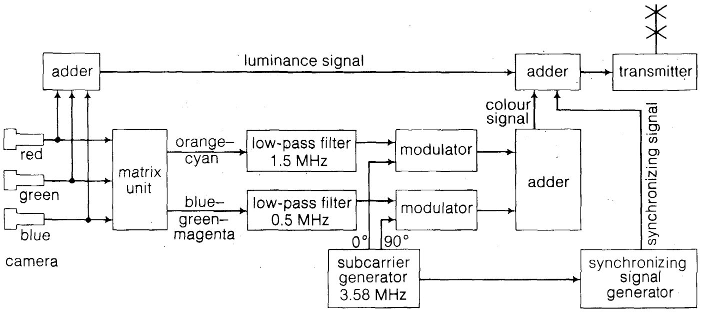

Figure 17: Block diagram of colour transmitter.

Immediately following the colour camera is the colour coder, which converts the primary-colour signals into the luminance and chrominance signals. The luminance signal is formed simply by applying the primary-colour signals to an electronic addition circuit that adds the values of the three signals at each point along the respective picture signal wave form. Since white light results from the addition, in appropriate proportions, of the primary colours, the resulting sum signal represents the black-and-white (luminance) version of the colour image. The luminance signal thus formed is subtracted individually, in three electronic subtraction circuits, from the original primary-colour signals, and the colour-difference signals are then further combined to produce two signals, which are then applied simultaneously to a modulator, where they are mixed with the chrominance subcarrier signal. The latter is thereby amplitude-modulated in accordance with the saturation values and phase-modulated in accordance with the hues. The luminance and chrominance components are then combined to form the overall colour picture signal, which is then carried to the transmitter over the network or studio–transmitter link.

The chrominance subcarrier is generated in a precise electronic oscillator at the standard value of 3.579545 megahertz. Samples of this subcarrier are injected into the signal wave form during the blank period between line scans just after the horizontal synchronizing pulses. These samples are employed in the receiver to control the synchronous detector, mentioned above. Finally, horizontal and vertical deflection currents, which produce the scanning in the three camera tubes, are formed in a scanning generator, the timing of which is controlled by the chrominance subcarrier. This common timing of deflection and chrominance transmission produces the dot-interference cancellation in monochrome reception and frequency interlacing in colour transmission, noted above.

At this stage, the colour picture signal can be handled in the same manner as the monochrome signal, except that throughout the network and in the transmitter special precautions must be taken to transmit the chrominance subcarrier at its correct amplitude, with its amplitude and phase modulations preserved against incidental distortions that would result in poor colour quality.

Colour receiver components

The colour receiver contains a tuner and intermediate-frequency amplifiers similar to those used in monochrome receivers, but its components are especially designed to preserve the chrominance subcarrier during its passage through these stages. The colour receiver also has power supplies, sound reception circuits and synchronization, and deflection current generators similar to those used in monochrome reception.

The colour reproduction processes are divided into the luminance and chrominance functions. A video detector develops the luminance component and applies it through video amplifiers simultaneously to all three electron guns of the picture tube. This part of the signal thereby activates all three primary-colour images, simultaneously and identically, in the fixed proportion needed to produce white light. When tuned to monochrome broadcasts, the colour receiver produces a monochrome image by means of this mechanism, the chrominance component then being absent.

When the receiver is tuned to a colour broadcast, the chrominance subcarrier component appears in the output of the video detector and it is thereupon operated on in circuits that ultimately recover the primary-colour signals originally produced by the colour camera.

The three colour-difference signals are applied separately to the respective electron guns, where each reduces the strength of the corresponding electron beam to change the white light, which would otherwise be produced, to the intended colour for each point in the scanning line. The net control signal applied to each electron gun bears a direct correspondence to the primary colour signal derived from the respective camera tube at the studio. In this manner, the three primary-colour signals are transmitted as though three separate channels had been used.

The colour receiver controls to be adjusted by the viewer (in addition to the tuning, brightness, contrast, and synchronizing controls present in monochrome receivers) are the hue control and the saturation control. The hue control shifts all the hues in the reproduced image. It is usually adjusted by reference to the colour of the flesh of the performers, since unnatural flesh tone is readily recognized even if the viewer has no knowledge of the intended hues in other parts of the scene. The saturation control adjusts the magnitudes of the colour-difference signals applied to the electron guns of the picture tube. If these magnitudes are reduced to zero, by turning the saturation control to the "off" position, no colour difference action occurs and the reproduction occurs in monochrome. As the saturation control is advanced, the colour differences become more accentuated, and the colours become progressively more vivid. In the late 1960s, the more elaborate colour television receivers began to employ a system known as "automatic hue control." In this system, the viewer makes an initial manual adjustment of the hue control to produce a rendition of flesh tones to suit his preference. Thereafter, the hue control circuit automatically maintains the preselected ratio of the primary colours corresponding to the viewer's choice. Thus the most critical aspect of the colour rendition, the appearance of the faces of the performers, is prevented from changing when cameras are switched from scene to scene or when tuning from one broadcast to another.

Automatic hue control

Since care in tuning is essential in colour receivers to assure correct reception of the chrominance signal, automatic circuits to set the fine-tuning adjustment are provided in the more expensive receivers. Another development is a single touch-button control that sets the fine tuning and adjusts the hue, tint, contrast, and brightness to preset ranges. These automatic adjustments override the settings of the corresponding knobs, which then function over narrow ranges only. Such refinements permit reception of acceptable quality by viewers who might otherwise be confused by the many misadjustments possible when ordinary manual controls are used.

TELEVISION RECORDING

Recording of television programs on photographic film or magnetic tape is an important technique, not only to preserve a permanent record of a live-scene program for subsequent rebroadcast but also to perfect a performance prior to its initial presentation. Recorded segments are often used in a "live" studio program when it is impractical to set up the desired scene in the studio. Transmission of films originally produced for motion-picture theatres is also a major activity in broadcasting.

The continuous projector. Television film projectors fall into two classes, continuous and intermittent, according to the type of film motion. In the continuous projector, a scanning spot from a flying spot camera tube is passed through a rotating optical system, known as an immobilizer, which focusses the scanning spot on the motion-picture film. As the film moves continuously through the projector, the immobilizer causes the scanning pattern as a whole to follow the motion of the film frame, so that there is no relative motion between pattern and frame. The light passes through the film to a phototube where the light, modified by the transmissibility of the film at each point, produces the picture signal. As one film frame moves out of the range of the immobilizer, the next moves into range and there is a condition of overlap between successive scanning patterns.

The optics are so arranged that the amount of light in the spot focussed on the film is constant at all times and in all positions. This constancy permits the film to be moved at any desired speed, while the pattern scans at the standard rate of 25 or 30 pictures per second. The film is actually moved at the standard rate for motion pictures, 24 frames per second, so the speed of objects and pitch of the accompanying sounds (picked up from the sound track by conventional methods) are reproduced at the intended values.

The intermittent projector. In the intermittent projector, which more nearly resembles the type used in theatre projection, each frame of film is momentarily held stationary in the projector while a brief flash of light is passed through it. The light (which passes simultaneously through all parts of the film frame) is focussed on the sensitive surface of a storage-type camera, such as the Vidicon. The light flashes are timed to occur during the intervals between successive field scans—that is, while the extinguished scanning spot is moving from the bottom to the top of the frame. The light is strong enough to produce an intense electrical image in the tube during this brief period. The electrical image is stored and then is scanned during the next scanning field, producing the picture signal for that field. Light is again admitted between fields, and the stored image is scanned thereupon by the second field. When one film frame has been thus scanned, it is pulled down by a claw mechanism and the next frame takes its place.

In Europe and other areas where the television scanning rate is 25 picture scans per second, it has been the custom to operate intermittent projectors also at 25 frames per second, or about 4 percent faster than the intended film projection rate of 24 frames per second. The corresponding increases in speed of motion and sound pitch were not so great as to introduce unacceptable degradations of the performance. In the United States and other areas where television scanning occurs at 30 frames per second, it is not feasible to run the film projector at 30 film frames per second, since this would introduce speed and pitch errors of 25 percent. Fortunately, a small common factor, 6, relates the scan rate of 30 and the film projection rate of 24 frames per second. That is, four film frames consume the same time as five scanning frames. Thus, if four film frames pass through the projector while five complete picture scans (10 fields) are completed, both the film motion and the scanning proceed at the standard rates The two functions are kept in step by holding one film frame for three scanning fields, the next frame for two scans, the next for three scans, and so on.

Magnetic video recording. Television program recording for rebroadcast is done on magnetic tape, although film is used for longer storage purposes. The tape technique permits prompt rebroadcast of programs the quality of which, when the tape equipment is in good adjustment, is virtually indistinguishable from the original broadcast. The magnetic tape, two inches (five centimetres) wide, is moved at 15 inches (38 centimetres) per second past a magnetic recording head that rotates across the width of the tape, imposing on it a series of crosswise magnetic line patterns that correspond to the lines of the scanning pattern. To keep the pickup and tape motions identical during recording and playback, index signals are imposed during recording, and these are used to control the drive motors during playback. The television signal is recorded by frequency modulation on a carrier signal, thus avoiding the difficult problem of direct recording at the extremely low frequencies present in the picture signal itself.

Magnetic video recording is widely used in broadcast operations, in colour as well as monochrome, not only because of its high quality but because it is immediately available (without subsequent processing) for playback. In the United States, many of the network programs broadcast in and west of Chicago are derived from magnetic recordings, stored for an hour or more after their release along the eastern seaboard to allow for the difference in time in western cities.

Special techniques. Many variations of the basic techniques of recording television program material were developed in sports telecasting. The first to be introduced was the "instant replay" method, in which a video tape recording is made simultaneously with the live-action pickup. When a noteworthy episode occurs, the live coverage is interrupted and the tape recording is broadcast, followed by a switch back to live action. Often the recording is made from a camera viewing the action from a different angle. Other variations include the slow-motion and stop-action techniques, in which magnetic recording plays the basic role.

Increasing use has been made, particularly in sports broadcasting, of split-screen techniques and the related methods of inserting a portion of the image from another camera into a circular (or rectangular, triangular, etc.) area cut out from the main image. These techniques employ an electronic switching circuit that turns off the signal circuit of one camera for a portion of several line scans, while simultaneously turning on the signal circuit of another camera, the outputs of the two cameras being combined before the signal is broadcast. The timing of the electronic switch is adjusted to blank out, on successive line scans of the first camera, an area of the desired size and shape. The timing may be shifted during the performance and the area changed accordingly. One example of this technique is the wipe, which removes the image from one camera while inserting the image from another, with a sharp, moving boundary between them. (D.G.F./Ed.)

The handbooks, yearbooks, annual reports, and occasional monographs of broadcasting organizations, supervisory bodies, and international organizations (particularly, the European Broadcasting Union in Geneva) are invaluable sources of basic and statistical information. (J.A.Ca./K.R.S./Ed.)

Radio systems and equipment: BRITISH STANDARDS INSTITUTION, *Glossary of Terms Used in Telecommunications,* 3rd ed. (1960), terms, general and esoteric, are defined, and alternatives listed; J.G. CROWTHER, *Discoveries and Inventions of the 20th Century,* 5th ed. rev. (1966), information on the early developments in radio transmission and reception; INTERNATIONAL TELEPHONE AND TELEGRAPH CORPORATION, *Reference Data for Radio Engineers,* 5th ed. (1968), data of value to those working in radio, and some information of interest to the layman; J.A. BETTS, *High Frequency Communications* (1967), a comprehensive survey of the problems of high-frequency communication; and K.W. GATLAND (ed.), *Telecommunication Satellites* (1964), an examination of the technical and economic problems associated with satellite communication. (K.R.S./Ed.)

Television systems and equipment: D.G. FINK and D.M. LUTYENS, *The Physics of Television* (1960), nontechnical treatment of television principles in paperback form, written for high school physics students; G.M. GLASFORD, *Fundamentals of Television Engineering* (1955), definitive textbook and reference work for the college student; D.G. FINK (ed.), *Television Engineering Handbook* (1957), standard reference work on all technical aspects of monochrome and colour television; B. GROB, *Basic Television,* 3rd ed. (1964), a comprehensive treatment of monochrome and colour television, particularly from the standpoint of receiver maintenance and service requirements; J.W. WENTWORTH, *Color Television Engineering* (1955), standard text and reference work on the USA (NTSC) compatible colour television system that covers the basic principles of colour vision, as well as equipment and system aspects; and K. SIMONS, *Technical Handbook for CATV Systems,* 3rd ed. (1968), standard reference work on cable television systems. (T.H.B./D.G.F./Ed.)

Brussels

Brussels (Dutch: Brussel; French: Bruxelles), the capital of the Kingdom of Belgium and of the Belgian province of Brabant, consists of an agglomeration of about 1,000,000 inhabitants. It is divided into 19 communes, or municipalities, each with a large measure of administrative autonomy. Although the average visitor might remain unaware of this dispersal of local government powers, it holds the key to an understanding of many of the urban problems afflicting the contemporary city. It has, for example, impeded the harmonious development of the spreading built-up areas that reflect the increase in population that has occurred since 1830, and an adequate solution to the traffic problem has been rendered especially difficult.

A further major problem arises from the geographic location of the city. It lies just a few miles north of the invisible "language boundary" separating the nation's Dutch-speaking region of Flanders in the north from the southern, French-speaking Walloon region. Brussels is thus surrounded by Flemish territory and was historically a predominantly Dutch-speaking city, but at present the majority of residents in the Brussels agglomeration speak French. Officially, as the Belgian capital, the city is strictly bilingual, and in all spheres of public life Dutch and French are used side by side. Nevertheless, increasingly in the 20th century Brussels has been the principal venue for political clashes between Flemings and Walloons. Partly as a result of these conflicts, the Belgian Parliament reorganized the nation's structure on the basis of three regions: Flanders, Wallonia, and Brussels. Although the city acquired a separate political identity, its exact place and role in Belgium's decentralization measures have not been defined by law.

Brussels is nevertheless the administrative, commercial, and financial heart of Belgium, and all services and institutions of national importance are based in the city. Brussels is, in addition, a major European tourist and cultural attraction, functioning simultaneously as regional metropolis, national capital, and international centre. The last-named role has flourished since the city became host to the European Communities (made up of the European Economic Community [EEC], or Common Market; the European Coal and Steel Community; and the European Atomic Energy Community) as well as to the North Atlantic Treaty Organization (NATO) headquarters.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Brussels lies in the central plateaus of Belgium, in the valley of the Senne River (Dutch: Zenne), a small tributary of the Scheldt (French: Escaut). Its relative proximity to the North Sea gives it a mild, moderate climate, with summer temperatures usually between 68° and 77° F (20° and 25° C) and winter temperatures rarely falling below 32° F (0° C).

Inner Brussels

Seen from the air, the historic Old Town of Inner Brussels has the shape of a pentagon. It forms the centre of the modern metropolis, but the walls that once surrounded it were replaced by a ring of boulevards in the mid-1800s, around the time that Belgium became an independent kingdom. Since then, Brussels has been transformed, in the Old Town as well as in the surrounding communes. The determining factor in this metamorphosis has been incessant population pressure, which caused a building boom and the development of an ever-widening network of streets, avenues, and roads crisscrossing the countryside and urbanizing the neighbouring villages.

At first the urban tentacles only pushed forward along the seven or eight routes radiating from the tollgates along the old city walls, but after the toll system was abolished in 1860 they also spread along new roads. The suburbs expanded rapidly beyond the town gates, and by the end of the 19th century the territory of several of the first ring of communes was completely or almost completely covered by residential buildings. The expansion continued into the 20th century, in all directions: north and south along the valley of the Senne, and east and west on the undulating plateaus separated by the tributaries of the Senne (Maalbeek, Woluwe, and others).

As a result, the landscape was entirely changed. With rare exceptions, the ponds and pools of earlier days were filled in; most of the hollows were banked up; the rivers and streams covered over and converted into sewers; the small woods cut down; fields, pastures, and orchards parceled out for development; and footpaths eliminated. The Senne River became a main sewer running under the wide, straight central boulevards of Inner Brussels, linking the North (1841) and the South (1869) railway stations. In 1911 the city began building a series of railway tunnels and viaducts connecting the North and South stations by way of the underground Central Station (1952). This so-called North–South link was completed in 1956. Although it has facilitated transportation, several decaying residential areas had to be demolished during its construction, an action that has since caused some regret.

Greater Brussels is not entirely built over, mainly because, with the introduction of rapid means of transport, urban development has leapfrogged to satellite communities rather than proceeding by continuous, uninterrupted expansion. Since the 19th century, the boundaries of the Brussels agglomeration changed repeatedly, giving the sprawling metropolis the appearance of an amoeba. In the latter third of the 20th century, however, legislation resulting from Belgium's linguistic and community conflicts strictly confined the city within the limits of its 19 constituent municipalities.

The Grand' Place

Inner Brussels is divided between the commercial quarter and the upper town, where the principal governmental buildings are situated. The commercial quarter extends from the western outer boulevards to a little east of the central boulevards and includes the medieval marketplace known as the Grand' Place. This square, with its elaborately decorated 17th-century guildhalls, lies at the heart of the Old Town. It is occupied on its south side by the imposing Town Hall and on its north by the ornate King's House (Maison du Roi; almost entirely rebuilt during 1873–95), which contains the historical museum.

The Town Hall in the Grand' Place, Brussels, built 1402–54.

One of the curiosities of this quarter is the Manneken-Pis Fountain (1619), noted for a small bronze statue of a boy urinating and known to the people of Brussels as their oldest "citizen."

The upper town is the remaining eastern area of the inner city. It is crossed from southwest to northeast by a major thoroughfare, on which stand the Royal Palace and the Palace of the Nation. The latter was erected (1779–83) by the Austrian governors and after independence became the home of the Senate and the Chamber of Representatives. It stands at the intersection of the rue Royale (Koningsstraat) and the rue de la Loi (Wetstraat), an area that has become a symbol for the national government.

THE PEOPLE

The population of the Brussels agglomeration grew steadily from 57,000 in 1755, when the first census was held, to 104,000 in 1830, 626,000 in 1900, and 892,000 in 1930. It reached a peak of a little more than 1,000,000 in 1970 but has since declined to just under 1,000,000. The population of the inner city increased in line with that of the total agglomeration until around 1890, when it stood at 160,000, but it has declined sharply since the beginning of the 20th century, falling to 141,000 in 1910, 84,000 in 1947, and around 60,000 in the 1960s.

The effect of immigration

Immigration has had a significant impact on the demographic and linguistic evolution of the city. In the 19th century the immigrants usually came from Flanders or Wallonia, although there was also a large expatriate community from France and, to a lesser extent, Germany. Until then Brussels remained the Flemish city it had always been, with only about one-third of its inhabitants speaking French. The new Flemish immigrants, however, belonged on the whole to the lower strata of society (domestic servants, labourers), whereas the Walloon immigrants were predominantly middle-class employees and civil servants. Largely as a result of social pressure and the prestige of French, by the mid-20th century a large majority of Bruxellois spoke French. No language census has been taken since the controversial 1947 census, the matter being politically too sensitive, but it is thought that at least three-quarters of the population of Brussels may now be predominantly French-speaking.

In many respects Dutch and French speakers have their own cultural circuits. Broadly speaking, Dutch-language cultural life is more in evidence in the northwestern part of the agglomeration and French-language culture in the southeastern part. A number of cultural establishments, however, from the Théâtre de la Monnaie (Muntschouwburg) to the Ancient Belgium cabaret, are shared by the two communities, many middle-class Bruxellois being conversant in both languages. In recent years a new Flemish elite has emerged, improving the prospects for the Dutch language in the Belgian capital.

Since the mid-1960s, immigration of EEC personnel from western European countries and, in much larger numbers, of manual workers and their families from various Mediterranean countries has substantially altered the composition of the population of Brussels. Whereas in 1961 foreigners accounted for less than 7 percent of the population, by 1985 their share was more than 25 percent. EEC employees generally live in the upper part of the city or in the leafier suburbs. The immigrants from the Mediterranean—from Spain, Italy, and Greece at first, but later also from Morocco and Turkey—form a much larger group in central Brussels. A young population with a high birth rate, they make up as much as half the population of such boroughs as Saint-Josse-ten-Node (Sint-Joost-ten-Node) and Saint-Gilles (Sint-Gillis). In general, these immigrants retain their cultural distinctness; the municipality of Schaerbeek (Schaarbeek), for example, has 18 mosques for its foreign residents.

THE ECONOMY

In the early days of national independence, in the 1830s, food markets in the Old Town were supplied by the neighbouring villages. These have since been urbanized, and industrial, commercial, and service activities have been substituted for rural work.

Brussels' most important industrial zone is located on the city's south–north axis, along the valley of the Senne, where the port of Brussels developed and where the railway lines run. Food processing and the manufacture of machinery, electrical products, chemicals, and textiles are the leading industries. White-collar workers far outnumber blue-collar workers, however. In fact, the financial and service industries account for more than two-thirds of all employment in Brussels.

Economic and financial importance of the city

The capital has been the financial heart of Belgium and a major commercial centre ever since the private and powerful holding company the Société Générale de Belgique was established there in 1822. Domestic and foreign banking institutions and insurance companies have appeared in increasing numbers. Because most of the large Belgian industrial and commercial concerns have their registered offices in Brussels, it constitutes the decision-making centre for economic and financial affairs. With the establishment of the European Common Market, many multinational corporations have set up their regional coordinating offices there. Brussels has also developed into an international economic centre, with an important stock exchange and an annual commercial fair.

Brussels' working population amounts to almost half of its total population; this high proportion is explained by the fact that many women are employed, usually in the commercial or service sectors. Both the standard and the cost of living are relatively high; the average income per person is significantly higher in Brussels than in either Flanders or Wallonia, although the gap is narrowing.

The importance of Brussels to the national economy is evident from the fact that, with 10 percent of the country's population, the city provides work for 17 percent of Belgium's economically active population. Commuters make up one-third of the entire Brussels work force; more than two-thirds of the commuters come from Flanders, mostly from Flemish Brabant. As a result, the streets of the city change dramatically at rush hours, when tens of thousands of commuters are traveling, predominantly by train and car. To alleviate the worsening traffic problems and to counter the diminishing use of communal transport in the agglomeration, in 1965 the city began developing a comprehensive subway network. The first line was opened in 1976; five lines now extend to all parts of Greater Brussels.

The city has also developed an extensive external transportation system. A ring of modern motorways surrounds Greater Brussels, forming a hub of radiating highways that link the major cities of Belgium. Brussels is also the focal point of the Belgian railway system, one of the densest in the world. At peak times the city's Central Station, which is restricted to six underground tracks, has up to 100 trains passing through every hour. A special line connects the Central Station with the Brussels National Airport (at Zaventem, to the east) in approximately 10 minutes.

The city's easy accessibility and central geographic location in western Europe have proved beneficial to its tourist trade. Many overseas visitors to the Continent use Brussels as a convenient base or starting point for their travels.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Brussels was the historic capital of the duchy of Brabant; after Belgian independence it continued as the capital of the province of Brabant and as such houses the provincial assembly and the governor. The de facto national capital since the 15th century, Brussels became the de jure capital of the Kingdom of Belgium in 1830. The king has his palace there, facing the Palace of the Nation, which houses the Chamber of Representatives and the Senate. For a long time the various ministries were close by, but several have migrated to the Residence Palace and to other, more functional administrative buildings.

The Belgian constitution stipulates that matters concerning individual communes only are to be settled by the local council, according to specified principles. In 1836 Parliament passed the "organic" communal law, which provided for the autonomy of each commune. This explains why Greater Brussels for long was governed by 19 separate authorities and not by one single authority. Attempts to coordinate administration, such as the formation of the Assembly of Burgomasters in 1933, had no official status.

Constitutional change of 1970–71

In 1970–71 Parliament amended the constitution to provide for the recognition of three regions (Dutch-speaking Flanders, French-speaking Wallonia, and bilingual Brussels) as well as federations of communes. Each of the 19 communes of Brussels continued, however, to have its own council, municipal establishments, burgomaster, and alderman. The council in each commune is a deliberative assembly whose members are elected by universal suffrage; the aldermen are chosen by the councillors from among themselves. The burgomaster is appointed by the king, usually from among the councillors. He represents the head of state in the commune and sees to it that laws and regulations are carried out. He acts as local chief of police and in emergencies can take whatever steps are necessary to maintain or restore public order. The burgomaster of Brussels is a political figure of importance.

The 1970–71 constitutional revision also created a Council for the Brussels Agglomeration, a directly elected assembly with its own president and executive. The council was assigned specific powers in such matters as urban planning, economic expansion, environmental issues, fire protection, and ambulance service. New elections for the council, scheduled for 1976, were postponed indefinitely in view of impending further reforms of the Belgian state. These reforms were implemented in 1980, but because the legal definition of the powers to be awarded to the Brussels region was again put off indefinitely, the metropolis provisionally came under the control of a ministerial committee, which consists of government ministers and is answerable only to the national parliament. The 1980 legislation did, however, place cultural matters and matters relating to health care and welfare in Brussels under the jurisdiction of either the Flemish Council or the French Community Council, depending on whether they affect the city's Dutch-speaking or French-speaking inhabitants.

Public services. Brussels' communal services proliferated after 1830 as the city's population grew and became more mobile. The effect of larger scale and faster speed has meant growth in existing administrative departments as well as the creation of many new ones, such as the water, gas, and electricity administrations and the departments for youth and sports, for the aged, for burial services, and for education and the fine arts. Several of the communal industrial administrations have been replaced by intercommunal corporations (water, gas, and electricity). The public transport services (trains and buses) have been entrusted to a corporation of this kind.

Education. Approximately half of the elementary-school population attends so-called free (*i.e.,* Roman Catholic, but state-subsidized) schools. "State" schools are run by the local communes, the province of Brabant, or the Belgian state. Families are free to send their children to either Dutch-language or French-language schools. The reluctance of some municipalities to provide facilities for primary and secondary education in Dutch caused resentment among Flemings in the 1950s; even in the mid-1980s seven of the 19 communes of the agglomeration had no Dutch-language municipal schools. Inner Brussels has played an exemplary role in setting up scholastic institutions, most notably its generous contributions to the foundation in 1834 of the Free University of Brussels and to its development.

CULTURAL LIFE

Educational institutions

Brussels is an artistic and tourist centre, with a wide variety of cultural activities. In addition to the Free University—divided since 1970 into a French-speaking and a Dutch-speaking university—the royal academies of science, medicine, French language and literature, and Dutch language and literature, are based there, as are various other institutes of higher learning, including the largest branch of the National Archive, the Albert I Royal Library, and many museums of national or local importance.

The Palace of Fine Arts, designed by the Art Nouveau architect Victor Horta and opened in 1928, provides a cultural centre for those interested in the visual arts, film, music, literature, and the theatre. Most of the city's large-scale art exhibitions are presented there, and it is the headquarters of the Philharmonic Society and the National Federation of Youth and Music. The annual Queen Elisabeth of Belgium International Music Contest attracts worldwide interest. Midday poetry readings and concerts are held weekly. Most of the communes in the agglomeration have, on the model of the Palace of Fine Arts, established cultural centres that organize exhibitions, stage shows, and concerts.

French cultural influence

The two outstanding periods in Brussels' cultural history were the late medieval flowering under the Burgundians (most of the town's Gothic churches date from this era) and the late 19th to early 20th century, when Brussels was a centre of innovation in literature, theatre, architecture (Henry van de Velde, Horta), and painting (the Surrealists Paul Delvaux and René Magritte). Contemporary cultural life is cosmopolitan, although France provides much of the inspiration. Foremost among the theatres are the French-language National Theatre and the National Opera House. The French choreographer Maurice Béjart and his Ballet of the 20th Century were based in the city from 1960 until 1987. The minority Dutch-language culture of Brussels is less visible but quite dynamic.

Not far from the urban centre are scenic walks in the magnificent beech groves of the Soignes Forest (Zoniënwoud) and its offshoot, the Cambre (Terkameren) Woods. The city's main sports stadium is located in Heysel (Heizel), a northern district of the Brussels commune, where the 1958 World Exhibition was held.

History

EARLY SETTLEMENT AND GROWTH

Origins. The oldest known reference to Brussels dates to the 7th century and has the form Bruocsella, which means "settlement in the marshes." The name reflects the fact that the city owes its origin to the establishment, in the 6th century, of a fortified castle on a small island in the Senne River, which flows from south to north, and to an east–west economic route linking Rhenish towns such as Cologne with Brugge (Bruges), Ypres (Ieper), and other towns in the county of Flanders. At the point where road and river crossed, a market and bartering place developed under the protection of the dukes of Brabant. By the 12th century the settlement was surrounded by defensive ramparts with towers and fortified gateways.

During the 12th, 13th, and 14th centuries Brussels grew to become one of the major towns of the duchy of Brabant. Its economic mainstay was the manufacture of luxury fabrics, which were exported to fairs in Paris, Venice, the Champagne region of France, and elsewhere. The cloth trade made fortunes for a few enterprising merchant families, who developed into seven dynasties that, with the help of the duke of Brabant, acquired a position of complete political mastery. In control of business and municipal affairs, they also exercised power as magistrates, giving rulings on disputes arising among the inhabitants, as well as acting as a court of appeal for neighbouring areas. The prevailing regime was, in fact, strongly plutocratic in nature.

Abuse of such powers provoked violent popular uprisings in 1280, 1303, 1360, and 1421. This last upheaval led to a more equitable system of government, with local powers divided between the patrician families and the emergent guilds of craftsmen and other workers. Gradually, however, the patrician elite regained political control; as late as 1719 a popular revolt led by Frans Anneessens ended with his public execution.

Centuries of occupation. Events of particular significance in the 14th century were the invasion of the duchy of Brabant by the Count of Flanders' troops, their brief occupation of Brussels, and the construction, immediately after the town's liberation, of huge fortified walls (1357–79), which survived until the first half of the 19th century.

Burgundian era

In 1430 the duchy was merged in the possessions of the duke of Burgundy. The Burgundian period, which lasted until 1477, was one of political and artistic prestige. Brussels became the seat of the central administrative bodies for the ducal possessions in the Low Countries, which constituted a rich centre of art and culture. Pictures by Rogier van der Weyden, the officially appointed town painter, sculptures in wood, large tapestries with historical motifs, plate, jewelry, and other products by Brussels craftsmen came to be exported in all directions.

Brussels began to beautify itself: by the marketplace, the Town Hall (1402–54) rose proudly, with its tall perforated steeple surmounted by a statue of the archangel Michael, the city's patron saint. Various Gothic churches and cathedrals and the ducal Coudenberg Palace, with its extensive park, added to the architectural splendour.

After a prolonged political crisis caused by an abortive rebellion against the future Holy Roman emperor Maximilian I at the end of the 15th century, Brussels regained its position as a capital during the reign of Charles V (1519–59). The three government councils (the Council of State, the Privy Council, and the Finance Council) were established there permanently. The city's population grew to nearly 50,000 by the mid-16th century. In 1561 a canal linking Brussels with Willebroek was dug, providing direct access to the Rupel and the Scheldt rivers and thus to the port of Antwerp and the North Sea. Replacing the sandy little Senne river, the Willebroek Canal played an important commercial role.

The Reformation did not leave Brussels untouched. Two Lutheran preachers died there at the stake in 1523, the first Protestant martyrs in the Low Countries; many more Lutherans, Anabaptists, and Calvinists followed. During the Revolt of the Netherlands, Brussels was under Calvinist rule from 1578 until 1585, when the southern provinces of the Low Countries (which included modern-day Belgium) separated from the northern provinces (now the Kingdom of The Netherlands), surrendered to the Spanish Habsburgs, and returned to the Roman Catholic fold.

The Counter-Reformation and the reign of Archduke Albert and Isabella (1598–1633) left their mark on the urban surroundings with the construction of a series of fine churches in the Italo-Flemish Baroque style, nearly all of which are still in existence. In the second half of the 17th century there were repeated invasions by the armies of Louis XIV of France. During a bombardment by his troops in 1695, hundreds of buildings were destroyed by fire, including the various craft headquarters. Out of this catastrophe there arose new guildhalls, the architectural landmarks now surrounding the Grand' Place.

Brussels suffered a brief but costly occupation by French troops in 1746–48, but as part of the Austrian Netherlands it profited from the general economic recovery in the latter half of the 18th century, becoming a financial centre and gaining new industries. The upper part of the town was the scene of urban planning on a large scale, which resulted in the Place Royale and Brussels Park. The park is, following the French model, perfectly symmetrical and surrounded by Neoclassical buildings, of which the largest is the Palace of the Nation.

Following the Brabant revolt (1788–90) against the government of Emperor Joseph II of Austria, the French republican armies made their appearance, and the Belgian principalities were annexed to France. During the Napoleonic era, Brussels was reduced to the rank of chief town of the French *département* of the Dyle, losing in addition all authority over its satellite villages.

One of the consequences of Napoleon's defeat at Waterloo was the creation of the United Kingdom of The Netherlands. This reunion of the southern and northern provinces, which had been separated in the 16th century, lasted 15 years (1815–30). During this period Brussels shared the status of capital with The Hague. Its appearance changed appreciably, above all because of the demolition of the city walls (1810–40) and their replacement by tree-lined boulevards, as well as the digging of the Brussels–Charleroi Canal, which from 1832 onward made waterborne transport possible from as far as the province of Hainaut to the port of Antwerp via the capital.

Independence of Belgium

In 1830 came revolution; Belgium won its independence, and, in the constitution adopted by the National Congress, Brussels, which had played a major role in the uprising against the Dutch, was named the capital of Belgium and the seat of government. As a result, the city's growing political and administrative role enhanced its importance as an economic and financial centre. With a population of more than 123,000 in 1846, it became the central node of Belgium's road and railway network. Its material infrastructure was greatly improved by means of a modern sewage and water supply system (1854–55), the introduction of public transport, and the development of new residential districts. The fragmented local administration, however, was to be streamlined only partly and gradually, as suburban areas were incorporated into the agglomeration; but the influence of the Brussels elite in Belgian national politics remained predominant throughout the 19th century.

THE 20TH CENTURY

In World War I the German occupation of Belgium lasted from August 1914 to November 1918. Numerous social relief movements were instituted; among them, the National Committee for Relief and Food (Comité National de Secours et d'Alimentation) had its headquarters in Brussels and with U.S. aid organized the feeding of the Belgian population. Adolphe de Max, the burgomaster of Brussels, acquired fame for his resistance to the abuses of the German occupiers. The Belgian army reoccupied the capital on Nov. 18, 1918, and four days later King Albert I and Queen Elisabeth reentered the city in state. After the war, the administrative expansion of metropolitan Brussels that had begun in the 19th century continued. The area grew from nine municipalities in 1878 to 16 in 1932 and to 19 in 1954. This metropolitan, or Greater, Brussels became an officially bilingual city in 1932.

In World War II Brussels fell to the invading German army on May 18, 1940. The city did not suffer extensive physical damage but was subjected to harsh terms of occupation. To facilitate control, General Eggert Reeder, chief of the German military administration for Belgium, decided to follow the Nazi policy of creating large urban zones by amalgamating the communes. In order to crush the spirited opposition to this measure, Reeder dissolved all municipal councils and dismissed Joseph van de Meulebroeck, the leader of the opposition, from his post as burgomaster of Brussels. Reeder then appointed a governing council headed by Jan Grauls, a pro-Nazi Flemish nationalist. As in World War I, Germany tried to divide the nation by supporting partisans of Flemish autonomy. Although few Flemings actually collaborated with the enemy, anti-Flemish feelings ran high in metropolitan Brussels. The city was liberated on Sept. 3, 1944, by the British. Five days later the legitimate Belgian government returned to its capital from London.

Since World War II, Brussels has become decidedly more international, with the establishment of the EEC Commission and Council offices in Inner Brussels (1958) and the move of the NATO headquarters from Paris to the northeastern commune of Evere (1967). The city also was host to a successful world's fair in 1958, which helped to rejuvenate the weakened postwar economy.

The Fleming-Walloon conflict

Domestically, however, the situation has been less harmonious. The city has repeatedly been at the centre of tensions between the Flemish and Walloon communities of Belgium, as the Flemings have pressed for effective bilingualism in the public services in Brussels itself and have opposed any further expansion of the mainly French-speaking metropolis into neighbouring Flemish areas. Massive Flemish demonstrations against "Frenchification and territorial annexation" were held in the streets of Brussels in 1961 and 1962. In an attempt to settle the issue, Parliament passed a law in 1963 that restricted the capital to its 19 officially bilingual municipalities but extended language facilities to French-speaking minorities in six suburban boroughs. The Francophone countermobilization against what was regarded as Flemish interference in city affairs led to the formation of the Brussels-based Francophone Democratic Front in 1964. Whereas the Flemings were intent on preventing the Francophone influence from spreading further, the French-speaking residents of Brussels resented the imposition of a legal *carcan,* or "straitjacket," on the city. The front's rapid growth gave it a firm political hold in the late 1970s, but its demise in the early 1980s was equally rapid, as the deepening national and international economic crisis drew attention away from the language conflict. The faltering economy also temporarily halted the reforms begun in 1962 devolving power from the central government to the communities and regions. The exact status of the capital in relation to Flanders and Wallonia thus remained unresolved.

BIBLIOGRAPHY

Descriptive works: Older standard books providing good coverage of historic buildings and monuments include ALEXANDRE HENNE and ALPHONSE WAUTERS, *Histoire de la ville de Bruxelles,* new ed., 4 vol. (1968–69); ALPHONSE WAUTERS, *Histoire des environs de Bruxelles: ou description historique des localités qui formaient autrefois l'ammanie de cette ville,* 3 vol. (1855–57, reprinted 1968); GUILLAUME JACQUEMYNS, *Histoire contemporaine du Grand-Bruxelles* (1936); and GUILLAUME DES MAREZ, *Guide illustré de Bruxelles, monuments civils et religieux,* 4th ed., supplemented by A. ROUSSEAU (1958), an excellent handbook. HANS VON STAHLBORN (comp.), *Baedeker's Brussels,* rev. ed., trans. from German (1987), is a useful handbook.

Social and economic conditions: Demographic and administrative aspects of the city's history are the subject of A.-M. BOGAERT-DAMIN and L. MARÉCHAL, *Bruxelles, développement de l'ensemble urbain, 1846–1961: analyse historique et statistique des recensements* (1978); W. DE LANNOY and M. RAMPELBERGH, *Atlas socio-géographique de Bruxelles et de sa périphérie* (1981); and ANNE-MARIE KUMPS, ROBERT WTTERWULGHE, and FRANCIS DELPÉRÉE (eds.), *L'Avenir de Bruxelles: aspects économiques et institutionnels* (1980). Bryophytes

Bryophytes (division Bryophyta) are among the simplest of the terrestrial plants. Most representatives lack complex tissue organization, yet they show considerable diversity in form and ecology. They are widely distributed throughout the world and are relatively small compared with most seed-bearing plants. Most are 2–5 centimetres (0.8–2 inches) tall or, if reclining, generally less than 10 centimetres long. The phylum Bryophyta (Figures 1 and 2) includes three main evolutionary lines: the mosses (class Bryopsida, or Musci), the liverworts (class Hepatopsida, or Hepaticae), and the hornworts (class Anthocerotopsida, or Anthocerotae). It is conservatively estimated that there are more than 1,000 genera and more than 18,000 species of bryophytes.

The bryophytes show an alternation of generations between the independent gametophyte generation, which produces the sex organs and sperm and eggs, and the dependent sporophyte generation, which produces the spores. In contrast to vascular plants, the bryophyte sporophyte usually lacks a complex vascular system and produces only one spore-containing organ (sporangium) rather than many. Furthermore, the gametophyte generation of the bryophyte is usually perennial and photosynthetically independent of the sporophyte, which forms an intimate interconnection with the gametophytic tissue, especially at the base, or foot, of the sporophyte. In most vascular plants, however, the gametophyte is dependent on the sporophyte. In bryophytes the long-lived and conspicuous generation is the gametophyte, while in vascular plants it is the sporophyte. Structures resembling stems, roots, and leaves are found on the gametophore of bryophytes, while these structures are found on the sporophytes in the vascular plants. The sporophyte releases spores, from which the gametophytes ultimately develop.

In some bryophytes, sporophytes are unknown. The gametophyte in these bryophytes often reproduces asexually, or vegetatively, by specialized masses of cells (gemmae) that are usually budded off and ultimately give rise to gametophytes. Fragmentation of the gametophyte also results in vegetative reproduction: each living fragment has the potential to grow into a complete gametophyte.

The mature gametophyte of most bryophytes is leafy, but some liverworts and hornworts have a flattened gametophyte, called a thallus (Figure 1). The thallus tends to be ribbonlike in form and is often compressed against the substratum to which it is generally attached by threadlike structures called rhizoids. Rhizoids also influence water and mineral uptake.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 313, and the *Index.*

This article is divided into the following sections:

GENERAL FEATURES

Thallose versus leafy bryophytes

Thallose bryophytes vary in size from a length of 20 centimetres (8 inches) and a breadth of 5 centimetres (2 inches; the liverwort *Monoclea*) to less than 1 millimetre (0.04 inch) in width and less than 1 millimetre in length (male plants of the liverwort *Sphaerocarpos*). The thallus is sometimes one cell layer thick through most of its width (*e.g.,* the liverwort *Metzgeria*) but may be many cell layers thick and have a complex tissue organization (*e.g.,* the liverwort *Marchantia*). Branching of the thallus may be forked, regularly frondlike, digitate, or completely irregular. The margin of the thallus is often smooth but is sometimes toothed; it may be ruffled, flat, or curved inward or downward.

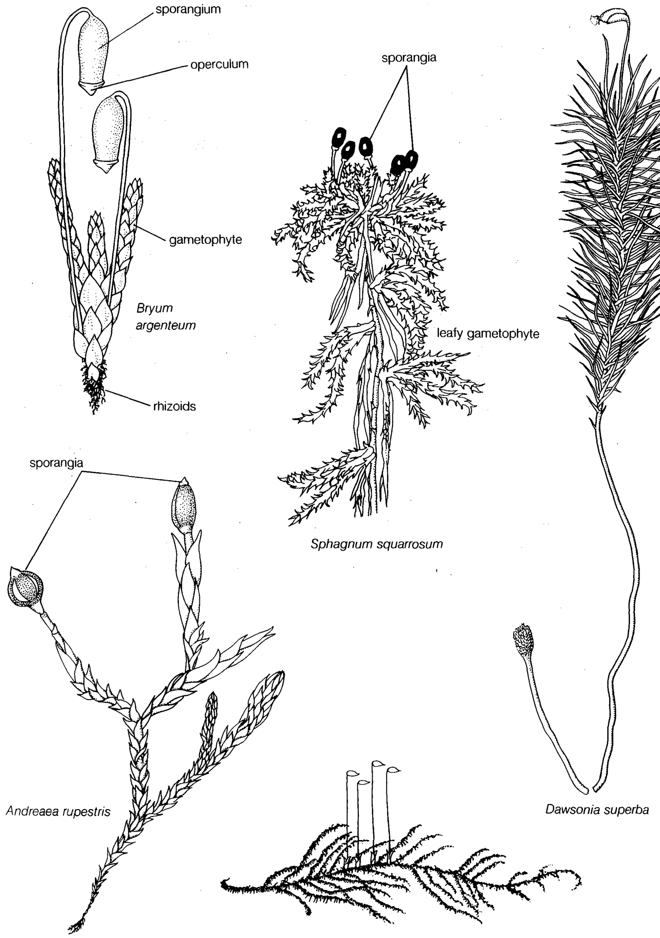

Figure 1: Representative mosses.

Leafy bryophytes grow up to 65 centimetres (2 feet) in height (the moss *Dawsonia*) or, if reclining, reach lengths of more than 1 metre (3.3 feet; the moss *Fontinalis*). They are generally less than 3 to 6 centimetres tall, and reclining forms are usually less than 2 centimetres long. Some, however, are less than 1 millimetre in size (the moss *Ephemerum*). Leaves are arranged in rows of two or three or more around a shoot or may be irregularly arranged (*e.g.,* the liverwort *Takakia*). The leafy shoot may or may not appear flattened. Leaves are usually attached by an expanded base and are mainly one cell thick. Many mosses, however, possess one or more midribs several cells in thickness. Leaves of liverworts are often lobed, while those of mosses are unlobed. Leaves diverge outward from the shoot; rigidity results from water pressure within the cells or from the support of a midrib, when present.

Most gametophytes are green, and all except the gametophyte of the liverwort *Cryptothallus* have chlorophyll.

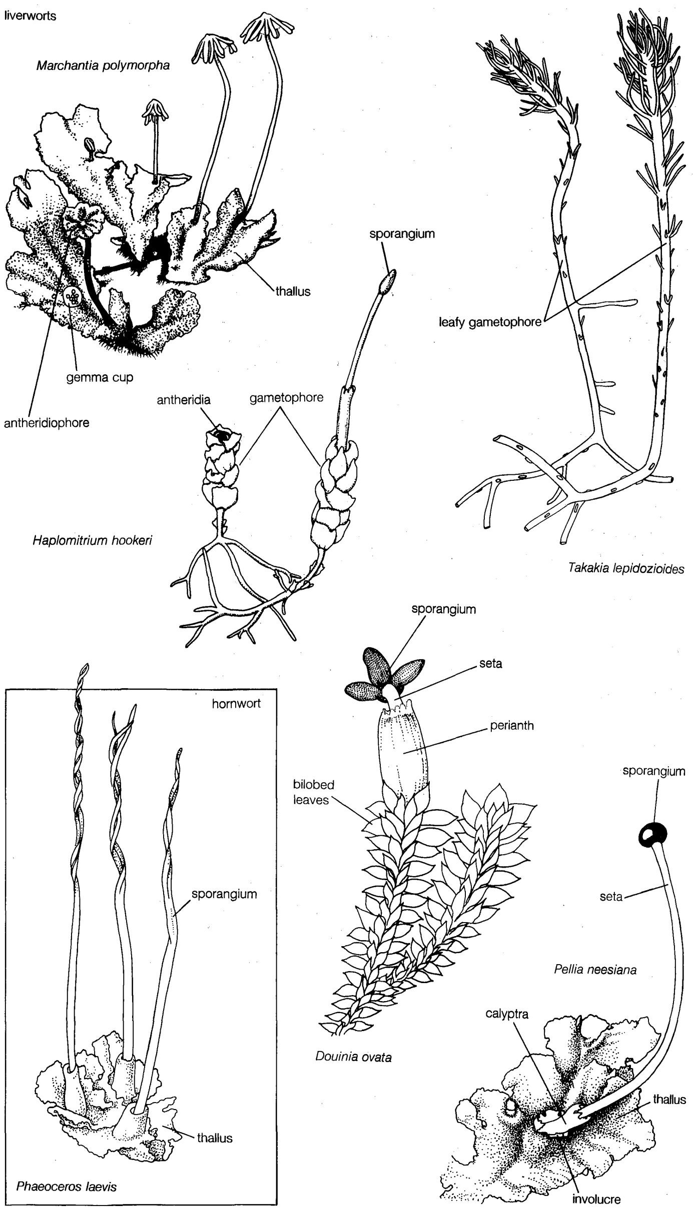

Figure 2: A hornwort and representative liverworts.

Adapted from W.B. Schofield, *Introduction to Bryology* (1985); McGraw-Hill Book Co., Inc.

Many have other pigments, especially in the cellulosic cell walls but sometimes within the cytoplasm of the cells.

Bryophytes form flattened mats, spongy carpets, tufts, turfs, or festooning pendants. These growth forms are usually correlated with the humidity and sunlight available in the habitat.

Importance of water

Distribution and abundance. Bryophytes are distributed throughout the world, from polar and alpine regions to the tropics. Water must, at some point, be present in the habitat in order for the sperm to swim to the egg (see below *Natural history*). Bryophytes do not live in extremely arid sites or in seawater, although some are found in perennially damp environments within arid regions and a few are found on seashores above the intertidal zone. A few bryophytes are aquatic. Bryophytes are most abundant in climates that are constantly humid and equable. The greatest diversity is at tropical and subtropical latitudes. Bryophytes (especially the moss *Sphagnum*) dominate the vegetation of peatland in extensive areas of the cooler parts of the Northern Hemisphere.

The geographic distribution patterns of bryophytes are similar to those of the terrestrial vascular plants, except that there are many genera and families and a few species of bryophytes that are almost cosmopolitan. Indeed, a few species show extremely wide distribution. Some botanists explain these broad distribution patterns on the theory that the bryophytes represent an extremely ancient group of plants, while others suggest that the readily dispersible small gemmae and spores enhance wide distribution.

The distribution of some bryophytes, however, is extremely restricted, yet they possess the same apparent dispersibility and ecological plasticity as do widespread bryophytes. Others show broad interrupted patterns that are represented also in vascular plants.

Peat moss

Importance to humans and ecology. The peat moss genus *Sphagnum* is an economically important bryophyte. The harvesting, processing, and sale of *Sphagnum* peat is a multimillion-dollar industry. Peat is used in horticulture, as an energy source (fuel), and, to a limited extent, in the extraction of organic products, in whiskey production, and as insulation.

Bryophytes are very important in initiating soil formation on barren terrain, in maintaining soil moisture, and in recycling nutrients in forest vegetation. Indeed, discerning the presence of particular bryophytes is useful in assessing the productivity and nutrient status of forest types. Further, through the study of bryophytes, various biological phenomena have been discovered that have had a profound influence on the development of research in such areas as genetics and cytology.

NATURAL HISTORY

Reproduction and life cycle. The life cycle of bryophytes (Figures 3 and 4) consists of two stages, or generations, called the sporophyte and the gametophyte. Each generation has a different physical form. When a spore germinates, it usually produces the protonema, which precedes the appearance of the more elaborately organized gametophytic plant, the gametophore, which produces the sex organs. The protonema is usually threadlike and is highly branched in the mosses but is reduced to only a few cells in most liverworts and hornworts. The protonema stage in liverworts is usually called a sporeling in other bryophytes (see below *Form and function*).

The gametophore—the thallose or leafy stage—is generally perennial and produces the male or female sex organs, or both. The female sex organ is a flask-shaped structure called the archegonium. The archegonium contains a single egg enclosed in a swollen lower portion that is more than one cell thick. The neck of the archegonium is a single cell layer thick and sheathes a single thread

The archegonium and antheridium

From R.R. Ireland, *Moss Flora of the Maritime Provinces* (Ottawa, 1982)

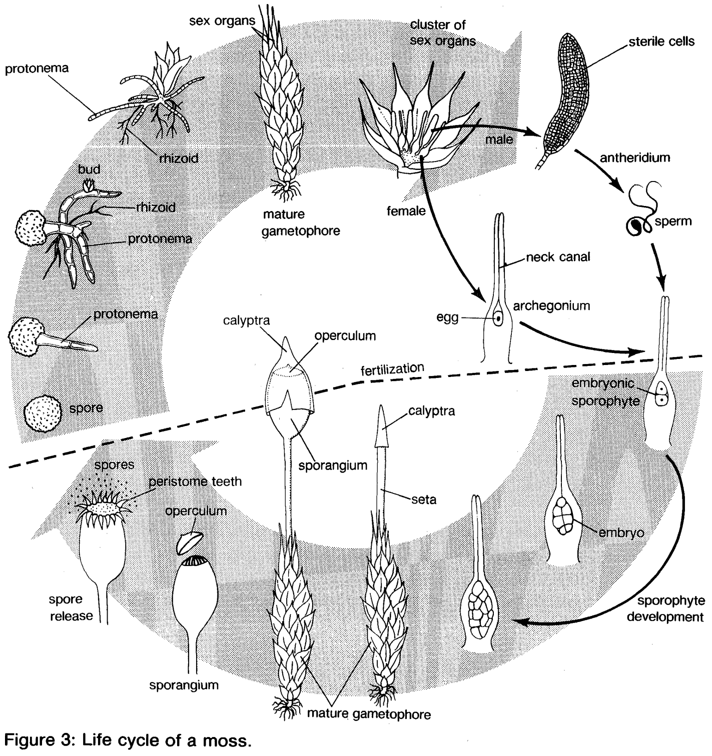

Figure 3: Life cycle of a moss.

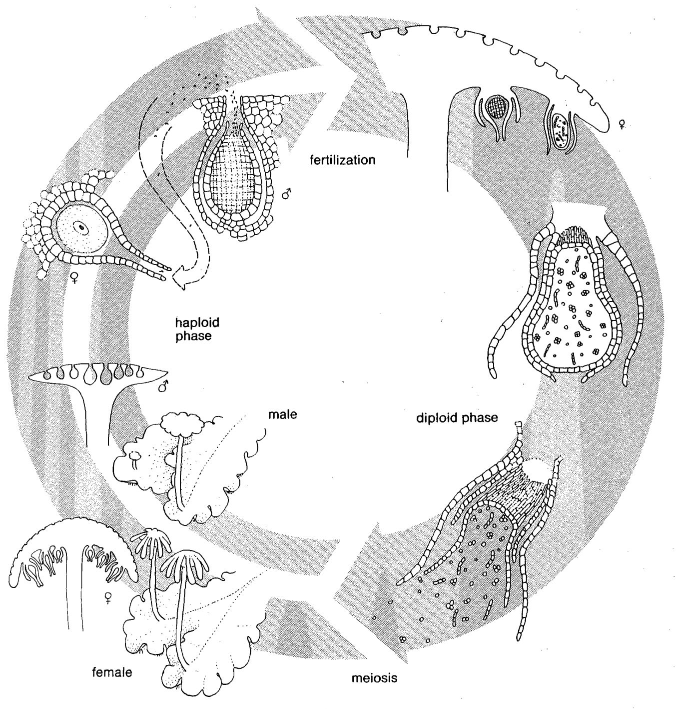

Figure 4: Life cycle of a liverwort (*Marchantia*).

of cells that forms the neck canal. When mature and completely moist, the neck canal cells of the archegonium disintegrate, releasing a column of fluid to the neck canal and the surrounding water. The egg remains in the base of the archegonium, ready for fertilization. The male sex organ, the antheridium, is a saclike structure made up of a jacket of sterile cells one cell thick; it encloses many cells, each of which, when mature, produces one sperm. The antheridium is usually attached to the gametophore by a slender stalk. When wet, the mature antheridium ruptures the jacket to release the sperm into the water. Each sperm has two flagella and swims in a corkscrew pattern. When a sperm enters the field of the fluid diffused from the neck canal, it swims toward the site of greatest concentration of this fluid, therefore down the neck canal to the egg. Upon reaching the egg, the sperm burrows into its wall, and the egg nucleus unites with the sperm nucleus to produce the diploid zygote. The zygote remains in the archegonium and undergoes many mitotic cell divisions to produce an embryonic sporophyte. The lower cells of the archegonium also divide and produce a protective structure, called the calyptra, that sheathes the growing embryo.

As the sporophyte enlarges, it is dependent on the gametophore for water and minerals and, to a large degree, for nutrients manufactured by the gametophore. The water and nutrients enter the developing sporophyte through the tissue at its base, or foot, which remains embedded in the gametophyte. Mature bryophytes have a single sporangium (spore-producing structure) on each sporophyte. The sporangium generally terminates an elongate stalk, or seta, when the sporangium is ready to shed its spores. The sporangium rupture usually involves specialized structures that enhance expulsion of the spores away from the parent gametophore.

Nutrition. Bryophytes generate their nutrient materials through the photosynthetic activity of the chlorophyll pigments in the chloroplasts. In addition, most bryophytes absorb water and dissolved minerals over the surface of the gametophore. Water retention at the surface is assisted by the shape and overlapping of leaves, by an abundance of rhizoids, or by capillary spaces among these structures. Water loss through evaporation is rapid in most bryophytes.

Conducting systems

A few bryophytes possess elaborate internal conducting systems (see below *Form and function*) that transfer water or manufactured nutrients through the gametophore, but most conduction is over the gametophore surface. In most mosses, water and nutrient transfer from the gametophore to the developing sporangium takes place along the seta and also via an internal conducting system. A protective cuticle covers the seta, reducing water loss. The calyptra that covers the developing sporangium prevents water loss in this fragile immature structure. In liverworts the sporangium remains close to the gametophore until it is mature; thus, a conducting system is not formed in the seta. In most hornworts there is also an internal conducting system within the developing horn-shaped sporangium. The internal movement of fluid in all parts of the bryophyte is extremely slow. Storage products include starch and lipids.

Ecology and habitats. Some bryophytes are unusually tolerant of extended periods of dryness and freezing, and, upon the return of moisture, they rapidly resume photosynthesis. The exact mechanism involved remains controversial.

Many bryophytes grow on soil or on the persistent remains of their own growth, as well as on living or decomposing material of other plants. Some grow on bare rock surfaces, and several are aquatic. The main requirements for growth appear to be a relatively stable substratum for attachment, a medium that retains moisture for extended periods, adequate sunlight, favourable temperature, and, for richest luxuriance, a nearly constantly humid atmosphere.

Unusual habitats include decomposing animal waste (many species in the moss family Splachnaceae), somewhat shaded cavern mouths (the liverwort *Cyathodium* and the mosses *Mittenia* and *Schistostega*), leaf surfaces (the moss *Ephemeropsis* and the liverwort genus *Metzgeria* and many species of the liverwort family Lejeuneaceae), salt pans (the liverwort *Carrpos*), bases of quartz pebbles (the moss *Aschisma*), and copper-rich substrata (the moss *Scopelophila*).

In humid temperate or subtropical climates, bryophytes often grow profusely, forming deep, soft carpets on forest floors and over rock surfaces, sheathing trunks and branches of trees and shrubs, and festooning branches. In broad-leaved forests of temperate areas, trees and boulders often harbour rich bryophyte stands, but it is near watercourses that bryophytes tend to reach their richest luxuriance and diversity.

In Arctic and Antarctic regions, bryophytes, especially mosses, form extensive cover, especially in wetlands, near watercourses, and in sites where snowmelt moisture is available for an extended part of the growing season. There they can dominate the vegetation cover and control the vegetation pattern and dynamics of associated plants. The same is true for alpine and subalpine environments in which many of the same species are involved.

Nutrient cycling

Bryophytes, especially mosses, are important in nutrient cycling, in some cases making use of limited precipitation and airborne minerals that are thus made unavailable to the seed plant vegetation. Rapid evaporation from the moss mat is probably critical to some vegetation types by impeding moisture penetration to the root systems of seed plants and therefore indirectly controlling the vegetational composition of some forests.

Bryophytes are fundamental to the development of wetland habitats, especially of peatland. The moss genus *Sphagnum* leads to the development of waterlogged masses of highly acid peatland, in which decomposition is relatively slow. The formation of extensive bogs can control the hydrology of much of the surrounding landscape by behaving like a gigantic sponge that absorbs and holds vast quantities of water and influences the water table. Extension of this saturated living moss mat into living forest can drown the root systems of the forest trees, killing the forest and replacing it with bog. Peatland can also develop on calcareous terrain through the growth of other mosses, including species of the genera *Drepanocladus* and *Calliergon.* These mosses also build up a moss mat that, through organic accumulation of its own partially decomposed remains, alters the acidity of the site and makes it attractive to the formation of *Sphagnum* peatland.

Bryophytes, especially mosses, colonize bare rock surfaces, leading ultimately to the initiation of soil formation. This in turn produces a substratum attractive to seed plant colonists that invade these mossy sites and, through their shading, eliminate the pioneer mosses but create a shaded habitat suitable for other bryophytes. These new colonists, in turn, are important in nutrient cycling in the developing forest vegetation.

FORM AND FUNCTION

The gametophyte form shows several developmental stages: the spore, the protonema, and the gametophore, which produces the sex organs. Spores of bryophytes are generally small, 5–20 micrometres on the average, and usually unicellular, although some spores are multicellular and considerably larger. Spores have chlorophyll when released from the sporangium. They are generally hemispheric, and the surface is often elaborately ornamented.

Spores

The protonema, which grows directly from the germinating spore, is in most mosses an extensive, branched system of multicellular filaments that are rich in chlorophyll. This stage initiates the accumulation of hormones that influence the further growth of newly formed cells. When specific concentrations of the hormones are reached, the branches of the protonema generate small buds, which in turn produce the leafy gametophore.

In most liverworts and hornworts, the protonema is usually limited to a short unbranched filament that rapidly initiates a three-dimensional cell mass, the sporeling. This sporeling is rich in chlorophyll and soon forms an apical cell from which the gametophore grows.

In moss gametophores the leaves of the shoots are spirally arranged on the stem in more than three rows. Leaves often have elaborate ornamentation on the cell surfaces. This ornamentation is often important in rapid water uptake. Although the leaf begins its growth from an apical cell, cells are soon cut off between the apical cell and the leaf base, and further division of these cells results in the elongation of the leaf and also in the production of one or more midribs. The gametophore is often attached to the substratum by rhizoids. The rhizoids are structurally similar to cells of the protonema, but they lack chlorophyll. In some mosses, rhizoids closely invest the stem among the leaf bases and perform a significant function in external water conduction and retention before its absorption by stem and leaves.

The internal structure of the stems of moss gametophores is usually simple. The outer cells are often thick-walled and supportive, while the inner cells are generally larger and have thinner walls. Some mosses, however, have considerable tissue differentiation in the stem. In the moss subclass Polytrichidae, for example, a complex conducting strand is often formed in the centre of the stem. It consists of an internal cylinder of water-conducting cells (the hydroids) surrounded by layers of living cells (leptoids) that conduct the sugars and other organic substances manufactured by the gametophore. This conducting system is analogous to that of the vascular plants, except that it lacks lignin (a carbohydrate polymer), and it closely resembles that found in the fossils of the earliest land plants.

In gametophores of leafy liverworts, the leaves are arranged in two or, usually, three rows. The plants are often flattened horizontal to the substratum. Lobing of these leaves is sometimes complex, as is their orientation on the stems as compared with the mosses. Rhizoids are generally confined to the undersurface of the stem and are important in that they form attachments and influence water retention and uptake by the leafy plant.

In gametophores of thallose liverworts and hornworts, an internal conducting strand is rarely developed. In a few genera of the liverwort order Metzgeriales, the water-conducting cells have a form similar to water-conducting cells of vascular plants, but the cells of the liverworts and hornworts, like those of mosses, lack the lignin that characterizes the cell walls of water-conducting cells of vascular plants.

The thalli of most liverworts and hornworts consist of relatively undifferentiated layers of cells. Those cells on the dorsal surface are rich in chlorophyll, while those situated deeper within the thallus lack chlorophyll but have storage products of photosynthesis, especially starch. Fungi are often present in the cells of many thalli (and also leafy liverwort stems) and are probably important in water and mineral uptake as well as in making organic compounds available for the nutrition of the gametophore. The thalli of the liverwort order Marchantiales show considerable tissue differentiation, which gives these complex thalli a structure analogous to that of the leaves of vascular plants and provides structural features which allow them to occupy habitats too dry for many other liverworts and hornworts.

Thalli

The sexual reproduction of bryophyte gametophores is usually seasonally restricted, often initiated by short-day or long-day illumination; thus, especially in temperate climates, sex organs appear and mature in the autumn, while in more extreme climates they appear in the spring or summer. In mosses, the sex organs are usually sheathed by specialized leaves and are embedded in a mass of filaments that protects the sex organs from drying out before maturity. Many mosses have antheridia and archegonia on separate gametophores, ensuring outbreeding, while others have both sexes on the same gametophore but apparently with features that discourage inbreeding.

The perianth

In many leafy liverworts the archegonia are often enclosed by a protective sleeve, the perianth, and have mucilage hairs among them with a function similar to that of the paraphyses of mosses. The antheridia of leafy liverworts are often on specialized branches and at the axils of specialized leaves that are usually swollen to enclose them. Most leafy liverworts have antheridia and archegonia on separate plants.

The archegonia of the hornworts are completely embedded in the dorsal surface of the thallus, while antheridia are found in chambers near the dorsal surface. Thalli may contain antheridia or archegonia or both.

Sporophytes of mosses usually consist of the foot, which penetrates the gametophore, the seta, with an internal conducting system, and a terminal sporangium. The seta contains chlorophyll when immature and cannot absorb moisture from the environment because its surface is covered by a water-impermeable layer, the cuticle. The sporophyte is photosynthetic when immature, but its restricted amount of chlorophyll-containing tissue rarely produces enough carbohydrates to nourish a developing sporangium. All water and much of the needed nutrients are absorbed from the gametophore and are conducted through the transfer tissue of the foot up the conducting strand that leads to the apex of the sporophyte. The seta is made rigid by thick-walled cells external to the conducting strand. The sporangium differentiates after the seta elongates and is protected from injury and drying by the calyptra.

The moss sporangium usually opens by way of an apical lid (the operculum). When the operculum falls, there is exposed a ring of teeth that controls the release of the spores over an extended period of time. These teeth usually respond to slight moisture changes and pulsate inward and outward, carrying spores out of the sporangium on their jagged inner surfaces. In the moss subclass Polytrichidae, however, the tiny spores exit through a series of holes between the teeth and a membrane that closes much of the mouth; thus, any slight movement of the sporangium causes spores to shake out into the air. In the moss subclass Andreaeidae, the spores are released when the sporangium wall gapes open in longitudinal slits. In the genus *Sphagnum,* air is trapped within the sporangium as it matures; as the sporangium dries out, it shrinks, until the buildup of internal pressure abruptly shoots the operculum and spores into the air.

In most liverworts, the sporangium matures before the seta elongates, pushing the sporangium above the calyptra that protected it. Elongation is rapid, and the seta is held erect by water pressure within its cells. The sporangium usually contains within it elongate cells (elaters) with coiled thickenings that are scattered among the spores. When the sporangium opens, usually very rapidly when dry, it does so along four longitudinal lines, exposing the elaters, which uncoil rapidly and throw themselves and the adjacent spores into the air. Other devices exist for spore release in the liverworts.

Hornworts are unusual among the bryophytes because the sporophyte has indeterminate growth. This means that throughout the growing season new tissue is continually produced, even when spores are being shed. Early in its growth within the archegonium, the embryo produces a foot that penetrates the thallus and an apical meristem that elongates the rest of the horn-shaped sporophyte to rupture the thallus surface. A meristem (an area of actively dividing cells that gives rise to all subsequent tissue) is soon differentiated just above the foot, between it and the horn-shaped sporophyte above, and this meristem contributes new growth to the elongating sporophyte throughout the growing season and ceases when the gametophore disintegrates around it. The sporophyte thus matures near the apex while new tissue is differentiated just above the foot, contributing to the elongation of the sporophyte. The sporangium usually opens by two longitudinal lines on opposite sides of the horn. As the apex matures, it exposes the spores and elaters, which are released to the air.

EVOLUTION AND PALEONTOLOGY

Poor fossil record

The fossil record of bryophytes is poor. Some fossils, however, show a morphology, size, and cellular detail that characterize bryophytes, and the specimens are treated as fossil bryophytes. Since sex organs and attached sporophytes are absent in nearly all fossil material and because the gametophytes of some living vascular plants resemble the gametophores of some bryophytes, the assignment of these fossils as bryophytes is by no means secure.

The earliest presumed bryophyte fossils are contemporaneous with the earliest vascular plants of the Late Devonian epoch, 374 to 360 million years ago. These fossils structurally resemble gametophores of the liverwort order Metzgeriales. Indeed, fossil material of the Carboniferous period (360 to 286 million years ago) also is structurally similar to genera of Metzgeriales. The specimens are surprisingly well preserved and show considerable cellular detail.

The most elegantly preserved bryophyte fossils are those in amber of the Eocene epoch (57.8 to 36.6 million years ago). The detailed cellular structure and morphology of the gametophore make the determination of the genus reasonably secure. The genera are still extant, although not where the fossil material was found, and even the species relationships can be suggested.

For mosses, the earliest material that appears unambiguous is in the Permian period (286 to 245 million years ago), and the detailed relationships are not clear. The subclass Bryidae is most likely, but more precise attribution is difficult.

Well-preserved material of mosses and liverworts appears in the Tertiary period (66.4 to 1.6 million years ago), and most of the main evolutionary lines are represented. Fossils of the Neogene (roughly equivalent to the last one-third of the Tertiary period, 23.7 to 1.6 million years ago) are relatively numerous, and subfossil material of the Quaternary period (1.6 million years ago to the present) can be determined with confidence as modern species. Mosses are most richly represented in this material, and species of wetland habitats predominate in the record.

CLASSIFICATION

Classification of the liverworts leans heavily on gametophyte structure, with sporophyte structure providing additional evidence of relationships. In the hornworts and mosses, the structure of the sporophyte, especially the sporangium, is important in distinguishing the main evolutionary lines, while gametophytic features provide the details for distinguishing genera and species.

Annotated classification. The classification presented here reflects main evolutionary lines. These seem best illustrated at the order level. Those orders that are considered to be most generalized are treated first; and those most specialized, last.

CLASS HEPATOPSIDA (or HEPATICAE; liverworts)

Protonema generally reduced to a few cells, with gametophore differentiated early after spore germination; rhizoids unicellular; gametophore leafy or thallose and generally flattened; sex organs lacking paraphyses; leaves lacking true midrib; leaf cells often with corner thickenings; complex oil bodies often in cells of gametophore; sporangium jacket lacking stomata, and often with transverse thickenings in cellwalls; sporangium usually opening by longitudinal lines; sporangium releasing all spores and elaters at the time it opens; calyptra remaining at base when seta elongates.

Order Takakiales

Leaves cylindrical and irregularly but radially arranged on an erect shoot that arises from a subterranean, colourless, rootlike system; sex organs lateral but near shoot apex; rhizoids absent; sporophytes unknown; Southeast Asian and northwestern American distribution; a single genus, *Takakia,* with two species.

Order Calobryales

Leaves flattened and in three rows on an erect shoot arising from a colourless, subterranean, rootlike system that lacks rhizoids; sex organs lateral but near shoot apices; sporophytes with elongate seta; sporangium elongate, with elaters and thickenings on the jacket cell walls; opening by 1–4 longitudinal lines; mainly of mid-latitudes, most species in the Australasian and Indo-Malayan region; 2 genera, *Haplomitrium* (12 species) and *Steereomitrium* (1 species).

Order Metzgeriales

Thallose, with the thallus mainly of uniformly thickened cell walls, usually reclining but sometimes erect; branching varies from forked to regularly pinnate or irregular; smooth rhizoids on the undersurface; sex organs lateral; sporophytes with elongate seta; sporangia spherical to elongate, with elaters and thickenings of the jacket cell walls; opening by 1–4 longitudinal lines or irregularly; widely distributed throughout the world; approximately 30 genera and 550 species; sometimes the order Treubiales is separated from this order.

Order Jungermanniales

Leaves flattened, in 2 or 3 rows, usually broadened to attachment, often lobed; shoots reclining, erect, or pendent; rhizoids smooth-walled; archegonia terminating shoot, surrounded by a chlorophyllose sheath (perianth); sporophyte with seta; sporangium spherical to elongate, with elaters and thickenings of the jacket cell walls, opening by 4 longitudinal lines (rarely helical); distributed throughout the world, reaching greatest abundance in humid subtropical to temperate climates; contains at least 85 percent of the liverworts; conservatively, 300 genera and more than 7,000 species.

Order Sphaerocarpales

Essentially lobate thallus in all modern representatives; thallus of parenchyma cells reclining or erect, with smooth-walled rhizoids; each sex organ surrounded by an enveloping sac, lateral; sporangium spherical, lacking seta and elaters, opening by disintegration of the unornamented jacket cells; terrestrial except the aquatic genus *Riella;* distributed mainly in milder temperate climates; 3 genera with approximately 30 species.

Order Monocleales

Large thalli of mainly uniformly parenchymatous cells, reclining; thallus forked to irregularly branched; archegonia within a sleevelike chamber behind the lobe apex; antheridia in padlike receptacles in the same location on different thalli; sporangia elongate on a massive elongate seta, with long elaters and opening by a single longitudinal line; jacket with thickenings on cell walls; in South and Central America and New Zealand; a single genus, *Monoclea,* with 1 species.

Order Marchantiales

Thallus often of complex anatomy, with air pores on the dorsal surface, air chambers with chlorophyllose cells forming a photosynthetic area, and cells of the remainder of the thallus serving for storage; ventral scales often present; rhizoids; sex organs sometimes borne on a stalked receptacle; sporophytes with short seta or seta absent; sporangia spherical or elongate, opening by regular or irregular longitudinal lines, a caplike lid, or decomposition; sporophytes often carried up from the thallus surface by elongation of the stalk of a receptacle, with the sporangia hanging downward; occupying a diversity of habitats—some can withstand extended periods of dryness while others are floating or submerged aquatics, and still others grow in humid shaded sites—approximately 27 genera and 450 species widely distributed throughout the world; the genus *Riccia* containing nearly half the species of the order.

CLASS ANTHOCEROTOPSIDA (or ANTHOCEROTAE; hornworts)

Protonema reduced to short filament or absent, differentiating the gametophore early after spore germination; rhizoids unicellular and smooth-walled; gametophore thallose, sometimes lobate; archegonium not a discrete structure, made up of an egg and neck canal cells embedded in the dorsal surface of the thallus; often several antheridia within a chamber embedded in the dorsal surface of the thallus; thallus sometimes with ventral pores, sometimes developing mucilage chambers; thallus lacking complex oil bodies; chloroplasts often solitary in each cell and often with pyrenoid; sporangium horn-shaped, usually with stomata in jacket; elaters often multicellular and often lacking helical thickenings; columella of sterile tissue extending the length of the sporangium, with the spore-bearing tissue overarching and sheathing it; sporangium indeterminate in growth from a basal meristem just above the foot; spores shed throughout the growing season by longitudinal lines of openings extending from the apex downward as the sporangium ages, sometimes (in *Notothylas*) by decomposition of the sporangium jacket.

Order Anthocerotales

Characteristics are those of the class; widely distributed in temperate to tropical latitudes, with greatest diversity in the tropics and subtropics; containing 6 or 7 genera and probably fewer than 300 species.

CLASS BRYOPSIDA (or MUSCI; mosses)

Protonema an extensive many-branched filament that precedes gametophore production; rhizoids multicellular, branched; gametophore leafy, with leaves spirally arranged, usually in more than 3 rows; gametophore usually not strongly flattened; sex organs usually with paraphyses among them; leaves unlobed and often with thickened midrib; cells usually lacking corner thickenings; oil bodies, if present, not complex; jacket of sporangium often with stomata; sporangium usually opening by apical cap (operculum); peristome teeth usually surrounding the sporangium mouth and influencing spore release; columella usually present, encircled or overarched by a spore-bearing layer; calyptra capping apex of elongating seta and influencing survival and differentiation of sporangium; spores generally shed over extended period; seta a rigid structure with internal conducting strand and holding sporangium well above gametophore in most instances.

Subclass Andreaeidae

Sporophytes usually lacking a seta; sporangium opening by longitudinal lines; sporangium with spore-bearing layer overarching and encircling the central columella; gametophore irregularly branched, dark-pigmented, with spirally arranged leaves, attached to the substratum by rhizoids; leaves with or without midrib; paraphyses few or absent; sporophytes usually pushed beyond perichaetium on an elongate leafless extension of the gametophore (pseudopodium); mainly in cooler climates throughout the world, confined mainly to siliceous rock surfaces; 2 genera, *Andreaea* and *Andreaeobryum*, with probably fewer than 100 species.

Subclass Sphagnidae

Sporophytes lacking a seta; subspherical sporangium opening by a lid (operculum) released explosively with the spores when sporangium dries, shrinks in diameter, and reaches high atmospheric pressure through compression of the gases within; protonema phase thalloid; branching in fascicles; leaf without midrib; leaf cells forming a network of elongate chlorophyllose cells surrounding dead swollen cells reinforced by fibril thickenings in walls and perforated by pores; sporophytes pushed beyond perichaetium by leafless extension of gametophore (pseudopodium); widely distributed in the world but forming extensive peatland mainly in boreal regions; 1 genus, *Sphagnum*, with more than 160 species.

Subclass Tetraphidae

Sporophytes with elongate seta; sporangium opening by an operculum exposing four multicellular peristome teeth that respond to moisture change to release spores gradually; spore layer forming a cylinder around central columella; protonema filamentous but with thallose flaps; gametophores erect, with rhizoids at base, leaves with midrib, all cells with chlorophyll; widely distributed in the Northern Hemisphere, with *Tetrodontium* also present, but rare, in the Southern Hemisphere; 2 genera, *Tetraphis* and *Tetrodontium*, with 3 or 5 species.

Subclass Polytrichidae

Sporophytes with elongate rigid seta containing conducting system; sporangium opening by operculum; numerous multicellular peristome teeth in a single concentric circle and overarching a membrane formed by the expanded apex of the columella (many rows of teeth and no membrane in *Dawsonia*); spores very small and released gradually through spaces between the teeth; spore layer forming a cylinder around central columella; gametophores erect, often with complex internal conducting system in stems and often leaves; leaves with numerous chlorophyllose elongate flaps on upper face; widely distributed throughout the world at most latitudes and altitudes, mainly terrestrial; approximately 16 genera and 370 species.

Subclass Buxbaumiidae

Sporophyte with elongate or short seta; sporangium asymmetrical, with operculum; peristome teeth sometimes in several concentric circles, the outer articulated, the inner forming a cone opened at the tip; spores released slowly when slight pressure on the sporangium surface causes the spores to puff out through the narrow mouth; gametophore sometimes extremely reduced and microscopic, always small but sometimes with leaves; widely but erratically distributed in temperate to tropical regions; 4 genera with approximately 40 species.

Subclass Bryidae

Sporophyte may have elongate seta, with or without conducting strand; sporangium diverse in form, with internal cylindric columella encircled by spore-bearing layer, usually opening by operculum to expose articulated peristome teeth in 1 or 2 concentric circles; peristome teeth pulsating in response to moisture changes, extracting the spores from the sporangium and gradually releasing them; gametophores diverse in form and structure; widely distributed throughout the world in most habitats except the sea, representing more than 95 percent of the mosses; more than 650 genera and more than 9,000 species.

Subclass Archidiidae

Sporophyte with no seta; sporangia containing a restricted number of large spores (sometimes 4), lacking columella, opening by decomposition of the jacket; gametophore small, leaves with midrib; attached to substratum by rhizoids; of scattered distribution in temperate to subtropical climates; a single genus, *Archidium*, with approximately 26 species.

Critical appraisal. The order Takakiales is highly controversial; some researchers consider it sufficiently distinctive to separate it from the bryophytes to another phylum, while others merge it with the Calobryales. Discovery of sporophytes could settle the question. The order Anthocerotales is considered by some researchers to be so unrelated to bryophytes that it is placed in its own phylum, the Anthocerotophyta. The evolutionary lines of the class Bryopsida are most easily demonstrated by the subclasses. The treatment of orders and families remains in a state of flux, with widely varying opinions derived from differing interpretations of the taxonomic importance of characteristics. Even phylogenetic placement of the sequence of subclasses is difficult.

Fundamental classification of bryophytes is hampered by a lack of agreement concerning not only the critical features that define a bryophyte but also the criteria that can be used to interpret relationships. Consequently, there are considerable differences among classification systems. It is vital that there be an adequate assessment concerning the diversity of bryophytes that now exist. The extremely limited number of researchers in the field of bryology greatly curtails the acquisition of this information, much of which is being lost when vegetation is destroyed before the floristic structure has been documented and conserved.

BIBLIOGRAPHY. W.B. SCHOFIELD, *Introduction to Bryology* (1985); and E.V. WATSON, *The Structure and Life of Bryophytes*, 3rd ed. (1971), are comprehensive introductions with extensive bibliographies that lead to more detailed treatises. Thorough analyses are found in RUDOLF M. SCHUSTER (ed.), *New Manual of Bryology*, 2 vol. (1983–84); R.N. CHOPRA and P.K. KUMRA, *Biology of Bryophytes* (1988); and *Advances in Bryology* (biennial), an official publication of the International Association of Bryologists. A comprehensive survey of ecology and habitats is presented in A.J.E. SMITH (ed.), *Bryophyte Ecology* (1982). G.C.S. CLARKE and J.G. DUCKETT (eds.), *Bryophyte Systematics* (1979), covers various aspects of classification. Works concerned with the botanical details of mosses include WILLIAM T. DOYLE, *The Biology of Higher Cryptogams* (1970); and N.S. PARIHAR, *An Introduction to Embryophyta*, 5th ed., vol. 1, *Bryophyta* (1965). References helpful in the identification of mosses include HENRY S. CONARD, *How to Know the Mosses and Liverworts*, 2nd rev. ed. (1979), a good manual for American mosses; and, still unsurpassed for its illustrations, PAUL W. RICHARDS, *A Book of Mosses* (1950). The following periodicals are devoted mainly to bryology: *The Bryologist* (quarterly); *Journal of Bryology* (semiannual); HATTORI BOTANICAL LABORATORY, *Journal* (semiannual), published in Japan with text in European languages; and *Lindbergia* (irregular), published by the Nordic and Dutch Bryological Societies.

Budapest

Once called the "Queen of the Danube," Budapest, the capital of Hungary, has long been the focal point of the nation and a lively cultural centre. The city straddles the Danube (Hungarian: Duna) River in the magnificent natural setting where the hills of western Hungary meet the plains stretching to the east and south. It consists of two parts, Buda and Pest, which are situated on opposite sides of the river and connected by a series of bridges.

Although the city's roots date to Roman times and even earlier, modern Budapest is essentially an outgrowth of the 19th-century empire of Austria-Hungary, when Hungary was three times larger than the present country. Hungary's reduction in size following World War I did not prevent Budapest from becoming, after Berlin, the second largest city in central Europe. One out of five Hungarians now lives in the capital, which, as the seat of government and the centre of Hungarian transport and industry, dominates all aspects of national life. Tens of thousands of commuters converge on Budapest daily, more than half of the nation's university students attend school in the city, and about half of the country's income from foreign tourism is earned there.

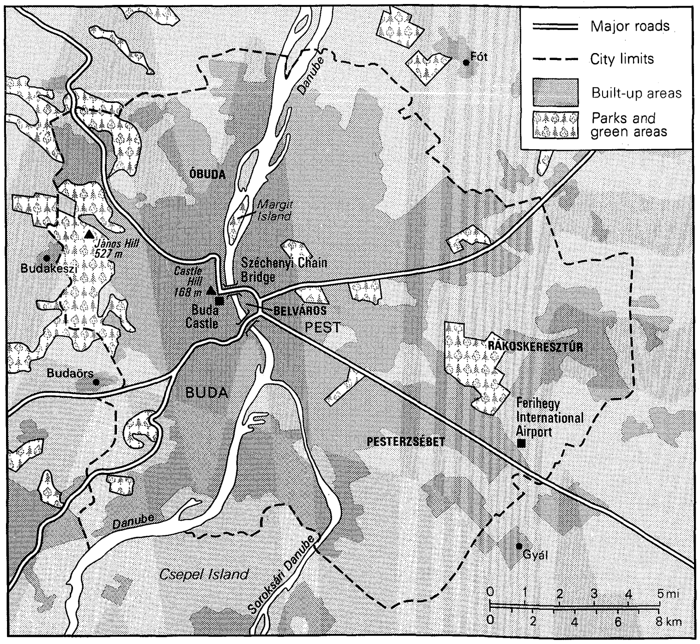
Although Hungary became a member of the Soviet bloc after World War II, the city has long received investment capital from the West, private enterprise has been encouraged, and the city's large black market has been tolerated. The impression of plenty—smart shops, restaurants with high culinary standards, and a casino—has increasingly set Budapest apart from the relatively drab capitals of most eastern European countries.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Strategically placed at the centre of the Carpathian Basin, Budapest lies on an ancient route linking the hills of Transdanubia (Hungarian: Dunántúl) with the Great Alfold (Great Hungarian Plain; Hungarian: Nagy Magyar Alföld). The wide Danube was always fordable at this point because of a few islands in the middle of the river. The city has marked topographical contrasts: Buda is built on the higher river terraces and hills of the western side, while the considerably larger Pest spreads out on a flat and featureless sand plain on the river's opposite bank.



Budapest and surrounding area.

Climate. The climate of Budapest is transitional between the extreme conditions of the Great Alfold and the more temperate climate of Transdanubia, with its abundant rainfall. Mean annual temperature is 52° F (11° C), ranging from a July average of 72° F (22° C) to 30° F (−1° C) in January. Mean annual precipitation is 24 inches (600 millimetres). Winter snowfalls can be heavy, and the temperature may fall below 5° F (−15° C), but, on the other hand, heat waves combined with humidity in the summer can make the air oppressive. Flooding in Pest was endemic before the river was regulated in the 19th century. The Danube (blue only in the Johann Strauss waltz) has become heavily contaminated, and air pollution, from which the inhabitants of Buda have largely been able to escape, has afflicted most districts in Pest.

The city layout. *Buda.* Buda was the kernel of settlement in the Middle Ages, and the cobbled streets and Gothic houses of the castle town have preserved its old layout. Until the late 18th century, Pest remained a tiny enclave, but then its population exploded, leaving Buda far behind. In the latter half of the 20th century, growth has been more evenly distributed between the two parts. Contemporary Budapest covers 203 square miles (525 square kilometres), of which about half is built up. Buda's hilltops, still crowned by trees, the Danube flanked by three lower hills, the bridges, Margit (Margaret) Island, and the riverfront of Pest lend a remarkable visual identity to the city.

The hills of Buda

In a central position is Castle Hill (Várhegy), 551 feet (168 metres) above sea level and crowned by the restored Buda Castle (Budai vár, commonly called the Royal Palace). In the 13th century a fortress was built on the site and was replaced by a large Baroque palace during the reign (1740–80) of Maria Theresa as queen of Hungary. The structure was destroyed or damaged and rebuilt several times over the centuries, most recently when it was razed during World War II. Restoration of the palace was completed in the mid-1970s, and it now houses the National Széchenyi Library, the Historical Museum of Budapest (commonly called the Vármúzeum, or Castle Museum), and the Hungarian National Gallery. The spire of the medieval Gothic Church of Our Blessed Lady (Nagyboldogasszony), com-

Budapest from the Fishermen's Bastion on Castle Hill.

Peggy Kahana—Peter Arnold, Inc.

monly called Matthias Church (Mátyás templom), also thrusts into the skyline above Castle Hill, with the late 19th-century Fishermen's Bastion (Halászbástya) in front and a contemporary hotel next to it.

To the south of Castle Hill rises the higher Gellért Hill (771 feet), a steep limestone escarpment overlooking the Danube, which provides a panoramic view of the whole city. At the top stands the Citadel (Citadella)—built by the Austrian army in the mid-19th century in order to keep watch over the town—which serves today as a hotel and restaurant and doubles on St. Stephen's Day (August 20) as the stage for a splendid fireworks display. The Liberation Statue near the Citadel commemorates the victory of the Soviet army over German forces in 1945. Rózsa (Rose) Hill, the third hill near the river, lies north of Castle Hill. It is the most fashionable district of Budapest, where Hungary's elite have houses. The Lukács (Lucas) Bath at the foot of the hill is frequented by Budapest's literati.

Below the three hills stretches the city. Opposite Rózsa Hill lies Margit Island, a mile-long park with hotels and swimming pools. Facing Margit Island on the Pest side is the headquarters of the Hungarian Socialist Party (until 1989 the Hungarian Socialist Workers' Party), an unprepossessing modern block standing next to the ornate Parliament Building (Országház). Designed in Neo-Gothic style and influenced by the Houses of Parliament in London, the building (completed in 1902) has been little used since the end of World War II. Further along the bank lies the Neo-Renaissance building of the Hungarian Academy of Sciences (1862–64); the Vigadó, a large hall built in the Romantic style (1859–64); and two obtrusive modern hotels.

The Belváros

Pest. The heart of Pest is the Belváros (Inner Town), an irregular pentagon with its longest side running parallel to the Danube; only traces of the original town walls remain. The district accommodates offices, parts of the Loránd Eötvös University, and shops. The Váci utca, a narrow street turned pedestrian thoroughfare, is the most fashionable shopping centre of Budapest. The Town Hall (Fővárosi Tanács), a Baroque building erected between 1724 and 1747, is in the northeast corner of the Belváros next to Pest County Hall (Pest megyei Tanács). The Inner Town Parish Church (Belvárosi plébániatemplom) is the oldest building in Pest. Rebuilt in the Baroque style in the 18th century, as were many other churches in Pest and Buda, the church had been the most impressive of medieval Pest. St. Stephen's Crown, the symbol of Hungarian nationhood, is on display in the Hungarian National Museum, a Neoclassical edifice located just outside the Belváros.

Pest's main boulevards form concentric semicircles around the Belváros. The nearest to the centre follows the line of the former city walls. The Nagykörút (Great Boulevard), which formerly bore the names of Habsburg archdukes and archduchesses and is now divided into four named sections, follows the riverbed of a dry tributary of the Danube. Most of the ministries and other government offices are to the north of the Belváros. The Neo-Romanesque St. Stephen's Basilica, the Italian Neo-Renaissance State Opera House, the National Theatre, and the concert hall of the Franz Liszt Academy of Music were all built in the 19th century. The stucco buildings of this eclectic architectural collection have not weathered well.

The finest thoroughfare in Budapest, Népköztársaság útja (People's Democracy Avenue, formerly Andrássy út), runs in a straight line from the centre of Pest to City Park (Városliget), which contains the Millennium Monument. The monument consists of a semicircular pillared colonnade displaying statues of Hungarian kings and national leaders, with a statue of the archangel Gabriel surmounting a 118-foot-high central column. The Museum of Fine Arts, other museums, the Budapest Zoo, the renowned city circus, and an amusement ground (which was once called the "English Park") are all found nearby.

THE PEOPLE

The capital is more than 10 times larger than Hungary's next largest city. The rise of population has been phenomenal: its rate of increase from about 100,000 in the 1840s to 1,000,000 in 1918, for example, far outstripped that of London during the same period. Natural population growth has never been a factor in this expansion. Rather, more die in the city than are born there, the result of a never-ending migration of people from villages and towns to the capital. By the late 20th century, however, the rate of growth had slowed, and the population had begun to shift from the central districts to the periphery. Residential districts—such as Pesterzsébet (Pestszenterzsébet) and Kelenföld in the south, Rákoskeresztúr in the east, and Óbuda, Békásmegyer, and Újpalota in the north—have been growing as the inner city has been redeveloped.

Always a city of marked social divisions, Budapest once revealed the deep-rooted contrast in life-styles between the aristocrats, who built palaces in the town centre, and those who lived in the slum districts and sprawling temporary barrack settlements on the city's perimeter. During the Stalinist period after World War II, these contrasts largely disappeared, but an acute housing shortage has persisted. The majority of the inhabitants continue to live in relatively small flats. Economic reforms since the late 1960s have created new wealth, which, in turn, has sharpened the differences between the more ostentatious life-style of the new middle classes—whose privileged members are able to build second homes in the Buda Hills and on Lake Balaton—and that of the workers who populate the gigantic, faceless housing estates of the drab outlying residential districts.

Ethnic diversity

The capital, apart from its large number of foreign visitors, is entirely Hungarian-speaking; in the past it never was. The remarkably diverse ethnic background of Budapest's population has been one of the city's greatest strengths. In the past Buda was run by German and later German and Hungarian burghers. In the early 19th century the government of Pest was in the hands of German burghers, shipping was controlled by Serbs, and the merchants were largely "Greek" (*i.e.,* Greek and other Balkan peoples). German-speaking industrial workers were brought in from the west and large numbers of Jews moved in from the east. By 1900 nearly one-fourth of the inhabitants of Budapest were Jewish, but the Jewish community was largely destroyed during World War II. Postwar Budapest has become culturally homogeneous.

THE ECONOMY

Developed from early times to be the true centre of the country's economy, the town was originally self-sufficient in food production. Buda's wine was renowned before *Phylloxera* and urban expansion destroyed the vineyards that once covered the higher river terraces of the Danube. Today the rest of Hungary supplies its capital with food, to which the orchards, gardens and nurseries, and dairy farms of the Buda Hills contribute only a small fraction.

Commerce and industry. In the past, all roads converged on Buda, and its market was always famous. By the 19th century, however, commerce had shifted to Pest; its wealthy merchants dominated Hungary's agricultural market, and its banks (by 1900 more than 100) controlled 60 percent of the country's bank capital. Commerce is still concentrated in Pest's Belváros, including the major banks, most of the foreign trading companies, the state travel agency (Idegenforgalmi, Beszerzési, Utazási és Szállítási R.T., or IBUSZ), and the best shops. To help mitigate the growing imbalance in consumer services, large shopping centres have been built in Óbuda, Lágymányos, Újpest, Zugló, and elsewhere. The national economic reforms introduced since 1968 have created a private sector in retailing and in service industries. Both the public and the private sectors have benefited from the increasingly important tourist industry.

Economic dominance

In the last quarter of the 19th century, the city—with neither local raw materials of any sort nor even skilled workers (they had to be imported from Austria and Moravia)—was transformed from a commercial base to the country's most prominent industrial centre. Except for a few engineering factories, manufacturing was at first limited to the processing of raw materials, particularly food, and huge grain mills were built on the Danube. Primary-metal and engineering works (especially for agricultural machinery and ships) and munitions and electronics factories soon followed. Automobiles have been produced since 1905, but light industries grew fast only after World War I. Possessing the bulk of the country's industrial production and, by 1938, about three-fifths of its factory workers, Budapest strangled the economic growth of all the other towns. The city's location on the Danube and especially the construction of the rigidly centralized Hungarian railways, which had preceded the growth of industry, were instrumental in this dominance. The influx of foreign capital, channeled through the large banks and through the government, and the control of large factories by leading Budapest banks reinforced the centralizing role played by the transport system. The loss of two-thirds of Hungary's territory in 1918 and the establishment of a centrally planned economy after 1945 have exacerbated the hypertrophy of Budapest in relation to the rest of the country, although by 1969 the capital's share of the country's industrial work force had been reduced to about one-half. More than half of the factory workers in Budapest are employed in heavy industry; the rest are divided between light industry and food processing.

Transportation. Transportation has been the key to Budapest's rapid expansion. A famous crossing point on the Danube where highways have always converged in the past, it has become the hub of the country's trunk roads and main railway lines, all of which radiate from the capital. It has also developed Hungary's largest bus terminal as well as its only commercial airport, Ferihegy International Airport. Csepel Free Port, downstream from the city centre on Csepel Island, handles international freight cargo on the Danube and is equipped to handle container traffic. The head office of the International Danube Commission is in Budapest. Of the capital's eight bridges, the oldest and best known is the Széchenyi Chain Bridge (Széchenyi Lánchíd), built in the 1840s and named for the 19th-century Hungarian reformer István Széchenyi.

Public transportation

Horse-drawn trams were introduced in 1866; and, after the first electric tramways were built in 1887, they soon expanded into a large network. The trams and buses (the latter introduced in 1915) met local transport needs before the 1940s, but they could not cope with the rapid growth of traffic after World War II. Yet, despite the congestion caused by the colossal expansion in the use of the private automobile and the reduction in the number of tramcars, city transport has once more become efficient. The Metro, a subway system constructed in the 1970s, operates three lines, including one that runs under the river and connects Buda to Pest; it is a showpiece that is clean, fast, and (like the city's buses and old-fashioned rattling trams) absurdly cheap.

The hills of Buda, with their pleasant wooded paths, can be reached easily from the town either by an old cog railway, bus, or a chairlift that takes sightseers to the top of János Hill, which at 1,729 feet (527 metres) above sea level is the highest point in Budapest. The Pioneers' Railway (Úttörővasút), which winds through the hills, is managed largely by children.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Budapest is the seat of the Hungarian government and of the central offices of the Hungarian Socialist Party; it is also the seat of Pest *megye* (county) and Buda *járás* (district). The city is divided into 22 administrative districts—six on the Buda side, 15 in Pest, and Csepel Island—each of which elects a councillor (*tanácstag*). Control of the city is formally vested in the Budapest Metropolitan Council (elected by the district councillors who in turn are elected by the whole adult population), to which the Management Committee (Végrehajtóbizottság) is responsible.

Public services. The city has a tradition of good public services, at least in the centre (gas was introduced there for private consumers in 1856 and electricity in 1893), as evidenced by the improvements in public transport and the renovation of the telephone system undertaken in the 1970s. Although the police can be rude and act arbitrarily, they are not overworked: crime, prostitution, and the use of drugs (other than alcohol) are not acute problems. Hospital care and other social services are adequate—particularly in the city centre—although the payment of bribes and gratuities for these services is widespread. Suicide figures are alarmingly high in Budapest, where the most pressing social problem has continued to be the shortage of decent housing.

CULTURAL LIFE

Cultural dominance

The economic hypertrophy of Budapest is compounded by its dominating position in Hungarian culture. Radio and television broadcasting and the film industry are the preserve of the capital, and publishing and the press are nearly so. Writers and poets, traditionally said to be excessively preoccupied with rural life and the peasantry, have nevertheless been drawn to Budapest, as have Hungary's composers: Ferenc Erkel, Ernő Dohnányi, Béla Bartók, and Zoltán Kodály all lived in the capital. The leading grammar schools are concentrated in Budapest, and its universities and colleges attract most of the country's best students. Furthermore, the Hungarian Academy of Sciences and the great majority of its research institutes are in Budapest.

The city also claims the best libraries, museums, art galleries, orchestras, sports facilities, and theatres in Hungary. The music academy, established in 1875 by the pianist and composer Franz Liszt, has acquired international fame. The Opera House was restored to its 19th-century splendour in 1984. The National Theatre, on the other hand, has been awaiting permanent accommodation since it left its building in 1964.

Budapest has more than its share of bookshops; an unparalleled number of hairdressing salons and swimming pools (sometimes the two are combined); and a large variety of thermal baths, including Császár, Lukács, Rác, Király, Rudas, Gellért (all on the Buda side) and Széchenyi and Dagály (in Pest). There are numerous underground hot springs that contain radium and other minerals, and since Roman times bathers have sought them out for their supposed healing properties.

History

EARLY SETTLEMENT AND THE EMERGENCE OF MEDIEVAL BUDA

The Roman settlement

Budapest's location is a prime site for habitation because of its geography, and there is ample evidence of human settlement on the Danube's western side from Neolithic times onward. Two miles north of Castle Hill, in what became Óbuda, a settlement named Ak-Ink ("Ample Water") was established by the Celtic Eravisci. This became Aquincum when the Romans established a military camp and civilian town there at the end of the 1st century AD. Becoming the seat of the province Pannonia Inferior (*c.* AD 106) and then acquiring the status of a municipium (124) and finally a full colony (194), Aquincum grew into a thriving urban centre with two amphitheatres. After the collapse of Roman authority in Pannonia in the early 5th century, some of the large buildings were inhabited by Huns and later by Visigoths and Avars, each group controlling the region for a while.

Kurszán, the Magyar tribal chieftain, probably took up residence in the palace of the former Roman governor at the end of the 9th century. The settlement shifted south to Castle Hill some time after Stephen I of Hungary had established a Christian kingdom in the early 11th century. Buda, for whom the settlement was named, was probably the first constable of the new fortress built on Castle Hill, and the old site to the north became known as Óbuda ("Old Buda"). On the opposite side of the river a Slavonic settlement, Pest (meaning "Lime Kiln," which is also suggested by Ofen, the German name for Buda), was already in existence.

Medieval Buda prospered and declined along with its patron, the Hungarian royal court. The municipality was established by royal charter in 1244, by Béla IV. He bestowed on the citizens of Pest, whose town had been devastated by the Mongols in 1241, the right to settle in full possession of their privileges in the fortified castle. The town administration, based on German law, had been dominated by German burghers before it became reorganized in 1439. At that time parity status was conferred on the Hungarians in municipal government. Buda's preeminence, developed under royal protection, was underlined by its judicial authority (as a higher court) over other free royal towns, although the proximity of the king's court undermined its own self-government. The palace was rebuilt by Matthias I, whose death in 1490 marked the decline of both royal power and the town. The Turks held Buda between 1541 and 1686. After a devastating siege it was liberated by a Christian army organized by the Holy Roman emperor Leopold I. Little of Matthias' Buda survived into the 18th century.

BUDA, ÓBUDA, AND PEST

Both Buda and Pest were recognized by Leopold I as royal free towns in 1703, while Óbuda, a village, belonged to Pest *megye,* the autonomous county that was in the hands of the local Hungarian nobility. In 1720 Buda and Óbuda had a combined population of about 9,600, while that of Pest was only 2,600; but by 1799 Buda had some 24,300 inhabitants to Pest's 29,870, demonstrating that the balance in the size of the two townships had shifted.

Pest, a German commercial centre in Hungary and by then part of the Habsburg empire of Austria, had begun to grow in the late 18th century. Buda, where in the early 18th century only German Roman Catholics were allowed to settle, remained an imperial garrison town and developed once more under the eye of the monarch. A new royal palace was built in the 1760s during the reign of Maria Theresa. The university was moved from Nagyszombat (modern Trnava, Czech.) to Buda in 1777; since 1949 it has been called Loránd Eötvös University. In 1783 Joseph II turned Buda into the country's administrative centre; that same year the Curia (High Court) was moved to Buda, and the university was transferred to Pest. For centuries floods were a serious problem, and one in 1838 took a particularly heavy toll: more than half of the houses in Pest were destroyed, and Buda suffered as well.

The character of Buda under the Habsburgs remained aristocratic and distinctly alien. Pest, into which the gentry and intelligentsia moved, became wedded to the national cause; the Széchenyi Chain Bridge, linking Buda with Pest, was a metaphor for unity. The town of Pest was still partly German, but the nobility of Pest *megye* led the campaign for Hungarian home rule. After the outbreak of revolution in Pest in March 1848, a Hungarian ministry, transferred from Pozsony (modern Bratislava, Czech.) and responsible to the Diet, was established there. In the ensuing civil war Buda was besieged in May 1849 by the revolutionary army of the patriot Lajos Kossuth. Repression followed the revolution until 1867, when the country, which became Austria-Hungary the following year, was placed under the Dual Monarchy. Governments were established in Vienna and Pest.

THE MODERN CITY

Amalgamation

"Buda-Pest" was created in 1872 when Pest, Buda, and Óbuda were united into a single municipal borough comprising 10 districts. Within a year, however, the hyphen had disappeared from the name of the new capital, even in official documents. Between 1873, when the law promulgating the unification went into effect, and the communist takeover after World War II, Budapest enjoyed self-government.

Its governing body, the City Council, consisted of 400 members elected by the districts. The influence of wealth was ensured by a provision of the law (Prussian in origin) that half of the council was to be elected from among the 1,200 highest taxpayers of the capital (the so-called *virilists*); while the other half of the council's membership was elected from the rest of the electorate, based on a rather narrow franchise. Property owners thus played an important role in the government of the city: aristocrats, grain and wine merchants, German burghers, a few solicitors, builders and architects, and later bankers and industrialists all went into real estate and became *virilists.*

Budapest dominated national politics. The Belváros was the constituency of Ferenc Deák, the creator of the Dual Monarchy system. After his death in 1876 the constituency was inherited by leading politicians.

After unification the spectacular growth of the city began in earnest. Baroque and Neoclassical Pest was ruthlessly sacrificed to the building fever that gripped the city fathers. The two most prominent buildings of the period, the new Parliament in Pest and the rebuilt Buda Castle, standing face-to-face over the Danube, were a powerful reminder of the age-old political conflict between the alien monarchy and the national Parliament. Meanwhile, the character of Budapest underwent a major change because of rapid industrialization. Protective tariffs could not be introduced under the dualist system, and the idea of state support for industry gained ground only in the late 1880s, but the result was runaway growth and the creation of an industrial city in which the work force lived in appalling conditions.

Explosive urban and industrial growth created social tension and the emergence of a working-class movement before World War I. After the disintegration of Austria-Hungary in the autumn of 1918, the National Council, a revolutionary body headed by Count Mihály Károlyi and supported by antiwar radicals and Socialists, took power in Budapest. The following March the Károlyi regime collapsed; communists seized power in the capital and held it for four months while also controlling the central regions of the country. Romanian troops occupied and sacked Budapest before the old social order was restored by a counterrevolutionary army marching into the *bűnös város* ("sinful town") in November 1919.

After the signing of the Treaty of Trianon in 1920, Budapest—now the capital of an independent Hungary—became disproportionately large compared to the rest of the country. Social conditions deteriorated in the interwar years. Buda Castle, where Miklós Horthy, the country's regent, resided after 1920, played a fateful role in World War II. Hungary, a satellite of Germany in the war, was occupied by the German army in March 1944. In October Horthy sued for a separate peace and renounced the German alliance, but the coup failed. Between the end of December and the middle of February 1945, German army units put up a fierce resistance to the Soviet advance. In the process, the fighting reduced Castle Hill to a large, sprawling ruin; more than a quarter of the city's buildings and factories were destroyed or damaged, and all the bridges were blown up. It took years for the town to recover from this devastation, but, as the centre of a planned economic system, Budapest resumed its rapid growth in the postwar years.

World War II
